An FLC includes three parts: fuzzifier, fuzzy reasoning unit, and defuzzifier. The fuzzifier converts ordinary inputs into their fuzzy counterparts, the fuzzy reasoning unit creates fuzzy control signals based on these fuzzy variables, and the defuzzifier converts the fuzzy control signals into the real control outputs. The block diagram of a fuzzy control system is shown in Figure 6.5.9, where e, d, and u are tracking error, derivative error, and output control action; $\tilde{e}$, $\tilde{d}$, and $\tilde{u}$ are their fuzzy counterparts, respectively; y is the controlled parameter; and r is the set point for y. K_p is the scale factor for e, K_d is the scale factor for d, and K_o is the output gain.

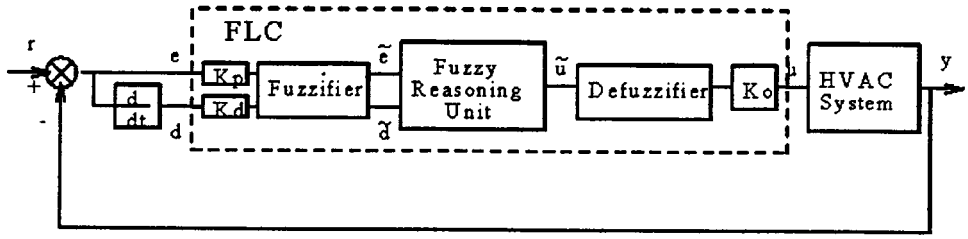

FIGURE 6.5.9 The block diagram of a fuzzy control system.

The control rules expressed in natural language are expressed in the following form:

IF (e is A) AND (d is B) THEN (u is C)

where A, B, and C are fuzzy subsets defined on the universes of discourse of e, d, and u, respectively. Every rule is interpreted into a fuzzy reasoning matrix:

$$R_k = \left[A_k(e) \otimes B_k(d)\right]^{\Theta} \otimes C_k(k) \qquad k = (1, N)$$

where N is the number of rules, the symbol $\otimes$ denotes aggregation operator, and the symbol Θ denotes an align-turning operator (see Section 19). The general fuzzy relation matrix R can be constructed as the union of the individual rules:

$$R = \bigcup_{k=1}^{N} R_k$$

© 1999 by CRC Press LLC

This matrix represents the relationship between the fuzzy inputs and the fuzzy control output. The fuzzy control output can then be calculated from the known fuzzy input $\tilde{e}$ and $\tilde{d}$ by

$$\tilde{u} = \left[\tilde{e} \otimes \tilde{d}\right]^{\Theta} \circ R$$

where the symbol ° denotes the max-min composition operator (see Section 19).

The input universe of discourse for tracking error *e* or derivative error *d* is divided into several degrees connected with a number of fuzzy subsets by membership functions. In this study, *e* and *d* can each range from –6 to +6, and 13 degrees are used:

$$-6, -5, -4, -3, -2, -1, 0, 1, 2, 3, 4, 5, 6$$

Also, seven fuzzy subsets are defined as:

$$\text{NL, NM, NS, ZZ, PS, PM, PL.}$$

where the first letters N and P mean negative and positive, the second letters L, M, and S mean large, middle, and small, and ZZ means zero. These degrees and fuzzy subsets are shown in Table 6.5.1 which uses a 1.0–0.8–0.5–0.1 distribution. For example, if *e* = 3, then its membership in PL is 0.1, its membership in PM is 0.8, etc.

The fuzzifier converts ordinary inputs into their fuzzy counterparts. In this study, a fuzzy singleton is used as a fuzzification strategy, which interprets an input, *e* (or *d*), into a fuzzy value, $\tilde{e}$ (or $\tilde{d}$), with membership function (μ) equal to zero except at the element nearest to the real input, where μ = 1.0. For example, if *e* = 3.2, the nearest element is 3, then the fuzzy singleton will be

© 1999 by CRC Press LLC

$$\tilde{d} = (0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 1,\ 0,\ 0,\ 0)$$

This fuzzy singleton has membership function $\mu = 1.0$ at the point of element $e = 3$. The defuzzifier converts the fuzzy control output created by the rule-based fuzzy reasoning unit into a real control action. In this study, weighted combination method is used as defuzzification strategy, which can be explained by the following example, if

$$\tilde{u} = (0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0.2,\ 0.4,\ 0.8,\ 0.7,\ 0.5,\ 0.1)$$

then

$$u = \left[0.2(1) + 0.4(2) + 0.8(3) + 0.7(4) + 0.5(5) + 0.1(6)\right] / \left[0.2 + 0.4 + 0.8 + 0.7 + 0.5 + 0.1\right] = 3.4$$

Rule Refinement. An FLC is characterized by a set of linguistic statements which are usually in the form of *if-then* rules. The initial set of rules is usually constructed based on the operators' experience, or sometimes by analyzing the dynamic process of the controlled plant. Both approaches require modifying the initial set of rules to obtain an optimal rule set. This is called *rule refinement.*

Figure 6.5.10 shows an initial rule set analyzed on a "linguistic plane". The horizontal axis expresses the fuzzy subsets defined on the universe of discourse for the tracking error (e), and the vertical axis expresses the fuzzy subsets defined on the universe of discourse for the derivative error (d). Both have seven fuzzy "values": NL, NM, NS, ZZ, PS, PM, PL. On the cross points of these fuzzy values there are output control action levels, which are also fuzzy subsets having seven "values" from Level 1 (TIny) to Level 7 (Very Strong). For example, the cross point of e = NM and d = PM indicates u = Level 3. This corresponds to the rule:

IF (e is NM) AND (d is PM) THEN (u is Level 3)

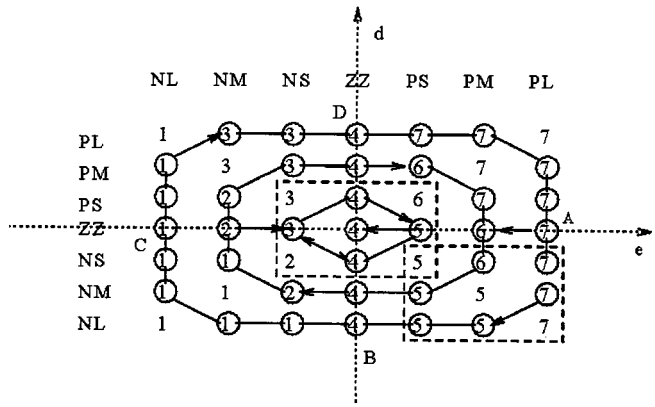

FIGURE 6.5.10 The initial rule set and performance trajectory on the linguistic plane.

For example, the initial rule set could be based on the following control strategies. First, it tries to keep a proportional relationship between the control action (u) and the tracking error (e). Note that if the derivative error (d) is ZZ, then the output control action (u) increases from Level 1 to Level 7 when the tracking error (e) changes from NL to PL. Second, the influence of derivative error (d) is considered such that, if it is positive, then increase the control action (u) a little bit, and if it is negative, then decrease the control action (u). For example, if the tracking error (e) keeps PM, the control action (u)

© 1999 by CRC Press LLC

increases from Level 6 to Level 7 when the derivative error (*d*) is positive, and it decreases from Level 6 to Level 5 when the derivative error (*d*) is negative.

Consider a second-order plant with a transfer function:

$$H(s) = \frac{1.0}{s^2 + 0.1s + 1.0}$$

that is controlled using the initial rule set to respond to a step input for computer simulation. The performance trajectory of the FLC is shown by the arrows in Figure 6.5.10 and the dynamic process of the normalized controlled parameter (CP) is shown in Figure 6.5.11 where the horizontal axis indicates the number of sample period (SP). The dynamic process can be divided into two stages. At the first stage, there is a strong oscillation with a higher frequency, and, at the second stage, there is a moderate swing with a smaller frequency. Looking at the performance trajectory in the linguistic plane, we can see that the stronger oscillation occurs at the out-cycle (points further from the center). As time increases, the state moves to the in-cycle near the center of the plane and becomes moderate. This shows that FLCs have the desirable property of a structure-variable controller. The rules at the out-cycle belong to one kind of structure for the first stage, and the rules at the in-cycle belong to another structure for the second stage.

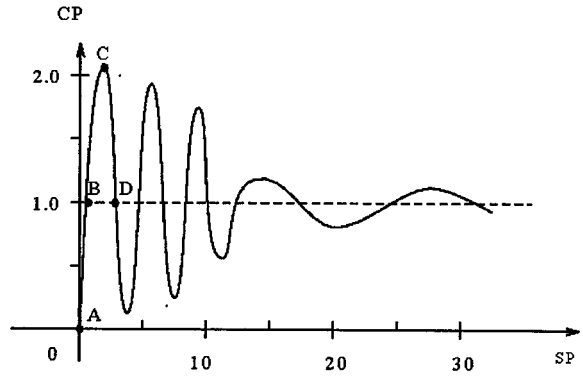

FIGURE 6.5.11 The dynamic process corresponding to Figure 6.5.10.

If the initial rule set does not satisfy a good design for a controller, then It can be modified by intuitive reasoning. A rule set is often symmetrically positioned about the central point, which is the desired stable operating point, where the tracking error (*e*) and the derivative error (*d*) both equal zero and the control action (*u*) is medium. When a positive step increase is imposed to the set point, the tracking error (*e*) has the biggest value and the derivative error (*d*) is zero at the beginning time (point A in the linguistic plane). With the regulating action, the tracking error (*e*) will decrease, the derivative error (*d*) will be negative, and the performance trajectory will enter into the right-bottom block in the linguistic plane. So, the rules in this area have the most important effect on the behavior of the first stage of the dynamic process. The most important area responsible for the behavior of the second stage is the central block.

To avoid strong oscillations, it is apparent that the control actions in the right-bottom block should be decreased. The modified rule set and its simulation of response to a step input are shown in Figure 6.5.12. The performance trajectory expressed in the linguistic plane is a spiral (Figure 6.5.12). We can see that the performance of the control system has been improved, but a small oscillation still exists and there is a little overshoot indicated by point C in Figures 6.5.12 to 6.5.13. Once again, the rule set is modified and the final rule set and its simulation of response to a step input are shown in Figure 6.5.14

© 1999 by CRC Press LLC

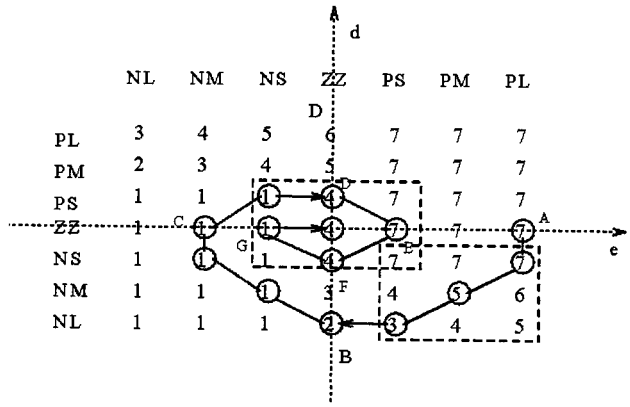

FIGURE 6.5.12 The second rule set on the linguistic plane.

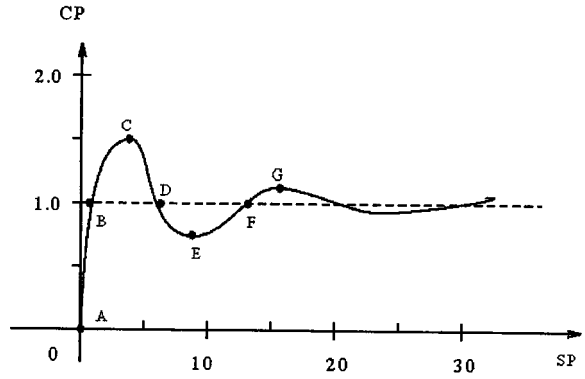

FIGURE 6.5.13 The dynamic process corresponding to Figure 6.5.12.

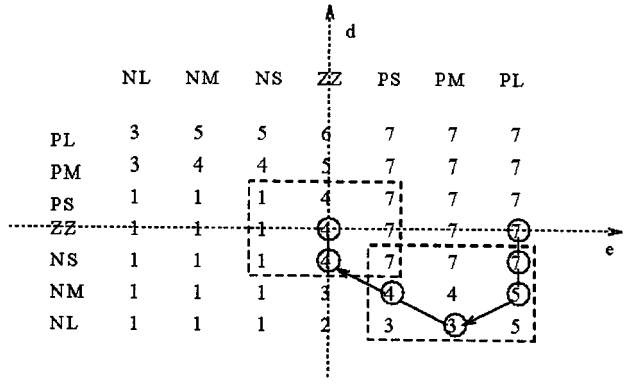

FIGURE 6.5.14 The third rule set on the linguistic plane.

and Figure 6.5.15. The final rule set gives good performance with a short rise time and a very small overshoot and it is considered satisfactory.

By analyzing the performance trajectory on the linguistic plane, a rule set is refined. It relies heavily on intuitive reasoning when comparing the dynamic process of the controlled parameter for the present rule set with the desired one.

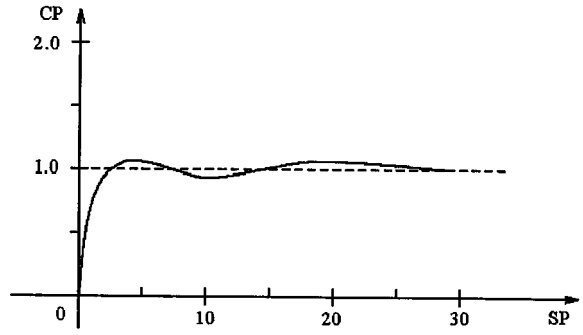

FIGURE 6.5.15 The dynamic process corresponding to Figure 6.5.14.

Completeness and Interaction of Rules and Selection of Membership Functions. The second significant influence on the behavior of an FLC is the membership functions. They should be chosen carefully in the adjustment process. As mentioned in Section 6.3, the fuzzy subsets, language variables NL, NM, NS, ZZ, PS, PM, and PL, are defined on the universe discourse of tracking error (e) or derivative error (d). Some possible membership functions are shown in Figures 6.5.16 to 6.5.18. The membership functions should be chosen to make these language variables have suitable coverage on the universe of discourse. For the case of Figure 6.5.16, the whole range is not covered by these language variables. There are some values of e or d, on which the membership functions of all language variables are zero. In this case, an empty output control action could be created. This means that the control actions are lost for those points which are not covered by any input fuzzy subset. This is referred as the non-completeness of control rules. FLCs should satisfy the condition of completeness for their membership functions. The membership function shown in Figure 6.5.17 cannot be used for an effective FLC. In other words, the union of all fuzzy subsets, X_i, i = [1,7], should be greater than zero for all $e \in E$, i.e.,

$$\forall e \in E \qquad \bigcup_{i=1}^{7} X_i(e) > 0$$

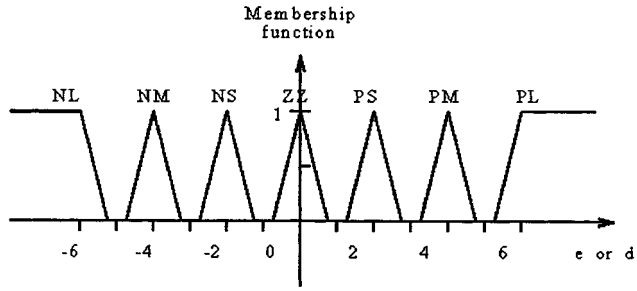

FIGURE 6.5.16 Non-complete membership function.

On the other hand, there can be interaction among the rules if the overlap of fuzzy subsets occurs on the range of the universe of discourse. In this case, the membership functions have the forms shown in Figures 6.5.17 and 6.5.18. The interaction tends to smooth out the set of control rules. Consider the single-input-single-output case for simplicity; the rule set is

$$\text{IF } (e \text{ is } A_i) \text{ THEN } (u \text{ is } C_i) \qquad i = [1,N]$$

© 1999 by CRC Press LLC

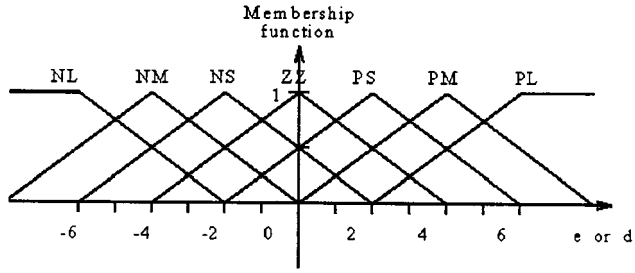

FIGURE 6.5.17 Heavy overlap membership function.

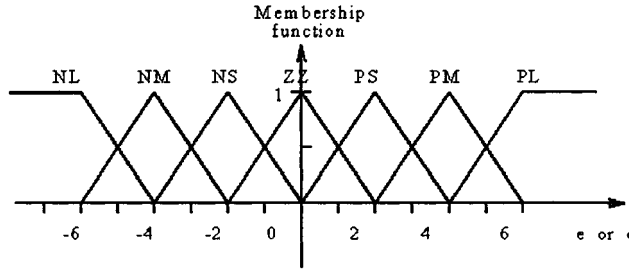

FIGURE 6.5.18 Moderate overlap membership function

where N is the number of rules in the set. These rules are incorporated into a fuzzy relation matrix as follows:

$$R = \bigcup_{i=1}^{N} R_i = \bigcup_{i=1}^{N} \left(A_i \otimes C_i\right)$$

If the fuzzy value of input e is known as $\tilde{e}$, the fuzzy output $\tilde{u}$ then can be calculated as follows:

$$\tilde{u} = \tilde{e} \circ R$$

If $\tilde{e}$ is A_i, $\tilde{u}$ is expected to be C_i. But now the interaction of rules due to overlap results in:

$$C_i \subseteq A_i \circ R$$

The equality is established only when no overlap occurs. This analysis is based on the fuzzy logic scheme including max-min composition operator. A more-detailed example of the numeric calculation is given in the appendices to this section.

If the overlap is heavy as shown in Figure 6.5.17, there will be large deformation and the control rules will lose their original shape. In the limit, as the membership functions become unity for all values, the output of the FLC will always be the same fuzzy quantity. This means that the fuzzy reasoning system conveys no valuable information and the FLC has lost its efficacy.

A moderate overlap, shown in Figure 6.5.18, is desirable to allow for reasoning with uncertainty and the need for completeness of the control rules. How does one determine the "size" of overlap? At present, we use intuitive judgment to choose membership functions when adjusting an FLC. There appears to be some latitude in choosing the amount of overlap, on which the performance of an FLC does not change significantly. The quantitative analysis will be given after further research.

© 1999 by CRC Press LLC

When we modify the control rules in the linguistic plane, the overlapping membership functions let the rules near the performance trajectory have an effect on the output control actions. This is because interactions occur among the neighboring rules.

Scale Factors and Output Gain

The scale factors, K_p and K_d, and the output gain, K_o, shown in Figure 6.5.19, also have significant influence on the behavior of an FLC. Their influence is not as complicated as those of rules and membership functions. The adjustment for the scale factors and output gain is comparatively simple. The scale factor K_p relates the actual range of tracking error (e) to the universe of discourse (E) defined in the fuzzy logic system. In this work, E consists of 13 degrees as indicated in earlier sections. Then K_p is determined as the ratio of the range of E to the range of the real variable:

$$K_p = \frac{E_{\max} - E_{\min}}{e_{\max} - e_{\min}}$$

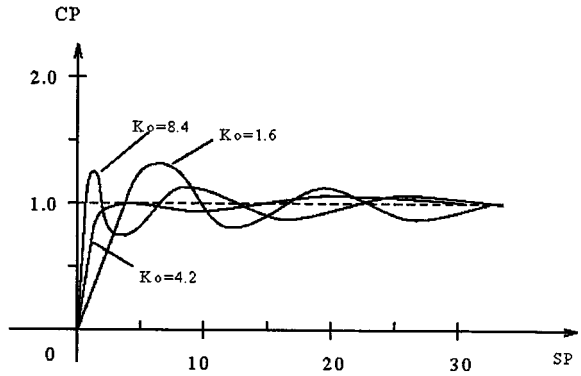

FIGURE 6.5.19 The influence of K_o on the behavior of FLCs.

For scale factor K_d, there is the similar analysis leading to

$$K_d = \frac{D_{\max} - D_{\min}}{d_{\max} - d_{\min}}$$

where D is the universe of discourse for derivative error (d) defined in the fuzzy logic system. Small K_p or K_d will narrow the control band, while large K_p or K_d will lead to loss of control for large inputs.

The output gain K_o is defined as follows:

$$K_o = \frac{u_{\max} - u_{\min}}{U_{\max} - U_{\min}}$$

It is the ratio of range of real output control action (u) to the range of its universe of discourse (U) defined in the fuzzy logic system. K_o acts as an amplification factor of the whole FLC. Figure 6.5.19 shows the influence of K_o on the step response simulation of an FLC with the final rule set used in Figure 6.5.14. Increasing K_o results in a shorter rise time. The performance trajectory in the linguistic plane will become steeper for the first stage and oscillation occurs. Decreasing K_o results in a longer rise time, and the performance trajectory in the linguistic plane will become moderate during the first stage. But, in our simulation, oscillation still occurred. This is because different K_o, larger or smaller, results in a new route of the performance trajectory which will activate the different rules which might

© 1999 by CRC Press LLC

cause oscillation. So the influence of output gain, K_o, should be considered together with the change of the activated rules.

Conclusion

An FLC can perform much better than a conventional controller, such as a PID controller, if the FLC has been well constructed. The main disadvantage of using FLCs today seems to be the lack of a systematic procedure for the design of FLCs. The general method for designing an FLC is to use trial and observation. No useful mathematical tool has yet been developed for the design of an FLC because of its fuzziness, complexity, and nonparameterization.

There are three significant elements that have notable influence on the behavior of an FLC:

1. The control rules expressed in linguistic language,
2. The membership functions defined for fuzzy subsets, and
3. The scale factors attached to the input and the output gains.

The control rules play the main role in forming the dynamics of FLCs. The rule set can be analyzed and modified using the performance trajectory technique and evaluated using the dynamic process curve of the controlled parameter. The membership functions define the "shape" of fuzzy subsets. They should have appropriate width to avoid noncompleteness and suitable interaction among the fuzzy control rules. The scale factors (K_p and K_d) and output gain (K_o) serve as amplification factors.

At present, each application must be individually designed. The initial sets of rules are specifically set up for different applications. Work is now underway to develop a self-adaptive FLC which will choose the initial set of rules automatically according to the process dynamics and refine it on the basis of the global performance evaluation.

Table of Transforms

The following table lists some of the more common transforms used in the analysis of building systems. More-extensive tables can be found in most mathematics and numerical analysis reference books.

List of Some *s*- and *z*-Transforms

Continous-Time Domain	Frequency Domain	Discrete-Time Domain
$1\ t=0 \quad 0\ t\neq 0$	—	1
$1\ t=k \quad 0\ t\neq k$	—	z^{-k}
1	$\frac{1}{s}$	$\frac{z}{z-1}$
t	$\frac{1}{s^2}$	$\frac{Tz}{(z-1)^2}$
e^{-at}	$\frac{1}{s+a}$	$\frac{z}{z-e^{-aT}}$
te^{-at}	$\frac{1}{(s+a)^2}$	$\frac{Tze^{-aT}}{\left(z-e^{-aT}\right)^2}$
$1-e^{-at}$	$\frac{a}{s(s+a)}$	$\frac{z\left(1-e^{-aT}\right)}{(z-1)\left(z-e^{-aT}\right)}$
$e^{-at}-e^{-bt}$	$\frac{b-a}{(s+a)(s+b)}$	$\frac{z\left(e^{-aT}-e^{-bT}\right)}{\left(z-e^{-aT}\right)\left(z-e^{-bT}\right)}$

Special FLC Mathematical Operations

- $\otimes$ aggregation operator
- Θ align-turning operator
- $\circ$ max-min composition operator
- $\bigcup$ union operator
- $\exists$ exists
- $\in$ in
- $\forall$ for all
- $\subseteq$ is the subset of

The aggregation operator ($\otimes$) is used to define a two-dimensional fuzzy variable F from fuzzy subsets A and B (one-dimensional fuzzy variables) as follows:

$$F = A(e) \otimes B(d) = \begin{bmatrix} \mu_F(1,1) & \cdots & \cdots & \cdots & \mu_F(1,N) \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \mu_F(i,j) & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ \mu_F(M,1) & \cdots & \cdots & \cdots & \mu_F(M,N) \end{bmatrix}$$

© 1999 by CRC Press LLC

where

$$\mu_F(i,j) = \min\left(\mu_A(i), \mu_B(j)\right)$$

$$A(e) = \left(e_i, \mu_A(i)\right)$$

$$B(d) = \left(d_j, \mu_B(j)\right)$$

e_i is the ith element of the subset $A(e)$ and $\mu_A(i)$ is its membership function; d_j is the jth element of the subset $B(d)$ and $\mu_B(j)$ is its membership function.

The align-turning operator (Θ) is an operator acting on a two-dimensional fuzzy variable to create a one-dimensional fuzzy variable, which has a set of membership functions aligned according to a certain order, as follows:

$$\begin{aligned} S &= \left[A \otimes B\right]^{\Theta} \\ &= \left(\mu_S(1,1), \mu_S(1,2), \ldots, \mu_S(i,j), \ldots, \mu_S(M,N)\right) \end{aligned}$$

where j varies from 1 to N first and i varies from 1 to M.

An Example of Numeric Calculation for Influence of Membership Function

Suppose that there are two rules:

R1: IF (e is PM) THEN (u is VS) and

R2: IF (e is PS) THEN (u is ST).

For the first rule,

$$\tilde{e}_1 = (0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0.1,\ 0.5,\ 0.8,\ 1.0,\ 0.8,\ 0.5)$$

$$\tilde{u}_1 = (0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0.2,\ 0.7,\ 1.0)$$

© 1999 by CRC Press LLC

Then the rule can be interpreted into a fuzzy reasoning matrix as follows:

$$R_1 = \tilde{e}_1 \otimes \tilde{u}_1$$

$$= \begin{bmatrix}
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1 & 0.1 & 0.1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 1.0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5
\end{bmatrix}$$

$$\equiv \mu_{R_1}(i, j)$$

where the membership in R_1 for the element (i,j) of the matrix, $\mu_{R_1}(i, j)$ is

$$\mu_{R_1}(i, j) = \min\left(\mu_{\tilde{e}_1}(i), \mu_{\tilde{u}_1}(j)\right)$$

For the second rule,

$$\tilde{e}_2 = (0,\ 0,\ 0,\ 0,\ 0,\ 0.1,\ 0.5,\ 0.8,\ 1.0,\ 0.8,\ 0.5,\ 0.1,\ 0)$$

$$\tilde{u}_2 = (0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0.2,\ 0.7,\ 1.0,\ 0.7,\ 0.2)$$

© 1999 by CRC Press LLC

Then the second rule can be interpreted into a fuzzy reasoning matrix as follows:

$$R_2 = \tilde{e}_2 \otimes \tilde{u}_2$$

$$= \begin{bmatrix}
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1 & 0.1 & 0.1 & 0.1 & 0.1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5 & 0.5 & 0.2 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 & 0.7 & 0.2 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 1.0 & 0.7 & 0.2 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 & 0.7 & 0.2 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5 & 0.5 & 0.2 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1 & 0.1 & 0.1 & 0.1 & 0.1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0
\end{bmatrix}$$

$$\equiv \mu_{R_2}(i,j)$$

where the membership in R_2 for the element (i,j) of the matrix, $\mu_{R_2}(i,j)$ is

$$\mu_{R_2}(i,j) = \min\left(\mu_{\tilde{e}_2}(i), \mu_{\tilde{u}_2}(j)\right)$$

The general fuzzy relation matrix R is then constructed as the union of these two rules:

$$R_2 = R_1 \cup R_2$$

$$= \begin{bmatrix}
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1 & 0.1 & 0.1 & 0.1 & 0.1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5 & 0.5 & 0.2 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 & 0.7 & 0.2 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 1.0 & 0.7 & 0.5 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.7 & 0.8 & 0.7 & 0.8 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5 & 0.7 & 1.0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.1 & 0.1 & 0.2 & 0.7 & 0.8 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.2 & 0.5 & 0.5
\end{bmatrix}$$

$$\equiv \mu_R(i,j)$$

© 1999 by CRC Press LLC

where

$$\mu_R(i,j) = \max\left(\mu_{R_1}(i), \mu_{R_2}(j)\right)$$

Assume that there is an input (e) and its fuzzy value $\tilde{e}$ = PM, then the output is expected to be VS according to the first rule. But now the output is calculated through the fuzzy matrix R as follows:

$$\begin{aligned}\tilde{u} &= \tilde{e} \circ R \\ &= \text{PM} \circ R \\ &= (0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0.1,\ 0.5,\ 0.8,\ 1.0,\ 0.8,\ 0.5) \circ R \\ &= (0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0.2,\ 0.7,\ 0.8,\ 0.7,\ 1.0)\end{aligned}$$

where

$$\mu_{\tilde{u}}(j) = \max_i\left(\min\left(\mu_{\tilde{e}}(i), \mu_R(i,j)\right)\right)$$

While

$$\begin{aligned}\tilde{u}_1 &= \text{VS} \\ &= (0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0.2,\ 0.7,\ 1.0)\end{aligned}$$

So,

$$\tilde{u}_1 \subseteq \tilde{u}$$

This chapter describes the primary as well as derived energy sources. The objective is to provide information on the extent, availability, measurements and estimation, properties, and limitations of each type of resource. These considerations are important for an engineer to know and understand before attempting selection and design of an energy conversion system. The chapter also includes environmental impacts of energy resources since the environmental aspects are expected to play a major role in the selection of energy resources. In addition, there is a brief discussion of the costs associated with each resource to help in the economic analysis and comparison the resources.

The chapter starts with an introduction and background of a historical perspective on energy use and projections of the future energy needs in the U.S., the industrialized countries, and the world. The primary energy sources described in this chapter include fossil fuels such as coal, natural gas, petroleum (including their synthetic derivatives), biomass (including refuse-derived biomass fuels), nuclear, solar radiation, wind, geothermal, and ocean. In addition there is a brief section on derived energy sources including electricity. So, the terminology and units used for each energy resource and their equivalence are provided.

7.1 Introduction

D. Yogi Goswami

Global energy consumption in the last 50 years has increased at a very rapid rate. Present trends in global population growth, rapid industrialization, and urbanization in major population centers of the world suggest that the world energy demand will continue to increase in the next 50 years (U.S. DOE, 1991). Figure 7.1.1 shows the historical and projected world energy consumption compiled by the Energy Information Agency.

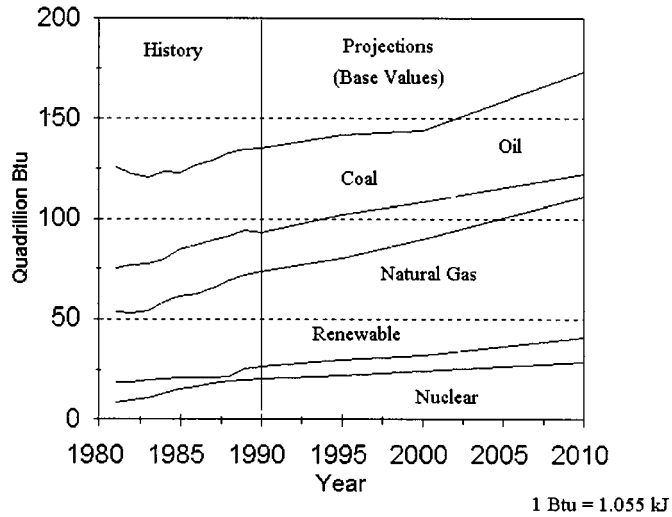

FIGURE 7.1.1 Historical and projected energy consumption. (From EIA. *Annual Energy Outlook 1992*, U.S. DOE, DOE/EIA-0484(92), Washington, D.C.)

The energy resources available to furfill the world demand include

Fossil fuels (oil, coal, natural gas)
Nuclear fuels
Geothermal
Solar radiation
Hydropower

© 1999 by CRC Press LLC

Biomass (crops, wood, municipal solid waste)
Wind
Ocean

Out of all the energy resources, fossil fuels have been used the most (88% of total consumption) because of their extremely high energy densities and simplicity of conversion and use. Figure 7.1.2 shows the world energy production by resource.

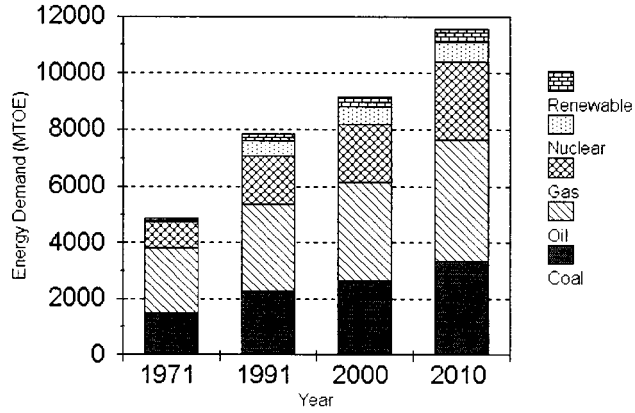

FIGURE 7.1.2 World energy production by resource. (From EIA. *World Energy Outlook*, International Energy Agency, Paris, 1994. With permission.)

Recent concerns about the environment are expected to increase the use of natural gas for power production. Renewable energy resources, such as solar energy, wind, and biomass, are also expected to increase their share of the energy use. There is a strong sentiment in the world in favor of exploiting renewable energy resources, especially because of environmental concerns. How far that sentiment translates into practical use will depend on the development of the renewable energy technologies and prices of the fossil fuels.

Defining Terms

MTOE: Mega tons of oil equivalent; 1 MTOE = 42.63×10^{12} Btu.
Quadrillion Btu: 10^{15} British thermal units (Btu), also known as Quad; 1 Btu = 1055 joules).

7.2 Types of Derived Energy

D. Yogi Goswami

Energy from renewable and nonrenewable fuels can be converted to the derived energy forms — thermal, mechanical, and electrical, which are useful for various end uses such as transportation, buildings (heating, cooling, lighting), agricultural, and industrial end uses. The derived energy forms are easily transformed from one type to the other. Figure 7.2.1 shows the projected U.S. energy use by end-use sector.

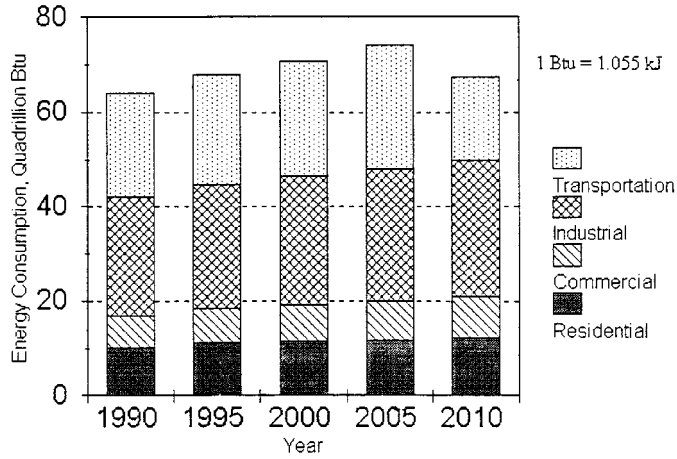

FIGURE 7.2.1 Projected U.S. energy use by end-use sector. (From EIA. *Annual Energy Outlook 1992*, U.S. DOE, DOE/EIA-0484(92), Washington, D.C., 1992.)

Transportation is mainly dependent on oil resources. Efforts to reduce urban air pollution are expected to increase the use of electricity as the preferred energy form for urban transportation. For most of the other end uses electricity will continue to be the preferred energy form. Therefore, it is important to understand the activity in the area of electricity production. Figure 7.2.2 shows the world installed electricity generation capacity by primary energy sources. The United States produces 700 GW (gigawatts or 10^9 W), representing more than 25% of the world electricity capacity. Other major electricity producers are Russia, Europe, Japan, and China. It is expected that China, India, and Southeast Asian countries will add major electricity capacity in the next 20 years.

Integrated resource planning (IRP), or least-cost planning, is the process used to optimize the resource options and minimize the total consumer costs including environmental and health costs that may be attributed to the resource. IRP examines all of the options, including the demand-side options, to minimize the total costs. There is considerable emphasis on IRP in a number of states in United States for future electric capacity and on **demand-side management** (DSM) for the current capacity (Kreith and Burmeister, 1993). The IRP process generally includes some combination of the following steps (Kreith and Burmeister, 1993): development of a load forecast; inventory of existing resources; identification of additional electrical capacity needs; demand-side management programs; screening and identification of options that are feasible; uncertainty analysis in view of uncertainty of future load, fuel prices, capital costs, etc; and selection of a resource or a mix of resources.

Demand Side Management DSM refers to a mix of electrical utility-sponsored custom incentives and disincentives that influence the amount and timing of customer demand in order to better utilize the available resources. Kreith and Burmeister (1993) and SERI (1991) list a number of DSM strategies.

© 1999 by CRC Press LLC

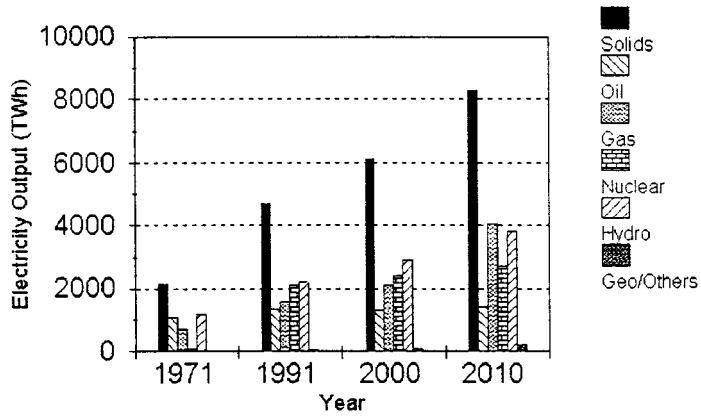

FIGURE 7.2.2 World electricity output. (From EIA, *World Energy Outlook*, International Energy Agency, Paris, 1994. With permission.)

Defining Terms

Demand-side management (DSM): Refers to a mix of incentives and disincentives that influence the amount and timing of energy use in order to better utilize the available resources.

Integrated resource planning (IRP): The process to optimize the resource options and minimize the total consumer costs including environmental and health costs that may be all attributed to the resource.

7.3 Fossil Fuels

Coal

Robert Reuther

Coal Composition and Classification

Coal is a sedimentary rock formed by the accumulation and decay of organic substances derived from plant tissues and exudates that have been buried over periods of geological time along with various mineral inclusions. Coal is classified by **type and rank.** Coal type classifies coal by the plant sources from which it was derived. Coal rank classifies coal by its degree of metamorphosis from the original plant sources and is therefore a measure of the age of the coal. The process of metamorphosis or aging is termed **coalification.**

The study of coal by type is known as coal petrography. Coal type is determined from the examination of polished sections of a coal sample using a reflected-light microscope. The degree of reflectance and color of a sample are identified with specific residues of the original plant tissues. These various residues are referred to as **macerals.** Macerals are collected into three main groups: vitrinite, inertinite, and exinite (sometimes referred to as liptinite). The maceral groups and their associated macerals are listed in Table 7.3.1 along with a description of the plant tissue from which each distinct maceral type is derived.

TABLE 7.3.1 Coal Maceral Groups and Macerals

Maceral Group	Maceral	Derivation
Vitrinite	Collinite	Humic gels
	Telinite	Wood, bark, and cortical tissue
	Pseudovitrinite	? (Some observors place in the inertinite group)
Exinite	Sporinite	Fungal and other spores
	Cutinite	Leaf cuticles
	Resinite	Resin bodies and waxes
	Alginite	Algal remains
Inertinite	Micrinite	Unspecified detrital matter, <10 μm
	Macrinite	Unspecified detrital matter, 10–100 μm
	Semifusinite	“Burned” woody tissue, low reflectance
	Fusinite	“Burned” woody tissue, high reflectance
	Sclerotinite	Fungal sclerotia and mycelia

Modified from Berkowitz, N., *An Introduction to Coal Technology.* Academic Press, New York, 1979.

Coal rank is the most important property of coal, since it is rank which initiates the classification of coal for use. Rank is a measure of the age or degree of coalification of coal. Coalification describes the process which the buried organic matter goes through to become coal. When first buried, the organic matter has a certain elemental composition and organic structure. However, as the material becomes subjected to heat and pressure, the composition and structure slowly change. Certain structures are broken down, and others are formed. Some elements are lost through volatilization while others are concentrated through a number of processes, including being exposed to underground flows which carry away some elements and deposit others. Coalification changes the values of various properties of coal. Thus, coal can be classified by rank through the measurement of one or more of these changing properties.

In the United States and Canada, the rank classification scheme defined by the American Society of Testing and Materials (ASTM) has become the standard. In this scheme, the properties of **gross calorific value** and **fixed carbon** or **volatile matter content** are used to classify a coal by rank. Gross calorific value is a measure of the energy content of the coal and is usually expressed m units of energy per unit mass. Calorific value increases as the coal proceeds through coalification. Fixed carbon content is a measure of the mass remaining after heating a dry coal sample under conditions specified by the ASTM.

© 1999 by CRC Press LLC

Fixed carbon content increases with coalification. The conditions specified for the measurement of fixed carbon content result in being able alternatively to use the volatile matter content of the coal measured under dry, ash-free conditions as a rank parameter. The rank of a coal proceeds from lignite, the "youngest" coal, through subbituminous, bituminous, and semibituminous, to anthracite, the "oldest" coal. There exist subdivisions within these rank categories which are defined in Table 7.3.2. (Some rank schemes include meta-anthracite as a rank above, or "older" than, anthracite. Others prefer to classify such deposits as graphite. Graphite is a minimal resource and is valuable primarily for uses other than as a fuel.) According to the ASTM scheme, coals are ranked by calorific value up to the high volatile A bituminous rank, which includes coals with calorific values (measured on a moist, mineral matter-free basis) greater than 14,000 Btu/lb (32,564 kJ/kg). At this point, fixed carbon content (measured on a dry, mineral matter-free basis) takes over as the rank parameter. Thus, a high volatile A bituminous coal is defined as having a calorific value greater than 14,000 Btu/lb, but a fixed carbon content less than 69 wt%. The requirement for having two different properties with which to define rank arises because calorific value increases significantly through the lower-rank coals, but very little (in a relative sense) in the higher-ranks, whereas fixed carbon content has a wider range in higher-rank coals, but little (relative) change in the lower-ranks. The most widely used classification scheme outside of North America is that developed under the jurisdiction of the International Standards Organization, Technical Committee 27, Solid Mineral Fuels.

