## Abstract

A set of 799 ground state nuclear charge radii is presented. Experimental data from elastic electron scattering, muonic atom X-rays,  $K_{\alpha}$  isotope shifts, and optical isotope shifts have been taken into account that were available up to January 2004. Wherever possible, connections and constraints between the data were applied to make the data system consistent. Based on the resulting data set, the smooth global structure of the radius surface  $R(N, Z)$  was investigated by fitting simple empirical functions to the intersections with constant  $Z$  and  $N$  as well as with constant  $A$  plains. The simple behavior of the surface rendered it possible to apply a simple model, the two-liquid drop model to reproduce the main tendencies, and to predict the existence of a indentation along the line of stability on the radius surface. This indentation suggests a decrease of average nucleon density away from stability. The fine structure in the mass number dependence of rms charge radii is briefly presented.

## 1. Introduction

The rms charge radius  $\langle r^2 \rangle^{1/2}$  is a fundamental property of the atomic nucleus. It can be measured by two experimental methods: electron scattering ( $e^-$ ) and muonic atom X-rays ( $\mu^-$ ), while the difference  $\delta_{1,2} \langle r^2 \rangle \equiv \langle r^2 \rangle_{A2} - \langle r^2 \rangle_{A1}$  between two isotopes of the same element is determined by the  $K_z$  isotope shift ( $K_z IS$ ) and by the isotope shift of optical spectrum lines ( $OIS$ ). Early compilations [1–8] contained separate tables of results from the four different methods. It is of importance to derive radius values using the results of all experimental methods. This is also for the benefit of data users, who generally prefer a single, unified data set to several separate tables.

In 1994, a compilation of rms charge radii was published [9] comprising 523 ground state and 75 isomer radius data for isotopes of 42 elements. It was followed by another compilation [10], where the main emphasis was laid on the simultaneous evaluation of two experimental methods:  $e^- + \mu^-$ . Moreover, for nine elements results from three methods were taken into account:  $e^- + \mu^- + OIS$ . In addition, this compilation contained an updated table of radius differences from  $K_z IS$ . Since then, several experimental results have been published mainly containing  $\delta \langle r^2 \rangle$  values from  $OIS$  along isotopic series.

Table 1 of the present paper contains rms radius data for 799 isotopes of 91 elements making use of results from the four methods:  $e^- + \mu^- + K_z IS + OIS$ . Whenever possible, advantage was taken of constraints between directly measured radii and differences. Often, easy-to-use radius formulae with limited number of parameters are required, for example, for the extrapolation of the radius surface  $R(N, Z)$  or  $R(A, I)$  to unknown regions. In order to facilitate the global description of the smooth surface, simple empirical formulae were fitted to the resulting radius data (see Section 3 and Tables 2 and 3). These formulae may be useful to estimate the values of unmeasured radii, and especially in extrapolating charge radius values for nuclei far from the valley of stability or to perform analytic calculations with the continuous function  $R(N, Z)$ . A simple two-component liquid-drop model is applied for the interpretation of the empirical results. Finally, in Section 4 a short survey on the fine structure is given.

## 2. Sources and treatment of data

First,  $\langle r^2 \rangle^{1/2}$  data were obtained from  $e^-$  and  $\mu^-$  measurements (from now on, the shorthand notation  $R \equiv \langle r^2 \rangle^{1/2}$  is used). Then, differences  $\delta R$  between non-isotope pairs were taken into account. These improve

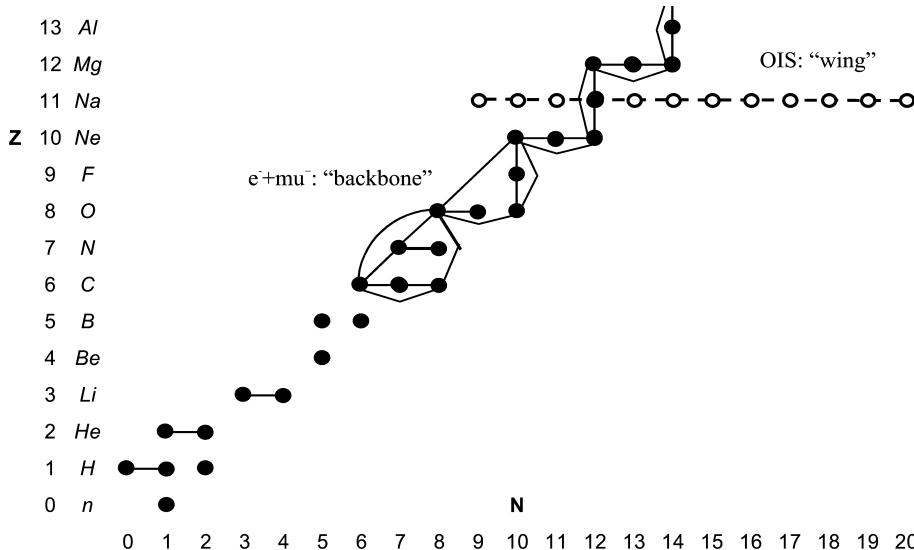

Fig. 1. Illustration of measured quantities and the links between them. Filled circles denote experimental rms radius data, continuous lines mark radius differences measured by electron scattering or muonic atom X-rays. These links are used as constraints to improve the input data and to search for inconsistencies (see Section 2). Broken lines denote differences from optical isotope shifts.

the links between different isotopic series, helping the study of isotonic and isobaric behavior. Then isotopic differences  $\delta R$  measured by  $e^-$  and  $\mu^-$  were taken into account, followed by  $\delta R$  from  $K_{\alpha}IS$ . Finally,  $\delta R$  values from OIS are included in two steps: (1) differences between isotopes for which there exist data from the previous steps; these altogether form a backbone for the data system in the  $(N, Z)$  plot, Fig. 1, and (2) the remaining differences  $\delta R$  constitute the wings that are adjusted to the backbone. Some details of this multi-step task have been published in previous papers, which will be cited in the respective sections (Table 4).