Coal Analysis

The composition of a coal is typically reported in terms of its **proximate analysis** and its **ultimate analysis.** The proximate analysis of a coal is made up of four constituents: volatile matter content, fixed carbon content, moisture content, and ash content, all of which are reported on a weight percent basis. The measurement of these four properties of a coal must be carried out according to strict specifications codified by the ASTM.

Volatile matter in coal includes carbon dioxide, inorganic sulfur- and nitrogen-containing species, and organic compounds. The percentage of various species present depends on rank. Volatile matter content can typically be reported on a number of bases, such as moist; dry, mineral matter-free (dmmf); moist, mineral matter-free; moist, ash-free; and dry, ash-free (daf); depending on the condition of the coal on which measurements were made.

Mineral matter and ash are two distinct entities. Coal does not contain ash, even though the ash content of a coal is reported as part of its proximate analysis. Instead, coal contains mineral matter, which can be present both as distinct mineral entities or inclusions and intimately bound with the organic matrix of the coal. Ash, on the other hand, refers to the solid inorganic material remaining *after combusting* a coal sample. Proximate ash content is the ash remaining after the coal has been exposed to air under specific conditions (ASTM Standard Test Method D 3174). It is reported as the mass percent remaining upon combustion of the original sample on either a dry or moist basis.

Moisture content refers to the mass of water which is released from the solid coal sample when it is heated under specific conditions of temperature and residence time as codified in ASTM Standard Test Method D 3173.

The fixed carbon content refers to the mass of organic matter remaining in the sample after the moisture and volatile matter are released. It is primarily made up of carbon with lesser amounts of hydrogen, sulfur, and nitrogen also present. It is typically reported by difference from the total of the volatile matter, ash, and moisture contents on a mass percent of the original coal sample basis. Alternatively, it can be reported on a dry basis; a dmmf basis; or a moist, mineral matter-free basis.

The values associated with the proximate analysis vary with rank. In general, volatile matter content decreases with increasing rank, while fixed carbon content correspondingly increases. Moisture and ash also decrease, in general, with rank. Typical values for proximate analysis as a function of the rank of a coal are provided in Table 7.3.3.

The ultimate analysis of a coal reports the composition of the organic fraction of coal on an elemental basis. Like the proximate analysis, the ultimate analysis can be reported on a moist or dry basis and on

Ash	8.6	7.8	25.6	7.4	9.7
Gross calorific value, Btu/lb	6,700	7,900	8,400	10,700	13,400

Modified from Probstein, R. and Hicks, R., *Synthetic Fuels*. McGraw-Hill, New York, 1982. With permission.

an ash-containing or ash-free basis. The moisture and ash reported in the ultimate analyis are found from the corresponding proximate analysis. Nearly every element on Earth can be found in coal. However, the important elements which occur in the organic fraction are limited to a few. The most important of these include carbon, hydrogen, oxygen, sulfur, nitrogen, and, sometimes, chlorine. The scope, definition of the ultimate analysis, designation of applicable standards, and calculations for reporting results on different moisture bases can be found in ASTM Standard Test Method D 3176M. Typical values for the ultimate analysis for various ranks of coal found in the United States are provided in Table 7.3.4.

Coal Properties

Other important properties of coal include swelling, caking, and coking behavior; ash fusibility; reactivity; and calorific value.

© 1999 by CRC Press LLC

Calorific value measures the energy available in a unit mass of coal sample. It is measured by ASTM Standard Test Method D 201 5M, Gross Calorific Value of Solid Fuel by the Adiabatic Bomb Calorimeter, or by ASTM Standard Test Method D 3286, Gross Calorific Value of Solid Fuel by the Isothermal-Jacket Bomb Calorimeter. In the absence of a directly measured value, the gross calorific value, *Q*, of a coal (in Btu/lb) can be estimated using the Dulong formula (Elliott and Yohe, 1981):

$$Q = 14,544\mathrm{C} + 62,028\left[\mathrm{H} - (\mathrm{O}/8)\right] + 4,050\mathrm{S}$$

where C, H, O, and S are the mass fractions of carbon, hydrogen, oxygen, and sulfur, respectively, obtained from the ultimate analysis.

Swelling, caking, and coking all refer to the property of certain bituminous coals, when slowly heated in an inert atmosphere to between 450 and 550 or 600°F, to change in size, composition, and, notably, strength. Under such conditions, the coal sample initially becomes soft and partially devolatilizes. With further heating, the sample takes on a fluid characteristic. During this fluid phase, further devolatilization causes the sample to swell. Still further heating results in the formation of a stable, porous, solid material with high strength. There are several tests which have been developed based on this property to measure the degree and suitability of a coal for various processes. Some of the more popular are the free swelling index (ASTM Test Method D 720), the Gray-King assay test (initially developed and extensively used in Great Britain), and the Gieseler plastometer test (ASTM Test Method D 2639), as well as a whole host of dilatometric methods (Habermehl et al., 1981). The results of these tests are often correlated with the ability of a coal to form a coke suitable for iron making. In the iron-making process, the high carbon content and high surface area of the coke are utilized to reduce iron oxide to elemental iron. The solid coke must also be strong enough to provide the structural matrix upon which the reactions take place. Bituminous coals which have good coking properties are often referred to as metallurgical coals. (Bituminous coals which do not have this property are, alternatively, referred to as steam coals because of their historically important use in raising steam for motive power or electricity generation.)

Ash fusibility is another important property of coals. This is a measure of the temperature range over which the mineral matter in the coal begins to soften and eventually to melt into a slag and to fuse together. This phenomenon is important in combustion processes; it determines if and at what point the resultant ash becomes soft enough to stick to heat exchanger tubes and other boiler surfaces or at what temperature it becomes molten so that it flows (as slag), making removal as a liquid from the bottom of a combustor possible.

Reactivity of a coal is a very important property fundamental to all coal conversion processes (the most important of which are combustion, gasification, and liquefaction). In general, lower-rank coals are more reactive than higher-rank coals. This is due to several different characteristics of coals, which vary with rank as well as with type. The most important characteristics are the surface area of the coal, its chemical composition, and the presence of certain minerals which can act as catalysts in the conversion reactions. The larger surface area present in lower-rank coals translates into a greater degree of penetration of gaseous reactant molecules into the interior of a coal particle. Lower-rank coals have a less aromatic structure than higher-rank coals, which, along with contributing to larger surface area, also corresponds to a higher proportion of lower-energy, more-reactive chemical bonds. Lower-rank coals also tend to have higher proximate ash contents, and the associated mineral matter is more distributed — down to the atomic level. Any catalytically active mineral matter is thus more highly dispersed, also. However, the reactivity of a coal also varies depending upon what conversion is being attempted. That is, the reactivity of a coal toward combustion (oxidation) is not the same as its reactivity toward liquefaction, and the order of reactivity established in a series of coals for one conversion process will not necessarily be the same as for another process.

Coal Reserves

Coal is found throughout the United States and the world. It is the most abundant fossil energy resource in the United States and in the world. It comprises 95% of United States fossil energy resources and

© 1999 by CRC Press LLC

70% of world fossil energy resources on an energy content basis. All coal ranks can be found in the continental United States. The largest resources in the United States are made up of lignite and subbituminous coals, which are found primarily in the western United States and Alaska. Bituminous coals are found principally in the Midwest, northern Alaska, and the Appalachian region. Principal deposits of anthracite coal are found in northeastern Pennsylvania. The Alaskan coals have not been extensively mined because of their remoteness and the harsh climate. Of the other indigenous coal resources, the anthracite coals have been extensively mined to where there is little economic resource left; the bituminous coals are being heavily mined in the lower 48 states, especially those with low sulfur contents (less than 2.5 wt%); and the low-rank coals in the West have historically been less heavily mined because of their low calorific value, high moisture and ash contents, and their distance from large markets, although with the enactment of the 1990 Amendments to the Clean Air Act of 1970, these coals are replacing high-sulfur Eastern coals in the marketplace. A map showing the general distribution of coal in the lower 48 states is included as Figure 7.3.1.

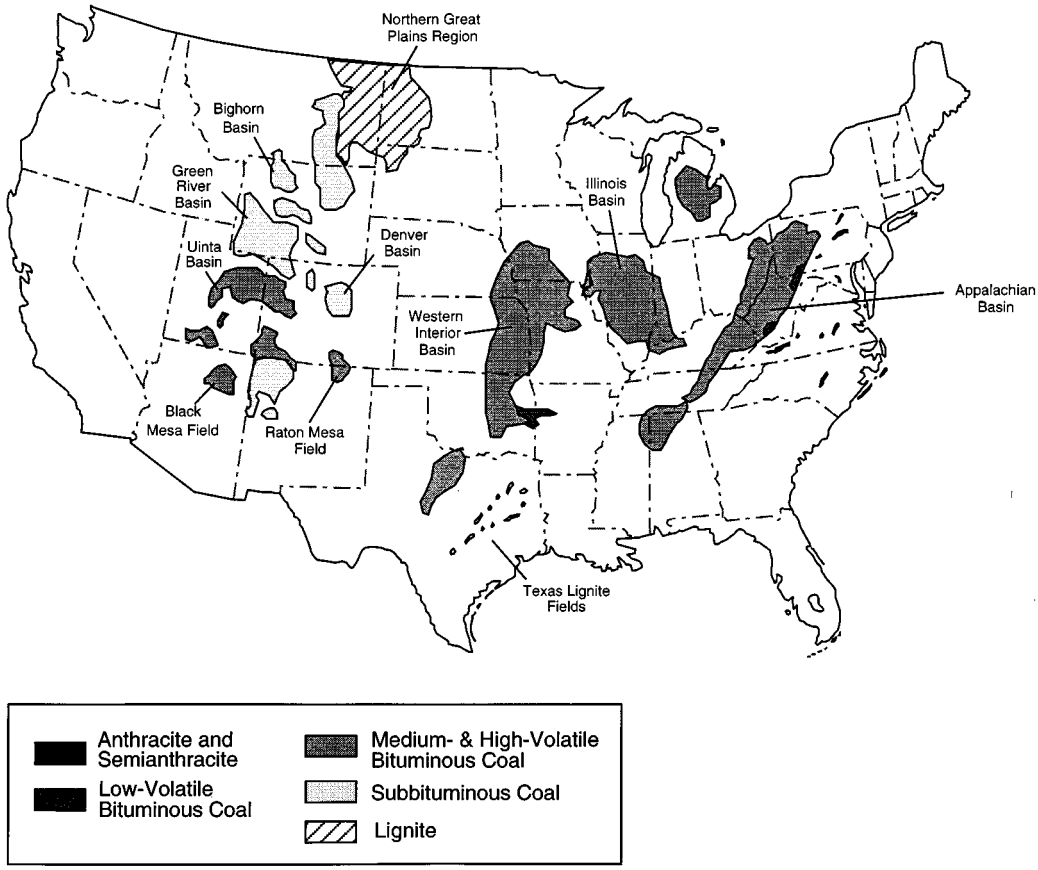

FIGURE 7.3.1 Coal fields of the conterminous (From Averitt, P., Coal Resources of the United States, January 1, 1974. U.S. Geological Survey Bulletin 1412, Government Printing Office, Washington, D.C., 1975.)

The amount of coal (or, for that matter, any minable resource) that exists is not known exactly and is continually changing as old deposits are mined out and new deposits are discovered or reclassified. Estimates are published by many different groups throughout the world. In the United States, the Energy Information Administration, an office within the U.S. Department of Energy, gathers and publishes estimates from various sources, including the World Energy Council and British Petroleum, Ltd. These

© 1999 by CRC Press LLC

latter groups subscribe to a set of definitions for classifying the estimates which are acknowledged both in the United States and the United Kingdom. The most commonly used terms are defined below (as taken from Averitt, (1981):

Resources: The total quantity of coal in the ground within specified limits of thickness of bed overburden. The thickness of overburden defining this term varies from region to region in the world.

Hypothetical Resources: The quantity of coal estimated to be in the ground in unmapped and unexplored parts of known coal basins to an overburden depth of 6000 ft; determined by extrapolation from the nearest areas of identified resources.

Identified Resources: The quantity of coal in the measured, indicated, and inferred resource categories.

Measured Resources: The quantity of coal in the ground based on assured coal bed correlations and on observations spaced about 0.5 mi apart.

Indicated Resources: The quantity of coal in the ground based partly on specific observations and partly on reasonable geological projections; the points of observation and measurement are about 1 mi apart but may be 1.5 mi apart for beds of known continuity.

Inferred Resources: The quantity of coal in the ground based on continuity of coal beds downdip from and adjoining areas containing measured and indicated resources. Generally, inferred resources lie 2 mi or more from outcrops or from points of more precise information.

Demonstrated Reserve Base: The quantity of coal in the ground in the measured and indicated resources categories; restricted primarily to coal in thick and intermediate beds less than 1000 ft below the surface and deemed to be economically and legally available for mining.

Reserves, or Recoverable Reserves: The quantity of coal in the ground that can be recovered from the demonstrated reserve base by application of the recoverability factor.

Recoverability Factor: The percentage of coal in the demonstrated reserve base that can be recovered by established mining practices.

The demonstrated reserve base for coals in the United States as of January 1, 1993, is approximately 474.1 billion (short) tons. It is broken out by rank, state, and mining method (surface or underground) in Table 7.3.5. As of December 31, 1990 (December 30, 1991, for the United States), the world recoverable reserves are estimated to be 1145 billion (short) tons. A breakdown by region and country is provided in Table 7.3.6. The recoverability factor for all coals can vary from approximately 40% to over 90% depending on the individual deposit. The recoverable reserves in the United States represent approximately 56% of the demonstrated reserve base. Thus, the United States contains (by weight) approximately 23% of the recoverable reserves of coal in the world.

Environmental Aspects

Richard Bajura

Along with coal production and use comes a myriad of potential environmental problems, most of which can be ameliorated or effectively addressed during recovery, processing, conversion, or reclamation.

Underground coal reserves are recovered using the two principal methods of room-and-pillar mining (60%) and longwall mining (40%). In room-and-pillar mining, coal is removed from the seam in a checkerboard pattern (the “room”) as viewed from above, leaving pillars of coal in an alternate pattern to support the roof of the mine. When using this technology, generally half of the reserves are left underground. Depending upon the depth of the seam and characteristics of the overburden, subsidence due to the removal of the coal may affect the surface many years after the mining operation is completed. Because of the danger of collapse and movement of the surface, undermined lands are not used as building sites for large, heavy structures.

Longwall mining techniques employ the near-continuous removal of coal in rectangular blocks with a vertical cross section equal to the height of the seam multiplied by the horizontal extent (width) of the panel being mined. As the longwall cutting heads advance into the coal seam, the equipment is

[1] Includes subbituminous coal.
[2] Includes 3,396.4 million short tons of surface mine reserves, of which 3,380.8 million tons are in Pennsylvania and 15.6 million tons are in Arkansas.
[3] There are no underground demonstrated reserves of lignite.
[4] Georgia, Maryland, North Carolina, and Tennessee.
[5] Arkansas, Kansas, Louisiana, and Michigan.
[6] Less than 0.05 billion short tons.
[7] Arizona, Idaho, Oregon, and South Dakota.

Notes: Data represent 100 percent of known measured and indicated coal, with qualifying seam thicknesses and depths, in place as of January 1, 1993. Recoverability varies from less than 40 percent to more than 90 percent for individual deposits. Fifty-six percent of the demonstrated reserve base of coal in the United States is estimated to be recoverable.

Totals may not equal sum of components due to independent rounding.

[1] See Note 3 at end of Section.
[2] U.S. data are more current than other data on this table. They represent recoverable reserves as of December 31, 1991; data for the other countries are as of December 31, 1990, the most recent period for which they are available. U.S. reserves represent both measured and indicated tonnage. The U.S. term "measured" approximates the term "proved," which is used by the World Energy Council and British Petroleum. The U.S. "measured and indicated" data have been combined prior to depletion adjustments and cannot be recaptured as "measured alone."

— = Not applicable.

Notes: The EIA does not certify the international reserves data but reproduces the information as a matter of convenience for the reader.

Totals may not equal sum of components due to independent rounding.

Source: EIA, *International Energy Annual 1992* (January 1994), Table 37.

automatically moved forward. The roof of the mine collapses behind the shields, and most of the effects of subsidence are observed on the surface within several days of mining. If the longwall mining operation proceeds in a continuous fashion, subsidence may occur smoothly so that little damage occurs to surface structures. Once subsidence has occurred, the surface remains stable into the future. Longwall mining operations may influence water supplies as a result of fracturing of water-bearing strata far removed from the panel being mined.

When coal occurs in layers containing quartz dispersed in the seam or in the overburden, miners are at risk of being exposed to airborne silica dust, which is inhaled into their lungs. Coal workers pneumonoconiosis, commonly called black lung disease, reduces the ability of a miner to breathe because of the effects of fibrosis in the lungs.

Surface mining of coal seams requires the removal of large amounts of overburden, which must eventually be replaced into the excavated pit after the coal resource is extracted. When the overburden contains large amounts of pyrite, exposure to air and water produces a discharge known as acid mine drainage, which can contaminate streams and waterways. Iron compounds formed as a result of the chemical reactions precipitate in the streams and leave a yellow- or orange-colored coating on rocks and gravel in the streambeds. The acid caused by the sulfur in the pyrite has been responsible for significant destruction of aquatic plants and animals. New technologies have been and continue to be developed to neutralize acid mine drainage through amendments applied to the soil during the reclamation phases of the mining operation. Occasionally, closed underground mines fill with water and sufficient pressure is created to cause "blowouts" where the seams reach the surface. Such discharges have also been responsible for massive fish kills in receiving streams.

The potential for acid rain deposition from sulfur and nitrogen oxides released to the atmosphere during combustion is a significant concern. About 95% of the sulfur oxide compounds can be removed through efficient stack gas cleaning processes such as wet and dry scrubbing. Also, techniques are available for removing much of the sulfur from the coal prior to combustion. Combustion strategies are also being developed which reduce the formation and subsequent release of nitrogen oxides.

The potential for greenhouse warming due to emissions of carbon dioxide during combustion (as well as methane during mining and mine reclamation) has also been raised as a significant concern. Since coal is largely composed of carbon with relatively little hydrogen, its combustion leads to a higher level of carbon dioxide emissions per unit of energy released than for petroleum-based fuels or natural gas.

Transportation

Larry Grayson

According to figures compiled by the United States Department of Energy's Energy Information Administration (Coleman, 1994), 878 million (short) tons of coal were distributed domestically in 1993, primarily via rail (59.6%), followed by barge (13.9%), truck (13.2%), and conveyor and slurry pipeline (10.8%). Shipments to electric utilities amounted to 773.5 million (short) tons during the same year, with 61.5% transported by rail, followed by 14.0% by barge, 11.7% by truck, and 11.0% by conveyor and slurry pipeline.

Villagran (1989) compared the cost advantage of barge transportation over rail transportation. For distances between 100 and 300 mi, the advantage is between $11 and 38/kilo ton-mi; while the advantage drops to $7 to 11/kilo ton-mi for distances greater than 300 mi. For distances less than 100 mi, rail hauls are very expensive, leading to the predominance of truck haulage in this range when river transportation is not possible.

Defining Terms:

Coalification: The physicochemical transformation which coal undergoes after being buried and subjected to elevated temperature and pressure. The classification of a particular coal by rank is a measure of the extent of its coalification. Thus, coalification is a measure of the "age" of a particular coal.

© 1999 by CRC Press LLC

Fixed carbon content: Fixed carbon content is one of the constituents which make up the proximate analysis of a coal. It is normally measured by difference. That is, one measures the volatile matter content and the moisture and ash contents, if the fixed carbon content is reported on a basis containing one or both of those constituents, and subtracts the result(s) from 100% to find the fixed carbon content. One should not confuse the fixed carbon content of a coal with its (elemental) carbon content found in the ultimate analysis. Although there is certainly carbon in the material making up the fixed carbon content, it is not all of the carbon present in the original coal, and other elements are also present.

Gross calorific value: Calorific value is a measure of the energy content of a material, in this case, a coal sample. Calorific value is measured by ASTM Standard Test Method D 2015M, Gross Calorific Value of Solid Fuel by the Adiabatic Bomb Calorimeter, or by ASTM Standard Test Method D 3286, Gross Calorific Value of Solid Fuel by the Isothermal-Jacket Bomb Calorimeter. The *gross* calorific value takes into account the additional heat gained by condensing any water present in the products of combustion, in contrast to the *net* calorific value, which assumes that all water remains in the vapor state.

Maceral: Macerals are organic substances or optically homogeneous aggregates of organic substances in a coal sample that possess distinctive physical and chemical properties.

Proximate Analysis: Proximate analysis is a method to measure the content of four separately identifiable constituents in a coal: volatile matter content, fixed carbon content, moisture content, and ash content, all of which are reported on a weight percent basis. The standard method for obtaining the proximate analysis of coal or coke is defined by the ASTM in Standard Test Method D 3172.

Rank: Coal rank is a classification scheme for coals which describes the extent of coalification which a particular coal has undergone. The structure, chemical composition, and many other properties of coals vary systematically with rank. The standard method for determining the rank of a coal sample is defined by the ASTM in Standard Test Method D 388.

Type: Coal type is a classification scheme for coals which references the original plant material from which the coal was derived.

Ultimate Analysis: Ultimate analysis is a method to measure the elemental composition of a coal sample. Typical ultimate analyses include carbon, hydrogen, oxygen, sulfur, and nitrogen contents, but other elements can also be reported. These other elements are usually not present to any appreciable extent. However, if they are reported, the sum of all the elements reported (including moisture and ash content) should equal 100%. The standard method for the ultimate analysis of coal or coke is defined by the ASTM in Standard Test Method D 3176.

Volatile matter content: Volatile matter content measures the mass of material released upon heating the coal sample under specific conditions, defined by the ASTM Standard Test Method D 3175.

Further Information

An excellent resource for understanding coal, its sources, its uses, and its limitations and potential problems is the book by Elliott referenced above under Averitt (1981), Habermehl et al. (1981), and Neavel (1981). A reader wishing an understanding of coal topics could find no better resource.

Another comprehensive book which includes more-recent information but is not quite as weighty as Elliott's (664 pages vs. 2374 pages) is *The Chemistry and Technology of Coal*, edited (second edition, revised and expanded) by James G. Speight.

For up-to-date information specific to the environmental problems associated with the use of coal, the reader is referred to Norbert Berkowitz's chapter entitled "Environmental Aspects of Coal Utilization" in *An Introduction to Coal Technology.*

For information on the standards for coal analyses and descriptions of the associated procedures, the reader is referred to any recent edition of the American Society for Testing and Materials's *Annual Book of ASTM Standards.* Section 5 covers petroleum products, lubricants, and fossil fuels, including coal and coke.

Oil

Philip C. Crouse, P.E.

Overview

Fossil fuel energy accounted for 86.3% of all world energy in 1990. The Energy Information Administration (EIA) of the U.S. Department of Energy estimates that in the year 2010, fossil fuels will account for 85.9% of all world energy consumption — only a 0.4% percentage decrease in usage (Figure 7.3.2). According to EIA estimates, coal is expected to decline slightly from about a 27% to about a 25% share of consumption, and consumption of natural gas is expected to increase from 21 to 24% over the 20-year period. Over the same period, oil is forecasted to continue to be world major energy source with only slight declines from the present 39% of consumption.

Recent efforts in the United States have been to foster growth in natural gas usage as an energy source, causing an estimated growth of 2.3% per year. Total energy usage is expected to grow from 345.6 to 476.0 quadrillion Btu — or a 38% growth in energy usage over 20 years.

Crude Oil Classification and World Reserves

Obtaining accurate estimates of world petroleum and natural gas resources and reserves is difficult and uncertain. Terminology used by industry to classify resources and reserves has no broadly accepted standard classification. Such classifications have been a source of controversy in the international oil and gas community. Confusion persists in regard to classification. This section uses information provided by the Department of Energy classification system. The next chart shows the relationship of resources to reserves. **Recoverable resources** include discovered and undiscovered resources. **Discovered resources** are those resources that can be economically recovered (Figure 7.3.3).

Discovered resources include all production already out of the ground and reserves. Reserves are further broken down into proved reserves and other reserves. Again, there are many different groups that classify reserves in different ways, such as *measured*, *indicated*, *internal*, *probable*, and *possible.* Most groups break reserves into producing and nonproducing categories. Each of the definitions is quite voluminous and the techniques for qualifying reserves vary globally.

Proved reserves are generally defined as: "Those volumes of oil and gas that geological and engineering data demonstrate with reasonable certainty to be recoverable in future years from known reservoirs under existing economic and operating conditions."

OPEC (the Organization of Petroleum-Exporting Countries) has been key in setting global fossil fuel prices over the last two decades. With very large reserves, OPEC can provide much of the world future needs for crude oil and petroleum products. About two-thirds of the world known petroleum reserves are located in the Middle East as shown in Table 7.3.7.

Table 7.3.8 shows that the annual world crude oil production has steadily grown from 16.7 billion barrels in 1970 to 22 billion barrels in 1990.

Both crude oil demand and production are forecast to increase over the next 20 years. OPEC production is relatively level at 8.6 billion barrels in 1990 compared with 8.5 billion barrels in 1970. During the same time, non-OPEC production increased from 8.1 to 13.6 billion barrels. As the "swing producer", OPEC's production in 1980 increased by over 1 billion barrels when non-OPEC production could not meet total demand. They then decreased production by a similar amount in 1990 when production in the rest of the world increased by 1 billion to a non-OPEC total of 13.6 billion barrels. With a low price environment, OPEC is expected to gain market share in global production over the next 20 years.

Standard Fuels

Petroleum is refined into petroleum products that are used to meet individual product demands. The general classifications of products are

© 1999 by CRC Press LLC

1. NATURAL GAS LIQUIDS AND LIQUEFIED REFINERY GASES
   This category includes ethane (C_2H_6), ethylene (C_2H_4), propane (C_3H_8), propylene (C_3H_6), butane and isobutane (C_4H_{10}), and butylene and isobutylene (C_4H_8).
2. FINISHED PETROLEUM PRODUCTS
   This category includes motor gasoline, aviation gasoline, jet fuel, kerosene, distillate, fuel oil, residual fuel oil, petrochemical feed stock, naphthas, lubricants, waxes, petroleum coke, asphalt and road oil, and still gas.
   - *Motor gasoline* includes reformulated gasoline for vehicles and oxygenated gasoline such as gasohol (a mixture of gasoline and alcohol).
   - *Jet fuel* is classified by use such as industrial or military and naphtha and kerosene-type. Naphtha fuels are used in turbo jet and turbo prop aircraft engines and excludes ram-jet and petroleum rocket fuel.
   - *Kerosene* is used for space heaters, cook stoves, wick lamps, and water heaters.
   - *Distillate fuel oil* is broken into subcategories: No. 1 distillate, No. 2 distillate, and No. 4 fuel oil which is used for commercial burners.
   - *Petrochemical feedstock* is used in the manufacture of chemicals, synthetic rubber, and plastics.
   - *Naphthas* are petroleums with an approximate boiling range of 122 to 400°F.
   - *Lubricants* are substances used to reduce friction between bearing surfaces, used as process materials, and as carriers of other materials. They are produced from distillates or residues. Lubricants are paraffinic or naphthenic and separated by viscosity measurement.
   - *Waxes* are solid or semisolid material derived from petroleum distillates or residues. They are typically a slightly greasy, light colored or translucent, crystallizing mass.
   - *Asphalt and road oil*. Asphalt is a cementlike material containing bitumens. Road oil is any heavy petroleum oil used as a dust pallatine and road surface treatment.
   - *Still Gas* is any refinery by-product gas. It consists of light gases of methane, ethane, ethylene, butane, propane, and the other associated gases. Still gas typically used as a refinery fuel.

World Refining Capacity. Refining capacity grew from 48 million barrels per day in 1970 to about 75 million barrels per day in 1990 — a 55% growth in capacity. Table 7.3.9 shows world refining capacity beginning in 1970. The peak year was 1982 in which capacity was 81.4 million barrels per day. Utilization of refinery capacity was about 80% in 1990, pointing to underutilization.

Natural Gas

Philip C. Crouse, P.E.

Natural gas has been called the environmentally friendly fossil fuel since it releases fewer harmful contaminants. World production of dry natural gas was 73.7 trillion ft^3 and accounted for over 20% of world energy production. In 1990 Russia accounted for about one third of world natural gas. The second largest producer was the United States having about one quarter of world 1990 natural gas production.

Natural Gas Production Measurement

Natural gas production is generally measured as "dry" natural gas production. It is determined as the volume of natural gas withdrawn from a reservoir less (1) the volume returned for cycling and repressuring reservoirs; (2) the shrinkage resulting from the removal of lease condensate and plant liquids; (3) the nonhydrocarbon gases. The parameters for measurement are 60°F and 14.73 lb standard per square inch absolute.

World Production and Reserves of Dry Natural Gas

From 1983 to 1992, dry natural gas production rose from 54.4 to 75 trillion ft^3. The breakdown by region of world is shown in Table 7.3.10.

TABLE 7.3.10 World Dry Natural Gas Production — trillion ft^3

	1983	1992
North, Central, and South America	21.20	25.30
Western Europe	6.20	7.85
Eastern Europe and former U.S.S.R.	21.09	28.60
Middle East and Africa	2.95	6.87

Africa	310,241
Asia-Pacific	299,288
Total	4,384,081
OPEC	1,729,205
Non-OPEC	2,654,876

Compressed Natural Gas

Environmental issues have countries examining and supporting legislation to subsidize the development of cleaner vehicles that use compressed natural gas (CNG). Even with a push toward the use of CNG-burning vehicles, the numbers are quite small when compared with gasoline vehicles. Italy has used

© 1999 by CRC Press LLC

CNG since 1935 and has the largest usage with 300,000 vehicles. The United States ranked fifth with an estimated 30,000 vehicles in 1994. Argentina, which ranked sixth, had 15,000 vehicles.

Liquefied Natural Gas (LNG)

Natural gas can be liquefied by lowering temperature until a liquid state is achieved. It can be transported by refrigerated ships. The process of using ships and providing special-handling facilities adds significantly to the final LNG cost. If oil prices stay low, prospects for LNG development will remain low in the future. However, LNG projects planned by OPEC member countries may become significant over the next 20 years with shipments of LNG exports ultimately accounting for up to 25% of all gas exports.

Physical Properties of Hydrocarbons

The most important physical properties from a crude oil classification standpoint are density or specific gravity and the viscosity of liquid petroleum. Crude oil is generally lighter than water. A Baume-type scale is predominantly used by the petroleum industry and is called the **API** (American Petroleum Institute) **gravity** scale (see Table 7.3.12). It is related directly to specific gravity by the formula:

$$\varphi = (141.5)/(131.5 + {}^{\circ}\text{API})$$

where φ = specific gravity. Temperature and pressure are standardized at 60°F and 1 atm pressure.

TABLE 7.3.12 Relation of API Gravity, Specific Gravity, and Weight per Gallon of Gasoline

Degree API	Specific Gravity	Weight of gallon in lbs.
8	1.014	8.448
9	1.007	8.388
10	1.000	8.328
15	0.966	8.044
20	0.934	7.778
25	0.904	7.529
30	0.876	7.296
35	0.850	7.076
40	0.825	6.870
45	0.802	6.675
50	0.780	6.490
55	0.759	6.316
58	0.747	6.216

Note: The specific gravity of crude oils ranges from about 0.75 to 1.01.

Other key physical properties involve the molecular weight of the hydrocarbon compound and the boiling point and liquid density. Table 7.3.13 shows a summation of these properties.

Defining Terms

API Gravity: A scale used by the petroleum industry for specific gravity.

Discovered resources: Discovered resources include all production already out of the ground and reserves.

Proved resources: Resources that geological and engineering data demonstrate with reasonable certainly to be recoverable in future years from known reservoirs under existing economic and operating conditions.

Recoverable resources: Recoverable resources include discovered resources.

7.4 Biomass Energy

Michael C. Reed, Lynn L. Wright, Ralph P. Overend, and Carlton Wiles

Biomass energy encompasses a wide variety of renewable energy technologies that use plant matter, plant residues, or plant-derived process wastes as fuel. These biomass resources can be used directly as solid fuels to produce heat, or they can be converted to other energy carriers such as liquid and gaseous fuels and electricity. Because the energy in biomass is less concentrated than the energy in fossil fuels, high-efficiency conversion technologies are necessary to make this energy resource cost competitive.

Photosynthesis

Biomass fuels are derived from green plants which capture solar energy and store it as chemical energy through the **photosynthetic** reduction of atmospheric carbon dioxide. Plant leaves are biological solar collectors while the stems, branches, and roots are the equivalent of batteries storing energy-rich complex carbon compounds. Elemental analysis shows both wood and grasses to be about 50% carbon. The average photosynthetic efficiency of converting solar energy into organic carbon compounds on an annual basis varies from less than 0.5% in temperate and tropical grasslands to about l.5% in moist tropical forests (Cralle and Vietor, 1989). While quite low, it represents stored energy on an annual basis and the diversity and adaptability of plants allows this solar collection to occur on most parts of Earth's surface. The worldwide annual storage of photosynthetic energy in terrestrial biomass is huge, representing approximately ten times world annual use of energy (Hall et al., 1993).

Biomass Production, Yield, and Potential

Forest Land

The amount of harvestable woody biomass produced by natural forests on an annual basis ranges from about 2 to 6 dry t/ha/year (metric ton/hectare/year), or 0.9 to 2.7 dry ton/acre/year with the higher yields usually in tropical regions. Managed forests often accumulate biomass at approximately double the rate of natural unmanaged stands. The productivity rates of natural forests could be increased to 4 to 12 dry t/ha/year (1.8 to 5.4 dry t/acre/year) if brought under active management. Such management might include optimizing harvesting strategies for production, fertilization, and replanting natural stands with faster-growing species. At present 10% of world forests, or 355 million ha (876 million acres), are actively managed. If managed forests were increased to 20%, and if 20% of the harvested material were used for energy, the annual worldwide resource of wood for energy from currently forested land would amount to somewhere between 284 and 852 million t (315 to 946 million dry tons) of available wood or about 5.6 to 17 Exajoules (5 to 14.5 quadrillion Btu) of primary energy based on potential yield ranges of managed forests. The most optimistic estimates of biomass potential would provide a total primary energy resource of about 30 Exajoules from managed forests (Sampson et al., 1993).

Cropland and Grassland

The production of perennial plants (either woody crops grown for 3 to 10 years between harvests or perennial grasses), using genetically superior materials, established on agricultural land and managed as an agricultural crop is believed to be the method of choice for producing biomass for energy on a large scale. Temperate shelterbelts and tropical agroforestry plantings could also contribute greatly to biomass energy resources. Energy crop yields are highest in locations where genetically superior material is planted on land with plenty of access to sunshine and water. Operational yields in the range of 20 to 30 dry t/ha/year (9 to 13 dry ton/acre/year) are achievable now. Such yields have been observed over large areas with eucalyptus and tropical grasses in the moist tropics and subtropics, and with hybrid poplars in irrigated portions of the dry Pacific Northwest of the United States. In many areas, however, suitable genetically superior materials are not yet available, water is a limiting factor, and irrigation may not be an economically or environmentally desirable alternative. Temperate wood energy yields are more

© 1999 by CRC Press LLC

commonly in the range of 9 to 13 dry t/ha/year (4 to 6 dry ton/acre/year) today with the expectation that they could increase to the 12 to 20 dry t/ha/year (5.5 to 9 dry ton/acre/year) relatively rapidly with continued genetic improvement and clonal selection (Wright, 1994). Yields of properly managed perennial grasses in field test plots are currently in the range of 11 to 22 dry t/ha/year (5 to 10 dry ton/acre/year) with the expectation that yields of 16 to 27 dry t/ha/year (7 to 12 dry ton/ac/year) could be attained with further breeding and improvement of management regimes. The best current perennial grass yields on nonirrigated test plots have averaged around 25 dry t/ha/year (11 dry ton/acre/year) for 6 years in the southeastern U.S. where a long growing season favors warm season grasses.

The total amount of biomass potentially available from cropland conversion can only be speculated on since it requires making a number of assumptions involving such issues as land availability, food crop requirements, development of biomass energy markets, and crop yields. Such speculations have been made to attempt to evaluate the potential effect of biomass energy use on carbon emission reduction. These speculations have assumed that 10 to 15% of cropland worldwide could be available for the production of biomass resources as energy crops, shelterbelts, or for agroforestry use with energy as one product (Hall et al., 1993; Sampson et al., 1993). The primary energy resource potential of cropland conversion has been estimated to range from a low of 18 Exajoules to a high of 49 Exajoules (Sampson et al., 1993). Another 25 to 110 Exajoules has been estimated to be available from the conversion of grasslands and degraded areas to the production of biomass energy resources worldwide (Sampson et al., 1993).

Biomass Residues

Biomass residues are the organic by-products of food, fiber, and forest production and processing. Major sources of residues include the residues of grain crops such as corn, wheat, rice; animal dung; and forest roundwood harvest and processing. A signifiant portion of residues is not economically collectible for energy because of wide dispersal and low bulk density, which makes recovery, transport, and storage too costly. In many cases, residues have greater economic value being left on the land to restore nutrients, reduce erosion, and stabilize soil structure, or they may be recovered for other domestic, industrial, or agricultural uses. Recoverable crop residues in the United States are estimated to range between 70 and 190 million dry tons (Day, 1989) and recoverable forest residues are about double the level of crop residues (Hall et al., 1993). Recoverable crop and forest residues worldwide are estimated to have an energy value of 12.5 and 13.5 Exajoules respectively (Hall et al., 1993).

Terrestrial Limitations

The biomass productivity of forests, grasslands, and energy crop plantings is considerably less than theoretically possible based on calculations of maximum photosynthetic potential. Under artificially optimal conditions of temperature, water, and nutrients, average solar radiation near Des Moines, Iowa, would theoretically be aufficient to produce maximum total tree dry weight yields (above and below ground) as high as 102 t/ha/year (45 ton/acre/year) (Sampson et al., 1993). Actual seasonal temperature variations alone, however, reduce the maximum yield potential to 60 t/ha/year (27 ton/acre/year). Of that, the usable biomass portion of trees (the stems and branches only) amounts to only about 35 t/ha/year (15 ton/acre/year). Yet this is many times the harvestable biomass dry weight yield of trees from natural forest stands and more than double the best tree yields observed in experimental trials in that region. Water stress is a major reason for reduced yields. Perennial grasses may have a slightly higher harvestable yield potential in the region because of their higher water use efficiency and the more-efficient carbon metabolism of warm season grasses in temperate climates (Jones, 1985). While water stress, pests outbreaks, and inadequate nutrients all contribute to reduced yields, it is also clear that the genetic potential of perennials is yet to be fully explored. Genetic improvement of perennials for energy is only beginning in most regions of the United States; thus, the potential for finding substantially higher-yielding varieties and clones is excellent.

© 1999 by CRC Press LLC

Environmental Impact

An emerging consensus of environmentalists, forestry organizations, researchers, and others is that if energy crops are treated as an agricultural crop and established and tended in a considered and informed way on appropriate land, environmental damage can be avoided. In fact, preliminary data suggests that there can be significant environmental and ecological benefits achieved in association with the development of a fully sustainable energy resource. Global benefits include the reduced emission of carbon into the atmosphere, while local benefits include soil conservation, reduction of chemical use, and wildlife biodiversity in an agricultural setting.

Biomass Conversion Technologies

As noted previously, biomass can be used to produce heat, electricity, and prepared fuels such as charcoal and liquid fuels. To do this, the biomass conversion technologies have to treat a wide range of biomass resources efficiently and convert them into the desired products. For example, biomass resources may include fuelwood, agricultural residues, farm animal wastes, forest industry processing residues (e.g., sawdust, black liquor from pulping processes), agricultural processing by-products (e.g., bagasse from sugarcane processing, food-processing by-products such as olive pits), and crops (e.g., grains, oil seeds, energy crops).

Each of these resources has different handling requirements and different process characteristics. Worldwide, the most common biomass resources are fuelwood and agricultural residues such as cereal straws. However, many other biomass resources offer opporturuties notjust for heat, but also in improving the environment (as when animal wastes are converted into methane and fertilizer through anaerobic fermentation processes). Each conversion process must take into account the differences in biomass composition which can vary widely in terms of moisture and ash content.

Biomass Composition

As received, biomass can range from very clean wood chips at 50% moisture to urban wood residues that are dry but contaminated with ferrous and other materials, animal residues, sludges, and the organic component of murucipal solid waste (MSW). Most biomass is a **lignocellulosic** material, such as wood or straw, which is composed of **cellulose**, **hemicellulose**, and **lignin**. Although different plant species have differing proportions of these polymers, it turns out that on a moisture and ash-free basis, the majority have essentially the same calorific values in the range of 16 to 19.6 GJ/t (8000 to 8500 Btu/lb). Biomass ash content varies considerably, being lowest in the clean wood fraction and very high in cereal straws such as rice straw, as can be seen in Table 7.4.1.