### 2.1. rms radii from $e^-$ and $\mu^-$

In addition to the compilations, original papers and personal communications have also been taken into account up to January 2004. Of outstanding importance is the compilation [10]. It contains precise rms radius data evaluated model independently by combining  $e^-$ ,  $\mu^-$ , and OIS. The sources and treatment of data have been described in [11,12] together with a list of the references,  $e^-$ : 316,  $\mu^-$ : 145. Therefore, this pre-1999 reference list for  $e^-$ ,  $\mu^-$  is not repeated here.

At this point, some remarks on the radius data for the proton and deuteron are appropriate. Worldwide data on elastic (el) electron–proton scattering have been re-analyzed taking into account corrections for Coulomb distortion and higher moments, resulting in an rms charge radius  $R_{p,el} = 0.895(18)$  fm [13]. The evaluation of high accuracy data of the  $1S$  Lamb shift (LS) in hydrogen yielded  $R_{p,LS} = 0.883(14)$  fm [14]. The weighted average (av) of these two independent data is  $R_{p,av} = 0.887(11)$  fm. For the deuteron, the analysis of world data on elec-

tron scattering resulted in  $R_{d,el} = 2.130(12)$  fm [15]. From the measurement of the hydrogen–deuterium isotope shift, the difference of deuteron–proton rms charge radii have been derived:  $R_d^2 - R_p^2 = 3.8212(15)$  fm<sup>2</sup> [16]. Using this as a constraint between  $R_{p,av}$  and  $R_{d,el}$  in a weighted least-squares adjustment procedure, we have  $R_p = 0.8791(88)$  fm and  $R_d = 2.1402(91)$  fm as listed in Table 1.

The final database selected contains 460 radius values (from the 1367 data published) for 285 nuclides. In some cases, the error estimates did not contain all components of uncertainty, e.g., model dependence, nuclear polarization correction, etc. In these cases a further error component was added, estimated after reading the respective literature. Quite often, there are several measured radius values for the same nucleus. To find the average value  $R_{av}$  and its uncertainty  $\Delta R_{av}$  of a data group, two different methods were used, an iteration procedure and a single-step one [11]. The results are more sensitive to the decision of which data are included in the procedure, and less sensitive to the way in which the individual data are weighted to form an average. The resulting data system contains 285 isotopes of 85 elements.

### 2.2. Differences of rms radii from $e^-$ and $\mu^-$ (not isotopes)

There are 94 data for 91 pairs of nuclei [7,10,17–20]; some data are from  $e^-$ , others from  $\mu^-$ , while most of them result from a simultaneous evaluation  $e^- + \mu^-$ . Results of  $\mu^-$  measurements are often published as Barrett moment [21] differences  $\delta R_B$ . Then the relationship [22]

$$\delta R = v(Z) \sqrt{\frac{3}{5}} \delta R_B, \quad v(Z) = 1 + 0.0035 \times \ln(0.22 \times Z + 1) \quad (1)$$

was applied to derive the rms radius difference  $\delta R$ , where  $Z = (Z_1 + Z_2)/2$ . In the deformed region the coefficient  $v(Z)$  is somewhat modified:  $v(Z)_{\text{def}} = v(Z) + 0.00054 \times \min(Z - 60, 77 - Z)$ .

### 2.3. Application of constraints

In several cases, there are redundant, independently measured differences in a group of  $\delta R$  data, that is, in addition to  $\delta R_{12}(\pm \Delta \delta R_{12})$  and  $\delta R_{23}(\pm \Delta \delta R_{23})$  the radius difference  $\delta R_{13}(\pm \Delta \delta R_{13})$  is also measured, e.g.,  $^{12}\text{C}$ – $^{14}\text{N}$ ,  $^{14}\text{N}$ – $^{16}\text{O}$ , and  $^{12}\text{C}$ – $^{16}\text{O}$ . In these cases the relation  $\delta R_{13}^0 = \delta R_{12}^0 + \delta R_{23}^0$  between the true values  $\delta R_{ik}^0$  can be exploited to improve the accuracy. To do this, the method of weighted least-squares was used. This also made it possible to check the internal consistency of the data group by a  $\chi^2/n'$  test. The new errors are less than the original ones, being always the least precise measurement that benefits most of the constraint. Some  $\mu^-$  data groups have already been conditioned during the evaluation of the experiment and so published. Naturally, for these groups the above procedure was not applied. Constraints of the type  $R_2^0 = R_1^0 + \delta R_{12}^0$  were also applied.

### 2.4. Radius differences between isotopes from $e^-$ and $\mu^-$

The main source for  $\delta R$  data between isotopes from electron scattering was the compilation [7], but original papers were also taken into account. There are altogether 88  $\delta R$  values for 66 isotope pairs. From multiple data a weighted average was formed. For  $\delta R$  values from muonic X-rays the main source was [10], but results from original papers were also included. Resulting in altogether 195 data for 184 isotope pairs. Most of these data are Barrett differences, so they had to be transformed to rms differences making use of Eq. (1).