TABLE 7.4.1 Some Fuel Properties of Four Different Biomass Types

Property	Pine Shavings	Switchgrass	Rice Hull	Rice Straw
Ash %	1.43	10.10	18.34	15.90
Carbon	48.54	47.79	40.96	41.78
Hydrogen	5.85	5.76	4.30	4.63
Nitrogen:	0.47	1.17	0.40	0.70
Sulfur	0.01	0.10	0.02	0.08
Oxygen	43.69	35.07	35.86	36.57
Btu/lb	8337	7741	6944	7004
GJ/t	19.38	17.99	16.14	16.28

Direct Combustion, Combined Heat, and Power and Steam Electric Generation

By far the most frequent use of biomass is in direct-combustion applications, with combustion devices ranging from 5 kW cook stoves (Prasad, 1985) to 125 MW boilers burning wood chips and producing 150 thm/hr of steam at 11 MPa and 540°C superheat temperatures (Anonymous, 1994). The available types of combustors range from pile burners or Dutch-oven-type burners, which can accept biomass in

© 1999 by CRC Press LLC

a large size range, to units that are suspension fired and require not only extensive fuel preparation but also fuel drying. The most popular types of boilers seem to be stoker-fired units with moving grates. More recently, the trend has been to bubbling and circulating fluidized-bed units, which offer a high degree of fuel flexibility by accepting fuel mixes ranging from coal to paper mill sludges that have very high moisture and ash contents. Boiler efficiency for typically moist biomass feedstocks ranges from 65 to 75%.

Biomass-fired steam turbine power generation technology is very similar to that of conventional fossil-fueled cycles. Biomass is combusted in a boiler, and the heat which is liberated is used to produce steam with conditions ranging from 28 bar and 398°C (400 psig and 750°F) for typical 25 MW units to 86 bar and 510°C (1250 psig and 950°F) for larger systems. The superheated steam generated in the boiler is used to drive a steam turbine generator. Net plant efficiency ranges from 20 to 30% (17,060 to 11,373 Btu/kWhr). Larger-scale boilers would permit several stages of reheat and the use of supercritical steam cycles. Developers of the Whole Tree Energy™ System have proposed the combustion of whole trees that are dried in a flue gas-assisted dome in order to provide supercritical steam to a turbine. System efficiencies are projected to be in the range of 40% (heat rate 8530 Btu/kWhr) and would be comparable to gas turbine-based combined-cycle units. The ability to utilize whole trees, as opposed to having to process wood feedstocks to "chip" size is a key advantage of the Whole Tree Energy System, as it can significantly reduce feedstock-handling costs.

Gasification

Biomass gasification processes can convert biomass materials into gaseous fuels (carbon- and hydrogen-rich fuel gases) that can be more easily utilized, often with a gain in efficiency and environmental performance. Gasification is a two-step, endothermic process in which a solid fuel (biomass or coal) is thermochemically converted into a low- or medium-Btu gas (see Figure 7.4.1). In the first reaction, pyrolysis, the volatile components of the fuel are vaporized at temperatures below 600°C (1100°F) by a set of complex reactions. Included in the volatile vapors are hydrocarbon gases, hydrogen, carbon monoxide, carbon dioxide tar, and water vapor. Because biomass fuels tend to have more volatile components (70 to 86% on a dry basis) than coal (30%), pyrolysis plays a larger role in biomass gasification than in coal gasification. Char (fixed carbon) and ash are the by-products of pyrolysis which are not vaporized. The second reaction, char conversion, involves the gasification and/or combustion of the carbon that remains after pyrolysis. In this reaction a portion of the char is burned to provide the heat required for pyrolysis and for gasification of any remaining char.

Thermal gasification is typically 80 to 85% efficient in converting the organic content of the feed into a fuel gas mixture mainly composed of hydrogen, carbon monoxide, and methane along with inert constituents. As a comparison, natural gas energy content, measured on a dry gas basis, is typically 37.8 $MJ \cdot m^{-3}$, or 1000 Btu/ft^3. Biomass gases produced through thermal gasification with air as the oxidant typically have gas energy content of less than 5.6 $MJ \cdot m^{-3}$ or 150 Btu/ft^3, while gasification with oxygen and steam or indirect gasification (which elimmintes the nitrogen dilution of the product) results in a heating value of 13 to 17 $MJ \cdot m^{-3}$ or about 350 to 450 Btu/ft^3. Typically, an air-blown gasifier would have over 50% nitrogen, a 25 to 30% by volume mix of hydrogen and carbon monoxide, and a small amount of methane, and the balance would be carbon dioxide.

Gasifier systems usually comprise the biomass fuel-handling and -feeding system which is coupled by means of air locks to the gasifier. In the thermal processes, the gasifier is usually a refractory-lined vessel and the gasification is carried out at high temperatures of approximately 850°C, at either atmospheric or elevated pressures. In a fluidized-bed gasifier, a continuous feed of biomass and inert heat-distributing material (e.g., sand) is "fluidized" by an oxidant and/or steam, and heat is supplied to the gasifier either "directly" or "indirectly" (U.S. Department of Energy, 1992).

In a directly heated fluidized-bed gasifier, heat required for gasification comes from char combustion in the gasifier reactor. The Institute of Gas Technology RENUGAS™ Pressurized Gasifier is an example of a direct-gasification technology. In the RENUGAS process, biomass is fed into a single, fluidized-bed gasifier vessel that operates at 300 to 500 psig. Inert solids in the vessel form the stable fluidized

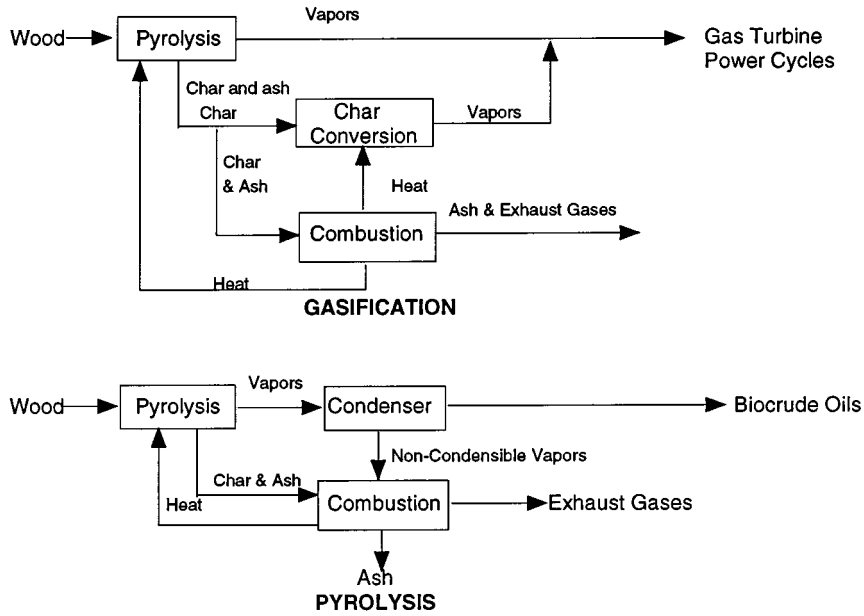

FIGURE 7.4.1. A diagram illustrating biomass gasification and pyrolysis processes. (From U.S. Department of Energy, *Electricity from Biomass: A Development Strategy.* DOE/CH10093-l52, DE920l0590. Washington, D.C., 1992.)

bed into which the biomass is fed. All of the biomass ash is carried overhead with the product gases. By using a deep, single-stage bed of inert solids, the RENUGAS process is able to achieve high carbon conversion with low oils and tars production. The gasifier is capable of producing either an industrial fuel gas or a chemical synthesis gas, depending on air- or oxygen-blown operation.

In an indirectly heated fluidized-bed gasifier, char is removed from the gasifier and burned in a separate vessel. The resulting heat is transferred to the gasifier by either in-bed heat exchangers or by recirculating the inert bed material heated in the char combustor. The advantage of indirect heating of the gasifier is that the gasification product is not diluted with the char combustion by-products (U.S. Department of Energy, 1992). The Battelle Gasification System is an example of an indirect gasification technology (see Figure 7.4.2). The Battelle system is a two-zone circulating-bed gasifier that produces a medium-energy content gas with a heating value of 500 Btu/ft^3 (18.63 MJ/m^3). The product gas can be used in existing natural gas-fired equipment including boilers, kilns, or gas turbines. The Battelle process produces this medium-Btu gas without the need for an oxygen plant, and uses two physically separate reactors (a gasification reactor in which biomass is converted into the product gas and residual char, which is then burned in a separate combustion reactor to provide the heat required for gasification). Heat transfer between the reactors is accomplished by circulating sand between the gasifier reactor and the combustor reactor. The separation of the gasifier from the combustor provides a means to maintain a constant heating value of the product gas regardless of changes in the feed moisture or ash content.

Biomass fuels can provide significant environmental advantages over competing fossil fuels, especially with regard to coal products. These advantages include little or no sulfur content and zero net carbon dioxide production. Additionally, chemicals produced during biomass combustion are absorbed in the photosynthesis process of new biomass growth. However, the fuel conversion process (gasification/combustion) generates emissions such as particulates, tar, and alkali that can cause erosion, corrosion, and deposition problems within the components of advanced conversion systems, especially combustion turbines. As such, some form of gas cleanup must be employed to ensure dependable system performance.

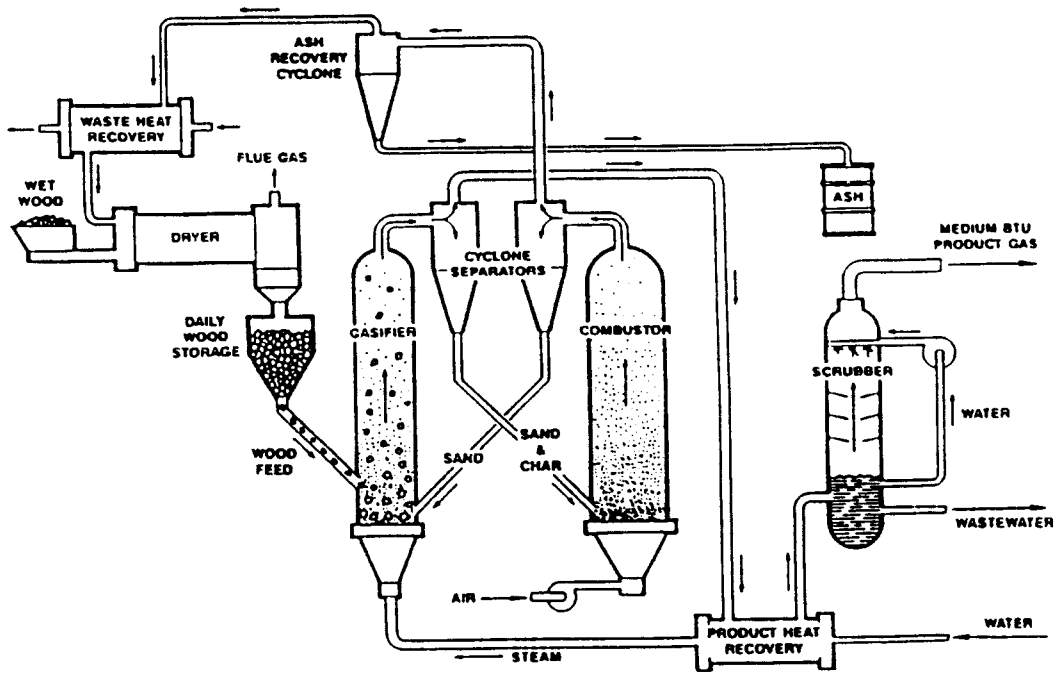

FIGURE 7.4.2. A diagram illustrating the Battelle Biomass Indirect Gasification System.

Biological Gasification or Anaerobic Digestion

The biological gasification process is carried out on feedstock which is either dissolved or slurried in water and typically produces a medium-energy-content gas composed of methane and carbon dioxide. A variety of designs are available, but all of them put anaerobic and methane-forming bacteria in contact with the biomass, the products are the gas (a mixture of methane and carbon dioxide) and a slurry of nonreacted feedstock which can usually be converted into a compost/fertilizer. In the case of landfill gas, the landfill "naturally" produces methane, which is currently being managed for greenhouse gas emissions. The contaminants, which can be highly odoriferous and include hydrogen sulfide, are removed with available technology prior to combustion in either a medium-speed diesel or turbine engine.

Liquefaction to Produce a Biofuel Oil

Biomass feedstocks can also be utilized to create biofuel oils, also known as biocrude. Through a process known as rapid pyrolysis, biofuel oils can be produced and used as fuel for gas turbines, diesel engines, or by co-firing the oil in an existing pulverized coal- or oil-fired boiler. Rapid pyrolysis occurs when heat is transferred to prepared biomass feedstocks (typical thickness <2 mm, moisture <8%) and the solid particles are thermochemically converted to a mixture of noncondensible gases, water vapor, char particles, and pyrolysis oil vapors. The pyrolysis oil vapors typically have a yield of 60 to 80% and are condensed to form a black, viscous, medium-Btu (9000 Btullb or 18.6 MJ/kg) mixture of organic compounds. Because the fuel oils can be stored and transported, the pyrolysis process can be decoupled from the power generation cycle, increasing the flexibility with respect to the proximity of the pyrolysis process to the end user.

Biofuel oil can be produced by pyrolyzing dried wood chips in a **vortex reactor**, followed by removal of solids and condensation of the vapors to recover the higher-molecular-weight hydrocarbons (see Figure 7.4.3). Noncondensible and light hydrocarbons are recycled as carrier gas, or burned with char to generate steam and/or electricity for internal use and export. Table 7.4.2 contains a comparison of biocrude oil characteristics and those of No. 6 fuel oil.

Biomass Liquefaction

Ethanol

Ethanol (CH_3CH_2OH) is a renewable liquid fuel that can be produced by fermenting a wide range of biomass materials, including sugars, starches, and lignocellulosics. It is an excellent fuel for spark-ignition internal combustion engines with a high octane number. The automobile industry has developed specifications for E85, an 85% by volume blend with gasoline. Lower-level blends such as El0 are in broad commercial use. Heavy-duty compression ignition engines are usually modified to provide ignition assistance such as glow or spark plugs because of the low cetane and poor autoignition qualities. Although the volumetric energy density of ethanol is two thirds that of gasoline, it has properties, such as the increased octane number, that allow the use of more-efficient high-compression engines. The heat of vaporization is twice that of gasoline, thus increasing the cooled fuel/air mixture that reaches each cylinder. This same property, however, increases cold-starting difficulties.

Currently, corn is used to provide the starch substrate for ethanol production in the United States which is about 1.4 billion gal. Lignocellulosic materials, such as short-rotation woody crops (SRWC) and herbaceous energy crops (HEC), offer an alternative feedstock, one that is dependent on the development of new technology that will allow the cellulose and hemicelluloses that make up

© 1999 by CRC Press LLC

approximately 70% of the lignocellulosic feedstocks to produce ethanol. Technology developments in the last decade in lignocellulosic-to-ethanol conversion have shown major potential for cost reductions that have positioned ethanol from lignocellulosics as a near commercial opportunity. These improvements have been in pretreatment, cellulase enzyme production, xylose fermentation, and cellulose conversion.

A typical flow sheet for ethanol production from lignocellulosics such as SRWC or HEC comprises the following operations: feedstock handling; pretreatment to expose the polymers such as hemicellulose and cellulose; production of the biocatalysts such as **cellulase** and hemicellulase that liberate the sugars glucose and xylose; fermentation to convert sugars into ethanol; ethanol recovery process such as distillation; and waste treatment with combined heat and power production from the lignin and other unconverted process residues. A combination of revolutionary advances and incremental improvements in this process chain has reduced costs of ethanol from $3.60 in 1980 to an estimated $1.27/gal in 1996; this latter is already below the cost of production of ethanol from corn. Further development promises to bring the cost into the range of $0.7 to 0.8/gal. This projected cost is competitive with equivalent fuels produced from oil costing $25/barrel.

Pretreatments to expose the carbohydrate polymers have been systematically optimized and developed to be low cost and to have low environmental impact. Dilute acid **hydrolysis** has been found to be effective at exposing cellulose for further hydrolysis. This pretreatment step is followed by a separation of the soluble hemicellulose sugars from the lignin and cellulose fiber. The cellulose material is used both to produce the cellulase enzymes for the hydrolysis and as the major source of sugar that produces ethanol in a combined saccharification and fermentation step. This combines the release of glucose with its immediate fermentation to ethanol in a single process step that results in a large capital cost saving, decreased fermentation times, and increased enzyme productivity, factors that have made a major reduction in overall cost. Work continues on improving the cellulase productivity, the tolerance of the fermentation yeasts to ethanol, and increases in the solids concentration in the fermenters. The current yield of xylose from the hemicellulose polymer, xylan, is also being improved from 80 to 90% (Zhang et al., 1995).

Methanol from Biomass

Methanol (CH_3OH) can easily be produced by gasifying biomass and then catalytically combining the carbon monoxide and the hydrogen. It is the one-carbon analog of ethanol and shares many of the same fuel properties such as a very high octane number. For spark-ignition engine use, M85, an 85% by volume blend with gasoline, is usually specified. The 15% gasoline provides added fuel volatility, which assists cold starting and adds luminosity to the flame for added safety since neat methanol (M100) burns with a nearly invisible flame.

Methanol is very toxic to humans, but is not a great threat to either soil or water environments, and like ethanol, it is essentially nonthreatening to the environment. In any case, methanol is an important industrial chemical and represents one third of the mass of the MTBE (methyl tertiarybutylether) oxygenate used in auto-fuel oxygenate programs. Currently, it is produced from natural gas using technology that has existed for over 50 years.

Biodiesel

Biodiesel is a diesel fuel that in the United States is derived from oil seed crops such as sunflower, soybean, and rape seed (canola). The oil is esterified in a simple process by reacting it with an alcohol such as methanol or ethanol to produce an ester that has been shown to be an attractive diesel fuel with an excellent cetane number and with much-reduced particulate emissions. The oil is isolated by pressing and solvent extraction from the seed cake, and the meal that remains is a nutritious animal feed. The esterification process produces a glycerine by-product. Both the meal and the glycerine have to be marketed in parallel with the oil production and currently the basic price of the oil seed — a food or feedstuff — is still too high, even though in subsidized markets in Europe production is increasing.

Municipal Solid Waste

Quantities, Characteristics, and Fuel Value

MSW contains energy, typically ranging from about 4000 to 6500 Btu/lb. MSW includes waste discarded from residential, commercial, institutional, and industrial sources. In 1993, over 200 million tons were generated with approximately 16% combusted for energy recovery. The quantities and heating values available will vary depending on the materials collected and processed into fuel. For instance, tires may be defined as MSW, but most will not be collected and processed into refuse-derived fuel (RDF). Yard waste contains some fuel value but may be composted. Of the approximate 207 million tons of MSW generated in the United States in 1993, paper and paperboard contributed about 77.8 million tons; plastics, 19.3 million tons; wood, 13.7 million tons. Paper has a typical heating value of 7200 Btu/lb; cardboard, 7000 Btu/lb; plastics, 14,000 Btu/lb; and wood, 8500 Btu/lb. Other components, such as leather, textiles, yard trimmings, rubber, etc., also have significant heating values. Processed RDF will have higher heating values depending on the degree of processing to remove noncombustibles and the components used to prepare the fuel. The average passenger tire has a heating value of 13,000 to 15,000 BtuAb. However, there are only two dedicated tires-to-energy facilities in the United States combusting tires for energy recovery; a third was scheduled to begin operation some time in 1995. There are a number of cement kilns, pulp and paper mills, electric-generating utility boilers, and industrial boilers that use tire-derived fuel as a portion of their fuel.

Refuse-Derived Fuels

Fuels derived from MSW have been classified according to the degree of processing. They range from waste used as a fuel in its discarded form with only bulky waste removed (RDF-1) to the combustible fraction of the waste processed into gaseous fuel (RDF-7). Some RDF may be densified (d-RDF) into pellets, cubes, or briquets for use in industrial and utility boilers as a supplement to coal.

MSW-to-Energy Conversion Technologies

Although there are several potential methods to recover energy from MSW (e.g., conversion to ethanol, anaerobic digestion, gasification, pyrolysis, etc.), combustion is the most-advanced and the most-applied conversion technology.

Combustion. Direct combustion is the most prevalent technology used to reclaim the energy value in MSW. In 1993, there were 125 municipal waste-to-energy facilities in the United States with a rated MSW capacity of approximately 2500 MW of energy. The most common options are mass burn and RDF facilities, with mass burn being the most prevalent.

In a typical mass burn facility, waste is received into a pit where an overhead crane mixes the waste and removes oversize materials. The waste is fed onto a grate of the furnace, which agitates and moves the waste across the combustion chamber. Air for combustion is introduced from under the grate (underfire air) and from nozzles located above the grate (overfire air). The formation and emission of pollutants (e.g., CO, NO_x, SO_x, hydrocarbons, dioxins, etc.) are affected significantly by the design and operation of the combustor. Energy is recovered from the hot flue gases in a waterwall boiler and is recovered as hot water and steam.

The cooled flue gases then pass through air pollution control (APC) equipment which normally includes combinations of scrubbers to remove acid gases (e.g., HCl) electrostatic precipitators (particulate removal), and/or fabric filters (fine particulates).

Anaerobic Digestion. Anaerobic digestion is the biological degradation of biodegradable materials, in the absence of oxygen. Anaerobic microorganisms convert the biodegradable fraction of the waste to carbon dioxide and methane, which can be collected and used as an energy source. Commercial-scale anaerobic digestion of MSW has not been successful in the U.S. There are approximately 24 plants operating outside of the U.S.

Defining Terms

Cellulase: A group of enzymes, found in many fungi and bacterial organisms, that hydrolyze the cellulose molecule into the component glucose molecules.

Cellulose: A complex carbohydrate found in stems, bark, and fibrous parts of plants and in products such as paper made from plant material. The insoluble molecule is a long chain of six carbon, glucose molecules linked together.

Hemicellulose: A complex carbohydrate molecule also found in plant material. This molecule is more soluble than cellulose and made up of five carbon sugars such as xylose.

Hydrolysis: Chemical decomposition involving the formation of water. Enzymes are capable of catalyzing the breakdown of cellulose resulting in the release of a water molecule and glucose molecules.

Lignin: A hard material embedded in the cellulose matrix of vascular plant cell walls. The molecule is a branched chain of organic rings, and gives strength to the fibers. This material is insoluble and must be removed in order to hydrolyze the cellulose.

Lignocellulosics: Substances composed of lignin and cellulose and/or hemicellulose, for example, wood. Lignocellulosic materials are the initial form of biomass feedstock before pretreatment removes or loosens the lignin and liberates the cellulose for further treatment

Photosynthesis: A process by which plants combine water and carbon dioxide in the presence of light and chlorophyll to make carbohydrates for food.

Vortex reactor: A pyrolysis reaction chamber design whereby a carrier gas and a dry feed stream are injected into a cylindrical reaction chamber, entering the reactor in a helical pattern and flowing over the inside surface of the cylinder, where heat is transferred to the biomass.

7.5 Nuclear Resources

James S. Tulenko

The Nuclear Fuel Cycle

Sources of Nuclear Fuels and World Reserves

Nuclear power can use two naturally occurring elements, uranium and thorium, as the sources of its fissioning energy. Uranium can be a fissionable source (fuel) as mined (Candu Reactors in Canada), while thorium must be converted in a nuclear reactor into a fissionable fuel. Uranium and thorium are relatively plentiful elements ranking about 60th out of 80 naturally occurring elements. All isotopes of uranium and thorium are radioactive. Today, natural uranium contains, in atomic abundance, 99.2175% Uranium-238 (U^{238}); 0.72% Uranium-235 (U^{235}); and 0.0055% Uranium-234 (U^{234}). Uranium has atomic number 92, meaning all uranium atoms contain 92 protons, with the rest of the mass number being composed of neutrons. Uranium-238 has a half-life of 4.5×10^9 years (4.5 billion years), U-235 has a half-life of 7.1×10^8 years (710 million years), and U-234 has a half-life of 2.5×10^5 years (250 thousand years). Since the age of the earth is estimated at 3 billion years, roughly half of the U-238 present at creation has decayed away, while the U-235 has changed by a factor of sixteen. Thus, when the earth was created, the uranium-235 enrichment was on the order of 8%, enough to sustain a natural reactor of (there is evidence of such an occurrence in Africa). The U-234 originally created has long disappeared, and the U-234 currently present occurs as a product of the decay of U-238.

Uranium was isolated and identified in 1789 by a German scientist, Martin Heinrich Klaproth, who was working with pitchblend ores. No one could identify this new material he isolated, so in honor of the planet Uranus which had just been discovered, he called his new material Uranium. It wasn't until 1896, when the French scientist Henri Becquerel accidentally placed some uranium salts near some paper-wrapped photographic plates, that radioactivity was discovered.

Until 1938, when the German scientists Otto Hahn and Fritz Shassroen succeeded in uranium fission by exposure to neutrons, uranium had no economic significance except in coloring ceramics, where it proved valuable in creating various shades of orange, yellow, brown, and dark green. When a uranium atom is fissioned it releases 200 million electron volts of energy; the burning of a carbon (core) atom releases 4 electron volts. This diffenence of 50 million times in energy release shows the tremendous difference in magnitude between chemical and nuclear energy.

Uranium is present in the earth's crust to the extent of four parts per million. This concentration makes uranium about as plentiful as beryllium, hafnium, and arsenic; and greater in abundance than tungsten, molybdenum, and tantalum. Uranium is an order of magnitude more plentiful than silver and a hundred times more plentiful than gold. It has been estimated that the amount of uranium in the earth's crust to a depth of 12 miles is of the order of 100 trillion tons.

Thorium, which is composed of only one isotope, Thorium-232, has a half-life of 14 billion years (1.4×10^{10} yr), is more than three times more abundant than uranium, and is in the range of lead and gallium in abundance. Thorium was discovered by Berjelius in 1828 and named after Thor, the Scandinavian god of war. For reference, copper is approximately five times more abundant than thorium and twenty times more abundant than uranium.

Uranium is chemically a reactive element; therefore, while it is relatively abundant, it is found chemically combined as an oxide (U_3O_8 or UO_2) and never as a pure metal. Uranium is obtained in three ways, either by underground mining, open pit mining, or in situ leaching. An economic average ore grade is normally viewed as .2% (4 pounds per short ton), though recently ore grades as low as .1% have been exploited. A large quantity of uranium exists in sea-water which has an average concentration of 3×10^{-3} ppm, yielding an estimated uranium quantity available in sea-water of 4000 million tons. A pilot operation was successfully developed by Japan to recover uranium from sea-water, but the cost was about $900/lb, and the effort was shut down as uneconomical.

© 1999 by CRC Press LLC

The major countries with reserves of urnaium in order of importance are Australia, United States, Russia, Canada, South Africa, and Nigeria. The countries with major thorium deposits are India, Brazil, and the United States. It is estimated that for a recovery value of $130/kg ($60/lb), the total uranium reserves in these countries are approximately 1.5 million tonnes of uranium in the U.S., 1 million tonnes of uranium in Australia, .7 million tonnes of uranium in Canada, and 1.3 million tonnes of uranium in the former Soviet Union. As mentioned earlier, thorium reserves are approximately four times greater. With the utilization of breeder reactors, there is enough uranium and thorium to provide electrical power for the next thousand years at current rates of usage.

Processing of Nuclear Fuel

Once the uranium ore is mined it is sent to a concentrator (mill) where it is ground, treated, and purified. Since the ore is of a grade of .1 to .2% uranium, a ton of ore contains only between 1 to 2 kilograms of uranium per 1000 kilograms of ore. Thus, thousands to tonnes of ore have to be extracted and sent to a mill to produce a relatively small quantity of uranium. In the concentration process approximately 95% of the ore is recovered as U_3O_8 (yellowcake) to a purity grade of about 80%. Thus, assuming 0.15% uranium ore, the milling and processing of a metric ton (1000 kg) of ore yields a concentrate of 1.781 kg (1.425 kg of uranium and 0.356 kg of impurities). For this reason the mills must be located relatively close to the mine site. The ore tailings (waste) amounts to 998.219 kg and contains quantities of radon and other urnaium decay products and must be disposed of as a radioactive waste.

The U_3O_8 concentrate is then taken to a conversion plant where the concentrate is further purified (the 20% impurities are removed) and the uranium yellowcake is converted to uranium hexafluoried UF_6). The uranium hexafluoride is a gas at fairly low temperature and is an ideal material for the U-235 isotope enriching processes of either gaseous diffusion or gaseous centrifuge. The UF_6 is shipped in steel cylinders in a solid state, and UF_6 is vaporized by putting the cylinder in a steam bath.

If the uranium is to be enriched to 4% U^{235}, then 1 kilogram of 4% U^{235} product will require 7.4 kilograms of natural uranium feed and will produce 6.4 kilograms of waste uranium (tails or depleted uranium) with a U^{235} isotope content of 0.2%. This material is treated as a radioactive waste. Large quantities of tails (depleted uranium) exist as UF_6 in their original shipping containers at the enriching plants. Depleted uranium (a dense material) has been used as shields for radioactive sources, armor piercing shells, balancing of helicopter rotor tips, yacht hold ballast, and balancing of passenger aircraft.

The enriched UF_6 is then sent to a fabrication plant where it is converted to a uranium dioxide (UO_2) powder. The powder is pressed and sintered into cylindrical pellets which are placed in zircaloy tubes (an alloy of zirconium), pressurized with helium, and sealed. The rods are collected in an array (~17 × 17) bound together by spacer grids, with top and bottom end fittings connected by tie rods or guide tubes. Pressurized water reactor fuel assemblies, each containing approximately 500 kilograms of uranium, are placed in a reactor for 3 to 4 years. A single fuel assembly produces 160,000,000 kilowatt hours of electricity and gives 8,000 people their yearly electric needs for its three years of operation. When the fuel assembly is removed from the reactor it must be placed in a storage pond to allow for removal of the decay heat. After approximately five years of wet storage, the fuel assembly can be removed to dry storage in concrete or steel containers. In the United States the current plan is to permanently store the nuclear fuel, with the Department of Energy assuming responsiblility for the "spent" fuel. The money for the government to handle the storage comes from a fee of 1 mill per kilowatt hour paid by consumers of nuclear-generated electricity. A mill is a thousandth of a dollar or a tenth of a penny. Thus, the fuel assembly described above would have collected $160,000 in the waste fund for the Department of Energy to permanently store the fuel. In Europe, when the fuel is taken out of wet storage it is sent to a reprocessing plant where the metal components are collected for waste disposal; and the fuel is chemically recovered as 96% uranium, which is converted to uranium dioxide for recycling to the enrichment plant, 1% plutonium, which is converted to fuel or placed in storage, and 3% fission products which are encased in glass and permanently stored.

© 1999 by CRC Press LLC

The important thing to remenber about the fuel cycle is the small quantitiy of radioactive fission products (1.5 kilograms) which are created as radioactive waste in producing power which can serve the yearly eletricity needs of 8,000 people for the three years that it operates. The schematic of the entire fuel cycle showing both the United States system (once-through) and the European (recycle) system is given in Figure 7.5.1.

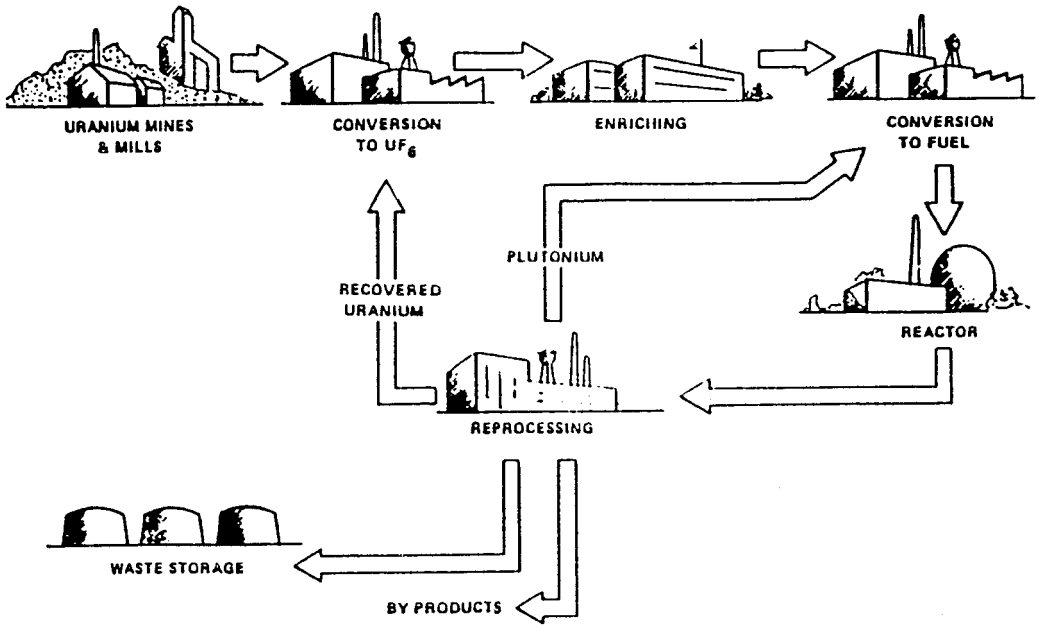

FIGURE 7.5.1 The nuclear fuel cycle.

7.6 Solar Energy Resources

D. Yogi Goswami

The sun is a vast nuclear power plant of the fusion variety which generates power in the form of radiant energy at a rate of 3.8×10^{23} kW. An extremely small fraction of this is intercepted by Earth, but even this small fraction amounts to the huge quantity of 1.8×10^{14} kW. On the average, about 60% of this energy, incident at the outer edge of the atmosphere, reaches the surface. To compare these numbers with our energy needs, consider the present electrical-generating capacity in the United States, which is approximately of 7×10^8 kW. This is equivalent to an average solar radiation falling on only 1000 square miles in a cloudless desert area. It must, however, be remembered that solar energy is distributed over the entire surface of Earth facing the sun, and it seldom exceeds 1.0 kW/m^2. Compared to other sources, such as fossil fuels or nuclear power plants, solar energy has a very low energy density. However, solar radiation can be concentrated to achieve very high energy densities. Indeed, temperatures as high as 3000 K have been achieved in solar furnaces.

Solar energy technology has been developed to a point where it can replace most of the fossil fuels or fossil fuel-derived energy. In many applications it is already economical, and it is a matter of time before it becomes economical for other applications as well.

This section deals in the availability of solar radiation, including methods of measurement, calculation, and available data.

Solar Energy Availability

Detailed information about solar radiation availability at any location is essential for the design and economic evaluation of a solar energy system. Long-term measured data of solar radiation are available for a large number of locations in the United States and other parts of the world. Where long-term measured data are not available, various models based on available climatic data can be used to estimate the solar energy availability. The solar energy is in the form of electromagnetic radiation with the wavelengths ranging from about 0.3 μm (10^{-6} m) to over 3 μm, which correspond to ultraviolet (less than 0.4 μm), visible (0.4 and 0.7 μm), and infrared (over 0.7 μm). Most of this energy is concentrated in the visible and the near-infrared wavelength range (see Figure 7.6.1). The incident solar radiation, sometimes called **insolation**, is measured as irradiance, or the energy per unit time per unit area (or power per unit area). The units most often used are watts per square meter (W/m^2), British thermal units per hour per square foot (Btu/hr-ft^2), and Langleys (calories per square centimeter per minute, cal/cm^2-min).

The amount of solar radiation falling on a surface normal to the rays of the sun outside the atmosphere of the earth (extraterrestrial) at mean Earth-sun distance (D) is called the **solar constant**, I_o. Measurements by NASA indicated the value of solar constant to be 1353 W/m^2 (±1.6%). This value was revised upward and the present accepted value of the solar constant is 1377 W/m^2 (Quinlan, 1979) or 437.1 Btu/hr-ft^2 or 1.974 langleys. The variation in seasonal solar radiation availability at the surface of Earth can be understood from the geometry of the relative movement of Earth around the sun.

Earth-Sun Relationships

Figure 7.6.2 shows the annual motion of Earth around the sun. The **extraterrestrial solar radiation** varies throughout the year because of the variation in the Earth-sun distance (D) as:

$$I = I_o\left(D/D_o\right)^2 \tag{7.6.1}$$

which may be approximated as (Spencer, 1971)

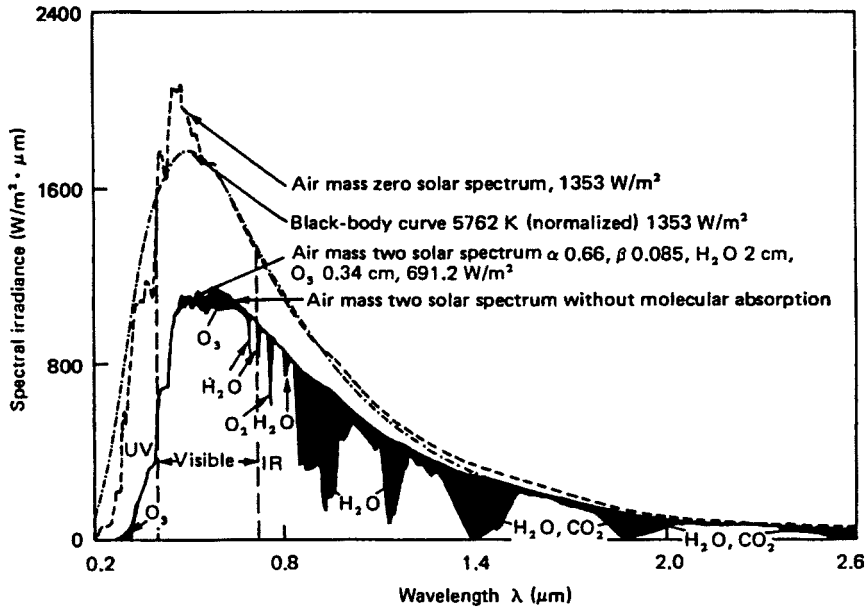

FIGURE 7.6.1 Spectral distribution of solar energy at sea level. (Reprinted by permission from Kreith, F. and Kreider, J.F., *Principles of Solar Engineering*, Hemisphere, Washington, D.C., 1978.)

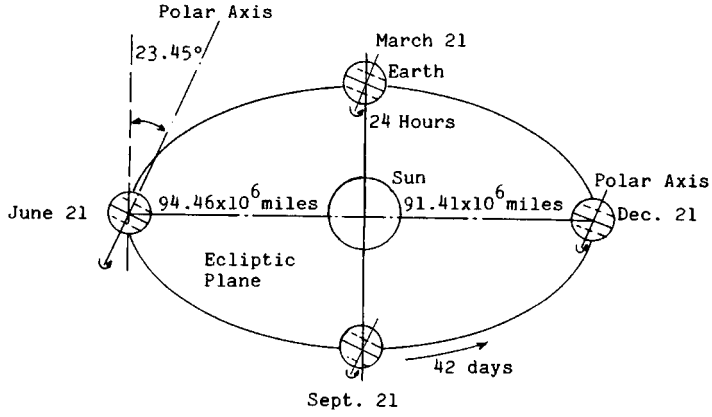

FIGURE 7.6.2 Annual motion of the Earth around the sun.

$$\left(D/D_o\right)^2 = 1.00011 + 0.034221\cos(x) + 0.00128\sin(x) + 0.000719\cos(2x) + 0.000077\sin(2x) \quad (7.6.2)$$

where

$$x = 360(N-1)/365° \quad (7.6.3)$$

and N = Day number (starting from January 1 as 1). The axis of the Earth is tilted at an angle of 23.45° to the plane of its elliptic path around the sun. This tilt is the major cause of the seasonal variation of solar radiation available at any location on Earth. The angle between the Earth-sun line and a plane through the equator is called **solar declination**, δ. The declination varies between –23.45° to +23.45° in 1 year. It may be estimated by the relation:

© 1999 by CRC Press LLC

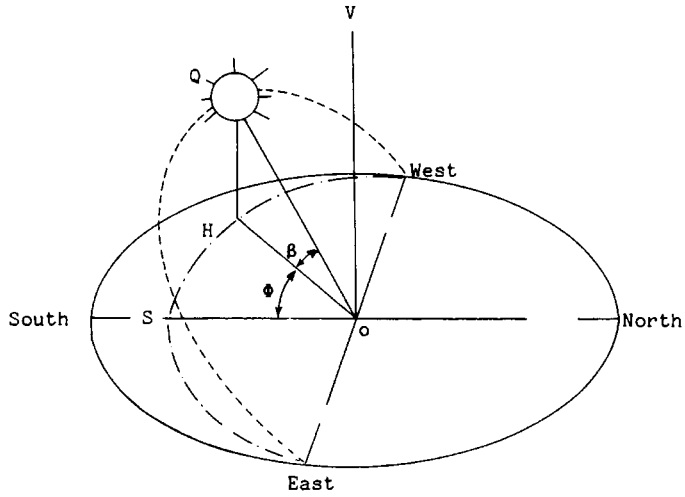

FIGURE 7.6.3 Apparent daily path of the sun across the sky from sunrise to sunset, showing the solar altitude and azimuth angles.

$$\delta = 23.45^\circ \sin\left[360(284 + N)/365^\circ\right] \tag{7.6.4}$$

The apparent motion of the sun around the earth is shown in Figure 7.6.3. The **solar altitude angle**, β, and the **solar azimuth angle**, Φ, describe the position of the sun at any time.

Solar Time

The sun angles are found from the knowledge of solar time, which differs from the local time. The relationship between solar time and local standard time (LST) is given by

$$\text{Solar Time} = \text{LST} + \text{ET} + 4\left(L_{st} - L_{loc}\right) \tag{7.6.5}$$

where ET is the **equation of time**, which is a correction factor in minutes that accounts for the irregularity of the motion of the Earth around the sun. L_{st} is the standard time meridian and L_{loc} is the local longitude. ET can be calculated from the following empirical equation:

$$\text{ET(in minutes)} = 9.87\sin 2B - 7.53\cos B - 1.5\sin B \tag{7.6.6}$$

where $B = 360(N - 81)/365^\circ$.
The sun angles β (altitude) and Φ (azimuth) can be found from the equations:

$$\sin\beta = \cos\ell\cos\delta\cos H + \sin\ell\sin\delta \tag{7.6.7}$$

where ℓ = latitude angle,

$$\sin\Phi = \cos\delta\sin H/\cos\beta \tag{7.6.8}$$

and

© 1999 by CRC Press LLC

$$H = \text{Hour angle} = \frac{\text{Number of minutes from local solar noon}}{4 \text{ min/degree}} \tag{7.6.9}$$

(At solar noon, $H = 0$, so $\beta = 90 - |\ell - \delta|$ and $\Phi = 0$.)

Solar Radiation on a Surface

As solar radiation, I, passes through the atmosphere, some of it is absorbed by air and water vapor, while some gets scattered by molecules of air, water vapor, aerosols, and dust particles. The part of solar radiation that reaches the surface of the Earth with essentially no change in direction is called **direct or beam normal radiation**, I_{bN}. The scattered radiation reaching the surface from the atmosphere is called **diffuse radiation**, I_d.

I_{bN} can be calculated from the extraterrestrial solar irradiance, I, and the atmospheric optical depth τ as (Goswami et al., 1981; ASHRAE, 1995)

$$I_{\text{bN}} = Ie^{-\tau \sec\theta_z} \tag{7.6.10}$$

where θ_z is the solar zenith angle (angle between the sun rays and the vertical). The atmospheric optical depth determines the attenuation of the solar radiation as it passes through the atmosphere. Threlkeld and Jordan (1958) calculated values of τ for average atmospheric conditions at sea level with a moderately dusty atmosphere and amounts of precipitable water vapor equal to the average value for the United States for each month. These values are given in Table 7.6.1. To account for the differences in local conditions from the average sea level conditions Equation (7.6.10) is modified by a parameter called Clearness Number, Cn, introduced by Threlkeld and Jordan (1958):

$$I_{\text{bN}} = \text{Cn}Ie^{-\tau \sec\theta_z} \tag{7.6.11}$$

values of Cn vary between 0.85 and 1.15.

TABLE 7.6.1 Average Values of Atmospheric Optical Depth (τ) and Sky Diffuse Factor (C) for 21st Day of Each Month

Solar Radiation on a Horizontal Surface

Total incident solar radiation on a horizontal surface is given by

$$I_{t,\text{Horizontal}} = I_{\text{bN}} \cos\theta_z + CI_{\text{bN}} \tag{7.6.12}$$

$$= I_{\text{bN}} \sin\beta + CI_{\text{bN}} \tag{7.6.13}$$

where θ_z is called the solar zenith angle and C is called the sky diffuse factor, as given in Table 7.6.1.

Solar Radiation on a Tilted Surface

For a surface of any orientation and tilt as shown in Figure 7.6.4, the angle of incidence, θ, of the direct solar radiation is given by

© 1999 by CRC Press LLC

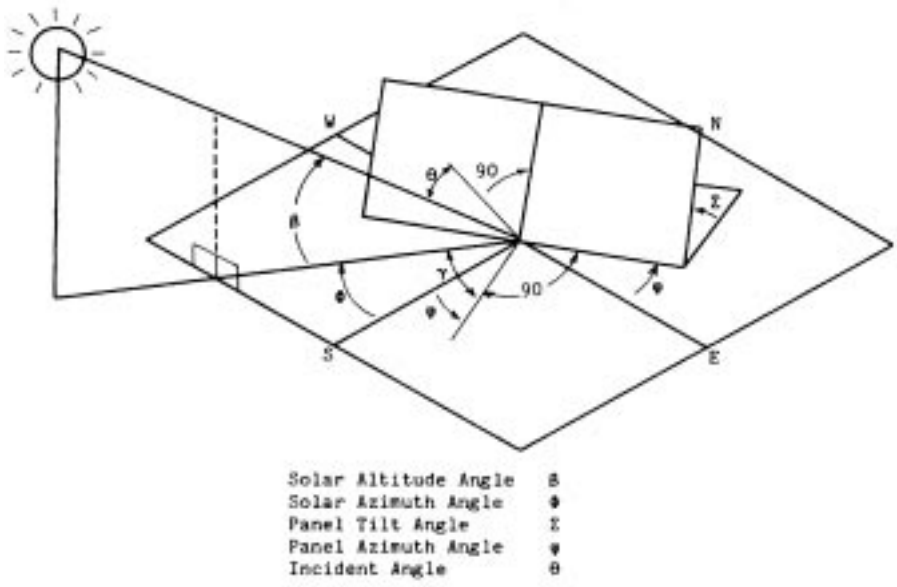

FIGURE 7.6.4 Definitions of solar angles for a tilted surface.

$$\cos\theta = \cos\beta\cos\gamma\sin\Sigma + \sin\beta\cos\Sigma \tag{7.6.14}$$

where γ is the angle between horizontal projections of the rays of the sun and the normal to the surface. Σ is the tilt angle of the surface from the horizontal.
For a tilted surface with angle of incidence θ, the total incident solar radiation is given by

$$I_b = I_{bN}\cos\theta + I_{diffuse} + I_{reflected} \tag{7.6.15}$$

where

$$I_{diffuse} = CI_{bN}(1+\cos\Sigma)/2 \tag{7.6.16}$$

and

$$I_{reflected} = \rho I_{bN}(C+\sin\beta)(1-\cos\Sigma)/2 \tag{7.6.17}$$

where ρ is the reflectivity of the surroundings. For ordinary ground or grass, ρ is approximately 0.2 while for ground covered with snow it is approximately 0.8.

Solar Radiation Measurements

Two basic types of instruments are used in measurements of solar radiation. These are (see Figure 7.6.5):

1. *Pyranometer:* An instrument used to measure global (direct and diffuse) solar radiation on a surface. This instrument can also be used to measure the diffuse radiation by blocking out the direct radiation with a shadow band.
2. *Pyrheliometer:* This instrument is used to measure only the direct solar radiation on a surface normal to the incident beam. It is generally used with a tracking mount to keep it aligned with the sun.

More-detailed discussions about these and other solar radiation measuring instruments can be found in Zerlaut (1989).

Solar Radiation Data

Measured values of solar radiation data for locations in the United States are available from the National Climatic Center in Asheville, NC. A number of states have further presented solar radiation data for locations in those states in readily usable form. Weather services and energy offices in almost all the countries have available some form of solar radiation data or climatic data that can be used to derive solar radiation data for locations in those countries. Tables 7.6.2 to 7.6.8 give solar radiation data for clear days for south-facing surfaces in the Northern Hemisphere (and northern-facing surfaces in the Southern Hemisphere) tilted at 0°, 15°, 30°, 45°, 60°, 75°, and vertical, for latitudes 0°, 10°, 20°, 30°, 40°, 50°, and 60°. The actual average solar radiation data at a location is less than the values given in these tables because of the cloudy and partly cloudy days in addition to the clear days. The actual data can be obtained either from long-term measurements or from modeling based on some climatic parameters, such as percent sunshine. Tables 7.6.9 to 7.6.12 give hourly solar angles for northern latitudes 0°, 20°, 40°, and 60°.

Defining Terms

Diffuse radiation: Scattered solar radiation coming from the sky.

Direct or beam normal radiation: Part of solar radiation coming from the direction of the sun on a surface normal to the sun's rays.

Equation of time: Correction factor in minutes, to account for the irregularity of the Earth's motion around the sun.

Extraterrestrial solar radiation: Solar radiation outside Earth's atmosphere.

Insolation: Incident solar radiation measured as W/m^2 or $Btu/hr\text{-}ft^2$.

Solar altitude angle: Angle between the solar rays and the horizontal plane.

Solar azimuth angle: Angle between the true south horizontal line and the horizontal projection of the sun's rays.

Solar constant: Extraterrestrial solar radiation at the mean Earth-sun distance.

Solar declination: Angle between the Earth-sun line and a plane through the equator.

7.7 Wind Energy Resources*

Dale E. Berg

The mechanical devices that are used to convert kinetic energy in the wind into useful shaft power are known as windmills (the earliest machines were used to mill grain), wind machines, or wind turbines. The earliest use of wind machines appears to have been in ancient Persia, where they were used for grinding grain and pumping water. By the 14th century, completely different types of mills known as post and cap mills had become a major source of energy for milling, water pumping, and other tasks throughout northern Europe, and they remained so well into the 19th century, when the steam engine displaced them in many applications.

A new form of windmill appeared in United States in the second half of the 19th century — the multivane or annular windmill, also sometimes known as the American windmill (see Figure 7.7.1). These small, lightweight machines were designed to survive high winds with no human intervention by automatically shedding power, and they played a large role in the settlement of the American West — an arid country where little surface water is available. Many windmills of this basic type are still in use for water pumping around the world today.

FIGURE 7.7.1 The multiblade American windmill Photograph by Paul Gipe. (Adapted from *Wind Power for Home & Business*, Chelsea Green Publishing. 1993).

By the end of the 19th century, efforts to adapt wind power to electricity generation were underway in several countries. In the early 20th century, small wind turbine generators utilizing only two or three aerodynamic blades and operating at a higher rotational speed than the multibladed windmills were developed. Many thousands of generators of this type have been used to provide electricity in the remote areas of the world over the past 85 years.

Large-scale wind turbines designed to generate electrical power were built and tested in several European countries and the U.S. between 1935 and 1970. However, economic studies showed that the electricity generated by the machines would be every expensive, and no effort was made to develop the machines as a serious alternative energy source.

* This work was supported by the United States Department of Energy under Contract DE-AC04-94AL85000.

As a result of research and development since the mid 1970s, the cost of energy or wind-generated electricity has decreased from around 30¢ per kilowatt-hour (kWhr) in the early 1980s to less than 5¢/kWhr for a modern wind farm at a good site in 1995, and wind turbine availability (the fraction of time the machine is operational; i.e., not disabled for repairs or maintenance) has increased from 50 to 60% to better than 95% over the same period. At the end of 1995, there were over 26,000 wind turbines operating worldwide with an installed capacity of over 5000 MW. Twenty-five percent of that capacity was installed in 1995, and plans for 1996 call for the installation of an additional 25%. About 2500 MW of the 5000 MW was in Europe, 1700 MW was in the U.S., and over 400 MW was in India.

Wind Characteristics

Wind Speed and Shear

The primary cause of atmospheric air motion, or wind, is uneven heating of Earth by solar radiation. For example, land and water along a coastline absorb radiation differently, and this creates the light winds or breezes normally found along a coast. Earth's rotation is also an important factor in creating winds.

Wind moving across Earth's surface is slowed by trees, buildings, grass, rocks, and other obstructions in its path. The effect of these obstructions decreases with increasing height above the surface, typically resulting in a wind speed that varies with height above the Earth's surface — phenomenon known as **wind shear**. For most situations, wind shear is positive and wind speed increases with height, but situations in which the wind shear is negative or inverse are not unusual. In the absence of actual data for a specific site, a commonly used approximation for wind shear is

$$U/U_o = \left(h/h_o\right)^{\alpha} \tag{7.7.1}$$

where U is the velocity at a height h, U_o is the measured velocity at height h_o, and α is the non-dimensional wind shear exponent.

The wind shear, α, varies with terrain characteristics, but usually is between 0.10 and 0.25. Over a smooth, level, grass-covered terrain such as the United States Great Plains, α is normally about 0.14. For wind over row crops or low bushes with a few scattered trees, a value of 0.20 is more common while a value of 0.25 is normally a good value for wind over a heavy stand of trees, several buildings, or hilly or mountainous terrain.

A specific site may display much different wind shear behavior than that given in Equation 7.7.1, and that will dramatically affect site energy capture, making it important to measure the wind resource at the specific site and height where the wind turbine will be located, if at all possible.

Wind Energy Resource

The available power in the wind passing through a given area at any given velocity is due to the kinetic energy of the wind and is given by

$$\text{Power} = \frac{1}{2}\rho A U^3 \tag{7.7.2}$$

where the power is in watts, ρ is the air density in kg/m^3, A is the area of interest perpendicular to the wind in m^2, and U is the wind velocity in m/sec.

Air density decreases with increasing temperature and increasing altitude. The effect of temperature on density is relatively weak and is normally ignored, as these variations tend to average out over the period of a year. The density difference due to altitude, however, is significant and does not average out. For example, the air density at sea level is approximately 14% higher than that at Denver, CO (elevation 1600 m or 5300 ft above sea level), so wind of any velocity at sea level contains 14% more power than wind of the same velocity at Denver.

© 1999 by CRC Press LLC

From Equation 7.7.2, it is obvious that the most important factor in the available power is the velocity of the wind — available wind power is proportional to the cube of the wind speed, so doubling the wind speed increases the available power by a factor of 8. An increase in wind velocity of only 20%, say, from 5 to 6 m/sec (11.2 to 13.4 mph), yields a 73% increase in available power.

The available wind power at a site can vary dramatically with height due to wind shear. For example, for $\alpha = 0.20$, Equations (7.7.1) and (7.7.2), reveal that the available power at a height of 30 m is approximately $\{(30/10)^{0.2}\}^3 = 1.93$ times the available power at 10 m. The amount of energy available from the wind (the **wind energy resource**) is the average amount of power available from the wind over a specified period of time, frequently a year. If the wind speed is 20 m/sec, the available power is very large, but if it only blows at that speed for 10 h/year and the rest of the time the wind speed is 0, the resource for the year is very small. Therefore, the site **wind speed distribution**, or frequency at which each wind speed occurs, is very important. The distribution is often presented in histogram form as the probability that the wind occurs at any particular wind speed between 0 and the maximum wind speed (see Figure 7.7.9). If the actual wind speed distribution is not available, it is frequently approximated with a Rayleigh distribution based on the yearly average wind speed. The Rayleigh distribution is given by

$$f(U) = \frac{\pi}{4} \cdot \frac{U}{\overline{U}} \exp\left[\frac{-\pi U^2}{4\overline{U}^2}\right] \tag{7.7.3}$$

where $f(U)$ is the frequency of occurrence of wind speed U and $\overline{U}$ is the yearly average wind speed.

How big is the wind energy resource? It varies dramatically from site to site. In 1981, scientists at Battelle Pacific Northwest Laboratory (PNL) in the U.S. analyzed national weather data, ship data, and terrain and made an estimate of the world-wide wind energy resource. That estimate is summarized in Figure 7.7.2. Very little data is available over much of the world, but even where excellent data is available, only very crude estimates can be portrayed on a map of this scale. More detailed analysis of available data for a specific country can yield a much better estimate of the wind resource for that country.

For example, the PNL scientists have carefully analyzed and interpreted the available long-term wind data for the U.S. and have summarized their estimate of the wind energy resource in a series of maps in the *Wind Energy Resource Atlas of the United States* (Elliott et al., 1987). A summary for the entire U.S. is reproduced in Figure 7.7.3 which presents the resource in terms of the power class rating. Sites with power class 4 (at least 250 W/m^2 at 10 m height or 500 W/m^2 at 50 m height) and above are considered economic for utility-scale wind power development with available wind technology, while sites with power class 3 are not considered economic today but are likely to become economic with near-term wind technology advances. Sites in power classes 2 or lower are not considered economic for utility-scale wind power development, but may well be economic for remote or hybrid wind power systems.

Much of the land in the United States is not available for wind energy development because it is in environmental exclusion areas such as parks, monuments, wilderness areas, wildlife refuges, and other protected areas, or only a portion of it may be developed because of land-use restrictions for forest, agriculture, range, and urban lands. Schwartz et al. (1992) estimated the wind energy that could be generated (the **wind energy potential**) for the United States land available for wind energy development. For the purposes of this study, they assumed that turbines with a 50-m hub height, arranged in arrays with 10 diameter by 5 diameter spacing, operating at 25% efficiency, and experiencing 25% power losses, were used to capture the available wind. Their results for power class 4 and above are summarized in Figure 7.7.4 and Table 7.7.1. They estimate that the average power that could be produced from this resource is 512,000 MW, significantly above the 1994 U.S. average electricity generation of 350,000 MW. They also estimate that the available windy lands with power class 3 or better resources could yield an average power of 1,241,000 MW, more than three times the current United States electricity generation. However, since wind energy is intermittent, is typically concentrated away from the major

TABLE 7.7.1 Estimates of Class 4 Wind Land Area and Wind Energy Potential

State	Average Power, MW	Windy Land, km^2
North Dakota	108,000	98,000
South Dakota	70,900	66,500
Wyoming	49,800	39,600
Montana	48,400	42,800
Minnesota	44,800	42,100
Kansas	35,700	33,600
Texas	28,900	27,100
Oklahoma	27,200	25,500
Colorado	26,400	24,300
Nebraska	22,200	20,900
Iowa	15,800	14,900
New Mexico	5,200	4,600
National	512,300	464,200

Note: The top 12 states and total for 48 contiguous states. Wind resource class 4 and above, for a 30-m hub height.

population centers where the electricity demand is highest, and is not always available when the demand is great, it will probably never supply more than 15 to 20% of the U.S. electricity needs.

Similar assessments may be performed for any country of interest. The PNL scientists have recently performed a similar assessment of the available long-term wind data for Mexico and have estimated the wind resource there (Schwartz and Elliott, 1995), as shown in Figure 7.7.5. While wind resources in class 2 are too low to be economic for grid-connected wind power, they are useful for rural power applications. Scientists at Denmark's Risø National Laboratory have done similar work in Europe,

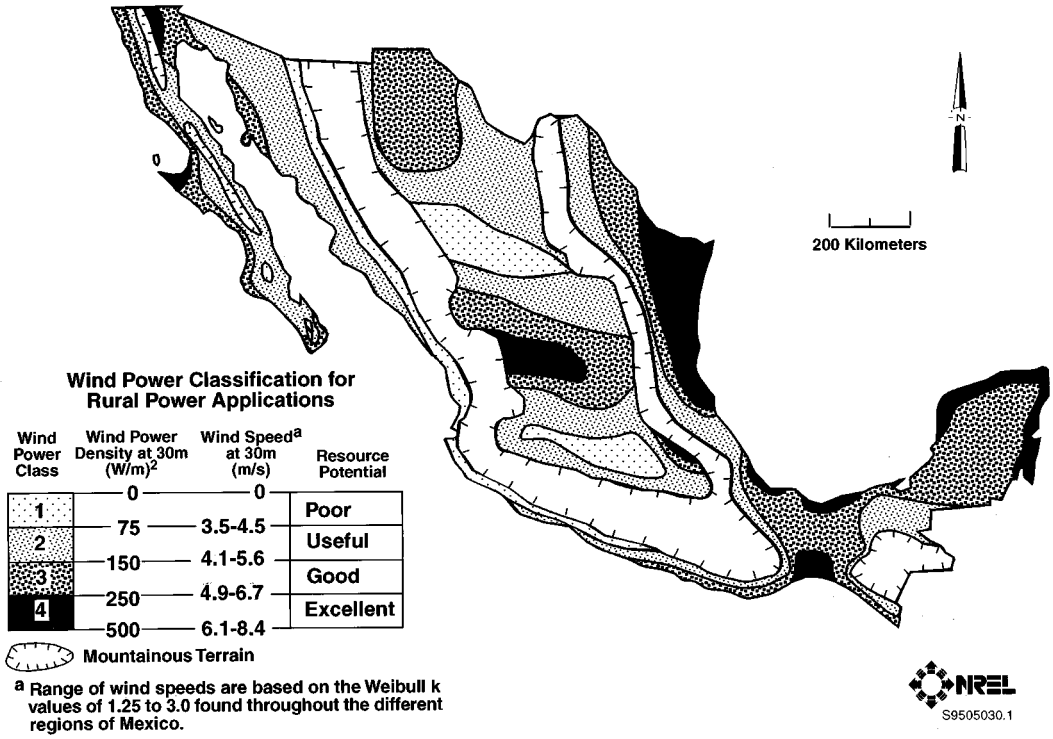

FIGURE 7.7.5 Map of Mexican remote application wind energy resources. Reproduced from Schwartz and Elliott, 1995. *Mexico Wind Resource Assessment Project*. (Courtesy of National Renewable Energy Laboratory, Golden, Colorado.)

producing a *European Wind Atlas* (Troen and Petersen, 1989) that examines the wind resources of the European Community countries and summarizes the resource available at a 50 m height above smooth, flat terrain, with no obstacles. These results are presented in Figure 7.7.6. Finland, Sweden, Algeria, and Jordan have produced similar reports, and atlases for Poland, Canada, Egypt, Syria, and Turkey are currently in preparation. Resource maps for several other countries may be found in Rohatgi and Nelson (1994).

Existing meteorological station data, in general, significantly underestimate the wind energy resources because of lack of maintenance of wind sensors, poor locations at which they are placed, and cursory methods used in analyzing these data. Assessments such as these only identify the wind energy resource or potential on a very coarse grid. The actual wind resources in any specific area can vary dramatically from those estimates and must be determined with site-specific measurements. Even areas with a very low large-scale resource may contain small areas with a very high resources.

Site Analysis and Selection

Biological Indicators

Many different methods may be used to identify areas of high wind resource. Persistent winds can cause plant deformation, and careful observation of these plants can be used to compare candidate sites and, in at least some cases, to estimate the average wind speed. The Griggs-Putnam index, shown in Figure 7.7.7 and explained in Hewson, Wade, and Baker (1979), is an example of a genus-specific correlation of tree deformation with wind speed. It should be noted that although wind-flagged trees (i.e., trees with branches bent away from a prevailing wind) may indicate that the annual average wind speed is quite strong, unflagged trees do not necessarily indicate that the winds are light. Unflagged trees may be

1. The resources refer to the power present in the wind. A wind turbine can utilize between 20 and 30% of the available resource. The resources are calculated for an air density of 1.23 $kg\,m^{-3}$, corresponding to standard sea level pressure and a temperature of 15°C. Air density decreases with height but up to 1000 m a.s.l. the resulting reduction of the power densities is less than 10%.
2. Urban districts, forest and farm land with many windbreaks (roughness class 3).
3. Open landscapes with few windbreaks (roughness class 1). In general, the most favourable inland sites on level land are found here.
4. The classes pertain to a straight coastline, a uniform wind rose and a land surface with few windbreaks (roughness class 1). Resources will be higher, and closer to open sea values, if winds from the sea occur more frequently, i.e. the wind rose is not uniform and/or the land protrudes into the sea. Conversely, resources will generally be smaller, and closer to land values, if winds from land occur more frequently.
5. More than 10 km offshore (roughness class 0).
6. The classes correspond to 50% overspeeding and were calculated for a site on the summit of a single axisymmetric hill with a height of 400 metres and a base diameter of 4 km. The overspeeding depends on the height, length and specific setting of the hill.

exposed to strong winds from all directions, with insufficient persistence in any one direction to cause flagging.

Effects of Topography

The effects of surrounding terrain on the wind speed at a specific site can be significant. If the proposed site is flat, the terrain texture is the area of most concern. The rougher the terrain, the more the wind flowing over it is retarded near the surface. Flat terrain, such as a large area of flat, open grassland, is the simplest type of terrain for selecting a turbine site. If there are no nearby obstacles (i.e., buildings, trees, or hills), the wind speed at a given height is nearly the same over the entire area, and the best way to increase the available power is to raise the rotor higher above the ground to take advantage of positive wind shear.

Siting turbines on elevated terrain such as hills, ridges, and cliffs takes advantage of the generally higher wind speed at increased altitudes. It may also help keep the turbine exposed to the winds above the calm, cool air that frequently accumulates in valleys and lowlands at night. In some cases, the elevated terrain may cause an acceleration of the wind and thus further improve the resource available to the turbine (see Figure 7.7.8). Depressions include such terrain features as valleys, basins, gorges, and passes. If the depressions channel the wind flow, they may provide good turbine sites. However, the power is

© 1999 by CRC Press LLC

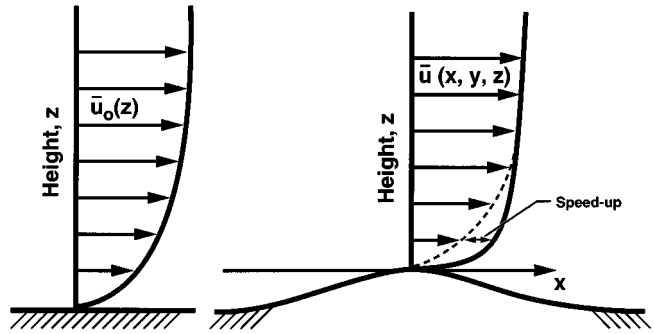

FIGURE 7.7.8 Effect of wind flow over a hill.

more likely to vary by time-of-day or by season than it is for elevated terrain. The impact of terrain on the wind resource and the best places to site turbines for various types of terrain are discussed by Wegley, et al. (1980).

Wind Speed Measurements

The amount of wind energy that can be captured at a site depends on the characteristics of the wind speed at that site. Wind characteristics (speed, direction, distribution, and shear) can vary widely over fairly short distances in either the horizontal or vertical direction. Therefore, in order to predict the energy capture of a turbine with the greatest possible accuracy, wind measurements at the precise site where the turbine will be located are needed. If the rotor, is relatively small, measurements at the hub height (or middle of the rotor) will suffice; for larger rotors, simultaneous measurements at several heights will be required to model the wind speed variation across the rotor disk.

Complete characterization of the wind resource at a specific site is a very time-consuming and expensive effort. A comprehensive site characterization normally requires measuring the wind for at least 12 months, according to Wegley et al. (1980). Even after acquiring the data, questions remain. Long-term data from the nearest airport or long-term weather recording station can help determine whether or not this was a normal wind year for the site and whether the winds were higher or lower than the long-term average (Gipe, 1993). If the costs and time requirements for on-site measurement are excessive, Wegley et al. (1980) and Gipe (1993) give suggestions on methods of using available data from nearby sites, together with a minimum of on-site data to estimate site wind speed.

In the absence of actual site data a Rayleigh distribution (Equation 7.7.3) for the proper yearly average wind speed may be used to estimate the site wind speed distribution. Wind resource estimates that are made with these approximations to the site wind speed and wind distribution will contain significantly larger errors than would be found if the measured site characteristics were used. Figure 7.7.9 illustrates the discrepancies between the measured wind speed distributions at the Amarillo, TX airport and a Bushland, TX test site 20 miles away, and a Rayleigh distribution for the same average wind speed. The measured distribution at the airport has far more energy in the 9 to 12 m/sec range, and this will yield far more energy production than that estimated with the Rayleigh distribution.

Wind Energy Capture Potential

With a wind speed distribution and a turbine power curve (power generated as a function of wind speed) properly adjusted for the local air density, the wind energy potential, or gross annual energy production for a specific site, can be estimated as:

$$\text{Energy} = 8760 \sum_{i=1}^{n} f(U_i) \cdot \Delta U_i \cdot P(U_i) \tag{7.7.4}$$

© 1999 by CRC Press LLC

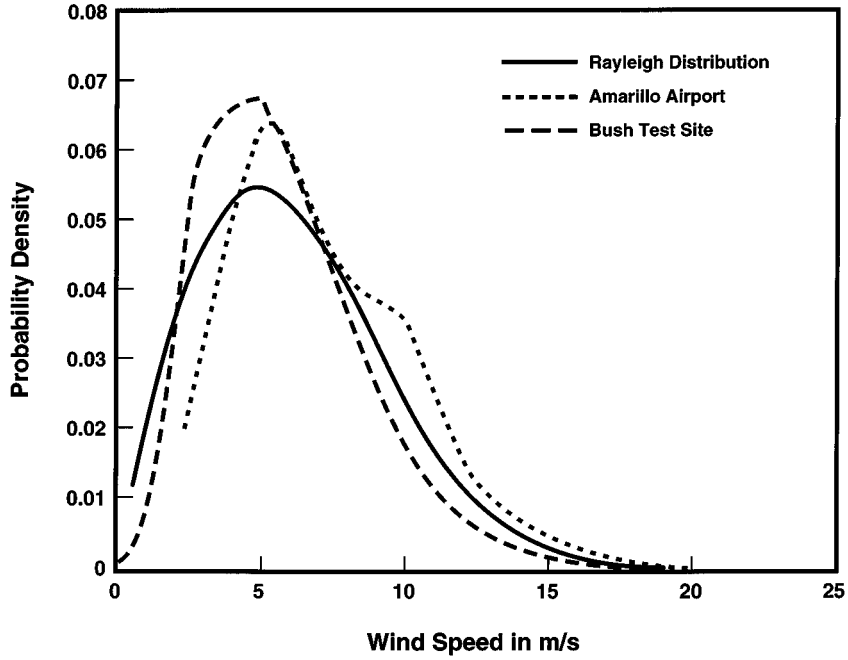

FIGURE 7.7.9 Rayleigh and measured wind frequency distributions.

where 8760 is the number of hours in a year, n is the number of wind speeds considered, $f(U_i) \cdot \Delta U_i$ is the probability of a given wind speed occurring, and $P(U_i)$ is the power produced by the turbine at wind speed U_i. If the measured wind speed distribution is used, replace $f(U_i) \cdot \Delta U_i$ by the probability for the appropriate wind speed (the height of the histogram bar for that wind speed times the wind speed increment). If the power curve is for the turbine aerodynamic or rotor power rather than the electrical power, subtract 10% to approximate the losses due to the turbine bearings and drivetrain. To estimate the net annual energy production, or amount of energy actually delivered to the grid by the turbine, subtract an additional 10% to approximate the electrical losses between the turbine and the grid, the control system losses, and the decreased performance due to dirty blades. If the turbine will be operated in an array, subtract another 5% for array-induced losses.

Environmental Impacts

Although wind turbines generate electricity without causing any air pollution or creating any radioactive wastes, they have an impact on the environment. Wind turbines require a lot of land, but most of that land (90% or so) will remain available for other uses such as farming or livestock grazing. Roads must be built to facilitate installation and maintenance of the wind turbines. Turbines generate noise, but newer turbines are much quieter than earlier models. Current industry standards call for characterization of turbine noise production and rate of decay with distance from the turbine as part of the turbine-testing process. In addition, turbines are large structures that will significantly change the landscape where they are installed, creating visual impact pollution. Another environmental issue facing the wind industry is that of bird deaths as a result of collisions with wind turbines. Preliminary studies indicate that the magnitude of the problem is site specific, and avoiding known bird migration corridors and areas of high bird concentrations when siting turbines and using tubular towers to offer fewer bird perch sites will help to minimize bird collisions with new turbine installations.

© 1999 by CRC Press LLC

Defining Terms

Wind energy potential: The total amount of energy that can actually be extracted from the wind, taking into account the efficiency of the wind turbines and the land available for wind turbine siting.

Wind energy resource: The total amount of energy that is present in the wind.

Wind shear: The change in wind velocity with increasing height above the ground.

Wind speed distribution: The frequency of occurrence of each wind speed over the course of a year. This is site specific.

7.8 Geothermal Energy

Joel L. Renner and Marshall J. Reed

The word *Geothermal* comes from the combination of the Greek words *gê*, meaning Earth, and *thérm*, meaning heat. Quite literally, geothermal energy is the heat of the Earth. Geothermal resources are concentrations of the Earth's heat, or geothermal energy, that can be extracted and used economically now or in the reasonable future. Currently, only concentrations of heat associated with water in permeable rocks can be exploited. Heat, fluid, and permeability are the three necessary components of all exploited geothermal fields. This section of Energy Resources will discuss the mechanisms for concentrating heat near the surface, the types of geothermal systems, and the environmental aspects of geothermal production.

Heat Flow

Temperature within the Earth increases with depth at an average of about 25°C/km. Spatial variations of the thermal energy within the deep crust and mantle of the Earth give rise to concentrations of thermal energy near the surface of the Earth that can be used as an energy resource. Heat is transferred from the deeper portions of the Earth by conduction of heat through rocks, by the movement of hot, deep rock toward the surface, and by deep circulation of water. Most high-temperature geothermal resources are associated with concentrations of heat caused by the movement of magma (melted rock) to near-surface positions where the heat is stored.

In older areas of continents, such as much of North America east of the Rocky Mountains, heat flow is generally 40 to 60 mWm^{-2} (milliwatts per square meter). This heat flow coupled with the thermal conductivity of rock in the upper 4 km of the crust yields subsurface temperatures of 90 to 110°C at 4 km depth in the Eastern United States. Heat flow within the Basin and Range (west of the Rocky Mountains) is generally 70 to 90 mWm^{-2}, and temperatures are generally greater than 110°C at 4 km. There are large variations in the Western United States, with areas of heat flow greater than 100 mWm^{-2} and areas which have generally lower heat flow such as the Cascade and Sierra Nevada Mountains and the West Coast. A more detailed discussion of heat flow in the United States is available in Blackwell et al. (1991).

Types of Geothermal Systems

Geothermal resources are hydrothermal systems containing water in pores and fractures. Most hydrothermal resources contain liquid water, but higher temperatures or lower pressures can create conditions where steam and water or only steam are the continuous phases (White et al., 1971; Truesdell and White, 1973). All commercial geothermal production is expected to be restricted to hydrothermal systems for many years because of the cost of artificial addition of water. Successful, sustainable geothermal energy usage depends on reinjection of the maximum quantity of produced fluid to augment natural recharge of hydrothermal systems.

Other geothermal systems that have been investigated for energy production are (1) geopressured-geothermal systems containing water with somewhat elevated temperatures (above normal gradient) and with pressures well above hydrostatic for their depth; (2) magmatic systems, with temperature from 600 to 1400°C; and (3) hot dry rock geothermal systems, with temperatures from 200 to 350°C, that are subsurface zones with low initial permeability and little water. These types of geothermal systems cannot be used for economic production of energy at this time.

Geothermal Energy Potential

The most recent report (Huttrer, 1995) shows that 6800 MW_e (megawatts electric) of geothermal electric generating capacity is on-line in 21 countries (Table 7.8.1). The expected capacity in the year 2000 is

9960 MW_e. Table 7.8.2 lists the electrical capacity of U.S. geothermal fields. Additional details of the U.S. generating capacity are available in DiPippo (1995) and McClarty and Reed (1992). Geothermal resources also provide energy for agricultural uses, heating, industrial uses, and bathing. Freeston (1995) reports that 27 countries had a total of 8228 MW_t (megawatts thermal) of direct use capacity. The total energy used is estimated to be 105,710 TJ/year (terajoules per year). The thermal energy used by the ten countries using the most geothermal resource for direct use is listed in Table 7.8.3.

The U.S. Geological Survey has prepared assessments of the geothermal resources of the U.S. Muffler(1979) estimated that the identified hydrothermal resource, that part of the **identified accessible base** that could be extracted and utilized at some reasonable future time, is 23,000 MW_e for 30 years. This resource would operate power plants with an aggregate capacity of 23,000 MW_e for 30 years. The undiscovered U.S. resource (inferred from knowledge of Earth science) is estimated to be 95,000 to 150,000 MW_e for 30 years.

Geothermal Applications

In 1991, geothermal electrical production in the United States was 15,738 GWh (gigawatt hours), and the largest in the world (McLarty and Reed, 1992).

Most geothermal fields are water dominated, where liquid water at high temperature, but also under high (hydrostatic) pressure, is the pressure-controlling medium filling the fractured and porous rocks of the reservoir. In water-dominated geothermal systems used for electricity, water comes into the wells from the reservoir, and the pressure decreases as the water moves toward the surface, allowing part of the water to boil. Since the wells produce a mixture of flashed steam and water, a separator is installed

between the wells and the power plant to separate the two phases. The flashed steam goes into the turbine to drive the generator, and the water is injected back into the reservoir.

Many water-dominated reservoirs below 175°C used for electricity are pumped to prevent the water from boiling as it is circulated through heat exchangers to heat a secondary liquid that then drives a turbine to produce electricity. **Binary geothermal plants** have no emissions because the entire amount of produced geothermal water is injected back into the underground reservoir. The identified reserves of lower-temperature geothermal fluids are many times greater than the reserves of high-temperature fluids, providing an economic incentive to develop more-efficient power plants.

© 1999 by CRC Press LLC

Warm water, at temperatures above 20°C, can be used directly for a host of processes requiring thermal energy. Thermal energy for swimming pools, space heating, and domestic hot water are the most widespread uses, but industrial processes and agricultural drying are growing applications of geothermal use. In 1995, the United States was using over 500 TJ/year of energy from geothermal sources for direct use (Lienau, et al., 1995). The cities of Boise, ID; Elko, NV; Klamath Falls, OR; and San Bernardino and Susanville, CA have geothermal district-heating systems where a number of commercial and residential buildings are connected to distribution pipelines circulating water at 54 to 93°C from the production wells (Rafferty, 1992).

The use of geothermal energy through ground-coupled heat pump technology has almost no impact on the environment and has a beneficial effect in reducing the demand for electricity. Geothermal heat pumps use the reservoir of constant temperature, shallow groundwater and moist soil as the heat source during winter heating and as the heat sink during summer cooling. The energy efficiency of geothermal heat pumps is about 30% better than that of air-coupled heat pumps and 50% better than electric-resistance heating. Depending on climate, advanced geothermal heat pump use in the United States reduces energy consumption and, correspondingly, power-plant emissions by 23 to 44% compared to advanced air-coupled heat pumps, and by 63 to 72% compared with electric-resistance heating and standard air conditioners (L'Ecuyer et al., 1993).

Environmental Constraints

Geothermal energy is one of the cleaner forms of energy now available in commercial quantities. Geothermal energy use avoids the problems of acid rain, and it greatly reduces greenhouse gas emissions and other forms of air pollution. Potentially hazardous elements produced in geothermal brines are removed from the fluid and injected back into the producing reservoir. Land use for geothermal wells, pipelines, and power plants is small compared with land use for other extractive energy sources such as oil, gas, coal, and nuclear. Geothermal development projects often coexist with agricultural land uses, including crop production or grazing. The average geothermal plant occupies only 400 m^2 for the production of each gigawatt hour over 30 years (Flavin and Lenssen, 1991). The low life-cycle land use of geothermal energy is many times less than the energy sources based on mining, such as coal and nuclear, which require enormous areas for the ore and processing before fuel reaches the power plant. Low-temperature applications usually are no more intrusive than a normal water well. Geothermal development will serve the growing need for energy sources with low atmospheric emissions and proven environmental safety.

All known geothermal systems contain aqueous carbon dioxide species in solution, and when a steam phase separates from boiling water, CO_2 is the dominant (over 90% by weight) **noncondensible gas.** In most geothermal systems, noncondensible gases make up less than 5% by weight of the steam phase. Thus, for each megawatt-hour of electricity produced in 1991, the average emission of carbon dioxide by plant type in the United States was 990 kg from coal, 839 kg from petroleum, 540 kg from natural gas, and 0.48 kg from geothermal flashed-steam (Colligan, 1993). Hydrogen sulfide can reach moderate concentrations of up to 2% by weight in the separated steam phase from some geothermal fields.

At The Geysers geothermal field in California, either the Stretford process or the incineration and injection process is used in geothermal power plants to keep H_2S emissions below 1 ppb (part per billion). Use of the Stretford process in many of the power plants at The Geysers results in the production and disposal of about 13,600 kg of sulfur per megawatt of electrical generation per year. Figure 7.8.1, shows a typical system used in the Stretford process at The Geysers (Henderson and Dorighi, 1989).

The incineration process burns the gas removed from the steam to convert H_2S to SO_2, the gases are absorbed in water to form SO_3^{-2} and SO_4^{-2} in solution, and iron chelate is used to form $S_2O_3^{-2}$ (Bedell and Hammond, 1987). Figure 7.8.2 shows an incineration abatement system (Bedell and Hammond, 1987). The major product from the incineration process is a soluble thiosulfate which is injected into the reservoir with the condensed water used for the reservoir pressure-maintenance program. Sulfur emissions for each megawatt-hour of electricity produced in 1991, as SO_2 by plant type in the United

States was 9.23 kg from coal, 4.95 kg from petroleum, and 0.03 kg from geothermal flashed-steam (Colligan, 1993). Geothermal power plants have none of the nitrogen oxide emissions that are common from fossil fuel plants.

The waters in geothermal reservoirs range in composition from 0.1 to over 25 wt% dissolved solutes. The geochemistry of several representative geothermal fields is listed in Table 7.8.4. Temperatures up to 380°C have been recorded in geothermal reservoirs in the United States, and many chemical species have a significant solubility at high temperature. For example, all of the geothermal waters are saturated

in silica with respect to quartz. As the water is produced, silica becomes supersaturated, and, if steam is flashed, the silica becomes highly supersaturated. Upon cooling, amorphous silica precipitates from the supersaturated solution. The high flow rates of steam and water from geothermal wells usually prevent silica from precipitating in the wells, but careful control of fluid conditions and residence time is needed to prevent precipitation in surface equipment. Silica precipitation is delayed in the flow stream until the water reaches a crystallizer or settling pond. There the silica is allowed to settle from the water, and the water is then pumped to an injection well.

Operating Conditions

For electrical generation, typical geothermal wells in the United States have production casing pipe in the reservoir with an inside diameter of 29.5 cm, and flow rates usually range between 150,000 and 350,000 kg/hr of total fluid (Mefferd, 1991). The geothermal fields contain water, or water and steam, in the reservoir, and production rates depend on the amount of boiling in the reservoir and the well on the way to the surface. The Geysers geothermal field in California has only steam filling fractures in the reservoir, and, in 1987 (approximately 30 years after production began), the average well flow had decreased to 33,000 kg/hr of dry steam (Mefferd, 1991) supplying the maximum field output of 2000 MW_2. Continued pressure decline has decreased the production.

In the Coso geothermal field near Ridgecrest, CA initial reservoir conditions formed a steam cap at 400 to 500 m depth, a two-phase (steam and water) zone at intermediate depth, and a liquid water zone at greater depth. Enthalpy of the fluid produced from individual wells ranges from 840 to 2760 kJ/kg (Hirtz et al., 1993), reservoir temperatures range from 200 to 340°C, and the fluid composition flowing from the reservoir into the different wells ranges from 100% liquid to almost 100% steam. Production wells have a wide range of flow rates, but the average production flow rate is 135,000 kg/hr (Mefferd, 1991). Much of the produced fluid is evaporated to the atmosphere in the cooling towers of the power plant, and only about 65% of the produced mass is available for injection into the reservoir at an average rate of 321,000 kg/hr (Mefferd, 1991).

The Salton Sea geothermal system in the Imperial Valley of southern California has presented some of the most difficult problems in brine handling. Water is produced from the reservoir at temperatures between 300 and 350°C and total dissolved solid concentrations between 20 and 25% by weight at an average rate of 270,000 kg/hr (Mefferd, 1991). When up to 20% of the mass of brine boils during production, the salts are concentrated in the brine causing supersaturation with respect to several solid phases. Crystallizers and clarifier and thickener tanks are needed to remove solids from the injection water. Figure 7.8.3 shows the flow stream for removal of solids from the vapor and brine (Signorotti and Hunter, 1992). Other power plants use the addition of acid to lower the pH and keep the solutes in solution (Signorotti and Hunter, 1992). The output from the crystallizers and clarifiers is a slurry of brine and amorphous silica. The methods used to dewater the salt and silica slurry from operations in the Salton Sea geothermal system are described by Benesi (1992). Approximately 80% of the produced water is injected into the reservoir at an average rate of 310,000 kg/hr.