### 2.5. Radius differences between isotopes from $K_\alpha$ isotope shifts

Most of the 89  $K_\alpha IS$  data are from Table II of [10], which is an extended version of [2]. Original papers have also been taken into account [23–25]. Two modifications were performed in Table II of [10]: (1) for uranium the correct mass interval is  $^{233}$ – $^{238}\text{U}$  instead of  $^{235}$ – $^{238}\text{U}$ , see [26] and (2) regarding the results of a  $\chi^2/n'$  test [27], the shift for  $^{121}$ – $^{123}\text{Sb}$  [28] was omitted and some error estimates increased. In the tables energy shifts  $\delta E_{\text{Coul}}$  are given, which can be expressed in terms of even moments of the charge distribution:  $\delta E_{\text{Coul}} = C_1 \lambda$ , where the nuclear parameter

$$\lambda = \delta \langle r^2 \rangle + \frac{C_2}{C_1} \delta \langle r^4 \rangle + \frac{C_3}{C_1} \delta \langle r^6 \rangle + \dots \quad (2)$$

contains information on the size of the nucleus. Seltzer [29] calculated the coefficients  $C_1$ ,  $C_2$ , and  $C_3$ . The ratios  $C_2/C_1$  and  $C_3/C_1$  have also been calculated by [30,31]. Dividing the measured energy shift  $\delta E_{\text{Coul}}$  by  $C_1$ , one arrives at  $\lambda$  that contains the rms radius difference. Although a plot of  $\lambda_{KIS}$  from  $K_\alpha IS$  against  $\lambda_{e\mu}$  values formed from  $e^-$  and  $\mu^-$  shows a linear correlation for three isotope pairs of Pb (Fig. 1 of [10]), the validity of  $C_1(Z)$  has not been tested experimentally for a wide range of atomic numbers. By 2000, the wealth of  $\delta R$  data from  $e^-$  and  $\mu^-$  experiments made it possible to compare the  $C_1$  value to experiment. In [27] 54 energy shifts  $\delta E_{\text{Coul}}$  of 18 elements and the respective radius differences  $\delta R$  from  $e^-$  and  $\mu^-$  are used to determine the experimental coefficients  $C_{1,\text{exp}} = \delta E_{\text{Coul}}/\lambda_{e\mu}$  in the atomic number interval  $Z = 42$ –92. These experimental coefficients were then compared to the theoretically calculated  $C_1$  values by a  $\chi^2(f)$  minimization analysis, where  $C_{1,\text{exp}} = f \times C_1$ . The result is  $f = 0.965(14)$ , i.e., the experimental  $C_{1,\text{exp}}$  values are, on the average, 3.5% lower than those calculated by Seltzer. It would be most desirable to have a new, more recent calculation of the momentum coefficients  $C_1$ ,  $C_2$ , and  $C_3$  with up-to-date theoretical methods.

Applying now the modified Seltzer coefficients  $C'_1 = f \cdot C_1$  ( $f = 0.965$ ), we have the modified nuclear parameter  $\lambda' = \lambda/f$ , from which the difference of mean square radii can be determined by a rapidly converging iteration procedure. Starting with  $\delta \langle r^2 \rangle_0 = \lambda'$ ,

$$\begin{aligned} \delta \langle r^2 \rangle_{i+1} &= \lambda' - \frac{C_2}{C_1} \left[ a_4 \left( \delta \langle r^2 \rangle_i \right)^2 + b_4 \delta \langle r^2 \rangle_i \right] \\ &\quad - \frac{C_3}{C_1} \left[ a_6 \left( \delta \langle r^2 \rangle_i \right)^3 + b_6 \left( \delta \langle r^2 \rangle_i \right)^2 + c_6 \delta \langle r^2 \rangle_i \right], \end{aligned} \quad (3)$$

where

$$a_4 \equiv \frac{25}{14} \left( \frac{A_2 + A_1}{A_2 - A_1} \right), \quad b_4 \equiv \frac{30}{7} (\pi a)^2,$$

$$\begin{aligned} a_6 &\equiv \frac{125}{48} \left( \frac{A_2 + A_1}{A_2 - A_1} \right)^2, \quad b_6 \equiv \frac{275}{18} (\pi a)^2 \left( \frac{A_2 + A_1}{A_2 - A_1} \right), \\ c_6 &\equiv \frac{239}{9} (\pi a)^4 \end{aligned}$$

refer to a Fermi distribution with a constant surface diffuseness  $a = t/(4 \ln 3)$  and a mass number dependence  $c = r_0 A^{1/3}$  for the half-density radius  $c$ . Note that the value of  $c$  and  $r_0$  does not appear in the expressions.

### 2.6. Radius differences from optical isotope shifts

The sources of  $\lambda$  or  $\delta \langle r^2 \rangle$  data published before 1989 are the compilations [6,8]. More recent results are taken from original papers, they are listed among the references. Not

all of the data are included in the table. Preference was given to long, recently measured isotopic series. Sometimes, however, results from two different measurements had to be merged. Wherever possible, relative (experimental) and total (experimental + systematic) errors were separately treated. This is because the main motivation of the present work was the investigation of the radius surface  $R(N, Z)$ . This necessitates the knowledge of absolute radii  $R$ . The procedure for the determination of  $\lambda$  and  $\delta\langle r^2 \rangle$  values from the measured  $\delta\nu$  frequency shifts is described in detail in [6,10,32], together with the limitations of the procedure. Here only the main steps will be recalled. The isotope shift consists of a mass shift and a field (or volume) shift:  $\delta\nu = \delta\nu_{MS} + \delta\nu_{FS}$ . The latter term can be written in the form  $\delta\nu_{FS} = F\lambda$ , where the nuclear parameter  $\lambda$  has the same form as in the case of  $K_zIS$  (Eq. (2)). Although the values of  $C_{i,\text{Opt}}$  for optical transitions are an order of magnitude less than those  $C_{i,K}$  for  $K_z$ , the corresponding ratios are practically equal:  $C_{2,\text{Opt}}/C_{1,\text{Opt}} \approx C_{2,K}/C_{1,K}$  and  $C_{3,\text{Opt}}/C_{1,\text{Opt}} \approx C_{3,K}/C_{1,K}$ . Therefore, the iteration procedure described above can be utilized for those  $OIS$  results, where only  $\lambda$  values are given. In [8] and in some recent papers the measurements have already been evaluated by the so-called two-parameter model [33,34]. These  $\delta\langle r^2 \rangle$  values were accepted without changes. A comparison of the two procedures (Table I of [35]) shows that the results are close to each other, the difference being an order of magnitude less than the total error. Radius differences  $\delta R \equiv \delta\langle r^2 \rangle^{1/2}$  were calculated from  $\delta\langle r^2 \rangle$  by the relation  $\delta R = \delta\langle r^2 \rangle/(R_1 + R_2)$ . For nuclei where no data for  $R_1$  and  $R_2$  existed, but there were  $R$  values for the neighbors on both sides, linear interpolation was used to estimate the missing radius. In the case of isotopic chains, the relation [36,37]

$$R(A) = R(A_0) \times \left( \frac{A}{A_0} \right)^{1/5} \quad (4)$$

was applied for extrapolation from the stable nucleus with mass number  $A_0$ . For the elements Re, Po, Rn, Fr, Ra, and Cm there are no measured  $R$  values. In these cases,  $R(A_0)$  was estimated by the expression [38]

$$R(A_0) = \left( r_0 + \frac{r_1}{A_0^{2/3}} + \frac{r_2}{A_0^{4/3}} \right) \times A_0^{1/3} \quad (5)$$

with  $r_0 = 0.891(2)$  fm,  $r_1 = 1.52(3)$  fm, and  $r_2 = -2.8(1)$  fm. Note that these elements are used in Section 3 only for the investigation of relative  $R_Z(N)$  dependence, but they were omitted while investigating the  $R_N(Z)$  and  $R_A(I)$  dependence, which necessitated the knowledge of absolute  $R$  values.

## 2.7. Adjusting OIS to $e^- + \mu^- + K_zIS$

The systematic errors arising from specific mass shift and electron factors can be reduced if  $\delta R$  values from other experimental methods are also available. Therefore,

weighted averages  $\delta R_{e\mu KO}$  were formed. In doing this, total errors  $\Delta\delta R_{O,\text{tot}}$  were used. The uncertainty  $\Delta\delta R_{e\mu KO}$  is significantly less than the original  $\Delta\delta R_{O,\text{tot}}$ . The reduction varies from element to element between 0.2 and 0.6. Using these improved rms differences  $\delta R_{e\mu KO}$  and the respective absolute  $R_{e\mu}$  radii, 32 data triplets ( $2R, 1\delta R$ ) and 63 quintets ( $3R, 2\delta R$ ) could be formed, and the respective constraints applied. This further improved the accuracy and rendered it possible to correct three inconsistencies. As a result, we have  $R$  and  $\delta R$  values that contain in a consistent way all of the experimental information from the four methods. These nuclei constitute the backbone along the valley of stability, onto which the wings, the isotopic series of  $\delta R$  values from  $OIS$ , will be fitted.

## 2.8. Fitting $\delta R_{OIS}$ series to the backbone

As described in the foregoing,  $\delta R_{e\mu KO}$  values were formed for those isotope pairs for which at least two of the four methods were available. Relating the  $\delta R_{e\mu KO}$  differences to those measured by  $OIS$ , correction factors  $\delta R_{e\mu KO}/\delta R_{OIS}$  were formed, their values varied between 0.9 and 1.3. These factors were used to correct those  $\delta R_{OIS}$  differences for which only  $OIS$  measurements were available, thus correcting for the eventual common systematic error factor. The corrected  $\delta R_{OIS}$  differences, i.e., the wings were added to the respective backbone  $R$  values obtained in the previous paragraph. In this way a set of rms charge radii was obtained, displayed in Table 1. As the correction factor has the same value for the element, this correction does not change the relative trend of  $R_Z(N)$  isotopic dependence. However, it improves the absolute  $R$  values, which are important for the investigation of the radius surface  $R(N, Z)$ .

## 3. Properties of the radius surface $R(N, Z)$

The set of data in Table 1 allows one to investigate the properties of the radius surface  $R(N, Z)$  or  $R(A, I)$ . It is practical to consider this complicated set of points as the superposition of two structures: a smooth, slowly varying surface describing the global or rough structure, and a fine structure having valleys near magic nucleon numbers and mountains at deformations; odd–even staggering is also observed. The shell and deformation dependence has long been investigated [9,37,39–42]. On the other hand, the slow variations almost escaped attention, in spite of the fact that it may be a useful tool for extrapolation of  $R$  values to the limits of nucleon stability.