Defining Terms

Binary geothermal plant: A geothermal electric generating plant that uses the geothermal fluid to heat a secondary fluid that is then expanded through a turbine.

© 1999 by CRC Press LLC

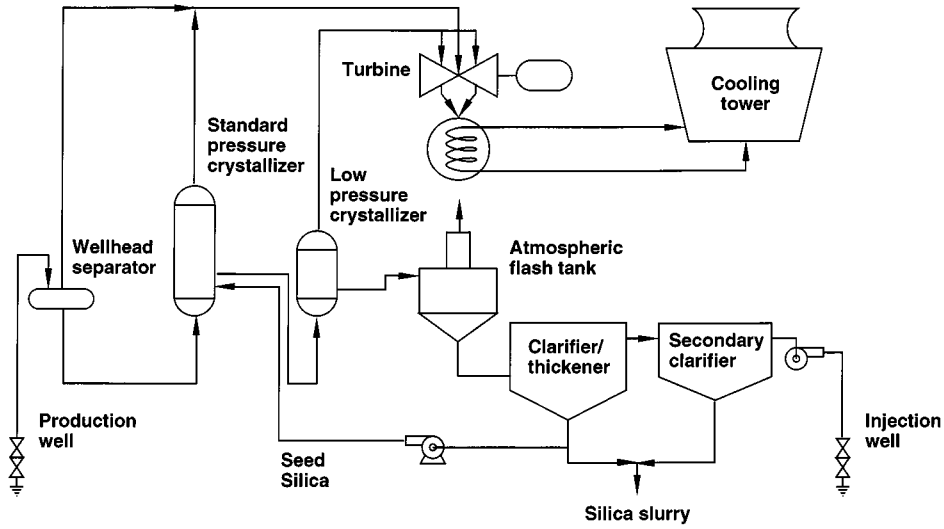

FIGURE 7.8.3 The flow stream for removal of solids from the vapor and brine in typical power plants in the Salton Sea geothermal field. (Modified from the diagram of Signorotti, V. and Hunter, C.C., *Geotherm. Resour. Counc. Bull.*, 21(9), 277–288, 1992).

Identified accessible base: That part of the thermal energy of the Earth that is shallow enough to be reached by production drilling in the foreseeable future. *Identifed* refers to concentrations of heat that have been characterized by drilling or Earth science evidence. Additional discussion of this and other resource terms can be found in Muffler (1979).

Noncondensible gases: Gases exhausted from the turbine into the condenser that do not condense into the liquid phase.

8.1 Steam Power Plant

Lawrence Conway

Introduction

This section provides an understanding, at an overview level, of the steam power cycle. References were selected for the next level of study if required. There are noteworthy omissions in the section: site selection, fuel handling, civil engineering-related activities (like foundations), controls, and nuclear power.

Thermal power cycles take many forms, but the majority are fossil steam, nuclear, simple cycle gas turbine, and combined cycle. Of those listed, conventional coal-fired steam power is predominant. This is especially true in developing third-world countries that either have indigenous coal or can import coal inexpensively. These countries make up the largest new product market. A typical unit is shown in Figure 8.1.1.

The Rankine cycle is overwhelmingly the preferred cycle in the case of steam power and is discussed first.

Topping and bottoming cycles, with one exception, are rare and mentioned only for completeness. The exception is the combined cycle, where the steam turbine cycle is a bottoming cycle. In the developed countries, there has been a move to the combined cycle because of cheap natural gas or oil. Combined cycles still use a reasonably standard steam power cycle except for the boiler. The complexity of a combined cycle is justified by the high thermal efficiency, which will soon approach 60%.

The core components of a steam power plant are boiler, turbine, condenser and feedwater pump, and generator. These are covered in successive subsections.

The final subsection is an example of the layout/and contents of a modern steam power plant.

As a frame of reference for the reader, the following efficiencies/effectivenesses are typical of modern fossil fuel steam power plants. The specific example chosen had steam conditions of 2400 psia, 1000°F main steam temperature, 1000°F reheat steam temperature: boiler thermal 92; turbine/generator thermal 44; turbine isentropic 89; generator 98.5; boiler feedwater pump and turbine combined isentropic 82; condenser 85; plant overall 34 (Carnot 64).

Nuclear power stations are so singular that they are worthy of a few closing comments. Modern stations are all large, varying from 600 to 1500 MW. The steam is both low temperature and low pressure (~600°F and ~1000 psia), compared with fossil applications, and hovers around saturation conditions

© 1999 by CRC Press LLC

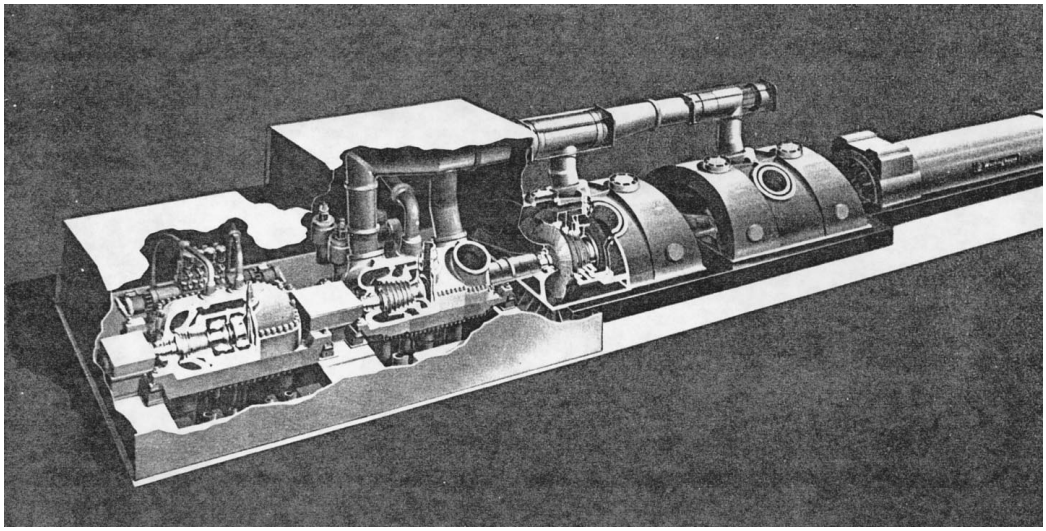

FIGURE 8.1.1 Modern steam turbine generator.

or is slightly superheated. Therefore, the boiler(s), superheater equivalent (actually a combined moisture separator and reheater), and turbines are unique to this cycle. The turbine generator thermal efficiency is around 36%.

Rankine Cycle Analysis

Modern steam power plants are based on the Rankine cycle. The basic, ideal Rankine cycle is shown in Figure 8.1.2. The ideal cycle comprises the processes from state 1:

1–2: Saturated liquid from the condenser at state 1 is pumped isentropically (i.e., $S_1 = S_2$) to state 2 and into the boiler.
2–3: Liquid is heated at constant pressure in the boiler to state 3 (saturated steam).
3–4: Steam expands isentropically (i.e., $S_3 = S_4$) through the turbine to state 4 where it enters the condenser as a wet vapor.
4–1: Constant-pressure transfer of heat in the condenser to return the steam back to state 1 (saturated liquid).

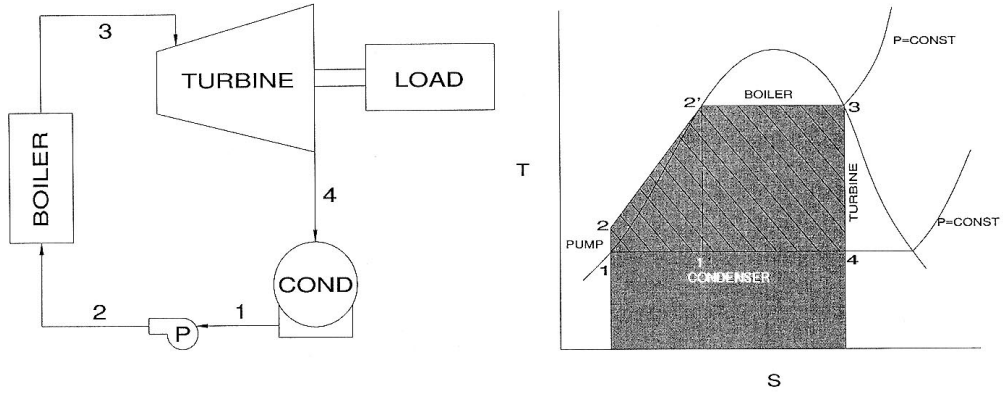

FIGURE 8.1.2 Basic Rankine cycle.

© 1999 by CRC Press LLC

If changes in kinetic and potential energy are neglected, the total heat added to the rankine cycle can be represented by the shaded area on the T-S diagram in Figure 8.1.2, while the work done by this cycle can be represented by the crosshatching within the shaded area. The thermal efficiency of the cycle (η) is defined as the work (W_{NET}) divided by the heat input to the cycle (Q_H).

$$\eta = W_{NET}/Q_H = \left(h_3 - h_4\right)/\left(h_3 - h_2\right)$$

The Rankine cycle is preferred over the Carnot cycle for the following reasons:

The heat transfer process in the boiler has to be at constant temperature for the Carnot cycle, whereas in the Rankine cycle it is superheated at constant pressure. Superheating the steam can be achieved in the Carnot cycle during heat addition, but the pressure has to drop to maintain constant temperature. This means the steam is expanding in the boiler while heat added which is not a practical method.

The Carnot cycle requires that the working fluid be compressed at constant entropy to boiler pressure. This would require taking wet steam from point 1′ in Figure 8.1.2 and compressing it to saturated liquid condition at 2′. A pump required to compress a mixture of liquid and vapor isentropically is difficult to design and operate. In comparison, the Rankine cycle takes the saturated liquid and compresses it to boiler pressure. This is more practical and requires much less work.

The efficiency of the Rankine cycle can be increased by utilizing a number of variations to the basic cycle. One such variation is superheating the steam in the boiler. The additional work done by the cycle is shown in the crosshatched area in Figure 8.1.3.

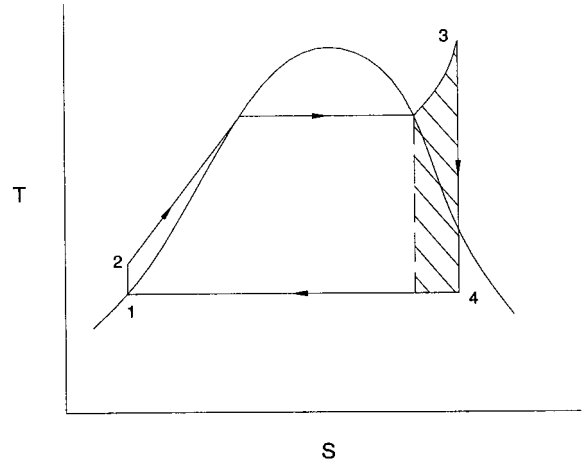

FIGURE 8.1.3 Rankine cycle with superheat.

The efficiency of the Rankine cycle can also be increased by increasing the pressure in the boiler. However, increasing the steam generator pressure at a constant temperature will result in the excess moisture content of the steam exiting the turbine. In order to take advantage of higher steam generator pressures and keep turbine exhaust moistures at safe values, the steam is expanded to some intermediate pressure in the turbine and then reheated in the boiler. Following reheat, the steam is expanded to the cycle exhaust pressure. The reheat cycle is shown in Figure 8.1.4.

Another variation of the Rankine cycle is the regenerative cycle, which involves the use of feedwater heaters. The regenerative cycle regains some of the irreversible heat lost when condensed liquid is pumped directly into the boiler by extracting steam from various points in the turbine and heating the condensed liquid with this steam in feedwater heaters. Figure 8.1.5 shows the Rankine cycle with regeneration.

© 1999 by CRC Press LLC

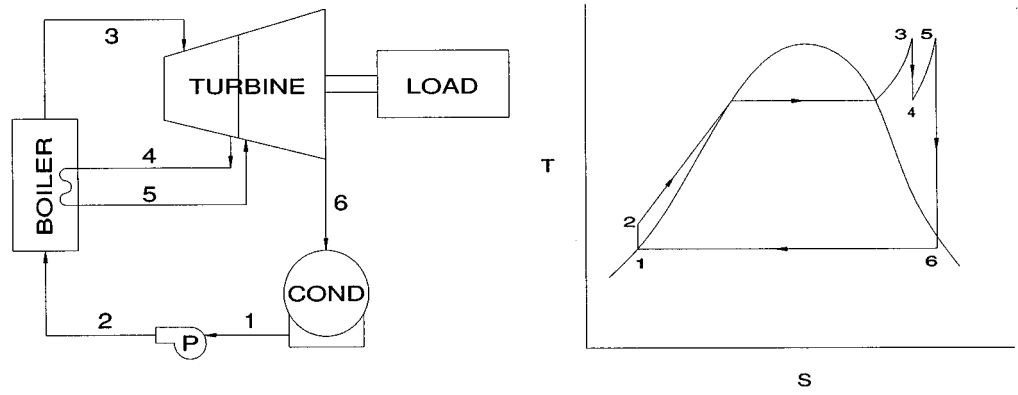

FIGURE 8.1.4 Rankine cycle with reheat.

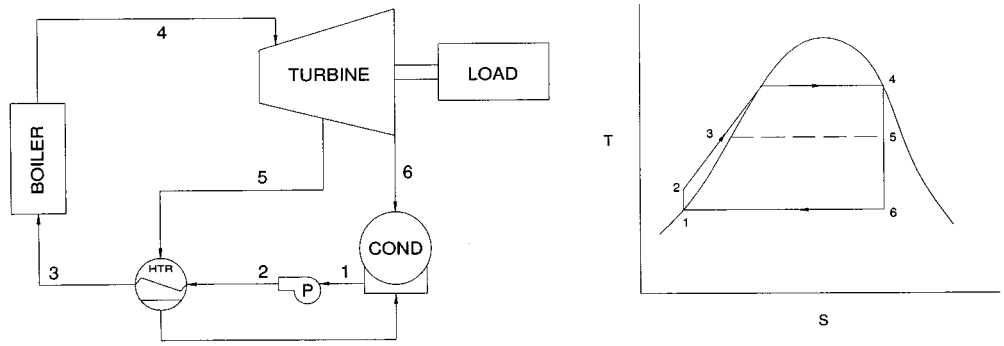

FIGURE 8.1.5 Rankine cycle with regeneration.

The actual Rankine cycle is far from ideal as there are losses associated with the cycle. They include the piping losses due to friction and heat transfer, turbine losses associated with steam flow, pump losses due to friction, and condenser losses when condensate is subcooled. The losses in the compression (pump) and expansion process (turbine) result in an increase in entropy. Also, there is lost energy in heat addition (boiler) and rejection (condenser) processes as they occur over a finite temperature difference.

Most modern power plants employ some variation of the basic Rankine cycle in order to improve thermal efficiency. For larger power plants, economies of scale will dictate the use of one or all of the variations listed above to improve thermal efficiency. Power plants in excess of 200,000 kW will in most cases have 300°F superheated steam leaving the boiler reheat, and seven to eight stages of feedwater heating.

Topping and Bottoming Cycles

Steam Rankine cycles can be combined with topping and/or bottoming cycles to form binary thermodynamic cycles. These topping and bottoming cycles use working fluids other than water. Topping cycles change the basic steam Rankine cycle into a binary cycle that better resembles the Carnot cycle and improves efficiency. For conventional steam cycles, state-of-the-art materials allow peak working fluid temperatures higher than the supercritical temperature for water. Much of the energy delivered into the cycle goes into superheating the steam, which is not a constant-temperature process. Therefore, a significant portion of the heat supply to the steam cycle occurs substantially below the peak cycle temperature. Adding a cycle that uses a working fluid with a boiling point higher than water allows more of the heat supply to the thermodynamic cycle to be near the peak cycle temperature, thus improving efficiency. Heat rejected from the topping cycle is channeled into the lower-temperature steam cycle. Thermal energy not converted to work by the binary cycle is rejected to the ambient-temperature reservoir. Metallic substances are the working fluids for topping cycles. For example, mercury was used as the topping cycle fluid in the 40-MW plant at Schiller, New Hampshire. This operated for a period of time but has since been dismantled. Significant research and testing has also been performed over the years toward the eventual goal of using other substances, such as potassium or cesium, as a topping cycle fluid.

Steam power plants in a cold, dry environment cannot take full advantage of the low heat rejection temperature available. The very low pressure to which the steam would be expanded to take advantage of the low heat sink temperature would increase the size of the low-pressure (LP) turbine to such an extent that it is impractical or at least inefficient. A bottoming cycle that uses a working fluid with a vapor pressure higher than water at ambient temperatures (such as ammonia or an organic fluid) would enable smaller LP turbines to function efficiently. Hence, a steam cycle combined with a bottoming cycle may yield better performance and be more cost-effective than a stand-alone Rankine steam cycle.

Steam Boilers

A boiler, also referred to as a steam generator, is a major component in the plant cycle. It is a closed vessel that efficiently uses heat produced from the combustion of fuel to convert water to steam. Efficiency is the most important characteristic of a boiler since it has a direct bearing on electricity production.

Boilers are classified as either drum-type or once-through. Major components of boilers include an economizer, superheaters, reheaters, and spray attemperators.

Drum-Type Boilers

Drum-type boilers (Figure 8.1.6) depend on constant recirculation of water through some of the components of the steam/water circuit to generate steam and keep the components from overheating. Drum-type boilers circulate water by either natural or controlled circulation.

Natural Circulation. Natural circulation boilers use the density differential between water in the downcomers and steam in the waterwall tubes for circulation.

Controlled Circulation. Controlled circulation boilers utilize boiler-water-circulating pumps to circulate water through the steam/water circuit.

Once-Through Boilers

Once-through boilers, shown in Figure 8.1.7, convert water to steam in one pass through the system.

© 1999 by CRC Press LLC

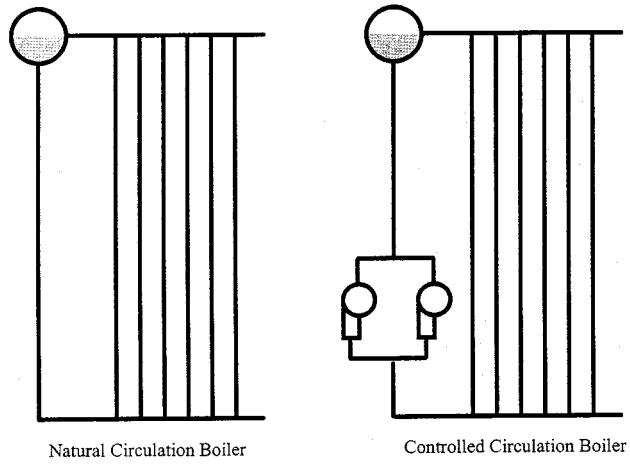

FIGURE 8.1.6 Drum boilers.

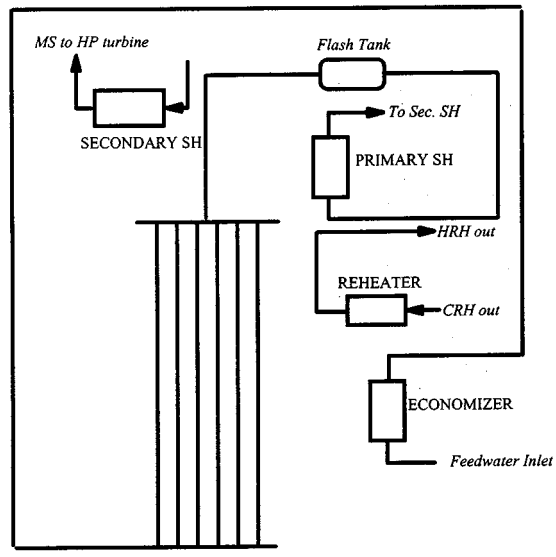

FIGURE 8.1.7 Once-through boilers.

Major Boiler Components

Economizer. The economizer is the section of the boiler tubes where feedwater is first introduced into the boiler and where flue gas is used to raise the temperature of the water.

Steam Drum (Drum Units Only). The steam drum separates steam from the steam/water mixture and keeps the separated steam dry.

Superheaters. Superheaters are bundles of boiler tubing located in the flow path of the hot gases that are created by the combustion of fuel in the boiler furnace. Heat is transferred from the combustion gases to the steam in the superheater tubes.

Superheaters are classified as primary and secondary. Steam passes first through the primary superheater (located in a relatively cool section of the boiler) after leaving the steam drum. There the steam receives a fraction of its final superheat and then passes through the secondary superheater for the remainder.

© 1999 by CRC Press LLC

Reheaters. Reheaters are bundles of boiler tubes that are exposed to the combustion gases in the same manner as superheaters.

Spray Attemperators. Attemperators, also known as desuperheaters, are spray nozzles in the boiler tubes between the two superheaters. These spray nozzles supply a fine mist of pure water into the flow path of the steam to prevent tube damage from overheating. Attemperators are provided for both the superheater and reheater.

Steam Turbines

General

Each turbine manufacturer has unique features in their designs that impact efficiency, reliability, and cost. However, the designs appear similar to a non-steam-turbine engineer. Steam turbines for power plants differ from most prime movers in at least three ways. (1) All are extremely high powered, varying from about 70,000 to 2 million hp, and require a correspondingly large capital investment, which puts a premium on reliability. (2) Turbine life is normally between 30 and 40 years with minimal maintenance. (3) Turbines spend the bulk of their life at constant speed, normally 3600 or 1800 rpm for 60 Hz. These three points dominate the design of the whole power station, particularly of the steam turbine arrangement and materials.

In an earlier subsection it was shown that high steam supply temperatures make for more-efficient turbines. Even so, the range of steam conditions in modern service has narrowed because of these three points. Figure 8.1.8 shows the distribution of steam conditions of one manufacturer for turbines recently put in service. They are reasonably typical of the industry. This is one of the primary reasons that the steam turbines appear similar.

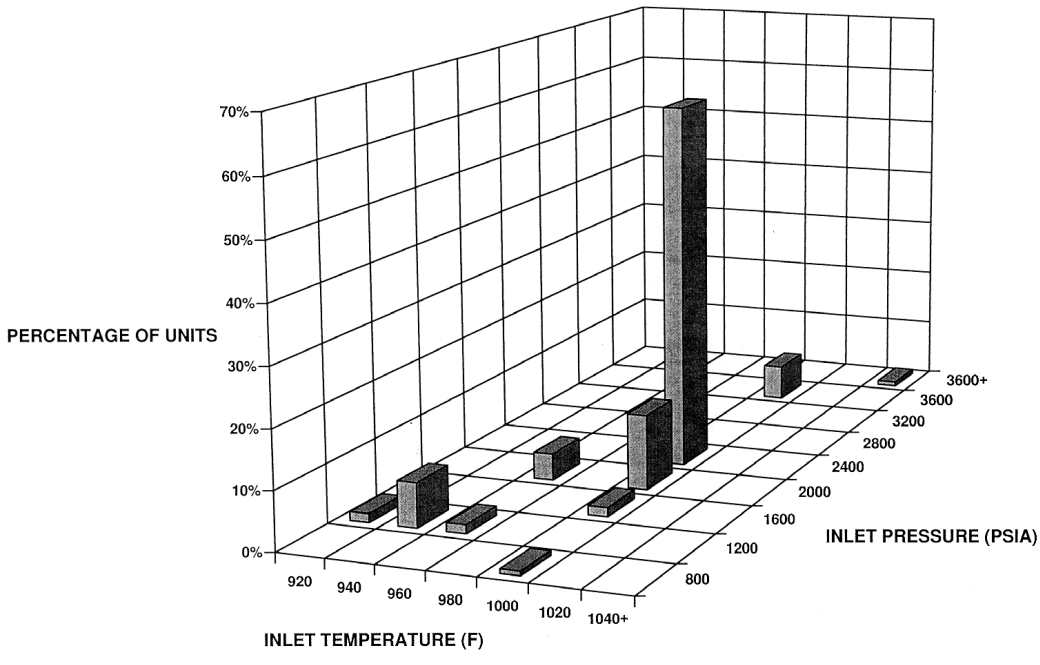

FIGURE 8.1.8 Steam turbine operating conditions.

Blading

The most highly stressed component in steam turbines are the blades. Blades are loaded by centrifugal and steam-bending forces and also harmonic excitation (from nonuniform circumferential disturbances

© 1999 by CRC Press LLC

in the blade path). All blades are loaded by centrifugal and steam-bending loads, and, in general, blades are designed to run when the harmonic excitation is resonant with the natural modes of the blade. If harmonic excitation is permitted on very long blades, the blades become impractically big. Fortunately, as the turbine runs at constant speed, the blade modes can be tuned away from resonant conditions so that the harmonic loads are significantly reduced. This forms a split in blade design, commonly referred to as tuned and untuned blading.

Blades guide steam throughout the turbine in as smooth and collision-free a path as possible. Collisions with blades (incidence) and sudden expansions reduce the energy available for doing work. Until recently, designers would match flow conditions with radially straight blades (called parallel sided). Turbine physics does not recognize this convenience for several reasons. The most visually obvious is the difference in tangential velocity between blade hub and tip. Twisted blades better match the flow (and area) conditions. The manufacturing process was costly and this cost confined application to long blades. Now, with numerical control machine tools, twist is being spread throughout the turbine. Twisted blades are a two-dimensional adjustment for a three-dimensional steam flow. The latest blades address the full three-dimensional nature of the flow by curving in three dimensions (bowed blades). Examples of all three classes of blades are shown in Figure 8.1.9.

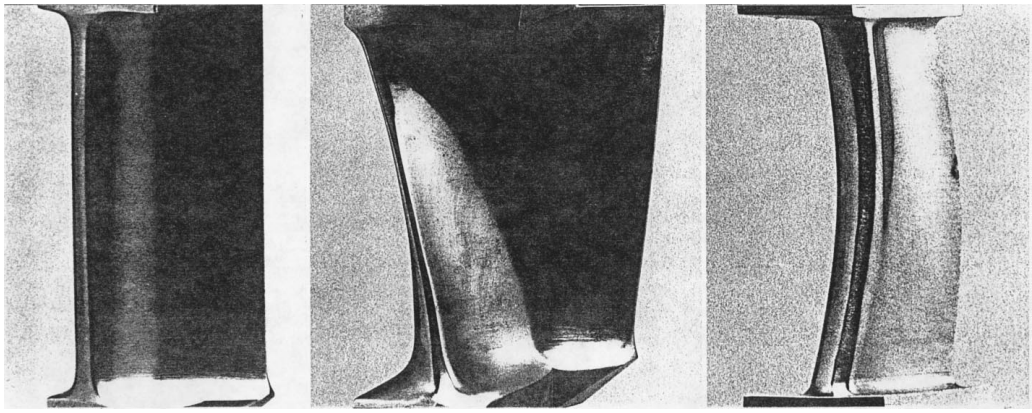

FIGURE 8.1.9 Typical steam turbine blades.

Rotors

After blades, steam turbine rotors are the second most critical component in the machine. Rotor design must account for (1) a large forging with uniform chemistry and properties in the high-strength alloys needed; (2) centrifugal force from the rotor itself and the increase from the centrifugal pull of the blades; (3) resistance to brittle fracture potentially occurring in the LP cylinder when the machine is at high speed, but the material is still not up to operational temperature; (4) creep of the high-pressure (HP) and intermediate-pressure (IP) rotors under steady high-temperature load. The life cycle is further complicated by the various transient fatigue loads occurring during load changes and start-up. Two further events are considered in rotor design: torsional and lateral vibrations caused by both harmonic steam and electrical loads. As with tuned blades, this is normally accommodated by tuning the primary modes away from running resonance.

Choosing the Turbine Arrangement

The turbine shaft would be too flexible in one piece if all the blades were to follow sequentially. It is therefore cut up into supportable lengths. The "cuts" in the shaft result in HP, IP, and LP cylinders. Manufacturers address the grouping of cylinders in many different ways, depending upon steam conditions. It is U.S. practice to combine HPs and IPs into one cylinder for the power range of about 250 to 600 MW (rare in the rest of the world). One manufacturer's grouping, shown in Figure 8.1.10, is fairly

© 1999 by CRC Press LLC

representative of the industry. So far, the text has discussed the steam flow as though it expanded monotonically through the turbine. This is usually not the case for two reasons. The most common steam conditions, shown in Figure 8.1.10, would cause the steam exiting the last row of blades to be very wet and cause excessive erosion. Thermal efficiency can be raised by removing the steam from the turbine, reheating, and then returning it to the blade path; this increases the "average" heat supply temperature. The turbine position for reheat is normally between the HP and IP turbines.

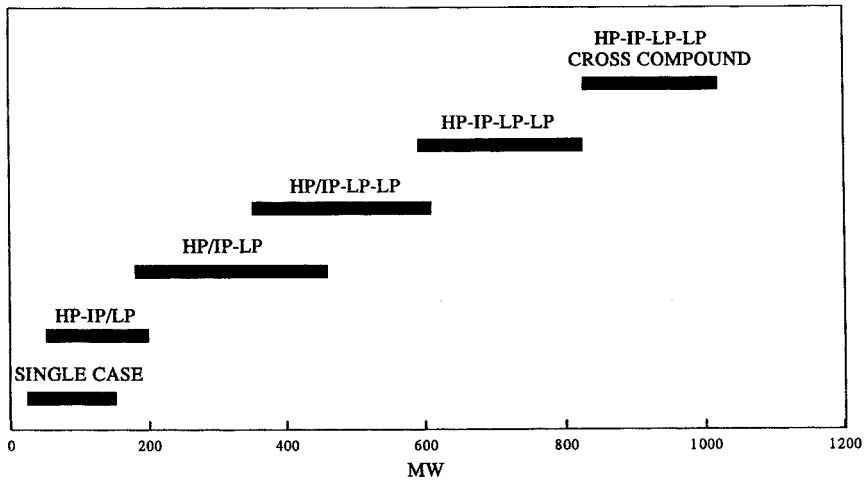

FIGURE 8.1.10 Steam turbine product combinations.

There is one further geometric arrangement. Cylinders need not be all on one shaft with a single generator at the end. A cross-compound arrangement exists in which the steam path is split into two separate parallel paths with a generator on each path. Commonly, the split will be with paths of HP-LP-generator and IP-LP-generator. Torsional and lateral vibration difficulties are more easily prevented with shorter trains, which make the foundation more compact. The primary shortcoming is the need for two generators and resultant controls.

Historically, steam turbines have been split into two classes, reaction and impulse, as explained in Basic Power Cycles. This difference in design makes an observable difference between machines. Impulse turbines have fewer, wider stages than reaction machines. As designs have been refined, the efficiencies and lengths of the machines are now about the same. For a variety of reasons, the longer blades in the LP ends are normally reaction designs. As each stage may now be designed and fabricated uniquely, the line between impulse and reaction turbines will probably disappear. Turbine blading is broadly split between machines as follows:

	Cylinder				
	HP			LP	
	Control Stage	Remainder	IP	Short Blades	End Blade(s)
Reaction turbines	Impulse	Reaction	Reaction	Reaction	Reaction
Impulse turbines	Impulse	Impulse	Impulse	Impulse	Reaction

Materials

Materials are among the most variable of all turbine parts with each manufacturer striving to improve performance by using alloying and heat-treatment techniques. It follows that accurate generalizations are difficult. Even so, the following is reasonably representative:

© 1999 by CRC Press LLC

Item	Common Material Description

Cylinders and Bolting

These items are relatively straightforward, especially the LP cylinder, except for the very large sizes and precision required for the castings and fabrications. A large HP-IP cylinder has the temperature and pressure loads split between an inner and outer cylinder. In this case, finding space and requisite strength for the bolting presents a challenge for the designer.

Valves

The turbine requires many valves for speed control, emergency control, drains, hydraulics, bypasses, and other functions. Of these, there are four valves distinguished by their size and duty. They are throttle or stop, governor or control, reheat stop, and reheat interceptor.

The throttle, reheat stop, and reheat interceptor valves normally operate fully open, except for some control and emergency conditions. Their numbers and design are selected for the appropriate combination of redundancy and rapidity of action. The continuous control of the turbine is accomplished by throttling the steam through the governor valve. This irreversible process detracts from cycle efficiency. In some circumstances, the efficiency detraction is reduced by a combination of throttling and reducing the boiler pressure (normally called sliding pressure).

Heat Exchangers, Pumps, and Other Cycle Components

Heater Exchangers

Heaters. There are two classifications of condensate and feedwater heaters: the open or direct contact heater and the closed or tube-and-shell heater.

Open Heaters. In an open heater, the extraction or heating steam comes in direct contact with the water to be heated. While open heaters are more efficient than closed heaters, each requires a pump to feed the outlet water ahead in the cycle. This adds cost, maintenance, and the risk of water induction to the turbine, making the closed heater the preferred heater for power plant applications.

Closed Heaters. These employ tubes within a shell to separate the water from the heating steam (see Figure 8.1.11). They can have three separate sections where the heating of the feedwater occurs. First is the drain cooler section where the feedwater is heated by the condensing heating steam before cascading back to the next-lower-pressure heater. The effectiveness of the drain cooler is expressed as the drain cooler approach (DCA), which is the difference between the temperature of the water entering the heater and the temperature of the condensed heating steam draining from the heater shell. In the second section (condensing section), the temperature of the water is increased by the heating steam condensing around

© 1999 by CRC Press LLC

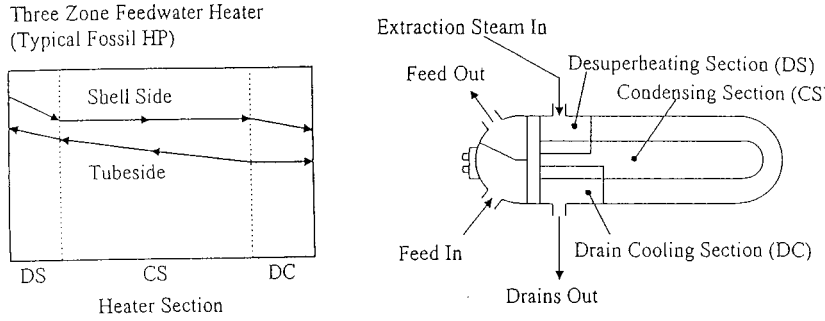

FIGURE 8.1.11 Shell and tube feedwater heater.

the tubes. In the third section (desuperheating section), the feedwater reaches its final exit temperature by desuperheating the extraction steam. Performance of the condensing and superheating sections of a heater is expressed as the terminal temperature difference (TTD). This is the difference between the saturation temperature of the extraction steam and the temperature of the feedwater exiting the heater. Desuperheating and drain cooler sections are optional depending on the location of the heater in the cycle (i.e., desuperheating is not necessary in wet extraction zones) and economic considerations.

The one exception is the deaerator (DA), which is an open heater used to remove oxygen and other gases that are insoluble in boiling water. The DA is physically located in the turbine building above all other heaters, and the gravity drain from the DA provides the prime for the boiler feed pump (BFP).

Two other critical factors considered in heater design and selection are (1) venting the heater shell to remove any noncondensable gases and (2) the protection of the turbine caused by malfunction of the heater system. Venting the shell is required to avoid air-bounding a heater, which reduces the performance or, in extreme cases, puts the heater out of service. Emergency drains to the condenser open when high water levels are present within the shell. Check valves on the heating steam line are also used, and a water detection monitor can be installed to enable operators to take prompt action when water is present.

Condenser. The steam turbines employ surface-type condensers comprising large shell-and-tube heat exchangers operating under vacuum. The condenser (1) reduces the exhaust pressure at the last-stage blade exit to extract more work from the turbine and (2) collects the condensed steam and returns it to the feedwater-heating system. Cooling water circulates from the cooling source to the condenser tubes by motor-driven pumps, which may be centrifugal, propeller, or mixed-flow type. Multiple pumps, each rated less than 100% of required pumping power, are used to allow to operation with one or more pumps out of service and operate more efficiently at part load. Cooling water is supplied from either a large heat sink water source, such as a river, or from cooling towers. The cooling in the cooling tower is assisted by evaporation of 3 to 6% of the cooling water. Airflow is natural draft (hyperbolic towers) or forced draft. The noncondensable gases are removed from the condenser by a motor-driven vacuum pump or, more frequently, steam jet air ejectors which have no moving parts.

Pumps

Condensate Pump. Condensate is removed from the hot well of the condenser and passed through the LP heater string via the condensate pump. Typically, there will be two or more vertical (larger units) or horizontal (medium and small units) motor-driven centrifugal pumps located near the condenser hot well outlet. Depending on the size of the cycle, condensate booster pumps may be used to increase the pressure of the condensate on its way to the DA.

Feedwater Booster Pump. The DA outlet supplies the feedwater booster pump which is typically a motor-driven centrifugal pump. This pump supplies the required suction head for the BFP.

© 1999 by CRC Press LLC

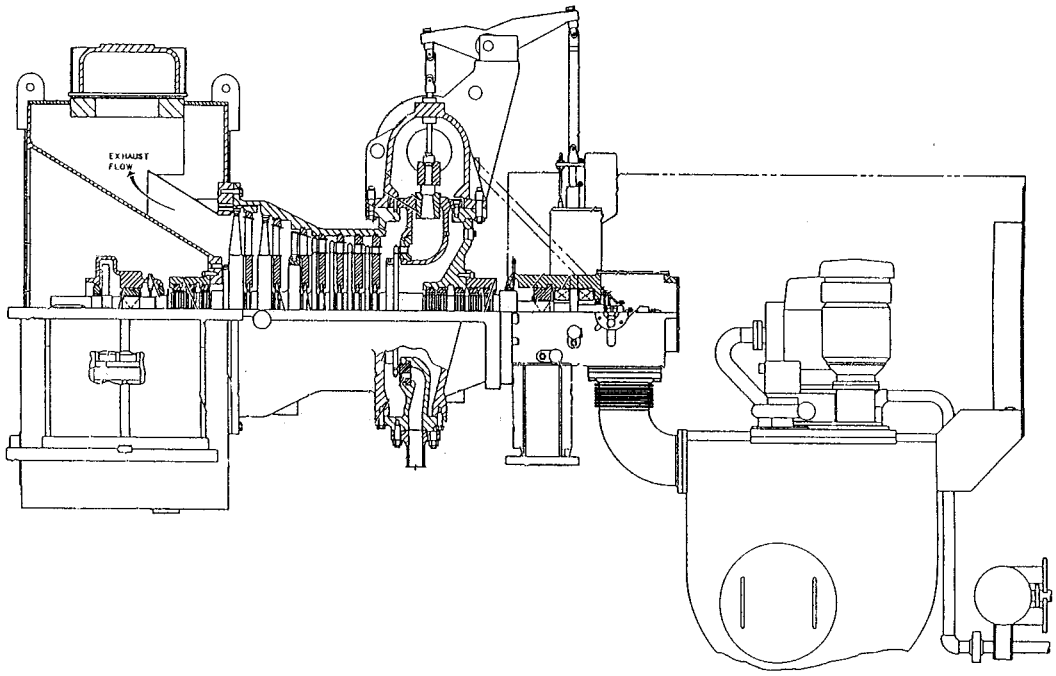

FIGURE 8.1.12 Boiler feed pump turbine.

Boiler Feed Pump. These pumps are multiple-stage centrifugal pumps, which, depending on the cycle, can be turbine or motor driven. BFP turbines (BFPT), Figure 8.1.12, are single-case units which draw steam from the main turbine cycle and exhaust to the main condenser. Typical feedpump turbines require 0.5% of the main unit power at full-load operation. Multiple pumps rated at 50 to 100% each are typically used to allow the plant to operate with one pump out of service.

Generators

The electric generator converts rotating shaft mechanical power of the steam turbine to three-phase electrical power at voltages of between 13.8 and 26 kV, depending upon the power rating. The generator comprises a system of ventilation, auxiliaries, and an exciter. Figure 8.1.13 shows an installed hydrogen-cooled generator and brushless exciter of about 400 MW. Large generators greater than 25 MW usually have a solid, high-strength steel rotor with a DC field winding embedded in radial slots machined into the rotor. The rotor assemblage then becomes a rotating electromagnet that induces voltage in stationary conductors embedded in slots in a laminated steel stator core surrounding the rotor (see Figure 8.1.14).

The stator conductors are connected to form a three-phase AC armature winding. The winding is connected to the power system, usually through a step-up transformer. Most steam turbines driven by fossil-fired steam use a two-pole generator and rotate at 3600 rpm in 60-Hz countries and 3000 rpm in

© 1999 by CRC Press LLC

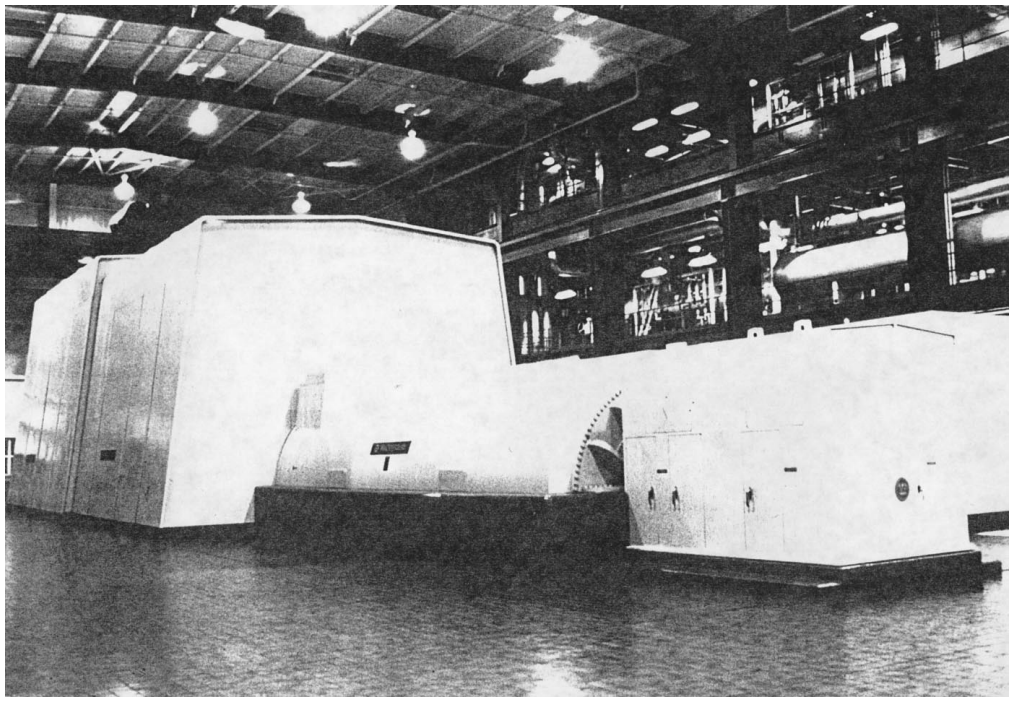

FIGURE 8.1.13 Generator and exciter.