### 3.1. Global behavior of the radius surface along the valley of stability

First, following tradition, the mass number dependence along the valley of stability is examined using 299

isotopes of 74 elements. The radius parameter  $r_{LD}$  of the well-known liquid-drop (LD) model [43]

$$R_{LD} = r_{LD} A^{1/3} \quad (6)$$

was determined by a minimum- $\chi^2$  procedure. The result is shown in Table 2 together with the standard deviation and the reduced  $\chi^2$  value  $\chi^2/n'$ . It is interesting to see that the purely empirical function

$$R_e = r_e A^e \quad (7)$$

has its best fit with an exponent value  $e = 0.294(1)$ , which significantly differs from 1/3. Taking into account the finite surface thickness, Elton [44] derived a three-parameter formula

$$R_s = \left( r_0 + \frac{r_1}{A^{2/3}} + \frac{r_2}{A^{4/3}} \right) \times A^{1/3}, \quad (8)$$

which yields a better fit to the data. During the work it was found that the parameters  $r_1$  and  $r_2$  are strongly anticorrelated, which can be described by the simple linear relation  $r_2 \approx -(1.4r_1 - 1)$ . Hence, there remain only two free parameters in Eq. (8).

### 3.2. Intersections of the radius surface

The properties of the radius surface can be investigated by studying its different intersections by planes perpendicular to the  $(N, Z)$  plane, namely the  $R_Z(N)$ ,  $R_N(Z)$ , and  $R_A(I)$  dependencies. As the latter is redundant information, its result can be used to apply a constraint with the former two. Finally, the direction  $\Delta Z/\Delta N$ , for which  $R(N, Z) \approx \text{constant}$ , is determined. For isotopic chains the radius formula

$$R_Z(N) = R_0 \left( \frac{A}{A_0} \right)^{k_Z}, \quad A = A_0 + \Delta N \quad (9)$$

was applied, where  $R_0$  is the rms charge radius of the reference isotope  $(Z, A_0)$ . Results of a weighted least-squares fit ( $k_Z$ , standard deviation (SD) and  $\chi^2/n'$ ) are indicated in Table 3 under the column “From experiment.” The procedure was also performed separately for proton-rich and neutron-rich nuclei. The  $Z$ -dependence along isotonic series was investigated by fitting the formula

$$R_N(Z) = R_0 \left( \frac{A}{A_0} \right)^{k_N}, \quad A = A_0 + \Delta Z. \quad (10)$$

The resulting value of the parameter  $k_N$  is shown in Table 3. The simplified neutron and proton number dependence is illustrated schematically in Fig. 2, using rounded values of the exponents. It follows that the smooth component of the radius surface, around the nuclid  $A_0 = Z_0 + N_0$ , can be described by

$$\begin{aligned} R(N, Z) &= R_0 \left( \frac{Z_0 + N}{A_0} \right)^{k_Z} \left( \frac{Z + N}{Z_0 + N} \right)^{k_N} \\ &\approx R_0 \left( 1 + \frac{\Delta N}{A_0} \right)^{k_Z} \left( 1 + \frac{\Delta Z}{A_0} \right)^{k_N}, \end{aligned} \quad (11)$$

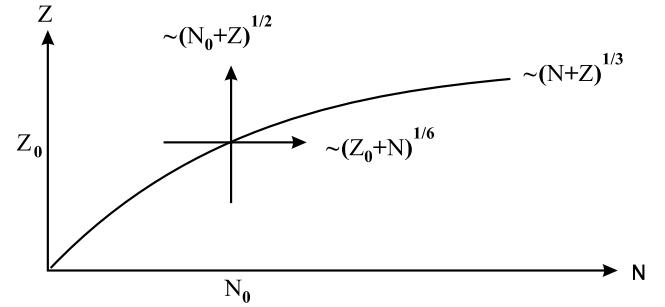

Fig. 2. Schematic illustration of the smooth radius surface  $R(N, Z)$  around a reference nuclide  $R(N_0, Z_0)$  (see Eqs. (9) and (10)). The exponents are rounded values of the empirical parameters shown in Table 3.

where  $R_0 \equiv R(N_0, Z_0)$ ,  $\Delta Z \equiv Z - Z_0$ , and  $\Delta N \equiv N - N_0 \ll N$ .

Next, referring to Fig. 3, the surface  $R(N, Z)$  can be represented by the level lines corresponding to rms radii with intervals  $\Delta R = 0.5 \text{ fm}$  (Fig. 3B). For comparison, contour lines of the liquid-drop formula, Eq. (6) are plotted in Fig. 3A.

Along isobaric series the dependence of rms radii on the symmetry parameter  $I \equiv (N - Z)/A$  was studied by  $R_A(I) = R_0[1 + f(I - I_0)]$ ,  $I_0 \equiv (N_0 - Z_0)/A$ . (12)

The results for  $f$  are also shown in Table 3. They are close to those published earlier [45,46]. The search for the level lines  $R(N, Z) = \text{constant}$  was performed considering a formula similar to those above

$$R_L(\Delta N, \Delta Z) = R_0 \left( \frac{A}{A_0} \right)^{k_{CR}} \quad (13)$$

( $k_{CR}$  is the parameter for constant radius) but it was used in a different way; during the fits the  $|k_{CR}| \approx 0$  value was sought by choosing different directions in the  $(N, Z)$  plane. A direction can be characterized by the slope  $\Delta Z/\Delta N$ , and also by the value of the invariant  $L$ . For example, nuclei on the line with slope  $(\Delta Z/\Delta N) = -(1/3)$  are characterized by  $L = 3Z + N = \text{constant}$  as  $^{20}_{11}\text{N}-^{22}_{10}\text{Ne}$ . This means that, on the average, a decrease of rms charge radius caused by picking out a proton from the nucleus can be compensated by adding three neutrons to it.

### 3.3. Application of constraints between the empirical parameters

Having these experimental parameters, their values can be improved by using the relations between them.

1. Starting from  $A_0 = N_0 + Z_0$  one can arrive at the isobar  $A = N + Z = A_0$  by the isotopic chain of element  $Z_0$  through  $A_1(N, Z_0)$  followed by the isotonic series containing  $N$  neutrons. Alternatively, one can step directly from  $(N_0, Z_0)$  to  $(N, Z)$  by varying the symmetry

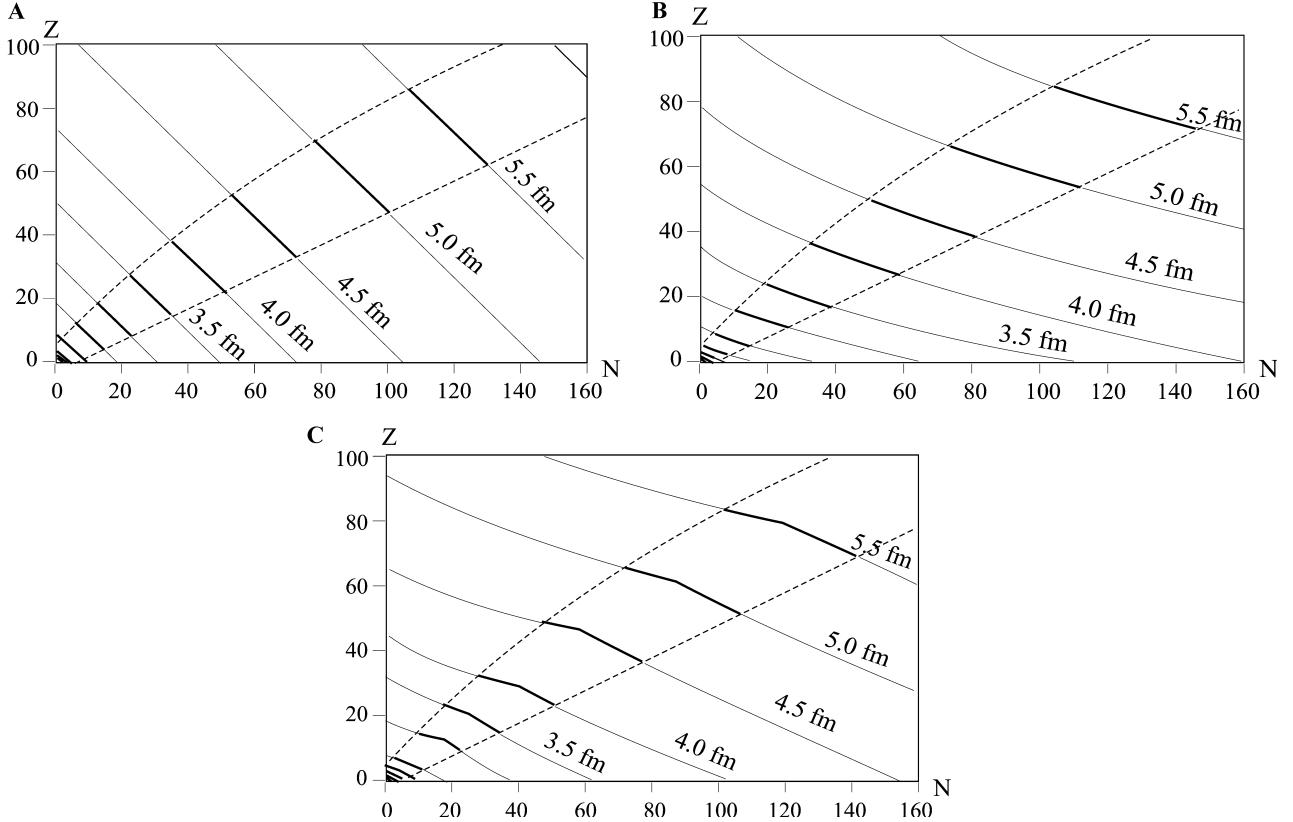

Fig. 3. (A) Level lines of the surface described by the liquid-drop model, Eq. (6) of Section 3. Broken lines show the region of nucleon stability. (B) Level lines of the surface described by the empirical formulae Eqs. (9) and (10) in Section 3. The slope  $-0.33$  means that a decrease in  $R$  caused by removing a proton from the nucleus can be compensated by adding three neutrons to it. Broken lines show the region of nucleon stability. (C) Same as (B) but with separate parameter values for proton-rich and for neutron-rich nuclei (see Table 3). The indentation on the radius surface along the line of stability is clearly seen (see also Section 3).

parameter  $I$ . It can be shown that the relation for the true values of the parameters

$$f^0 \approx \frac{1}{2}(k_Z^0 - k_N^0) \quad (14)$$

is valid to a good approximation. The systematic error of this approximation ( $\leq 1\%$ ) is much less than the experimental uncertainties of the parameters. The results for  $k_Z$ ,  $k_N$ , and  $f$  derived by this constraint are shown in the last column of Table 3.

2. It can also be shown that for nuclei along iso-radius series ( $R \approx \text{constant}$ ) the ratio  $-k_Z/k_N$  is close to the slope  $\Delta Z/\Delta N$ . Therefore, this ratio can be regarded as an independent estimation of the slope. Here, the systematic error of the approximation ( $\sim 10\%$ ) is about the same size as the experimental one. This is taken into account by choosing the weights accordingly. Then the weighted average of  $-k_Z/k_N$  and  $\Delta Z/\Delta N$  was formed. These are shown for  $\Delta Z/\Delta N$  in the last column of Table 3.