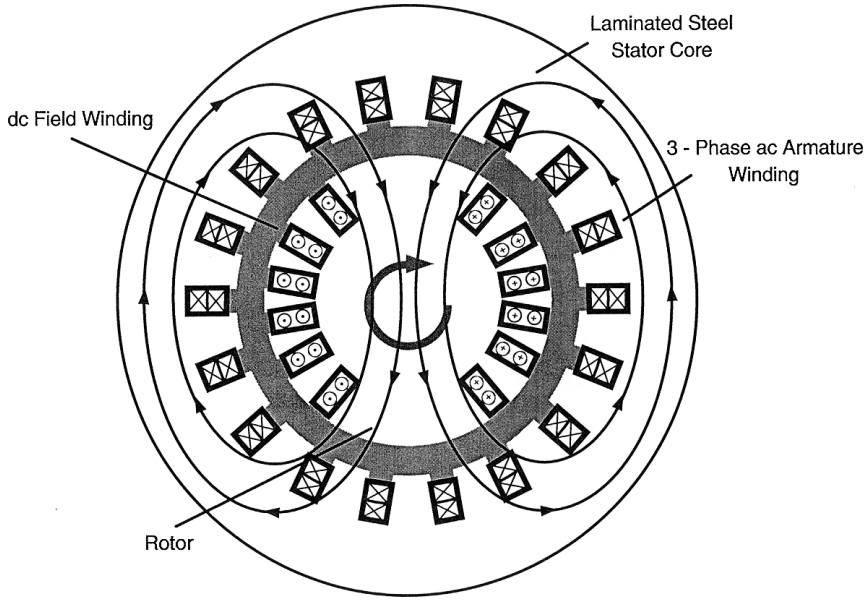

FIGURE 8.1.14 Generator magnetic paths.

© 1999 by CRC Press LLC

50-Hz countries. Most large steam turbines driven by nuclear steam supplies use a four-pole generator and rotate at 1800 or 1500 rpm for 60 and 50 Hz, respectively.

Generator Ventilation

Cooling the active parts of the generator is so important that generators are usually classified by the type of ventilation. Air-cooled generators are used commonly up to 100 MW, though some applications exist up to 200 MW. Some use ambient air drawing air through filters and others recirculate air through air-to-water heat exchangers. Above 100 MW, most manufacturers offer hydrogen for the overall cooling, sometimes up to 1400 MW. Hydrogen has 14 times the specific heat of air and is used at lower density. This contributes to much better cooling and much lower windage and blower loss. The frame must be designed to withstand the remote circumstance of a hydrogen explosion and requires shaft seals. Hydrogen is noncombustible with purities greater than 70%. Generator purities are usually maintained well above 90%. Depending upon the manufacturer, generators with ratings above 200 to 600 MW may have water-cooled stator winding, while the remaining components are cooled with hydrogen.

Generator Auxiliaries

Large generators must have a lubrication oil system for the shaft journal bearings. Major components of this system are pumps, coolers, and a reservoir. In most cases, the turbine and generator use a combined system. For hydrogen-cooled generators, a shaft seal system and hydrogen supply system are needed. The shaft seal system usually uses oil pumped to a journal seal ring at a pressure somewhat higher than the hydrogen pressure. Its major components are pumps, coolers, and reservoir, similar to the lubrication system. The hydrogen supply system consists of a gas supply and regulators. A CO_2 supply is used to purge the generator when going from air to hydrogen or vice versa to avoid a combustible hydrogen/air mixture. The stator winding water supply again uses pumps, coolers, and a reservoir. It needs demineralizers to keep the water nonconducting and provisions to control oxygen content to avoid copper oxide corrosion which might break off and clog water passages.

Excitation

The rotor field winding must have a DC source. Many generators use rotating "collector" rings with stationary carbon brushes riding on them to transfer DC current from a stationary source, such as a thyristor-controlled "static" excitation system, to the rotor winding.

A rotating exciter, known as a brushless exciter, is used for many applications. It is essentially a small generator with a rotating rectifier and transfers DC current through the coupling into the rotor winding without the need for collectors and brushes.

Modern Steam Power Plant — An Example

The purpose of a power plant is to generate electric power. It does so by converting chemical energy contained in fuel into thermal energy in steam; thermal energy in steam into mechanical energy in the turbine/generator; and mechanical energy in the turbine/generator into electrical energy.

Operating efficiency of a typical modern steam plant is about 35 to 45%. The primary losses result from (1) heat sink losses in the condenser, (2) boiler losses, and (3) electrical losses.

Steam plant capacities have ranges from 50 to 1600 MW; however, modern plants are being designed for more than 250 MW due to energy demands, system load requirements, and economies of scale in the larger centralized stations.

© 1999 by CRC Press LLC

Major Steam Plant Components

Steam plants comprise three major components (1) boiler, (2) turbine, and (3) main steam condenser. The boiler and turbine are covered in earlier subsections and neither will be repeated here. A graphic of the entire fluid or work cycle is shown in Figure 8.1.15.

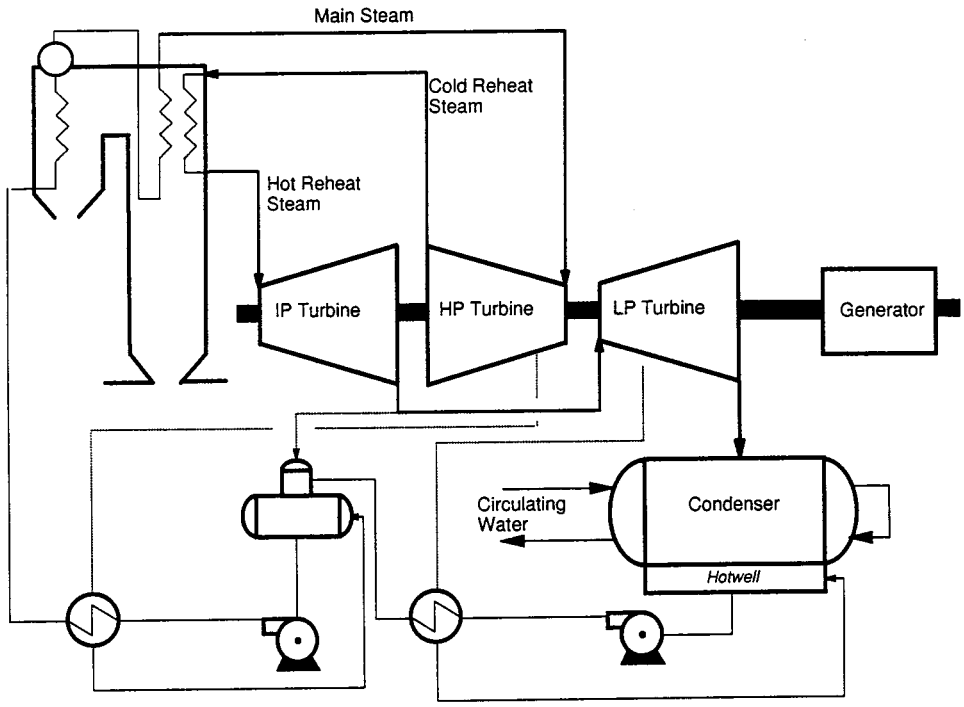

FIGURE 8.1.15 Steam power plant schematic.

Condenser. The condenser (also discussed earlier) is a large heat exchanger that takes the LP turbine exhaust steam and converts it back to water. The steam passes over a bundle of tubes located in the condenser and is cooled by the circulating water which passes through the tubes. The steam is condensed into water drops and collected in the condenser hot well. The condensate is delivered from the condenser hot well through the condensate and feedwater systems and back to the boiler where it becomes steam again.

Fuels. Coal, oil, and gas are used to fuel fossil plants. Although coal possesses the highest carbon content, it also possesses the highest sulfur, nitrogen, and ash content, thereby requiring air pollution-control equipment. Controlling these pollutants requires the installation of scrubbers for sulfur control; overfire air or gas recirculation for in-furnace nitrous oxides (NO_x) control; selective catalytic reduction (SCR) for post-combustion NO_x control; electrostatic precipitators (ESP) or baghouse for fly ash control; and pneumatic, hydraulic, or mechanical ash-handling systems for bottom ash removal. Fuel oil and natural gas are chiefly composed of compounds of hydrogen and carbon (hydrocarbons) with very low percentages of sulfur, nitrogen, and ash and do not require pollution-control equipment.

Power Plant System

Power plants comprise the following main systems: fuel handling, air handling, gas handling, main steam, reheat steam, auxiliary steam, extraction steam, condensate, feedwater, circulating water, and air removal.

© 1999 by CRC Press LLC

Fuel-Handling System. The fuel-handling system consists of delivery, transfer, and processing. Fuel is delivered to the plant from the fuel source by truck, boat, rail (coal and oil), or pipeline (oil and gas). Once delivered, the fuel is transferred from the delivery point to various locations throughout the fuel-handling system. For coal and oil, the fuel is either transferred to storage or sent directly to the boiler. For gas, the fuel is directly transferred to the boiler without any storage. Prior to delivery to the boiler for burning, the fuel must be processed so that it will readily mix with air and burn completely. Coal must be broken down into smaller pieces by breakers and crushers. Oil requires steam, air, or mechanical atomization. Gas requires no processing.

Air/Gas-Handling Systems. Steam plants are classified as either pressurized or balance draft. Pressurized systems include forced-draft fans to provide the necessary air for fuel, an air heater to transfer heat from the exit gas to the inlet air, and a wind box where the air is stored and then directed to the individual burner ports. A balanced draft system includes all of the components of the pressurized systems and induced-draft fans to exhaust the combustion products from the boiler, thus maintaining the furnace under slightly negative pressure.

Main Steam System. The main steam system controls and regulates the flow of high-temperature, HP steam generated in the boiler furnace as it moves from the boiler to the turbine. The components in this system include main steam piping, safety valves, main steam stop valve, steam chest, and turbine control valve.

Reheat Steam System. The reheat steam system improves overall plant efficiency by increasing the energy of steam that has been exhausted from the HP turbine. Steam from the hot reheat steam system is delivered to the IP turbine. The components of the reheat steam system are cold reheat piping, the reheater section of the boiler, hot reheat piping, safety relief valves, reheat stop valves, reheater desuperheater, and intercept valves.

Auxiliary Steam System. The auxiliary steam system directs and regulates auxiliary steam from the cold reheat line to the auxiliary steam users. The auxiliary steam system users are typically steam/air preheating coils, outdoor freeze protection/heat tracing, deaerating heater pegging, turbine-driven BFP testing, turbine seals, and plant heating.

Extraction Steam System. The extraction steam system directs and regulates the flow of the extraction steam from the turbine to the feedwater heaters, BFPT, and auxiliary steam system. The extraction steam heats the feedwater that flows through the heaters, thus improving overall plant efficiency. In large steam plants, six to eight stages of feedwater heating are typical.

Condensate System. The condensate system consists of condensate pumps, LP feedwater heaters, and DA. The condensate pumps remove condensate from the main condenser hot well, increase condensate pressure, and deliver it through the LP heaters to the DA. During this process, the condensate is heated, deaerated, and chemically treated.

Feedwater System. The feedwater system consists of BFPs, HP feedwater heaters, piping, and valves. The boiler feedwater pumps deliver water from the DA storage tank, through the HP heaters, and into the boiler. Feedwater is supplied at sufficient quantities and pressure to satisfy unit demands during startups, shutdowns, and normal operation. The BFP is also the primary source of spray water for the superheater and reheater desuperheaters for control of the main and reheat steam temperatures, respectively.

BFPs can either be turbine or motor driven. Booster pumps may be required to provide additional net positive suction head (NPSH) to the main and start-up BFPs for plants designed with a low DA setting.

Circulating Water System. The circulating water system pumps cooling water through the condenser tubes at sufficient capacity, temperature, and pressure to absorb the latent heat in the LP exhaust steam.

© 1999 by CRC Press LLC

Circulating water systems are classified as once-through systems, when a large water source is available, or recirculating systems employing cooling towers. In once-through systems, circulating water pumps deliver water from the plant water supply (river, lake, or ocean) through the condenser tubes to absorb latent heat in the exhaust steam. Water flows through the system once and is returned to its source. The major parts of this system are screens, pumps, expansion joints, valves, and piping. In recirculating systems, the cooling tower cools the heated circulating water from the main condenser by exposing it to air. The cooled water is stored in a basin located below the tower and is then circulated back through the system by the circulating water pumps.

Air Evacuation System. The air evacuation system removes air and noncondensable gases in the main steam condenser and helps maintain the vacuum created by the volume reduction of the condensing steam during normal operation. The system also establishes a normal vacuum in the condenser prior to turbine start-up.

8.2 Gas Turbines

Steven I. Freedman

Overview

Gas turbines are steady-flow power machines in which a gas (usually air) is compressed, heated, and expanded for the purpose of generating power. The term *turbine* is the component which delivers power from the gas as it expands; it is also called an expander. The term *gas turbine* refers to a complete power machine. The term gas turbine is often shortened to simply turbine, which can lead to confusion with the term for an expander.

The basic thermodynamic cycle on which the gas turbine is based is known as the Brayton cycle. Gas turbines may deliver their power in the form of torque or one of several manifestations of pneumatic power, such as the thrust produced by the high-velocity jet of an aircraft propulsion gas turbine engine.

Gas turbine machines vary in size from large, 250,000-hp utility machines, to small automobile, truck, and motorcycle turbochargers producing as little as 5 hp.

Gas turbines are used in electric power generation, propulsion, and compressor and pump drives. The most efficient power generation systems in commercial service are gas turbine combined cycle plants with power-to-fuel energy efficiencies of more than 50% (higher heating value basis) or 55% (lower heating value basis). Systems five points higher in efficiency are now under development and are being offered commercially, and systems of even higher efficiency are considered feasible.

History

The fourth quarter of the 19th century was one of great innovation in power machinery. Along with the spark-ignited gasoline engine, the compression-ignited diesel engine, and the steam turbine, engineers applied their skills to several hot-air engines. Charles Curtis received the first U.S. patent for a complete gas turbine on June 24, 1895. Aegidius Elling built the first gas turbine in 1903, which produced 11 hp.

The first commercial stationary gas turbine engineered for power generation was a 4000-kW machine built by the Brown Boverei Company in Switzerland in 1939.

Aviation provided the impetus for gas turbine development in the 1930s. In Germany, Hans von Ohain's first engine ran in March 1937. Frank Whittle's first engine ran in England in April 1937. The first airplane flight powered by a gas turbine jet engine was in Germany on August 27, 1939. The first British airplane powered by a gas turbine flew on May 15, 1941.

A Swiss railway locomotive using a gas turbine was first run in 1941. The first automobile powered by a gas turbine was a British Rover, which ran in 1950. And, in 1956, a gas turbine-powered Plymouth car drove over 3000 miles on a coast-to-coast exhibition trip in the United States.

Fuels and Firing

The first heat engines were external combustion steam engines. The combustion products never came in contact with the working fluid, so ash, corrosive impurities, and contaminants in the fuel or exhaust did not affect the internal operation of the engine. Later, internal combustion (piston) engines were developed. In these engines, a mixture of air and fuel burned in the space enclosed by the piston and cylinder walls, thereby heating the air. The air and combustion products formed the working fluid, and contacted internal engine parts.

Most gas turbines in use today are internal combustion engines and consequently require clean fuels to avoid corrosion and erosion of critical turbine components. Efforts were made to develop gas turbines rugged enough to burn residual or crude oil. However, due to the higher efficiencies obtainable by burning extremely clean fuel at higher temperatures, there is little current interest in using liquid fuel other than (clean) distillate oil in gas turbines. Interest in the use of residual oil is now centered on gasifying and cleaning these fuels prior to use.

© 1999 by CRC Press LLC

A few externally heated gas turbines have been built for use with heavy oil, coal, nuclear reactor, radioisotope, and solar heat sources. However, none of these has become commercial. The added cost and pressure drop in the externally fired heater make externally fired gas turbines expensive. Because the working fluid temperature cannot be greater than that of the walls of the fired heater, externally fired gas turbines are substantially less efficient than modern internal combustion gas turbines with internally cooled blades.

The only internal combustion coal-fired gas turbine entering commercial service is the pressurized fluidized bed (PFB) combustion system. In the PFB, air discharged from the compressor of the turbine is used to fluidize a bed of limestone or dolomite in which coal is burned. The bed is maintained at modest temperature so that the ash in the coal does not form sticky agglomerates. Fortuitously, this temperature range also minimizes NO_x formation and allows capture of sulfur dioxide (SO_2) in the bed. Bed temperature is maintained in the desired range by immersed boiler tubes. Carryover fly ash is separated from gaseous combustion products by several stages of cyclone inertial separators and, in some cases, ceramic filters. The power turbine is modified to accommodate the combustion products, which after mechanical cleanup may still contain particles as large as 3 to 5 μm.

The most common gas turbine fuels today are natural gas and distillate oil. To avoid hot corrosion by alkali metal sulfates, the total sodium and potassium content of the fuel is typically limited to less than 5 ppm. Liquid fuels may also contain vanadium, which also causes corrosion. Fuels must be ash-free because particles larger than 3 to 5 μm rapidly erode blades and vanes. Experimental prototype gas turbines using pulverized coal pressurized combustors have not demonstrated adequate life. Hybrid systems — in which the moderate-temperature coal combustion products are mechanically cleaned and heated to higher temperature by use of a clean fuel such as natural gas or distillate oil — are the subject of ongoing development.

Efficiency

The term *efficiency* is applied not only to complete power generation machines but also to the individual compression, expansion, and combustion processes that make up the gas turbine operating cycle. Different definitions of efficiency apply in each case. In an **expansion process**, the **turbine efficiency** is the ratio of the actual power obtained to the maximum power that could have been obtained by expanding the gas reversibly and adiabatically between the same initial and final pressures.

Gas turbines typically involve high-speed gas flows, so appreciable differences exist between the static pressure and temperature and the total (or stagnation) pressure and temperature. Care must be taken in interpreting data to be sure that the pressure condition — static or stagnation — at each component interface is properly used.

Irreversible losses in one stage of an expansion process show up as heat (increased temperature) in later stages and add to the power delivered by such stages. Hence, a distinction exists between the polytropic efficiency (used to describe the efficiency of a process of differential pressure change) and the adiabatic (complete pressure change) efficiency. The efficiency of compressors and turbines based on their inlet and outlet pressures is called the isentropic or adiabatic efficiency. Unfortunately, both terms are reported in the literature, and confusion can exist regarding the meaning of the term *efficiency* .

Combustion efficiency in well-engineered and well-built internal combustion gas turbines is almost always close to 100%. The combustion losses appear as carbon monoxide, unburned hydrocarbons, and soot, which are typically below 100 ppm, with clean fuels.

The **gas turbine or engine efficiency** is the ratio of the net power produced to the energy in the fuel consumed. The principal gas turbine fuels are liquid and gaseous hydrocarbons (distillate oil and natural gas) which have high hydrogen content. Consequently, the term *engine efficiency* needs to be qualified as to whether it is based on the higher or the lower heat content of the fuel (the difference between the two being the latent heat of condensation of the water vapor in the products of combustion). Utility fuel transactions are traditionally based on higher heating values, and most engine publications presume the lower heating value of the fuel as the efficiency basis.

© 1999 by CRC Press LLC

Engineers analyze gas turbine machines to evaluate improvements in component performance, in higher temperature and pressure ratio designs, and in innovative cycles. Ideal case cycle calculations generally assume the following:

- Air (with either constant or temperature-dependent specific heats) is the working fluid in both turbine and compressor (with equal mass flows);
- Air is the working fluid in both turbine and compressor but with the turbine mass flow greater by the amount of fuel used.

Components are modeled with or without frictional pressure drops, and heat transfer effectiveness may be ideal (unity) or actual, depending on the purpose of the analysis. Use of compressor air for cooling of high-temperature structure, nozzles, and blades are modeled in varying degrees of complexity. Two-dimensional temperature profiles or pattern factors exist. Component inlet and exit total pressure losses should be included in cycle analyses.

Gas Turbine Cycles

Gas turbine cycles are usually plotted on temperature-entropy (T-S) coordinates. Readers unfamiliar with entropy are referred to the chapter on thermodynamics. The T-S plot is useful in depicting cycles because in an adiabatic process — as is the case for turbines and compressors — the power produced or consumed is the product of the mass flow and the enthalpy change through the process. Thus, temperature difference, which is found on a T-S plot, is proportional to the power involved. Additionally, the heat exchange in a process involving zero power — such as a combustor or heat exchanger — is the product of the absolute temperature and the entropy change. On a T-S chart, the area under a process line for a combustor or heat exchanger is the heat exchanged.

The slope of a constant-pressure line on a T-S diagram is proportional to the absolute temperature. Consequently, lines of constant pressure become steeper, and diverge as the temperature increases. This illustrates that more work is obtained expanding a gas between fixed pressures at higher temperatures than at lower temperatures. Figure 8.2.1 shows a comparison of the process of an ideal and an actual simple cycle gas turbine on a T-S diagram. The increased compressor power consumption and the decreased turbine power generation in the actual cycle are shown to provide an understanding of the differences that component efficiencies make on machine performance.

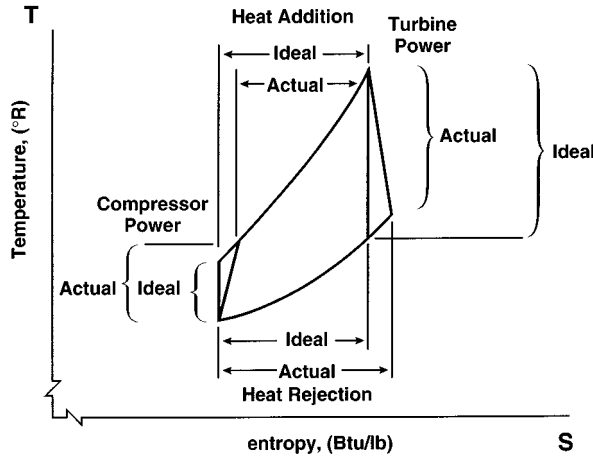

FIGURE 8.2.1 T-S diagram for a simple cycle illustrating the differences in compressor and turbine power for ideal (100% efficient) and actual components.

© 1999 by CRC Press LLC

The incremental amount of power produced per differential pressure change in the gas is given by

$$d(\text{Power/mass flow}) = -RT\, dp/p$$

Two phenomena are illustrated by this equation. First, power is proportional to the absolute temperature of the gas. Second, power is proportional to the percent change in pressure. This latter point is important in understanding the effect of pressure losses in cycle components. In heat exchangers, the proper measure of power lost is the percent pressure drop.

Cycle Configurations

The basic Brayton cycle consists of a compressor, a combustor or burner, and an expander. This configuration is known as the simple cycle. In idealizing the actual cycle, combustion is replaced by constant-pressure heat addition, and the cycle is completed by the assumption that the exhaust to ambient pressure could be followed by a zero-pressure-loss cooling to inlet conditions.

A T-S diagram of the simple cycle gas turbine with an upper temperature limit set by metallurgical conditions is illustrated in Figure 8.2.2 for cycles of low, medium, and high pressure ratios. The heat addition is only by fuel combustion, simplified here to be without mass addition or change in specific heat of the working fluid.

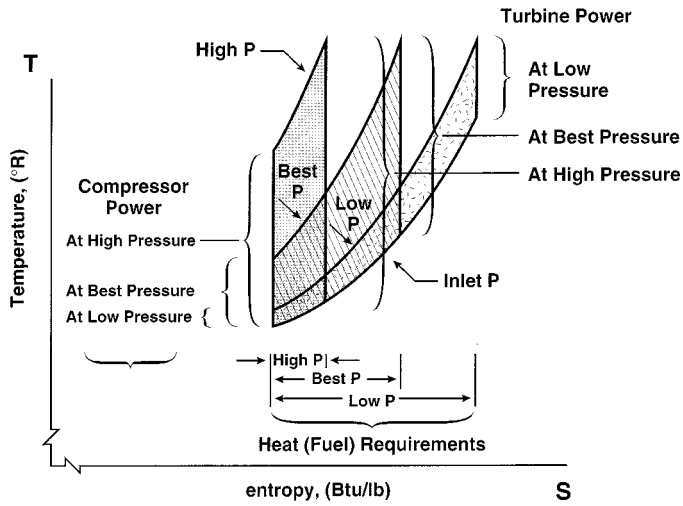

FIGURE 8.2.2 T-S diagram illustrating the power and heat (fuel) requirements at low, best, and high cycle pressures.

It is seen that the low-pressure-ratio cycle requires a large heat addition, which leads to a low efficiency, and the high-pressure-ratio cycle has turbine power output barely greater than the compressor power requirement, thereby leading to low net output and low efficiency. At intermediate pressure ratios, the turbine power output is substantially higher than the compressor power requirement, and the heat addition is modest in comparison with the difference between the turbine and compressor powers. There is an optimum pressure ratio for maximum efficiency, which is a function mainly of the maximum gas temperature in the machine, and to a lesser extent, by the component efficiencies, internal pressure losses, and the isentropic exponent. There is another optimum pressure ratio for maximum specific power (power per unit mass flow).

As the achievable turbine inlet temperature increases, the optimum pressure ratios (for both maximum efficiency and maximum specific power) also increase. The optimum pressure ratio for maximum specific power is at a lower pressure level than that for maximum efficiency for all cycles not employing a recuperator. For cycles with a recuperator, the reverse is true: maximum efficiency occurs at a lower

© 1999 by CRC Press LLC

pressure ratio than maximum specific power. Heavy-duty utility and industrial gas turbines are typically designed to operate near the point of maximum specific power, which approximates lowest equipment cost, while aeroderivative gas turbines are designed to operate near the point of maximum efficiency, approximating highest thrust. Figure 8.2.3 shows a performance map (efficiency as a function of power per unit of air flow) for a simple cycle gas turbine for two turbine inlet temperatures. It is seen that at higher temperature, both the efficiency and specific power increase, as well as the optimum pressure ratios for both the maximum efficiency and maximum specific power conditions.

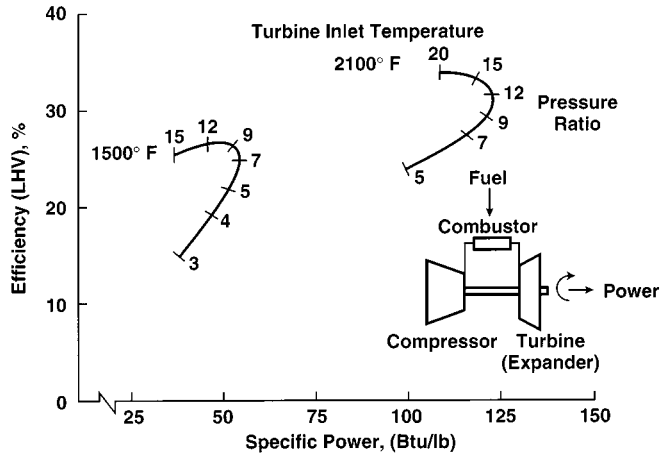

FIGURE 8.2.3 Performance map of a simple cycle gas turbine.

Aircraft gas turbines operate at temperatures above the limit of turbine materials by using blades and vanes with complex internal cooling passages. The added cost is economically justified because these machines can command high prices in the aircraft propulsion marketplace. Aeroderivative engines have higher pressure ratios, higher efficiencies, and lower exhaust temperatures than heavy-duty machines. The stationary power markets served by aeroderlvative gas turbines are principally pipeline compressor stations and oil/gas production wells. Aeroderivative gas turbines also are economically advantageous for intermediate-duty applications.

Components Used in Complex Cycles

Recuperators and **regenerators** recover heat from the turbine exhaust and use it to preheat the air from the compressor before it enters the combustor, thereby saving fuel. This heat transfer is shown in Figure 8.2.4. While recuperators and regenerators are quite similar thermodynamically, they are totally different in design. Recuperators are conventional heat exchangers in which hot and cold gases flow steadily on opposite sides of a solid (usually metal) wall.

Regenerators are periodic-flow devices. Fluid streams flow in opposite directions through passages in a wheel with heat storage walls. The wheel rotates, transferring heat from one stream to the other. Regenerators usually use a nest of very small parallel passages oriented axially on a wheel which rotates between hot and cold gas manifolds. Such regenerators are sometimes used in industrial processes for furnace heat recovery, where they are referred to as heat wheels. Because regenerators are usually more compact than recuperators, they are used in automotive gas turbines (under development). The difficulty in using regenerators on gas turbines intended for long life is that the two gas streams are at very different pressures. Consequently, the seals between the manifolds and the wheel must not leak excessively over the maintenance overhaul interval of the engine. If they do, the power loss due to seal leakage will compromise engine power and efficiency. Figure 8.2.5 shows a performance map for the regenerative

© 1999 by CRC Press LLC

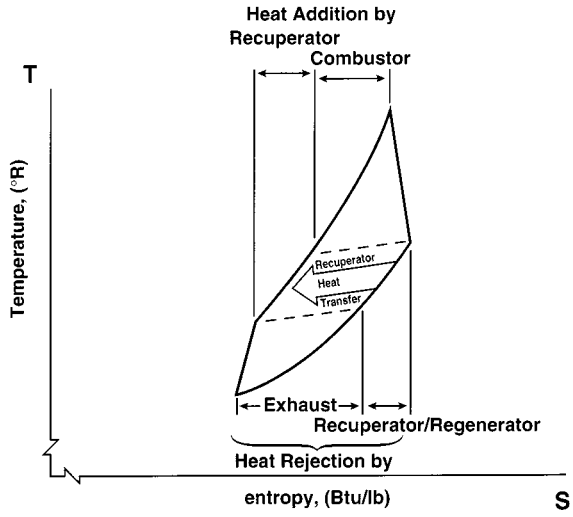

FIGURE 8.2.4 T-S diagram illustrating the heat transfer from the turbine exhaust to the compressor discharge accomplished by a recuperator/regenerator.

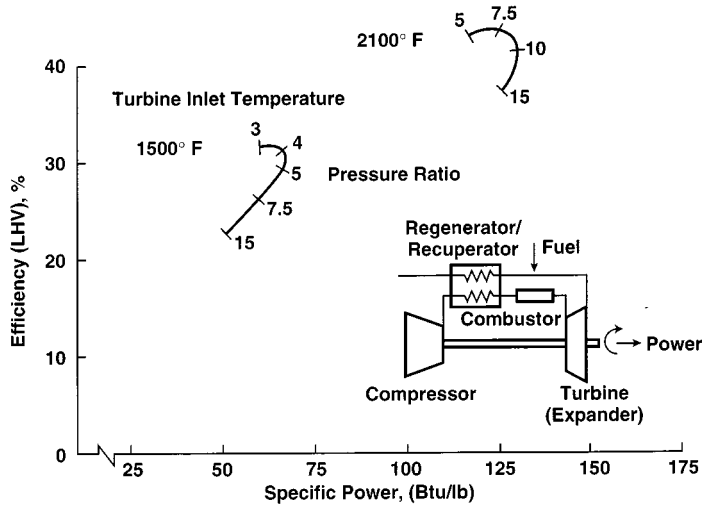

FIGURE 8.2.5 Performance map of a regenerative cycle gas turbine.

gas turbine cycle for two temperatures. It is seen that as the temperature increases, the efficiency, specific power, and optimum pressure ratio all increase.

Current research on the recovery of gas turbine exhaust heat includes examination of thermochemical recuperation, where exhaust heat is used to effect a chemical reaction (reforming) of the fuel with steam, thereby increasing the heating value of the fuel. Although this process is feasible, research is underway to determine if it is practical and economic.

Industrial process compressors frequently use **intercoolers** to reduce compressor power when the compressor has a high pressure ratio and operates for a large number of hours per year. When analyzing cycles with intercoolers, the added pressure drops in the compressor interstage entrance and exit diffuser and scroll and the pressure drop in the intercooler itself should be included.

In a similar manner, turbine reheat can be used to increase the power output of a large-pressure-ratio turbine. This is the thermodynamic principle in turbojet afterburner firing. Turbine reheat increases

© 1999 by CRC Press LLC

power, but decreases efficiency unless the turbine exhaust heat is used for additional power generation, as is the case with a combined cycle, or is used with a recuperator to preheat combustor inlet air.

Intercoolers and reheat burners increase the temperature difference between the compressor and turbine discharges, thereby increasing the opportunity to use a recuperator to preheat the burner air with exhaust heat. An intercooled recuperated (ICR) machine is at present in development. The efficiency decrease at part load of an ICR gas turbine is much less than of conventional simple cycle machines.

Small gas turbines have uncooled turbine blades as a result of the difficulty in manufacturing extremely small cooling passages in small blades. This results in low efficiencies, making it difficult for such turbines to compete with high-volume production (low-cost) reciprocating (piston) engines. The low-pressure-ratio recuperated cycle has greater efficiency, although at higher cost. The recuperated cycle is finding favor in programs for small (under 300-kW) gas turbines used for stationary power. The recuperated cycle is efficient enough in comparison with piston engines (Otto cycles) to be of interest to automotive power plant engineers. Current designs of automotive gas turbines (AGT) have ceramic turbines and combustors and use ceramic regenerators made from a spirally wound corrugated structure with gas passages about a millimeter in diameter.

Because of their compact size, low emissions, and light weight, gas turbines are also being considered for hybrid engine-battery vehicles. Proponents are pursuing the low-pressure-ratio recuperated gas turbine as the way to obtain high efficiency and low emissions in a compact power plant.

An ingenious gas turbine cycle is the closed cycle in which the working fluid is sealed in the system. Heat is added to the fluid with an externally fired heater and extracted from the fluid through heat exchangers. The working fluid may be any gas, and the density of the gas may be varied — to vary the power delivered by the machine — by using a gas storage cylinder connected to the compressor discharge and inlet. The gas storage system is at an intermediate pressure so that it can discharge gas into the lowest pressure point in the cycle and receive gas from the highest pressure point in the cycle. About ten such units were built between 1938 and 1968; however, in spite of its sophistication, the added cost and low efficiency prevented this system from becoming economic.

The exhaust from a gas turbine is quite hot and can be used to raise steam, which can then be used to generate additional power with a steam turbine. Such a compound gas turbine-steam turbine system is referred to as a **combined cycle**. Figure 8.2.6 shows a schematic diagram of the equipment in a combined cycle. Because the exhaust of heavy-duty machines is hotter than that of aeroderivative machines, the gain in combined cycle system efficiency through use of the steam bottoming cycle described above is greater for heavy-duty machines than for aeroderivatives. Indeed, heavy-duty machines are designed with two criteria in mind: achieving lowest cost for peaking (based on the simple cycle configuration) and achieving highest efficiency in combined cycle configuration for baseload use. The optimum pressure ratios for these two system configurations are very close. Steam bottoming cycles used in combined cycles usually use steam at multiple pressure levels to increase efficiency.

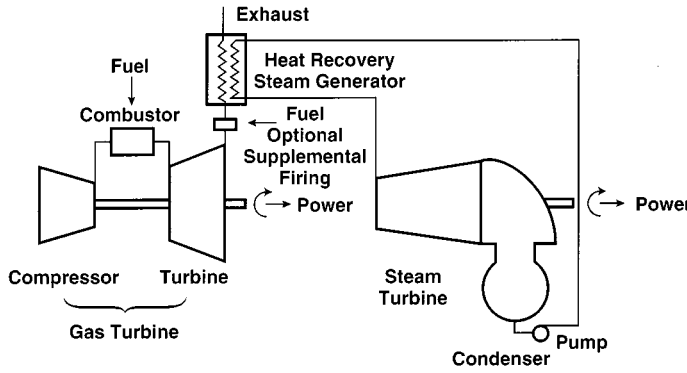

FIGURE 8.2.6 Combined (Brayton-Rankine) cycle.

© 1999 by CRC Press LLC

Another system in which the power and efficiency of a gas turbine is increased through the use of steam is the **steam-injected gas turbine**. Figure 8.2.7 shows a schematic diagram of a steam-injected gas turbine cycle. Here the turbine exhaust flows into a heat recovery steam generator (HRSG) operating at a pressure somewhat higher than the compressor discharge pressure. The steam is introduced into the gas turbine at the combustor. The steam-air mixture then passes into the turbine, where the augmented mass flow increases the power produced by the turbine. Additional fuel is required by the combustor because the steam must be heated from the HRSG delivery temperature to the combustor discharge temperature. Typical turbines can accommodate only a limited additional mass flow — from 5 to 15%, depending on the design of the original gas turbine. Steam-injected gas turbines enable the host to use the steam for industrial purposes, space heating, or for the generation of additional power.

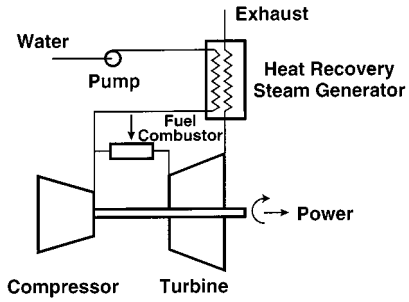

FIGURE 8.2.7 Steam-injected gas turbine.

A group of cycles under consideration for development involve the use of **adiabatic saturators** to provide steam at compressor discharge pressure to augment greatly the mass flow through the turbine, and consequently increase cycle power and efficiency. In the adiabatic saturator, water flows in a countercurrent path to the compressor discharge air in a mass transfer tower. Such equipment is often used in the chemical processing industries. The saturated air is preheated in a turbine exhaust heat recuperator. This cycle is called the **humid air turbine**, or HAT, cycle. The HAT cycle is particularly useful in using the low-temperature heat generated in coal-gasification-fueled gas turbine power plants. As the mass flow through the turbine is significantly augmented, engineers can no longer use the expansion turbine which was matched to the compressor in a conventional simple cycle gas turbine.

Figure 8.2.8 shows performance maps for the gas turbine cycles of major interest for a turbine inlet temperature typical of new products. Intercooling increases the specific power appreciably when compared with a simple cycle; however, such improvement requires an increase in pressure ratio. Recuperated cycles have considerably higher efficiency than similar cycles without recuperation. The effect of pressure ratio on the performance of recuperated cycles is opposite to that of similar cycles without recuperation. For recuperated cycles, the pressure ratio for maximum efficiency is considerably lower than for maximum specific power. Performance maps such as these are used in screening cycle alternatives for improved performance. Individual curves are generated for specific component performance values for use as a guide in developing new or improved machines.

Upper Temperature Limit

Classically, gas turbine engineers often spoke of a metallurgical limit in reference to maximum turbine inlet temperature. Later, turbine vane and blade cooling became standard on large machines. This situation creates a temperature difference between the combustion products flowing through the turbine and the turbine blade wall. Thus, because heat can be removed from the blades, the turbine can be operated with a combustion gas temperature higher than the metallurgical limit of the blade material. As a rule, the blades and vanes in new large gas turbines contain complex internal passages, through which up to 20% of compressor discharge air is directed. The cooling air first flows through internal convective cooling

© 1999 by CRC Press LLC

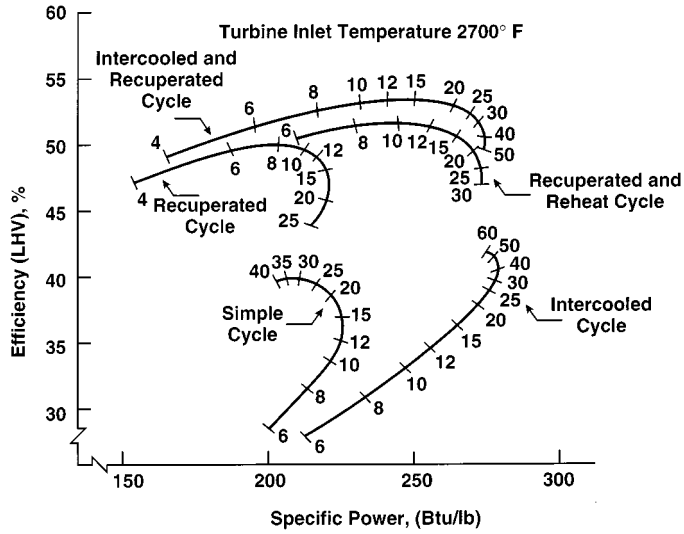

FIGURE 8.2.8 Specific power (Btu/lb).

passages, then through impingement passages, where the air is directed at the blade and vane walls, and finally through small holes in the blade, where it is used to provide a low-temperature film over the blade surface. This film cooling of the surface reduces heat transfer to the blade.

The design of blade and vane cooling passages is an extremely competitive endeavor because greater cooling enables use of higher combustion temperatures without exceeding the metallurgical limit of the blade material. However, a balance between air flow for cooling and air flow for power must be achieved; the cooling air flowing within a blade drops in pressure without producing any power within that stage (although it is available for power in later stages). In the newest gas turbines, blade cooling, the difference between turbine inlet gas temperature and blade metal temperature, is around 1000°F.

Some of the latest large gas turbines being introduced to the market in the 1997 to 2000 period are being offered for combined cycle application with closed-circuit **steam cooling** of selected hot section parts. Steam cooling reduces the need for air cooling, so that more of the compressor discharge air can be used for NO_x reduction in the combustor and for power generation. The heat transferred to the steam increases the efficiency of the bottoming cycle. The additional combustion products which flow through the high-pressure portions of the turbine generate substantially more power, thereby increasing both the power output and the efficiency of the machine. With more air for combustion, the fuel can be burned as a leaner mixture, with either less NO_x produced, or, as is preferred, with higher-temperature gases going to the turbine and the same NO_x (or a combination of these benefits).