#### 3.4. The two-liquid drop model

The smooth behavior of the radius surface renders its interpretation possible by a simple model, which is a

simple extension of the traditional liquid-drop approach. Here only the main characteristics and results are described and details will be published elsewhere. The model works with uniform density distributions (by sections) for protons and neutrons separately. Their sum  $\rho_0 = \rho_P + \rho_N$  is assumed constant within a radius  $R_0 = (3A/4\pi\rho_0)^{1/3}$ . In the calculations an average nucleon density  $\rho_0 = 0.128 \text{ n}/\text{fm}^{-3}$  was used, as obtained from fitting the liquid-drop formula (6) to stable nuclei. (The value  $\rho_{0,F} \approx 0.17 \text{ n}/\text{fm}^{-3}$ , as often found in the literature, refers to the maximum density of a Fermi-like distribution fitted to measurements on the heaviest nuclei [44, p. 50].) It is assumed that in stable nuclei  $\rho_{P,st}$  and  $\rho_{N,st}$  both extend to  $R_0$ . Away from stability the extension and ratio of  $\rho_P$  and  $\rho_N$  are different. In proton-rich nuclei there is a proton skin from  $R_N$  to  $R_0$ ; in neutron-rich nuclei there is a neutron skin from  $R_p$  to  $R_0$ . In the case of tin isotopes, rms radius values calculated by the model and by Eq. (9) are close to each other, the standard deviation being  $SD = 0.004 \text{ fm}$ . The skin thickness formed by the majority nucleons depends almost linearly on  $dA \equiv A - A_{\text{stab}}$ :  $dR = 0.008 \times dA$ . Here the skin thickness  $dR$  is defined naturally as the difference between the radius parameters of the model, while

most experiments generally yield the difference of rms neutron and proton radii. For uniform density distributions with radius difference  $dR_{np}$  the simple relation holds:  $d\langle r^2 \rangle_{np}^{1/2} = \sqrt{3/5} dR_{np}$ . It should be noted that in the present simple form of the model it was postulated that at the line of stability the proton and neutron densities have the same radius, the skin thickness vanishes. This may not be true. There is evidence for a finite neutron skin, e.g. [47].

Small differences between the model and the empirical formula (9) suggested that different values for the empirical parameters should be used for proton-rich and neutron-rich nuclei, respectively. Results of these parameter searches are shown in Table 3. The level lines of the surface  $R(N, Z)$  calculated with these parameters are plotted in Fig. 3C. It seems that there is an indentation in the radius surface along the stability line.

A possible interpretation for the indentation may be a decrease in  $\rho_0$  as one moves away from the line of stability. Assuming a linear dependence on  $|I - I_{st}|$ , the nuclear density  $\rho_0 = \rho_{0,st}(1 + g|I - I_{st}|)$  was introduced into the model by varying the value of the parameter  $g$ , so that the minimum SD was searched. In the case of the  $Z = 50$  isotopic series the result is  $g = -0.12$  ( $SD = 0.0021$ ). That is, going away from the line of stability to  $|I - I_{st}| = 0.1$ , e.g., from  $A = 118$  to 105, the density  $\rho_0$  decreases by 1%.

#### 4. Fine structure in the charge radii

Along the valley of stability radii of nuclei near or at magic nucleon numbers are significantly less than the average trend, while they deviate upwards in between. These deviations can be described by the nucleonic promiscuity factor [48]  $P \equiv N_p N_n / (N_p + N_n)$  in the formula [45]

$$R_p = R_{0,p} + dR_p \\ = \left( r_{0,p} + \frac{r_{1,p}}{A^{2/3}} + \frac{r_{2,p}}{A^{4/3}} \right) \times A^{1/3} + a \frac{P}{R_{0,p}} \quad (15)$$

where  $R_{0,p}$  is the radius for closed-shell nuclei, while  $N_p$  and  $N_n$  are numbers of valence protons and neutrons (or holes), respectively. Values of the parameters  $r_{0,p}$ ,  $r_{1,p}$ ,  $r_{2,p}$ , and  $a$  are shown in Table 2. For the calculation of the factor  $P$  the following magic numbers produced the best fit:  $Z_M = 2, 6, 14, 28, 50, 82, (114)$ , and  $N_M = 2, 8, 14, 28, 50, 82, 126, (184)$ . It should be noted that in other investigations [42,49,50], too, the irregular magic numbers 6 and 14 proved to be present. Other semi-magic proton and neutron numbers at  $Z_M = 40, 64$  and  $N_M = 56$  [51] were also tested in several combinations but without positive result. The parameters of the formula vary somewhat with mass number; therefore, the

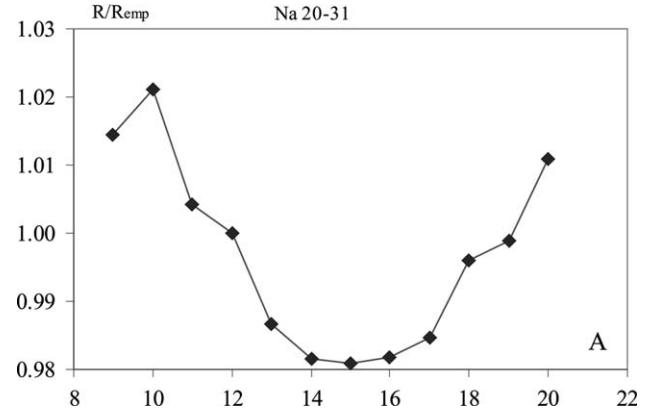

Fig. 4.  $R/R_{emp}$  values for sodium isotopes.  $R$ , Experimental rms charge radii from [52];  $R_{emp}$ , radii calculated by the empirical formula Eq. (9) in Section 3.

parameter set for light nuclei  ${}^9Be$ – ${}^{27}Al$  is separately given in Table 2.

Along isotopic series the smooth function  $R(N, Z)$  may be used to divide the individual experimental  $R$  values. The resulting  $R/R_{emp}$  values (where  $R_{emp}$  is the value of the smooth empirical function for the given nucleus) along isotopic series follow nearly the same systematics as observed earlier [9,37,39–42], showing pronounced shell effects for neutron numbers  $N = 28, 50, 82$ , and  $126$ . In the case of light nuclei  $N \sim 14$ – $16$  they seem to have magic character (see Fig. 4 regarding experimental data from [52]). (Figures for other elements can be obtained from the author.) A sudden increase at the transitional region  $N \sim 88$ – $90$  can also be clearly observed. Isotonic series are less accurate, but the main shell effects at  $Z = 28, 50$ , and  $82$  are clearly noticeable.

#### Acknowledgments

This work was supported by the International Atomic Energy Agency under Research Contract No. 9333. The author is indebted to Dr.G. Varga for his contribution to this work. Thanks are also due to Professor R. Boehm for helpful information.

## Explanation of Tables

**Table 1.** Nuclear rms charge radii

Z	Atomic (proton) number of the element
EI	Chemical symbol of the element
(El)	For six elements, designated by parentheses (El) there are only $\delta R$ measurements; the reference $R_0$ values were estimated by Eq. (5)
A	Mass number of the isotope
$R$ (fm)	$\equiv \langle r^2 \rangle^{1/2}$ . Experimental root-mean-square charge radius in fm = $10^{-15}$ m. For the neutron $\langle r^2 \rangle$ is given in fm <sup>2</sup> . For the proton, see also paragraph 3 in Section 2.
$\Delta_{\text{tot}}R$ (fm)	Total error of $R$ , including both experimental and systematic errors, in fm = $10^{-15}$ m. See Section 2
$\Delta_{\text{rel}}R$ (fm)	Relative error of $R$ with respect to the radius of the reference isotope; in fm = $10^{-15}$ m. See Section 2

**Table 2.** Parameters of radius formulae for nuclei near the stability line

Model	Model underlying the radius formula
Equation	Number of the equation of the radius formula in Section 1
Parameters	Best-fit parameter values of the formula
St. Dev. (fm)	Standard deviation of the experimental data from the formula
$\chi^2/n'$	Reduced $\chi^2$ value

**Table 3.** Empirical parameters characterizing the radius surface  $R(N, Z)$

Equation	Number of the empirical formula
Parameter	Parameter of the formula
Region	Region of nuclei where the fit was performed
From experiment	Result of the best-fit procedure to the experimental data
St. Dev. (fm)	Standard deviation of the experimental data from the formula
$\chi^2/n'$	Reduced $\chi^2$ value
With constraint	Parameter values improved by the constraints, see Eq. (14) in Section 3.

**Table 4.** Annotated references for the Introduction and for the Tables

Table 1

Nuclear rms charge radii. (For the neutron the entry is  $\langle r^2 \rangle$  (fm $^2$ ) and for the proton and deuteron, see Section 2.) See page 194 for Explanation of Tables

Table 2

Parameters of radius formulae for nuclei near the stability line. See page 194 for Explanation of Tables

Model	Equation	Parameters	St. Dev. (fm)	$\chi^2/n'$
Liquid drop	(6)	$r_{LD} = 0.9542(13) \text{ fm}$	0.106	2894
Empirical exponent	(7)	$r_e = 1.153(7) \text{ fm}$ $e = 0.2938(12)$	0.05	669
Finite surface	(8)	$r_0 = 0.9071(13) \text{ fm}$ $r_1 = 1.105(25) \text{ fm}$ [ $r_2 = -0.548(34) \text{ fm}$ ]	0.04	467
Finite surface + P	(15)	$r_{0,P} = 0.8966(20) \text{ fm}$ $r_{1,P} = 1.128(35) \text{ fm}$ [ $r_{2,P} = -0.58(05) \text{ fm}$ ] $a = 0.0809(19) \text{ fm}^2$	0.023	167
Finite surface + P (light nuclei)	(15)	$r_{0,P} = 0.982(10) \text{ fm}$ $r_{1,P} = 0.32(10) \text{ fm}$ [ $r_{2,P} = +0.55(14) \text{ fm}$ ] $a = 3.93(42) \text{ fm}^2$	0.034	93

Table 3

Empirical parameters characterizing the radius surface  $R(N, Z)$ . See page 194 for Explanation of Tables

Equation	Parameter	Region	From experiment	St. Dev. (fm)	$\chi^2/n'$	With constraint
(9)	$k_Z$	All nuclids	0.149(15)	0.036	64	0.156(14)
		Proton-rich	0.131(25)	0.027	27	0.128(23)
		Neutron-rich	0.219(30)	0.025	35	0.240(27)
(10)	$k_N$	All nuclids	0.484(15)	0.027	29	0.478(14)
		Proton-rich	0.482(25)	0.027	23	0.485(23)
		Neutron-rich	0.484(30)	0.017	20	0.463(27)
(12)	$f$	All nuclids	-0.148(15)	0.032	38	-0.161(9)
		Proton-rich	-0.185(25)	0.027	17	-0.179(14)
		Neutron-rich	-0.070(30)	0.019	16	-0.112(17)
(13)	$\Delta Z/\Delta N$	All nuclids	-0.33(4)	0.035	34	-0.33(4)
		Proton-rich	-0.25(6)	0.029	18	-0.25(5)
		Neutron-rich	-0.67(10)	0.027	19	-0.62(8)