Materials

The high-technology parts of a gas turbine are its hot section parts: blades, vanes, combustors and transition pieces. Gas turbine power, efficiency, and economics increase with the temperature of the gas flowing through the turbine blade passages. It is in the fabrication of these hot section parts that manufacturers are most competitive. Materials are selected to survive in serviceable condition for over 50,000 hr and associated numbers of thermal cycles. Ceramic coatings protect materials from oxidation and corrosion and provide thermal insulation, permitting higher gas temperatures.

Gas turbine alloys are frequently referred to as superalloys because of their extremely high strength at high temperatures. These superalloys are nickel based (such as IN 738), cobalt based (such as FSX-414), or with a nickel-iron base such as Inconel 718. Nickel resists oxidation and is creep resistant, but is subject to corrosive sulfidation. Alloy and manufacturing advancements have been led by the needs of military aircraft engines. Coating developments for corrosion resistance have been led by the needs

© 1999 by CRC Press LLC

of stationary power for overhaul intervals as large as 50,000 hr. The developmental needs of automotive gas turbines have led to significant advances in strength and reliability of high-temperature ceramic components, including radial inflow turbines. Ceramic materials, principally silicon nitride, are expected to enter service soon in small gas turbines.

Combustion

Gas turbine combustors appear to be simple in design, yet they solve several difficult engineering challenges. Until relatively recently, gas turbine combustors employed a (turbulent) diffusion flame design approach, which created the most compact flame. European heavy-duty gas turbine manufacturers — with substantial interest in burning heavy fuel oils — preferred large, off-engine combustors, often called silo combustors because of their appearance, in order to obtain lower flame velocities and longer residence times. American heavy-duty gas turbine manufacturers use compact on-engine combustors and design for gaseous and clean (distillate) liquid fuels. Aeropropulsion gas turbines require the smallest possible frontal area and use only clean liquid fuels; hence, they use on-engine combustors.

Recently, stationary engines have been required to reduce NO_x emissions to the greatest extent possible, and combustors on stationary gas turbines first modified their diffusion flame combustors and employed water and steam injection to quench flame hot spots. Most recently, designs changed to the lean-premixed process. With the improved blade cooling, materials, and coatings now in use, the material limits on turbine inlet temperature and the NO_x emission limits on combustor temperature appear to be converging on a combustion-temperature asymptote around 2700°F (1482°C). This may be increased if catalytic combustors prove practical.

Mechanical Product Features

In view of the need to achieve all the performance features described above, one must keep in mind that a gas turbine is a high-speed dynamic machine with numerous machine design, materials, and fabrication features to consider. Major issues include the following: critical shaft speed considerations, bearing rotational stability, rotor balancing, thrust bearing design, bearing power loss, oil lubrication system, oil selection, air filter design and minimization of inlet and exhaust diffuser pressure drops, instrumentation, controls, diagnostic systems, scheduled service and inspection, overhaul, and repair. All of these topics must be addressed to produce a cost-effective, reliable, long-lived, practical gas turbine product that will satisfy users while also returning to investors sufficient profit for them to continue to offer better power generation products of still higher performance.

Defining Terms

Adiabatic saturator: A combined heat-and-mass-exchanger whereby a hot gas and a volatile liquid pass through a series of passages such that the liquid is heated and evaporates into the gas stream.

Combined cycle: An arrangement of a gas turbine and a stream turbine whereby the heat in the exhaust from the gas turbine is used to generate steam in a heat recovery boiler which then flows through a steam turbine, thereby generating additional power from the gas turbine fuel.

Combustion efficiency: Ratio of rate of heat delivered in a device which burns fuel to the rate of energy supplied in the fuel.

Expansion process: Process of power generation whereby a gas passes through a machine while going from a condition of high pressure to one of low pressure, usually the machine produces power.

Gas turbine or engine efficiency: The ratio of the net power delivered (turboexpander power minus compressor and auxiliary power) to the rate of energy supplied to the gas turbine or engine in the form of fuel, or, in certain cases such as solar power, heat.

Humid air turbine: A gas turbine in which the flow through the expander is augmented by large amounts of steam generated by use of an adiabatic saturator.

© 1999 by CRC Press LLC

Intercooler: A heat exchanger used to cool the flow between sections of a compressor such that the high pressure section acts on a stream of reduced volumetric flow rate, thereby requiring less overall power to compress the stream to the final pressure.

Recuperator: A heat exchanger in which the hot and cold streams pass on opposite sides of a wall through which heat is conducted.

Regenerator: A heat exchanger in which the hot and cold streams alternately heat and cool a wall whose temperature rises and falls, thereby transferring heat between the streams.

Steam cooling: A process in which steam is used as the heat transfer fluid to cool a hot component.

Steam-injected gas turbine: A system in which the gas turbine flow is augmented by steam, thereby generating additional power.

Turbine efficiency: Ratio of the power delivered in an expansion process employing a turbine as the expander to the maximum power which could be produced by expanding the gas in a reversible adiabatic (isentropic) process from its initial pressure and temperature to its final pressure to the actual power.

8.3 Internal Combustion Engines

David E. Klett and Elsayed M. Afify

Introduction

This section discusses the two most common reciprocating internal combustion (IC) engine types in current use; the **spark ignition** (SI) and the **compression ignition** (CI or diesel) **engine**. Both the Stirling engine (technically, an external combustion engine) and the gas turbine engine are covered in other sections of this chapter. Space limitations do not permit detailed coverage of the very broad field of IC engines. For a more detailed treatment of SI and CI engines and for information on variations, such as the Wankel rotary engine and the Miller cycle engine (a variation on the reciprocating four-stroke SI engine introduced in production by Mazda in 1993), the reader is referred to the several excellent textbooks on the subject, technical papers, and other sources that are included in the list of references and the Further Information section.

Basic SI and CI engines have not fundamentally changed since the early 1900s with the possible exception of the introduction of the Wankel rotary SI engine in the 1960s (Norbye, 1971). However, major advances in the areas of materials, manufacturing processes, electronic controls, and computer-aided design have led to significant improvements in dependability, longevity, thermal efficiency, and emissions during the past decade. Electronic controls, in particular, have played a major role in efficiency gains in SI automotive engines through improved control of the fuel injection and ignition systems that control the combustion process. Electronic control of diesel fuel injection systems is also becoming more common and is producing improvements in diesel emissions and fuel economy.

This section presents the fundamental theoretical background of IC engine function and performance, including **four-stroke** and **two-stroke** SI and CI **engines**. Sections on combustion, emissions, fuels, and intake pressurization (**turbocharging** and **supercharging**) are also included.

Engine Types and Basic Operation

IC engines may be classified by a wide variety of characteristics, the primary ones being SI vs. CI, four-stroke vs. two-stroke, and reciprocating vs. rotary. Other possible categories of classification include intake type (naturally aspirated vs. turbocharged or supercharged), number of cylinders, cylinder arrangement (in-line, vee, opposed), cooling method (air vs. water), fueling system (injected vs. carbureted), valve gear arrangement (overhead cam vs. pushrod), type of **scavenging** for two-stroke engines (cross, loop, or uniflow), and type of injection for diesel engines (direct vs. indirect).

Four-Stroke SI Engine

Figure 8.3.1 is a cross-section schematic of a four-stroke SI engine. The SI engine relies on a spark plug to ignite a volatile air-fuel mixture as the piston approaches **top dead center** (**TDC**) on the compression stroke. This mixture may be supplied from a carburetor, a single throttle-body fuel injector, or by individual fuel injectors mounted in the intake port of each cylinder. One combustion cycle involves two revolutions of the crankshaft and thus four strokes of the piston, referred to as the intake, compression, power, and exhaust strokes. Intake and exhaust valves control the flow of mixture and exhaust gases into and out of the cylinder, and an ignition system supplies a spark-inducing high voltage to the spark plug at the proper time in the cycle to initiate combustion. On the intake stroke, the intake valve opens and the descending piston draws a fresh combustible charge into the cylinder. During the compression stroke, the intake valve closes and the fuel-air mixture is compressed by the upward piston movement. The mixture is ignited by the spark plug, typically somewhat before TDC. The rapid **premixed homogeneous combustion** process causes a sharp increase in cylinder temperature and pressure that forces the piston down for the power stroke. Near **bottom dead center** (BDC) the exhaust valve opens and the cylinder pressure drops rapidly to near atmospheric. The piston then returns to TDC, expelling the

© 1999 by CRC Press LLC

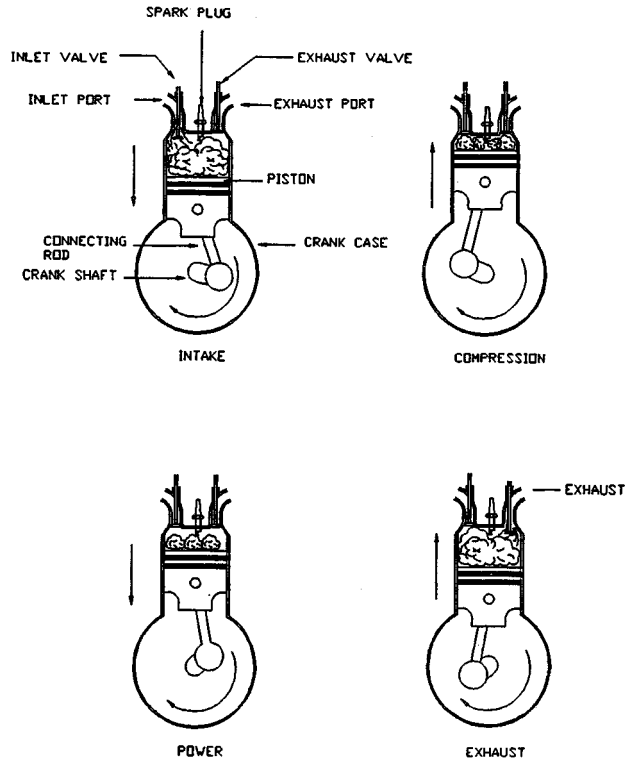

FIGURE 8.3.1 Schematic diagram of four-stroke SI engine.

exhaust products. At TDC, the exhaust valve closes and the intake valve opens to repeat the cycle again. Figure 8.3.2 is a cutaway drawing of a modern high-performance automotive SI engine. This is a fuel-injected normally aspirated aluminum alloy V-8 engine of 4.6 L displacement with dual overhead cams for each cylinder bank. Peak power output is 228 kw at 5800 rpm.

Two-Stroke SI Engine

The two-stroke SI engine completes a combustion cycle for every revolution of the crankshaft by essentially overlapping the power and exhaust functions in one downward stroke and the intake and compression processes in one upward stroke. A single-cylinder, crankcase-scavenged, two-stroke SI engine is illustrated schematically in Figure 8.3.3. The operation is as follows. On the upward stroke, the piston first covers the transfer port and then the exhaust port. Beyond this point the fresh charge is compressed and ignited near TDC. During the upward stroke, the negative pressure created in the crankcase below the piston draws in a fresh charge of fuel-air mixture through a one-way valve. On the downward power stroke, the mixture in the crankcase is pressurized. The piston uncovers the exhaust port and the high-pressure exhaust gases exit. Near BDC the transfer port is uncovered and the pressurized mixture flows from the crankcase into the cylinder and the cycle repeats. Since the crankcase is part of the induction system, it does not contain oil, and lubrication is accomplished by mixing oil with the fuel. With the cross-flow scavenging configuration illustrated in Figure 8.3.3, there will be a certain degree of mixing of the fresh charge with the combustion products remaining in the cylinder and some loss of fresh charge out the exhaust port.

Since two-stroke engines produce twice the power impulses of four-stroke engines for the same rpm, a two-stroke engine has a higher **power density** and is thus smaller and lighter than a four-stroke engine of equal output. The disadvantages of the two-stroke engine have historically been lower fuel efficiency and higher exhaust emissions because of the overlapping of the intake and exhaust processes and the

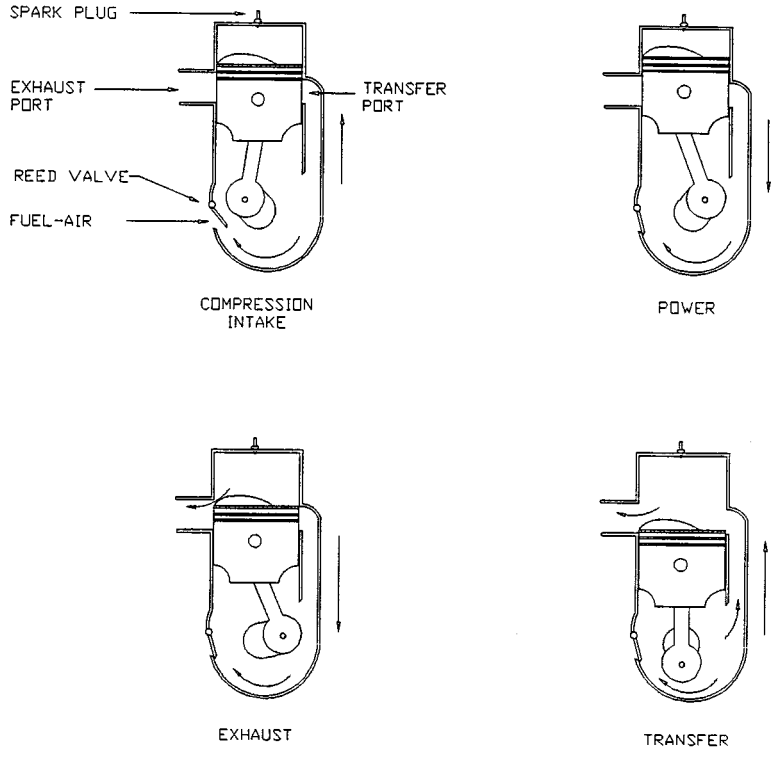

FIGURE 8.3.3 Schematic drawing of two-stroke SI engine.

© 1999 by CRC Press LLC

loss of some fresh intake mixture with the exhaust products. For this reason, two-stroke SI engines have largely been confined to small-displacement applications, such as motorcycles, outboard marine engines, and small equipment. Several manufacturers have addressed these shortcomings in recent years and have achieved significant improvements in two-stroke engine fuel economy and emissions (Blair, 1988). The Orbital OCP (Orbital Combustion Process) engine, illustrated in Figure 8.3.4, is a modern two-stroke engine that utilizes direct injection of fuel into the cylinder in conjunction with a high-turbulence combustion chamber design and an electronically controlled exhaust port scavenging control valve to achieve very favorable fuel economy and significantly reduced levels of NO_x and hydrocarbon emissions. This engine, in three and six cylinder versions, is currently being used in automotive and marine applications.

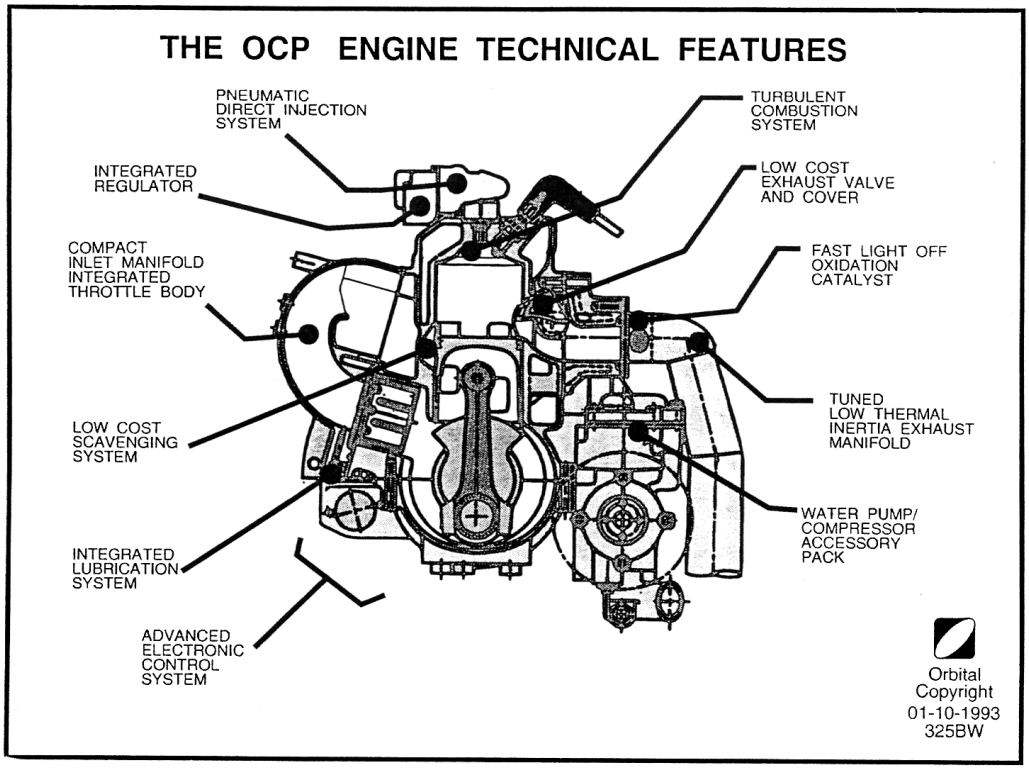

FIGURE 8.3.4 Orbital OCP two-stroke SI engine. (Courtesy of Orbital Engine Company.)

Compression Ignition Engine

The basic valve and piston motions are the same for the CI, or diesel, engine as discussed above for the SI engine. The CI engine relies on the high temperature and pressure of the cylinder air resulting from the compression process to cause **autoignition** of the fuel, which is injected directly into the combustion chamber of **direct injection (DI)** engines or into the prechamber of **indirect injection (IDI)** engines, when the piston approaches TDC on the compression stroke. The compression ratios are typically much higher for CI than for SI engines to achieve the high air temperatures required for autoignition, and the fuels used must have favorable autoignition qualities.

The time period between the start of fuel injection and the occurrence of autoignition is called the **ignition delay period**. Long ignition delay periods allow more time for fuel vaporization and fuel-air mixing, resulting in objectionable diesel knock when this larger premixed charge ignites. Combustion chambers and fuel injection systems must be designed to avoid extended ignition delay periods. Diesel

© 1999 by CRC Press LLC

engines may be classified as DI or IDI. In DI engines, the combustion chamber consists of a bowl formed in the top of the piston and the fuel is injected into this volume. The injector tip generally has from four to eight holes to form multiple spray cones. Two variations are illustrated in Figure 8.3.5. The quiescent chamber engine utilizes a large-diameter shallow bowl shape that produces low **swirl** and low turbulence of the air during compression. Fuel is injected at high pressure through a multihole nozzle, and mixing of the fuel and air relies primarily on the energy of the injected fuel to cause air entrainment in the spray cone and diffusion of vaporized fuel into the air. This system is suited to large slow-speed engines that are operated with significant excess air.

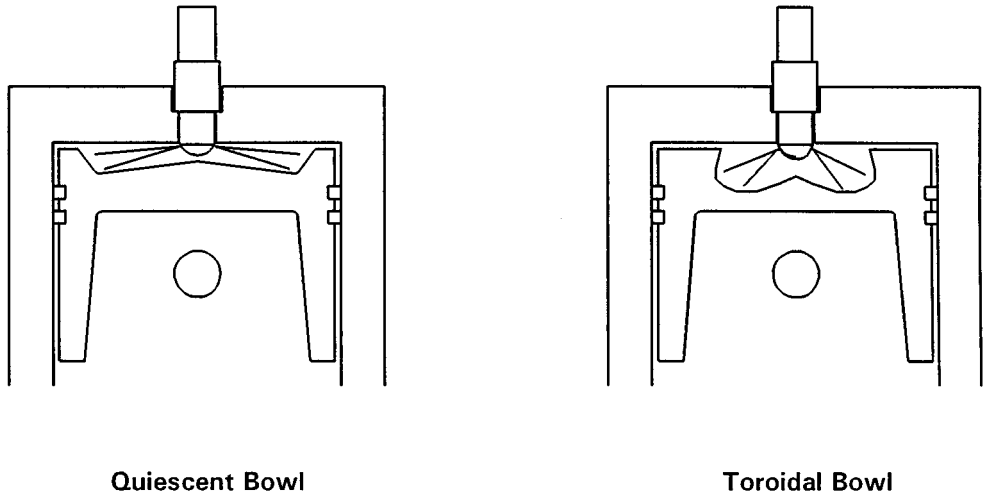

FIGURE 8.3.5 Examples of DI diesel combustion chamber design.

The toroidal bowl combustion chamber is used in conjunction with intake ports and/or valve shrouds designed to produce air swirl to enhance fuel-air mixing. The **swirl ratio** is defined by swirl ratio = swirl speed (rpm)/engine speed (rpm). The swirl velocity component is normal to the fuel spray direction and tends to promote mixing in the regions between the individual spray cones. This system makes better use of the available air and is utilized extensively in moderate-speed engines such as over-the-road truck engines. DI does not lend itself well to high-speed operation, as the time available for proper mixing and combustion is less. Diesel engines for passenger car applications are generally designed for higher-speed operation to produce higher specific output, and typically utilize IDI combustion systems, two of which are illustrated in Figure 8.3.6.

IDI systems make use of small prechambers incorporated in the cylinder head to promote rapid mixing of fuel and air and shorten the ignition delay period. Swirl chambers are designed to produce a strong vortex in the prechamber during compression. The fuel is sprayed into the chamber through a single-hole nozzle and the high vorticity promotes rapid mixing and short ignition delay periods. Precombustion chambers do not attempt to generate an orderly vortex motion within the chamber, but instead rely on a high level of turbulence, created by the rush of air into the chamber during compression, to promote mixing. Both types of prechambers generally include a lining of low-conductivity material (ceramic) to increase the surface temperature to promote further fuel evaporation. Prechambers can be used in small-displacement diesel engines to achieve operating speeds up to 5000 rpm. Disadvantages of the IDI system include poor cold-start characteristics due to high heat-transfer rates from the compressed air to the chamber wall that result from the high velocities and turbulence levels in the chamber. **Glow plugs** are often installed in each prechamber to heat the air to improve cold starting. Higher compression ratios are also used for IDI engines to further improve cold starting. The compression ratios, typically 18 to 24, are higher than the optimum for fuel efficiency (due to decreased mechanical efficiency), and IDI

© 1999 by CRC Press LLC

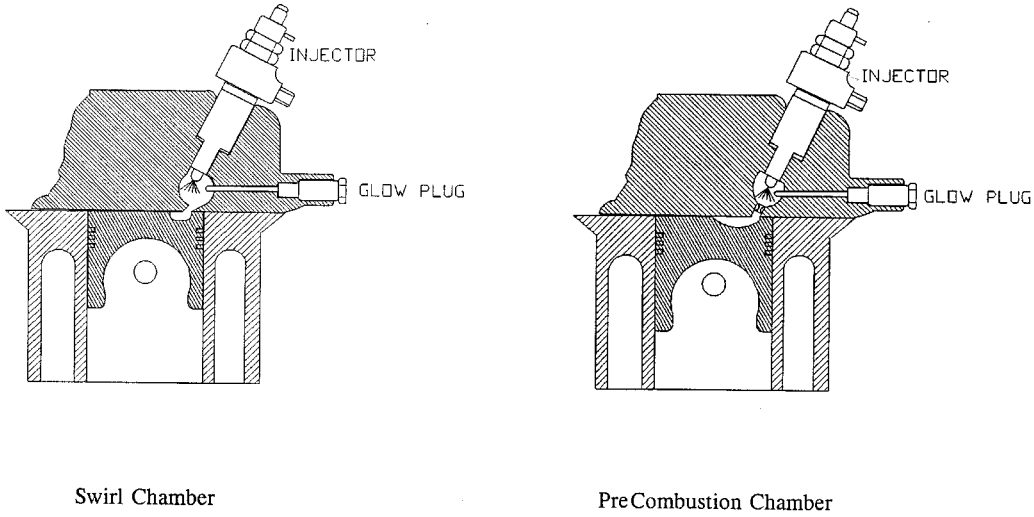

FIGURE 8.3.6 Two examples of IDI combustion chambers.

engines are typically less efficient than larger, slower, DI engines. The use of IDI is generally restricted to high-speed automotive engines, with displacements in the range of 0.3 to 0.8 liter per cylinder, and some degree of fuel economy is sacrificed in the interest of improved driveability.

CI engines are produced in both two-stroke and four-stroke versions. Since the fuel is injected directly into the combustion chamber of CI engines just prior to TDC, two-stroke CI engines do not suffer the same emission and efficiency shortcomings as do two-stroke SI engines. Hence, they are available in much larger displacements for high-power-requirement applications such as locomotive and ship propulsion and electric power generation systems. Two-stroke CI engines are generally of the DI type as the use of IDI in a two-stroke engine would lead to aggravated cold-start problems.

Air Standard Power Cycles

The actual operation of IC engines is idealized at a very basic level by the air standard power cycles (ideal thermodynamic models for converting heat into work on a continuous basis). The following simplifying assumptions are common to the air standard cycles: (1) the working substance is air, (2) the air is assumed to behave as an ideal gas with constant specific heats, (3) heat is added to the cycle from an external source, and (4) expansion and compression processes not involving heat transfer occur isentropically. The air standard cycles, while grossly oversimplified in terms of the complex processes occurring within actual engines, are nevertheless useful in understanding some fundamental principles of SI and CI engines. The simplified models also lend insight into important design parameters, e.g., **compression ratio**, that govern theoretical maximum cycle thermal efficiencies.

Constant-Volume Heat Addition — Ideal Otto Cycle

The theory of operation of the SI engine is idealized by the Otto cycle which assumes that heat is added to the system at constant volume. Constant-volume heat addition is approximated in the SI engine by virtue of the combustion process taking place rapidly when the piston is near TDC. A *P-V* diagram for the Otto cycle is illustrated in Figure 8.3.7. The cycle consists of the following processes: 1 → 2 isentropic compression, 2 → 3 constant-volume heat addition, 3 → 4 isentropic expansion, and 4 → 1 constant-volume heat rejection. The constant-volume heat rejection process is approximated in SI engines by the exhaust valve opening near BDC and the rapid blow down of exhaust gases.

Thermal efficiency for a power cycle is defined as the ratio of work output to heat input per cycle,

© 1999 by CRC Press LLC

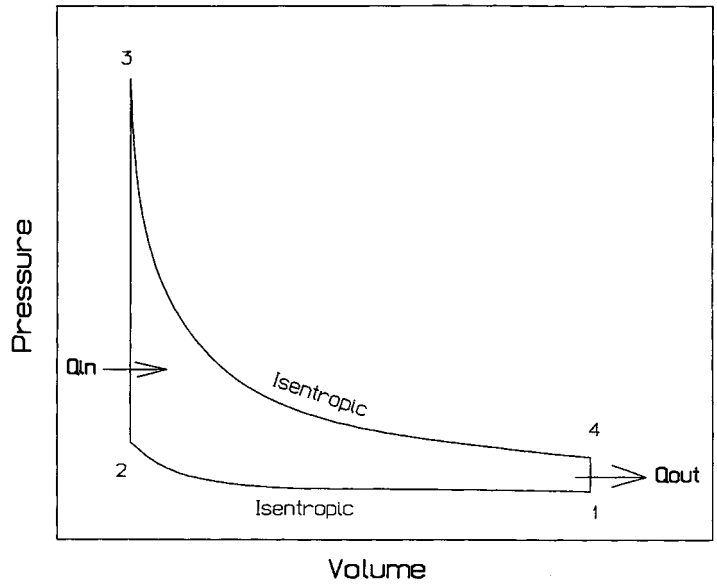

FIGURE 8.3.7 Schematic pressure-volume diagram for the ideal Otto cycle.

$$\eta = \frac{W_{\text{out}}}{Q_{\text{in}}} \tag{8.3.1}$$

For the Otto cycle, the basic efficiency expression can be manipulated into the form

$$\eta = 1 - \frac{1}{r^{\gamma - 1}} \tag{8.3.2}$$

where γ is the ratio of specific heats ($\gamma = C_p/C_v$) and r is the compression ratio, or ratio of the maximum to minimum cycle volumes ($r = V_1/V_2$). In actual IC engines, the minimum cycle volume is referred to as the **clearance volume** and the maximum cycle volume is the **cylinder volume**. The ideal Otto cycle efficiency for air, with $\gamma = 1.4$, is shown plotted in Figure 8.3.8. The theoretical efficiency of the constant volume heat addition cycle increases rapidly with compression ratio, up to about $r = 8$. Further increases in compression ratio bring moderate gains in efficiency. Compression ratios in practical SI engines are limited because of autoignition (knock) and high NO_x emission problems that accompany high compression ratios. Production SI automotive engines typically have compression ratios in the range 8 to 10, whereas high-performance normally aspirated racing engines may have compression ratios as high as 14, but they require the use of special fuels to avoid autoignition.

Constant-Pressure Heat Addition — Ideal Diesel Cycle

The air standard diesel cycle is the idealized cycle underlying the operation of CI or diesel engines. The diesel cycle, illustrated by the *P-V* diagram in Figure 8.3.9, consists of the following processes: 1 → 2 isentropic compression from the maximum to the minimum cycle volume, 2 → 3 constant-pressure heat addition during an accompanying increase in volume to V_3, 3 → 4 isentropic expansion to the maximum cycle volume, and 4 → 1 constant-volume heat rejection.

Actual diesel engines approximate constant-volume heat addition by injecting fuel for a finite duration which continues to burn and release heat at a rate that tends to maintain the pressure in the cylinder over a period of time during the expansion stroke. The efficiency of the ideal diesel cycle is given by

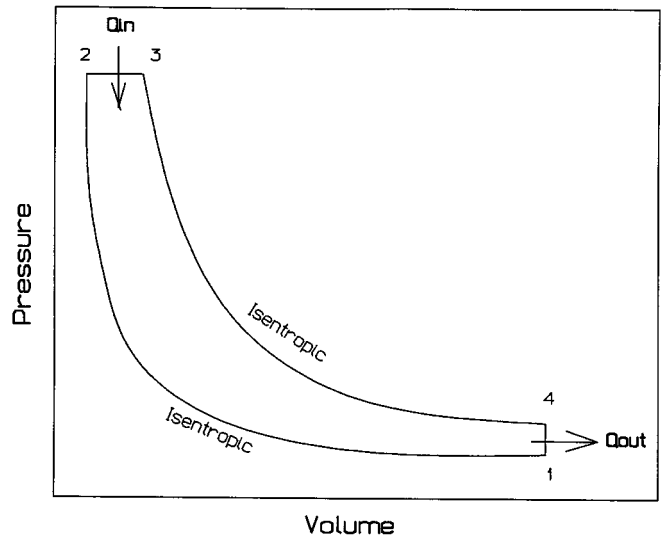

FIGURE 8.3.9 Schematic pressure-volume diagram of ideal diesel cycle.

$$\eta = 1 - \frac{1}{r^{\gamma-1}}\left[\frac{r_c^{\gamma} - 1}{\gamma\left(r_c - 1\right)}\right] \tag{8.3.3}$$

The efficiency of the ideal diesel cycle depends not only on the compression ratio, r, but also on the **cut-off ratio**, $r_c = V_3/V_2$, the ratio of the volume when heat addition ends to the volume when it begins. Equation (8.3.3) is shown plotted in Figure 8.3.10 for several values of r_c and for $\gamma = 1.4$. An r_c value of 1 is equivalent to constant-volume heat addition, i.e., the Otto cycle. The efficiency of the ideal Diesel cycle is less than the efficiency of the ideal Otto cycle for any given compression ratio and any value of the cut-off ratio greater than 1. The fact that CI engines, by design, operate at much higher compression ratios than SI engines (generally between 12 and 24) accounts for their typically higher operating efficiencies relative to SI engines.

Actual Cycles

IC engines do not operate on closed thermodynamic cycles, such as the air standard power cycles, but rather on open mechanical cycles, and heat addition occurs neither at constant volume or constant

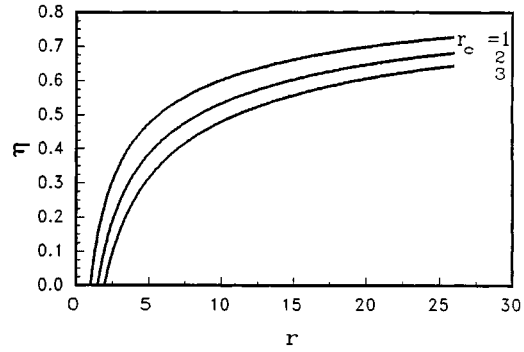

FIGURE 8.3.10 Efficiency of the ideal diesel cycle.

pressure. Figure 8.3.11 is a schematic representation of an **indicator diagram** (pressure-volume history) of a four-stroke IC engine; it could be either SI or CI. The pressure changes during the intake and exhaust strokes are exaggerated in the diagram. The **indicated work** performed per cycle can be calculated by taking the integral of *PdV* for the complete cycle. The **indicated mean effective pressure**, **imep**, is defined as the ratio of the net indicated work output to the **displacement volume**:

$$\text{imep} = \frac{\text{indicated work output per cycle}}{\text{displacement volume}} \tag{8.3.4}$$

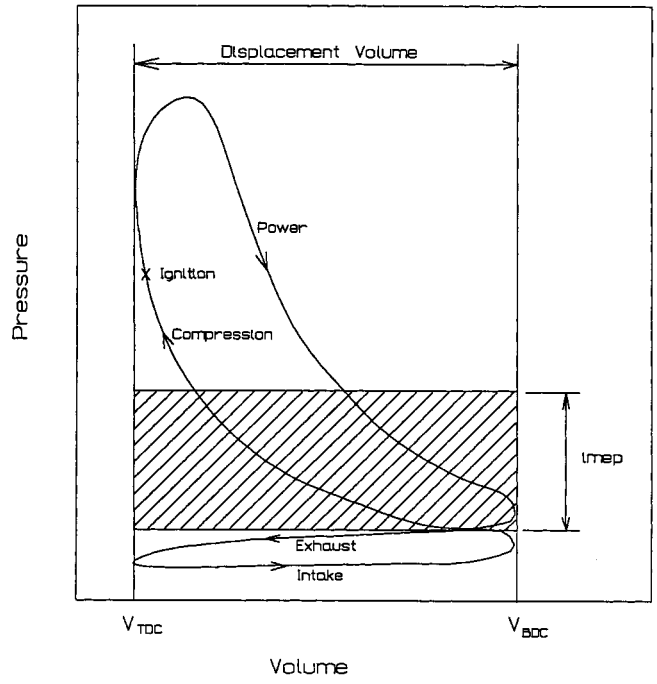

FIGURE 8.3.11 Schematic indicator diagram.

The shaded area in Figure 8.3.11 thus represents the net indicated work output per cycle. During intake and exhaust, the negative work performed represents pumping losses and acts to decrease the net work output of the engine. The magnitude of the pumping losses depends on the flow characteristics of the intake and exhaust systems including the valves, ports, manifolds, piping, mufflers, etc. The more

© 1999 by CRC Press LLC

restrictive these passages, the higher will be the pumping losses. SI engines control power output by throttling the intake air. Thus, under partial-load conditions, the pressure drop resulting from the air throttling represents a significant increase in pumping loss with a corresponding decrease in operating efficiency. SI engines are therefore less efficient at partial-load operation than at full load. The power level of CI engines, on the other hand, is controlled by varying the amount of fuel injected, as opposed to throttling the intake air, making them significantly more efficient than SI engines under partial-load conditions.

Brake work (or power) is the actual work (or power) produced at the output shaft of an engine, as measured by a dynamometer. The brake work will be less than the indicated work due to friction losses and any parasitic power requirements for oil pumps, water pumps, etc. The **brake mean effective pressure**, **bmep**, is defined as

$$\text{bmep} = \frac{\text{brake work output per cycle}}{\text{displacement volume}} \tag{8.3.5}$$

The mechanical efficiency can then be defined as

$$\eta_m = \frac{\text{brake work (power)}}{\text{indicated work (power)}} = \frac{\text{bmep}}{\text{imep}} \tag{8.3.6}$$

Engine thermal efficiency can be determined from the ratio of power output to rate of fuel energy input, or

$$\eta_t = \frac{\text{Power}}{m_f Q_c} \tag{8.3.7}$$

where m_f is the rate of fuel consumption per unit time and Q_c is the heat of combustion per unit mass of fuel. The thermal efficiency in Equation (8.3.7) could be either indicated or brake depending on the nature of the power used in the calculation. Uncertainty associated with variations of energy content of fuels may present a practical difficulty with determining engine thermal efficiency. In lieu of thermal efficiency, **brake specific fuel consumption** (**bsfc**), is often used as an efficiency index.

$$\text{bsfc} = \frac{\text{fuel consumption rate (kg/hr)}}{\text{brake power (kW)}} \tag{8.3.8}$$

The efficiency of engines operating on the same fuel may be directly compared by their bsfc.

Volumetric efficiency, η_v, is an important performance parameter for four-stroke engines defined as

$$\eta_v = \frac{m_{\text{actual}}}{m_d} \tag{8.3.9}$$

where m_{actual} is the mass of intake mixture per cycle at inlet conditions (pressure and temperature near the inlet port) and m_d is the mass of mixture contained in the displacement volume at inlet conditions. For SI engines the mixture mass includes both air and fuel; for CI engines only air is present during intake. With the intake mixture density determined at inlet conditions, η_v accounts for flow losses associated with the intake ports, valves, and cylinder. Sometimes, for convenience, the mixture density is taken at ambient conditions. In this case, η_v is called the overall volumetric efficiency and includes the flow performance of the entire intake system. Since a certain minimum amount of air is required for complete combustion of a given amount of fuel, it follows that the maximum power output of an engine

© 1999 by CRC Press LLC

is directly proportional to its air-flow capacity. Thus, while not affecting in any way the thermal efficiency of the engine, the volumetric efficiency directly affects the maximum power output for a given displacement, and thus can affect the efficiency of the overall system in which the engine is installed because of the effect on system size and weight. Volumetric efficiency is affected primarily by intake and exhaust valve geometry, valve lift and timing, intake port and manifold design, mixing of intake charge with residual exhaust gases, engine speed, ratio of inlet pressure to exhaust back pressure, and heat transfer to the intake mixture from warmer flow passages and combustion chamber surfaces. For further information on the fundamentals of IC engine design and operation see Taylor (1985), Ferguson (1986), Heywood (1988), and Stone (1993).

Combustion in IC Engines

Combustion in Spark Ignition Engines

Background. In SI engines, combustion of the fuel-air mixture is initiated by a spark generated between the electrodes of a spark plug. The intake and compression strokes are designed to prepare the mixture for combustion by completely vaporizing the fuel and heating the mixture to just below its autoignition temperature. This is one reason, in addition to controlling emissions, for the current practice of limiting the maximum compression ratio of SI engines to about 10:1. Near the end of compression, the mixture is well conditioned for combustion and the spark is discharged to initiate the combustion process. For best fuel economy, the combustion process must be completed as close as possible to TDC. This requires that the spark timing be controlled for varying operating speed and load conditions of the engine. Fuel metering and control, according to the engine load requirements, and with minimum variation from cylinder to cylinder and cycle to cycle, is essential for good fuel economy, power output, and emission control of the engine.

Both carburetors and fuel injection systems are used for fuel-metering control. Because of the superior control capabilities of fuel injection systems, they are nearly universally used today in production automotive applications. Carburetors are used for applications with less-stringent emission requirements, e.g., small engines for lawn and garden equipment. Figure 8.3.12 illustrates the effect of **fuel-air ratio** on the indicated performance of an SI engine. The **equivalence ratio** (γ) is defined by the ratio Fuel-Air_{actual}/Fuel-$Air_{stoichiometric}$. Rich mixtures have fuel-air ratios greater than stoichiometric ($\gamma > 1$) and lean mixtures have fuel-air ratios less than stoichiometric ($\gamma < 1$). Optimum fuel economy, coinciding with maximum thermal efficiency, is obtained at part throttle with a lean mixture as a result of the fact that the heat release from lean mixtures suffers minimal losses from dissociation and variation of specific heat effects when compared with stoichiometric and rich fuel-air ratios. Maximum power is obtained at full throttle with a slightly rich mixture, an indication of the full utilization of the air inside the cylinders. Idling, with a nearly closed throttle, requires a rich mixture because of the high percentage of exhaust gas residuals that remains in the cylinders. The fuel-air mixture requirement under transient operation, such as acceleration, requires a rich mixture to compensate for the reduced evaporation caused by the sudden opening of the throttle. Cold starting also requires a rich mixture to ensure the vaporization of sufficient amounts of the highly volatile components in the fuel to achieve proper ignition.

Normal Combustion Process. The combustion processes in SI engines can be divided into two categories, normal and abnormal. The normal combustion process occurs in three stages: initiation of combustion, flame propagation, and termination of combustion. Combustion normally starts across the spark plug gap when the spark is discharged. The fuel molecules in and around the spark discharge zone are ignited and a small amount of energy is released. The important criterion for the initial reaction to be self-sustaining is that the rate of heat release from the initial combustion be larger than the rate of heat transfer to the surroundings. The factors that play an important role in making the initial reaction self-sustaining, and thereby establishing a flame kernel, are the ignition energy level, the spark plug gap, the fuel-air ratio, the initial turbulence, and the condition of the spark plug electrodes.

© 1999 by CRC Press LLC

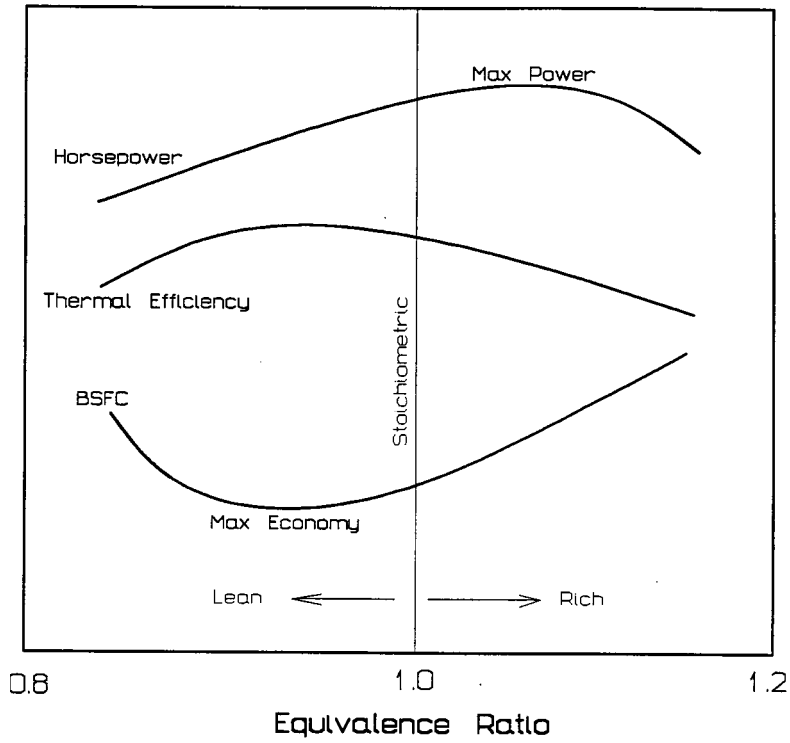

FIGURE 8.3.12 Effect of fuel-air mixture on indicated performance of an SI engine.

After a flame kernel is established, a thin spherical flame front advances from the spark plug region progressively into the unburned mixture zone. Flame propagation is supported and accelerated by two processes. First, the combined effect of the heat transfer from the high-temperature flame region and the bombardment by the active radicals from the flame front into the adjacent unburned zone raises the temperature and accelerates the rate of reactivity of the unburned mixture region directly adjacent to the flame front. This helps condition and prepare this zone for combustion. Second, the increase in the temperature and pressure of the burned gases behind the flame front will cause it to expand and progressively create thermal compression of the remaining unburned mixture ahead of the flame front. It is expected that the flame speed will be low at the start of combustion, reach a maximum at about half the flame travel, and decrease near the end of combustion. Overall, the flame speed is strongly influenced by the degree of turbulence in the combustion chamber, the shape of the combustion chamber, the mixture strength, the type of fuel, and the engine speed.

When the flame front approaches the walls of the combustion chamber, the high rate of heat transfer to the walls slows down the flame propagation and finally the combustion process terminates close to the walls because of surface quenching. This leaves a thin layer of unburned fuel close to the combustion chamber walls which shows up in the exhaust as unburned hydrocarbons.

Abnormal Combustion. Abnormal combustion may occur in SI engines associated with two combustion phenomena: **knock** and **surface ignition**. Knock occurs near the end of the combustion process if the end portion of the unburned mixture, which is being progressively subjected to thermal compression, autoignites prematurely before the flame front reaches it. As a result of the sudden energy release, a violent pressure wave propagates back and forth across the combustion chamber, causing the walls or other parts of the engine to vibrate, producing a sharp metallic noise called knock. If knock persists for a period of time, the high rate of heat transfer caused by the traveling high pressure and temperature wave may overheat the spark plug electrode or ignite carbon deposits that may be present in the

© 1999 by CRC Press LLC

combustion chamber, causing uncontrolled combustion and preignition. As a result, loss of power and serious engine damage may occur.

Knock is sensitive to factors that increase the temperature and pressure of the end portion of the unburned mixture, as well as to fuel composition and other time factors. Factors that increase the probability of knock include (1) increasing the temperature of the mixture by increasing the charge intake temperature, increasing the compression ratio, or turbo/supercharging; (2) Increasing the density of the mixture by turbo/supercharging or increasing the load; (3) advancing the spark timing; (4) increasing the time of exposure of the end portion of the unburned mixture to autoignition conditions by increasing the length of flame travel or decreasing the engine speed and turbulence; and (5) using low-octane fuel and/or maximum power fuel-air ratios. Engine design factors that affect knock in SI engines include the shape of the combustion chamber and the location of the spark plug and inlet and exhaust valves relative to the location of the end portion of the unburned mixture.

Surface ignition is the ignition of the unburned mixture by any source in the combustion chamber other than the normal spark. Such sources could include overheated exhaust valves or spark plug electrodes, glowing carbon deposits, or other hot spots. Surface ignition will create secondary flame fronts which cause high rates of pressure rise resulting in a low-pitched, thudding noise accompanied by engine roughness. Severe surface ignition, especially when it occurs before spark ignition, may cause serious structural and/or component damage to the engine.

Combustion in Compression Ignition Engines

Unlike the SI engine, in which the charge is prepared for combustion as a homogeneous mixture during the intake and compression strokes, fuel preparation for combustion in CI engines occurs in a very short period of time called the ignition delay period. During this period, the fuel injected into the high-temperature air near the end of the compression stroke undergoes two phases of transformation. A physical delay period, during which the fuel is vaporized, mixed with the air, and raised in temperature, is followed by a chemical delay period during which fuel cracking and decomposition occur which leads to autoignition and combustion of the fuel.

The combustion process is **heterogeneous** and involves two modes, usually identified as premixed combustion and diffusion combustion. Premixed combustion occurs early in the process when the fuel which has evaporated and mixed with air during the ignition delay period ignites. This mode is characterized by uncontrolled combustion and is the source of combustion noise since it is accompanied by a high rate of heat release which produces a high rate of pressure rise. When the premixed fuel-air mixture is depleted, diffusion combustion takes over, characterized by a lower rate of heat release and producing controlled combustion during the remainder of the process. Figure 8.3.13 depicts the different stages of the combustion process in CI engines.

The ignition delay period plays a key role in controlling the time duration of the two modes of combustion. Prolonging the ignition delay period, either through engine design factors or variations in operating conditions, will generate a larger portion of premixed fuel-air mixture and will thus tend to increase the premixed combustion mode duration and decrease the diffusion mode duration. This may lead to higher peak cylinder pressure and temperature which may improve thermal efficiency and reduce CO and **unburned hydrocarbon (UHC)** emissions at the expense of increased emissions of oxides of nitrogen ($\mathbf{NO_x}$). Large increases in the ignition delay period will cause high rates of pressure rise during the premixed combustion and may lead to objectionable diesel knock. Reducing the ignition delay period causes the premixed combustion duration to decrease while increasing the diffusion combustion duration. A large reduction in ignition delay may lead to loss of power, decrease in thermal efficiency, and possible deterioration of exhaust emissions. Several factors related to the fuel-air mixture temperature and density, engine speed, combustion chamber turbulence, injection pressure, rate of injection, and fuel composition influence the duration of the ignition delay period.

Knock in CI Engines. As the combustion process in CI engines is triggered by autoignition of the fuel injected during the ignition delay period, factors that prolong the ignition delay period will increase the

© 1999 by CRC Press LLC

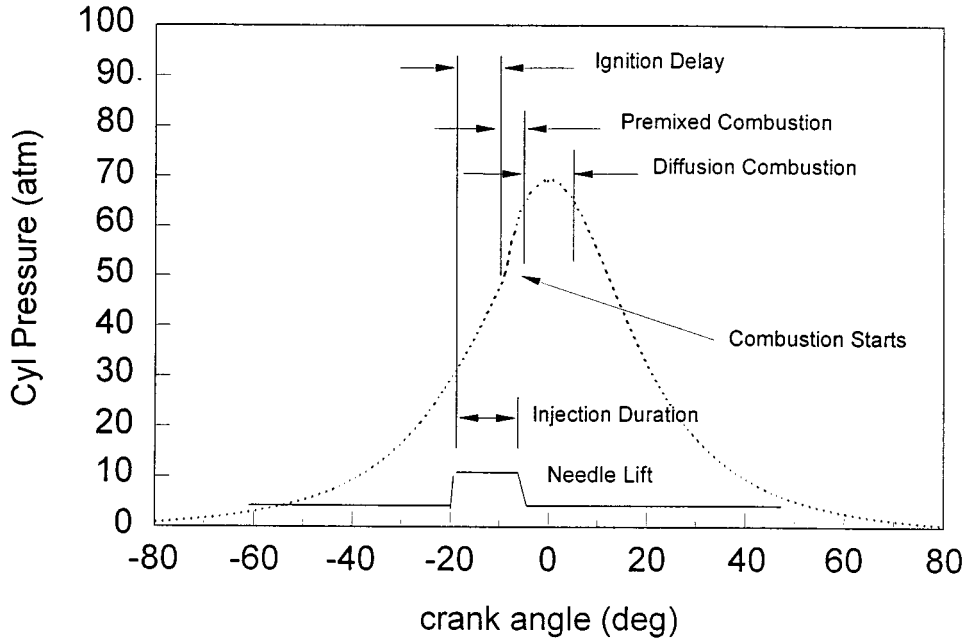

FIGURE 8.3.13 Combustion process in a CI engine.

premixed combustion duration causing very high rates of energy release and thus high rates of pressure rise. As a result, diesel knock may occur. The phenomenon is similar to knock in SI engines except that it occurs at the beginning of the combustion process rather than near the end, as observed in SI combustion. Factors that reduce the ignition delay period will reduce the possibility of knock in diesel engines. Among them are increasing the compression ratio, supercharging, increasing combustion chamber turbulence, increasing injection pressure, and using high-**cetane-number (CN)** fuel. For a more detailed discussion of the combustion process in IC engines, see Henein (1972), Lenz (1992), and Keating (1993).

Exhaust Emissions

Harmful Constituents

The products of combustion from IC engines contain several constituents that are considered hazardous to human health, including CO, UHCs NO_x, and **particulates** (from diesel engines). These emission products are discussed briefly below followed by a description of the principal schemes for their reduction.

Carbon Monoxide. CO is a colorless, odorless, and tasteless gas that is highly toxic to humans. Breathing air with a small volumetric concentration (0.3%) of CO in an enclosed space can cause death in a short period of time. CO results from the incomplete combustion of hydrocarbon fuels. One of the main sources of CO production in SI engines is the incomplete combustion of the rich fuel mixture that is present during idling and maximum power steady state conditions and during such transient conditions as cold starting, warm-up, and acceleration. Fuel maldistribution, poor condition of the ignition system, very lean combustion, and slow CO reaction kinetics also contribute to increased CO production in SI engines. CO production is not as significant in CI engines since these engines are always operated with significant excess air.

Unburned Hydrocarbons. When UHCs combine with NO_x (see below) in the presence of sunlight, ozone and photochemical oxidants form that can adversely affect human health. Certain UHCs are also

© 1999 by CRC Press LLC

considered to be carcinogenic. The principal cause of UHC in SI engines is incomplete combustion of the fuel-air charge, resulting in part from flame quenching of the combustion process at the combustion chamber walls, and engine misfiring. Additional sources in four-stroke engines may include fuel mixture trapped in crevices of the top ring land of the piston and outgassed fuel during the expansion (power) stroke that was absorbed into the lubricating oil film during intake. In two-stroke SI engines, the scavenging process often results in a portion of the fresh mixture exiting the exhaust port before it closes, resulting in large UHC emissions.

The presence of UHC in CI engines is related to the heterogeneous nature of the fuel-air mixture. Under certain conditions, fuel-air mixtures that lie outside the flammability limits at both the lean and rich extremes can exist in portions of the combustion chamber and escape combustion, thus contributing significantly to UHC in the exhaust. Fuel injected near the end of the combustion process, and fuel remaining in the nozzle **sac volume** at the end of injection, both contribute to UHC emission in CI engines. Engine variables that affect UHC emissions include the fuel-air ratio, intake air temperature, and cooling water temperature.

Oxides of Nitrogen. Nitric oxide (NO) is formed from the combination of nitrogen and oxygen present in the intake air under the high-temperature conditions that result from the combustion process. As the gas temperature drops during the expansion stroke, the reaction is frozen, and levels of NO persist in the exhaust products far in excess of the equilibrium level at the exhaust temperature. In the presence of additional oxygen in the air, some NO transforms to nitrogen dioxide (NO_2), a toxic gas. The NO and NO_2 combined are referred to as oxides of nitrogen or NO_x. The production of NO_x is in general aggravated by conditions that increase the peak combustion temperature. In SI engines the most important variables that affect NO_x production are the air/fuel ratio, spark timing, intake air temperature, and amount of residual combustion products remaining in the cylinder after exhaust. In CI engines, ignition delay, which affects the degree of premixed combustion, plays a key role in NO_x formation. A larger premixed combustion fraction will produce higher combustion temperatures and higher levels of NO_x.

Particulates. Particulates are a troublesome constituent in the exhaust from CI engines. Particulates are defined by the US Environmental Protection Agency (EPA) as any exhaust substance (other than water) that can be trapped on a filter at a temperature of 325 K or below. Particulates trapped on a filter may be classified as soot plus an organic fraction of hydrocarbons and their partial oxidation products. Soot consists of agglomerates of solid uncombusted carbon particles. Particulates are of concern because their small size permits inhalation and entrapment in the lung walls, making them potential lung carcinogens.

Soot is formed in CI engines under conditions of heavy load when the gas temperature is high and the concentration of oxygen is low. Smoke production is affected by such parameters as fuel CN, rate of fuel injection, inlet air temperature, and the presence of secondary injection.

Control of Emissions from IC Engines

Figure 8.3.14 depicts the relative concentrations of CO, NO_x, and UHC in the exhaust products of an SI engine as a function of the fuel-air mixture. Lean mixture combustion, which promotes good thermal efficiency, also results in low UHC and CO production but causes high levels of NO_x emission. Increasing the fuel/air ratio to reduce NO_x results in increased CO and UHC emission. Approaches to reduce total emissions fall under two categories; the first concentrates on engine design and fuel modifications and the second involves treatment of exhaust gases after leaving the engine. In SI engines, the first approach focuses on addressing engine variables and design modifications which improve in-cylinder mixing and combustion in an effort to reduce CO and UHC emissions. To reduce NO_x, attention is focused on factors that reduce peak combustion temperature and reduce the oxygen available in the flame front. Design and operating parameters that have been implemented or modified for decreased emissions include compression ratio reduction, increased coolant temperature, modification of the combustion chamber shape to minimize surface-to-volume ratio and increase turbulence, improvement of intake manifold design for better charge distribution, use of fuel injection instead of carburetors for better mixture control,

© 1999 by CRC Press LLC

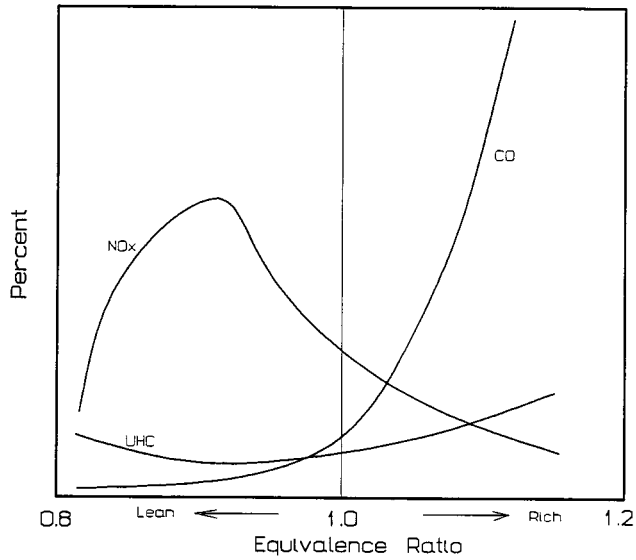

FIGURE 8.3.14 Emission levels from an SI engine vs. fuel-air mixture.

use of exhaust gas recirculation to reduce NO_x by lowering combustion temperatures, positive crankcase ventilation to reduce UHC, and increased aromatic content in gasoline.

Engine modifications that have been implemented to reduce emissions from CI engines include modifications to the combustion chamber shape to match the air swirl pattern and fuel spray pattern for better mixing and complete combustion, use of exhaust gas recirculation to limit NO_x production, use of higher injection pressure for better atomization to reduce soot and UHC, and the use of precise injection timing with electronic control.

In the second approach, several devices have been developed for after treatment of exhaust products. A thermal reactor may be used to oxidize UHC and CO. These typically consist of a well-insulated volume placed close to the exhaust manifold, with internal baffles to increase the gas residence time and an air pump to supply fresh oxygen for the oxidation reactions. Thermal reactors are ineffective for NO_x reduction and thus have limited application.

Catalytic converters utilize a catalyst, typically a noble metal such as platinum, rhodium, or palladium, deposited on a ceramic substrate to promote reactions at lower temperatures. Two types are in use, oxidation converters and reduction converters. Oxidation catalytic converters use the excess air available in lean mixtures (or supplied from an external air pump) to oxidize CO and UHC emissions. Reduction catalytic converters operate with low levels of oxygen to cause reduction of NO_x. Sometimes, dual catalytic converters are employed to treat all three pollutants with a reducing converter, to reduce NOx, placed upstream of an oxidation converter for treating CO and UHC. This arrangement requires that the engine be operated with a rich mixture which decreases fuel economy.

Three-way catalytic converters are a recent development that permits treatment of NO_x, CO, and UHC in a single device, thus reducing size and weight of the exhaust system. Proper operation of a three-way catalyst requires very nearly stoichiometric combustion. If the combustion is too lean, NO_x is not adequately reduced, and if it is too rich, UHC and CO are not adequately oxidized. There is a narrow band for equivalence ratio from about 0.999 to 1.007 within which conversion efficiency is 80% or better for all three pollutants (Kummer, 1980). Maintaining engine operation within this narrow mixture band requires a closed-loop fuel-metering system that utilizes an oxygen sensor placed in the exhaust system to monitor excess oxygen and control the fuel injection to maintain near stoichiometric combustion.

Reduction catalytic converters cannot be used with CI engines to reduce NO_x since they normally run lean with significant amounts of excess oxygen in the exhaust. Thus, engine design factors must be relied on to keep NO_x as low as possible. Soot emission may be reduced by after treatment using a

© 1999 by CRC Press LLC

device called a trap oxidizer. A trap oxidizer filters particulate matter from the exhaust stream and oxidizes it, usually with the aid of a catalyst for reducing the oxidation temperature. They have been used on small, high-speed automotive diesel engines, but their application to larger, slower-speed engines is limited because of the higher level of particulate production and the lower exhaust temperature. For additional information on emissions see Henein (1972), Obert (1973), and *SAE Surface Vehicle Emissions Standards Manual* (1993).

Fuels for SI and CI Engines

Background

The primary distinguishing factor between SI and CI engines is the fundamental difference in the combustion process. SI engines rely on homogeneous, premixed combustion, while CI engines are designed for heterogeneous combustion with a premixed combustion period followed by a diffusion combustion period. The differences in the combustion process call for quite different qualities in the fuels to achieve optimum performance.

By far the most common fuel for SI engines is gasoline, although other fuels can be used in special circumstances including alcohol, natural gas, and propane. Even such low-grade fuels as wood gas and coal gas have been used to fuel SI engines during wartime when conventional fuels were in short supply. Diesel fuel is the predominant fuel for CI engines, but they too can be designed to operate on a variety of other fuels, such as natural gas, bio-gas, and even coal slurries. This discussion is confined to gasoline and diesel fuel, both of which are distilled from crude oil.

Crude oil is composed of several thousand different hydrocarbon compounds, which upon heating are vaporized at different temperatures. In the distillation process, different "fractions" of the original crude are separated according to the temperatures at which they vaporize. The more volatile fraction, naphtha, is followed in order of increasing temperature of vaporization by fractions called distillate, gas oil, reduced crude, and residual oil. These fractions may be further subdivided into light, middle, and heavy classifications. Light virgin naphtha can be used directly as gasoline, although it has relatively poor antiknock quality. The heavier fractions can be chemically processed through coking and catalytic cracking to produce additional gasoline. Diesel fuel is derived from the light to heavy virgin gas oil fraction and from further chemical processing of reduced crude.

Gasoline

Gasoline fuels are mixtures of hydrocarbon compounds with boiling points in the range of 32 to 215°C. The two most important properties of gasoline for SI engine performance are volatility and octane rating. Adequate volatility is required to ensure complete vaporization, as required for homogeneous combustion, and to avoid cold-start problems. If the volatility is too high, however, vapor locking in the fuel delivery system may become a problem. Volatility may be specified by the distillation curve (the distillation temperatures at which various percentages of the original sample have evaporated). Higher-volatility fuels will be characterized by lower temperatures for given fixed percentages of evaporated sample, or conversely, by higher percentages evaporated at or below a given temperature. Producers generally vary the volatility of gasoline to suit the season, increasing the volatility in winter to improve cold-start characteristics and decreasing it in summer to reduce vapor locking.

The octane rating of a fuel is a measure of its resistance to autoignition or knocking; higher-octane fuels are less prone to autoignition. The octane rating system assigns the value of 100 to iso-octane (C_8H_{18}, a fuel that is highly resistant to knock) and the value 0 to *n*-heptane (C_7H_{16}, a fuel that is prone to knock). Two standardized methods are employed to determine the octane rating of fuel test samples, the research method and the motor method; see ASTM Standards Part 47 — Test Methods for Rating Motor, Diesel and Aviation Fuels (ASTM, 1995). Both methods involve testing the fuel in a special variable-compression-ratio engine (cooperative fuels research or CFR engine). The test engine is operated on the fuel sample and the compression ratio is gradually increased to obtain a standard knock intensity reading from a knock meter. The octane rating is obtained from the volumetric percentage of iso-octane

© 1999 by CRC Press LLC

in a blend of iso-octane and *n*-heptane that produces the same knock intensity at the same compression ratio. The principal differences between the research method and the motor method are the higher operating speed, higher mixture temperature, and greater spark advance employed in the motor method. Ratings obtained by the research method are referred to as the **research octane number** (RON), while those obtained with the motor method are called the motor octane number (MON). MON ratings are lower than RON ratings because of the more stringent conditions, i.e., higher thermal loading of the fuel. The octane rating commonly advertised on gasoline pumps is the **antiknock index**, $(R + M)/2$, which is the average of the values obtained by the two methods. The typical range of antiknock index for automotive gasolines currently available at the pump is 87 to 93. In general, higher compression SI engines require higher-octane fuels to avoid autoignition and to realize full engine performance potential from engines equipped with electronic control systems incorporating a knock sensor.

Straight-run gasoline (naphtha) has a poor octane rating on the order of 40 to 50 RON. Higher-octane fuels are created at the refinery by blending with higher-octane components produced through alkylation wherein light olefin gases are reacted with isobutane in the presence of a catalyst. Iso-octane, for example, is formed by reacting isobutane with butene. Aromatics with double carbon bonds shared between more than one ring, such as naphthalene and anthracene, serve to increase octane rating because the molecules are particularly difficult to break.

Additives are also used to increase octane ratings. In the past, a common octane booster added to automotive fuels was lead alkyls, either tetraethyl or tetramethyl lead. For environmental reasons, lead has been removed from automotive fuels in most countries. It is, however, still used in aviation fuel. Low-lead fuel has a concentration of about 0.5 g/L which boosts octane rating by about five points. The use of leaded fuel in an engine equipped with a catalytic converter to reduce exhaust emissions will rapidly deactivate the catalyst (typically a noble metal such as platinum or rhodium), quickly destroying the utility of the catalytic converter. Octane-boosting additives that are in current use include the oxygenators methanol, ethanol, and methyl tertiary butyl ether (MTBE).

RON values of special-purpose high-octane fuels for racing and aviation purposes can exceed 100 and are arrived at through an extrapolation procedure based on the knock-limited indicated mean effective pressure (klimep). The klimep is determined by increasing the engine intake pressure until knock occurs. The ratio of the klimep of the test fuel to that for iso-octane is used to extrapolate the octane rating above 100.

Diesel Fuels

Diesel fuels are blends of hydrocarbon compounds with boiling points in the range of 180 to 360°C. Properties that are of primary importance for CI fuels include the density, viscosity, cloud point, and ignition quality (CN). Diesel fuel exhibits a much wider range of variation in properties than does gasoline. The density of diesel fuels tends to vary according to the percentages of various fractions used in the blend. Fractions with higher distillation temperatures tend to increase the density. Variations in density result in variations in volumetric energy content and hence fuel economy, since fuel is sold by volume measure. Higher-density fuel will also result in increased soot emission. Viscosity is important to proper fuel pump lubrication. Low-viscosity fuel will tend to cause premature wear in injection pumps. Too high viscosity, on the other hand, may create flow problems in the fuel delivery system. Cloud point is the temperature at which a cloud of wax crystals begins to form in the fuel. This property is critical for cold-temperature operation since wax crystals will clog the filtration system. ASTM does not specify maximum cloud point temperatures, but rather recommends that cloud points be no more than 6°C above the tenth percentile minimum ambient temperature for the region for which the fuel is intended; see ASTM D 975 (ASTM 1995).

CN provides a measure of the autoignition quality of the fuel and is the most important property for CI engine fuels. The CN of a fuel sample is obtained through the use of a CI CFR engine in a manner analogous to the determination of octane rating. The test method for CN determination is specified in standard ASTM D 613. *n*-Cetane (same as hexadecane, $C_{16}H_{34}$) has good autoignition characteristics and is assigned the cetane value of 100. The bottom of the cetane scale was originally defined in terms

© 1999 by CRC Press LLC

of α-methyl naphthalene ($C_{11}H_{10}$) which has poor autoignition characteristics and was assigned the value 0. In 1962, for reasons of availability and storability, the poor-ignition-quality standard fuel used to establish the low end of the cetane scale was changed to heptamethylnonane (HMN), with an assigned CN of 15. The CN of a fuel sample is determined from the relative volumetric percentages of cetane and HMN in a mixture that exhibits the same ignition delay characteristics as the test sample using the relation

$$\text{CN} = \%\ n\text{-cetane} + 0.15\,(\%\ \text{HMN}) \tag{8.3.10}$$

ASTM standard D 976 (ASTM, 1995) provides the following empirical correlation for calculating the **cetane index** of straight petroleum distillate fuels (no additives) as an approximation to the measured CN:

$$\text{Cetane Index} = 454.74 - 1641.416D + 774.74D^2 - 0.554B + 97.803\,(\log B)^2 \tag{8.3.11}$$

where D = density at 15°C (g/mL) and B = mid-boiling temperature (°C).

ASTM standard D 975 (ASTM, 1995) establishes three classification grades for diesel fuels (No. 1-D, No. 2-D, and No. 4-D) and specifies minimum property standards for these grades. No. 1-D is a volatile distillate fuel for engines that must operate with frequent changes in speed and load. No. 2-D is a lower-volatility distillate fuel for industrial and heavy mobile service engines. No. 4-D is a heavy fuel oil for low- and medium-speed engines. Nos. 1-D and 2-D are principally transportation fuels, while No. 4-D is for stationary applications. The ASTM minimum CN for No. 1-D and No. 2-D is 40, and for No. 4-D the minimum is 30. Typical CNs for transportation fuels lie in the range 40 to 55. Use of a low-cetane fuel aggravates diesel knock because of the longer ignition delay period which creates a higher fraction of premixed combustion.

Antiknock quality (octane number) and ignition quality (CN) are opposing properties of distillate fuels. The CN increases with decreasing octane rating of various fuels. Gasoline, with good antiknock quality, has a CN of approximately 10, while a diesel fuel with a CN of 50 will have an octane number of about 20. Thus, gasoline is not a suitable fuel for CI engines because of its poor autoignition quality, and diesel fuel is inappropriate for use in SI engines as a result of its poor antiknock quality. For additional information on fuels for IC engines see Owen and Coley (1995) and the *SAE Fuels and Lubricants Standards Manual* (1993).

Intake Pressurization — Supercharging and Turbocharging

Backround

Pressurizing the intake air (or mixture) by means of a compressor may be used to boost the specific power output of both SI and CI engines. Supercharging generally refers to the use of compressors that are mechanically driven from the engine crankshaft, while turbocharging refers to compressors powered by a turbine which extracts energy from the exhaust stream. Increasing the intake pressure increases the density and hence the mass flow rate of the intake mixture, allowing an increase in the fueling rate, thereby producing additional power. The mere process of increasing the cylinder pressure results in increased work output per cycle, as illustrated in the *P-V* diagram in Figure 8.3.15 which compares supercharged and naturally aspirated, air standard Otto cycles having the same compression ratio. The work done for the compressed intake cycle (Area 1,2,3,4,1 and Area 5,6,7,1,5) is greater than that for the naturally aspirated cycle (Area 1′,2′,3′,4′,1′) due to the boost of the intake pressure. Positive-displacement superchargers are capable of producing higher boost pressures than turbochargers, which are nearly always centrifugal-type fans. From a practical standpoint, the maximum useful boost pressure from either system is limited by the onset of autoignition in SI engines, and by the permissible mechanical and thermal stresses in CI engines.

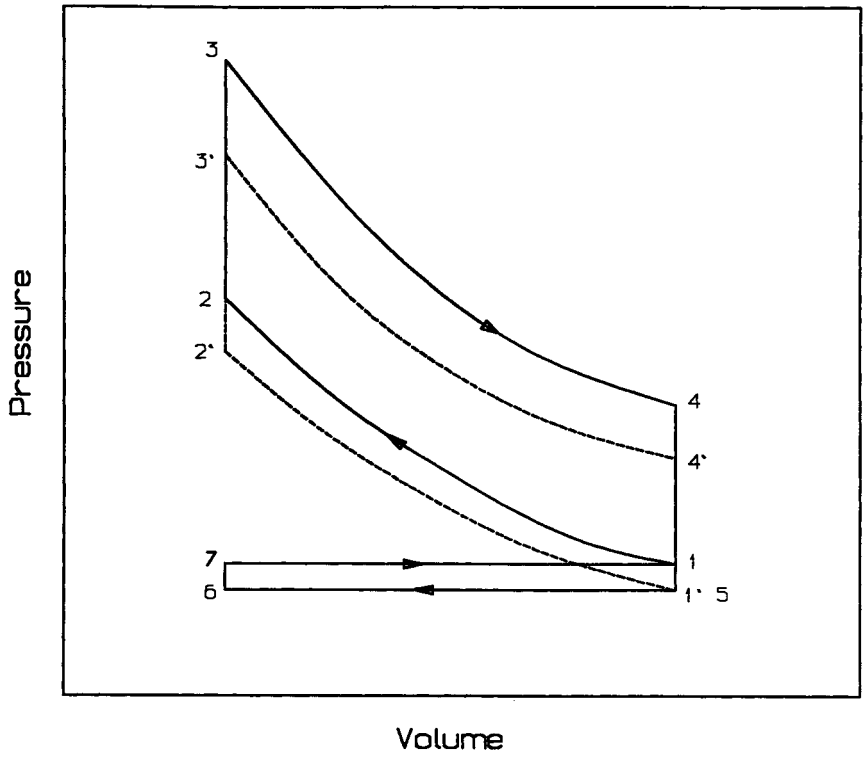

FIGURE 8.3.15 Comparison of supercharged and naturally aspirated Otto cycle.

Supercharging

The principal applications of supercharging of SI engines are in high-output drag-racing engines and in large aircraft piston engines to provide high specific output at takeoff and to improve power output at high altitudes. For diesel applications, supercharging is used mainly in marine and land-transportation applications. It is common to use either supercharging or turbocharging to improve the scavenging process in two-stroke diesel engines. Figure 8.3.16 is a schematic of an engine with a mechanically driven supercharger. Superchargers may be belt, chain, or gear driven from the engine crankshaft.

Two types of superchargers are in use: the positive displacement type (Roots blower) and the centrifugal type. Roots blowers may be classified as: (1) straight double lobe, (2) straight triple lobe, and (3) helix triple lobe (twisted 60%). The helix-triple-lobe-type runs quieter than the others and is generally recommended, especially for diesel engines operating under high torque at various speed conditions. The centrifugal-type, because of its high capacity and small weight and size, is best suited for applications where power and volumetric efficiency improvement are required at high engine speed, e.g., with aircraft engines. A centrifugal blower will also survive a backfire more readily than a Roots blower in SI applications. Since superchargers are directly driven from the engine output shaft, there is no inherent lag in the rate of pressure increase with engine speed, as is typically the case with turbochargers.

Turbocharging

Turbochargers utilize a centrifugal compressor that is directly connected to a turbine which extracts energy from the exhaust gases of the engine and converts it to the shaft work necessary to drive the compressor. Turbocharging is widely used to increase power output in automotive and truck applications of four-stroke SI and CI engines and to improve scavenging of two-stroke CI engines.

There are three methods of turbocharging: the constant-pressure, the pulse, and the pulse converter methods. In the constant-pressure method, as illustrated in Figure 8.3.17, the exhaust pressure is main-

© 1999 by CRC Press LLC

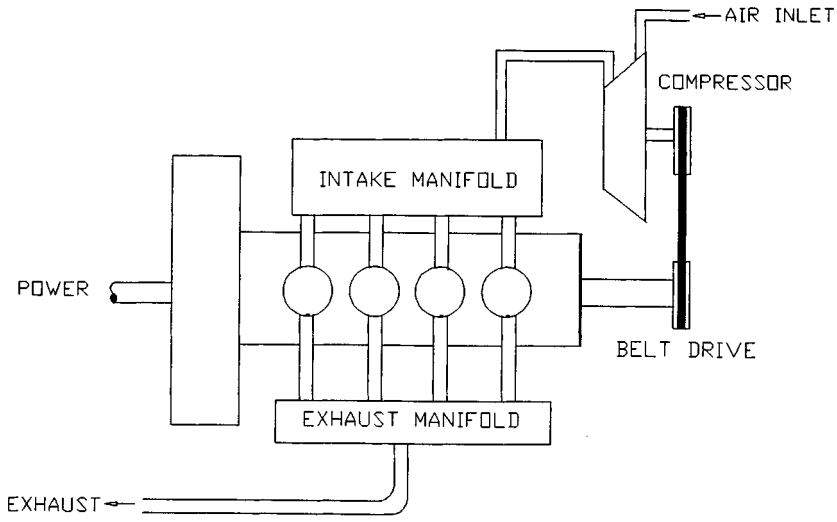

FIGURE 8.3.16 Schematic diagram of supercharged engine.

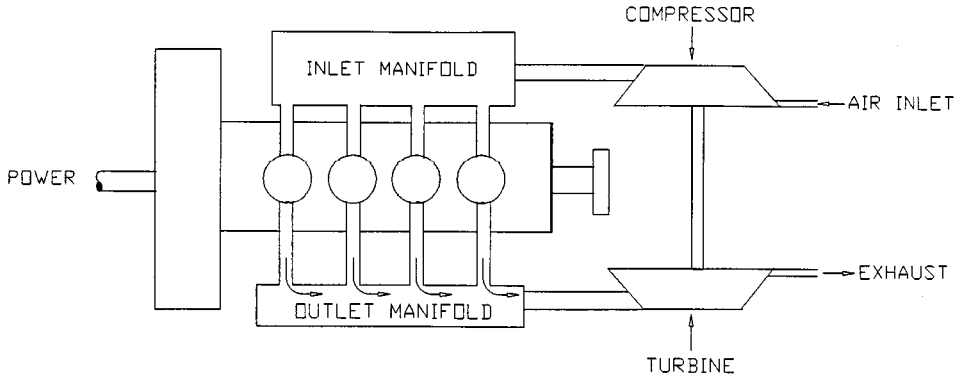

FIGURE 8.3.17 Schematic diagram of a constant-pressure turbocharger.

tained at a nearly constant level above atmospheric. To accomplish this, the exhaust manifold must be large enough to damp out the pressure fluctuations caused by the unsteady flow characteristic of the engine exhaust process. In this method, the turbine operates efficiently under steady-flow conditions; however, some engine power is lost because of the increased backpressure in the exhaust manifold.

The pulse turbocharger, as illustrated in Figure 8.3.18, utilizes the kinetic energy generated by the exhaust blow-down process in each cylinder. This is accomplished by using small exhaust lines grouped together in a common manifold to receive the exhaust from the cylinders which are blowing down sequentially. In this method, the pressure at the turbine inlet tends to fluctuate, which is not conducive to good turbine efficiency. This is offset to a large degree, however, by improved engine performance as a result of the lower exhaust backpressure relative to the constant-pressure method. The pulse converter method represents a compromise between the previous two techniques. In principle, this is accomplished by converting the kinetic energy in the blow-down process into a pressure rise at the turbine by utilizing one or more diffusers. Details of the different methods of turbocharging may be found in Watson and Janota (1982).

Recent advances in turbocharging technology have focused mainly on (1) improvement of the turbine transient response (turbo-lag), (2) improvement of the torque-speed characteristics of the engine, and (3) increasing the power output by increasing the boost pressure and using charge cooling (intercooling).

© 1999 by CRC Press LLC

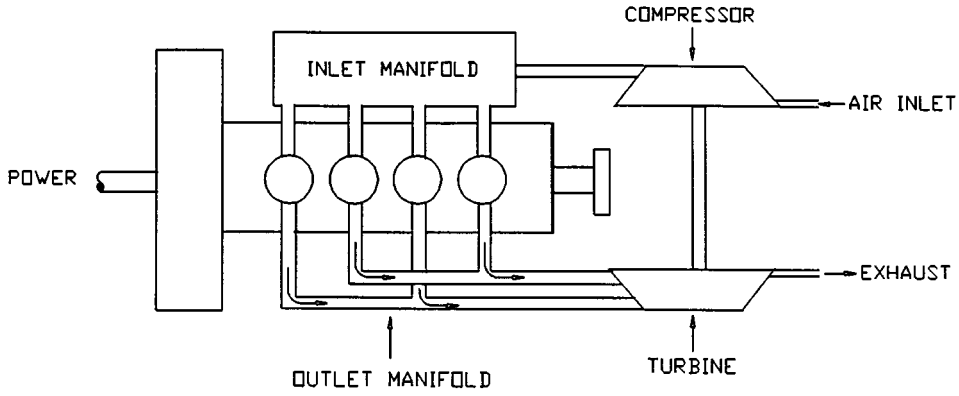

FIGURE 8.3.18 Schematic diagram of a pulse turbocharger.

The use of ceramic materials in fabricating turbine rotors improves the turbine transient response since they are lighter in weight and have less rotational inertia. Ceramic rotors also have greater thermal operating range because of their lower thermal expansion. The use of variable-geometry turbochargers can improve the low-speed torque characteristics of the engine and help reduce the transient response time. This is due to the ability of the variable-geometry turbocharger to change its internal geometry to accommodate low flow rates at low engine speeds and higher-volume flow rates at high engine speeds. However, since the geometry of the turbine rotor remains unchanged while the internal geometry varies, the turbine efficiency will be reduced for all internal geometries other than the optimum design geometry. In response to increased demand for diesel engines with high boost pressure and with size constraints, advances in the aerothermodynamics of axial/radial flow and of two-stage turbochargers, and also in the design of compressor and turbine blades, have allowed high boost pressure at improved overall turbocharger efficiency.

Charge cooling by means of a heat exchanger (intercooler) between the compressor and the intake ports is effective in reducing NO_x emissions and improving the power output of turbocharged diesel engines and in reducing the probability of knock in SI engines. There are two types of charge cooling in use, air-to-air and air-to-water. Air-to-water cooling is used in marine applications, where a source of cool water is available, while air-to-air intercoolers are used for automotive and truck applications.

Defining Terms

Antiknock index: The average of the two octane numbers obtained by the research method and the motor method.

Autoignition: The ability of a fuel-air mixture to spontaneously ignite under conditions of high temperature and pressure.

Bottom dead center (BDC): Piston located at its lowest position in the cylinder. Cylinder volume is maximum at BDC.

Brake mean effective pressure (bmep): Ratio of brake work output per cycle to the displacement volume.

Brake specific fuel consumption (bsfc): The ratio of fuel consumption rate in kg/hr to the engine output in kw.

Brake work: Work produced at the output shaft of an IC engine as measured by a dynamometer.

Cetane index: An approximation to the measured cetane number determined from an empirical relationship specified in ASTM D 976.

Cetane number: A measure of the autoignition quality of a fuel important for proper performance of CI engines determined experimentally through use of a CI CFR test engine.

Clearance volume: Combustion chamber volume remaining above the piston at TDC.

© 1999 by CRC Press LLC

Compression ignition (CI) engine: Air alone is compressed in the cylinder and fuel is injected near TDC. Combustion results from autoignition of the fuel-air mixture due to the high temperature of the air.

Compression ratio: The ratio of the cylinder volume at BDC to the volume at TDC.

Cut-off ratio: Ratio of cylinder volume at the end of heat addition to the volume at the start of heat addition in the ideal diesel cycle.

Cylinder volume: Volume above piston at BDC. Equals displacement volume plus clearance volume.

Direct injection (DI): Method of fuel injection in low- and medium-speed CI engines wherein fuel is injected into the main combustion chamber which is formed by a bowl in the top of the piston.

Displacement volume: Difference in cylinder volume between TDC and BDC.

Equivalence ratio: Actual fuel-air ratio divided by stoichiometric fuel-air ratio.

Four-stroke engine: Entire cycle completed in two revolutions of the crankshaft and four strokes of the piston.

Fuel-air ratio: Ratio of mass of fuel to mass of air in the cylinder prior to combustion.

Glow plug: Electric heater installed in prechamber of an IDI diesel engine to aid cold starting.

Heterogeneous combustion: Refers to the mixture of liquid fuel droplets and evaporated fuel vapor and air mixture that is present in CI engine combustion chambers prior to ignition.

Ignition delay period: Period between start of injection and onset of autoignition in a CI engine.

Indicated mean effective pressure (imep): Ratio of net indicated work output of an IC engine to the displacement volume.

Indicated work: Work output of an IC engine cycle determined by an area calculation from an indicator diagram.

Indicator diagram: Pressure-volume trace for an IC engine cycle. Area enclosed by diagram represents work.

Indirect injection (IDI): Method of fuel injection used in high-speed CI engines wherein the fuel is injected into a precombustion chamber to promote fuel-air mixing and reduce ignition delay.

Knock: In SI engines: the noise that accompanies autoignition of the end portion of the uncombusted mixture prior to the arrival of the flame front. In CI engines: The noise that accompanies autoignition of large premixed fractions that are generated during prolonged ignition delay periods. Knock is detrimental to either type of engine.

NO_x: Harmful oxides of nitrogen (NO and NO_2) appearing in the exhaust products of IC engines.

Octane number: Antiknock rating for fuels important for prevention of autoignition in SI engines.

Particulates: Any exhaust substance, other than water, that can be collected on a filter. Harmful exhaust product from CI engines.

Power density: Power produced per unit of engine mass.

Premixed homogeneous combustion: Fuel and air are mixed in an appropriate combustible ratio prior to ignition process. This is the combustion mode for SI engines and for the initial combustion phase in CI engines.

Sac volume: Volume of nozzles below the needle of a diesel fuel injector that provides a source of UHC emissions in CI engines.

Scavenging: The process of expelling exhaust gases and filling the cylinder with fresh charge in two-stroke engines. This is often accomplished in SI engines by pressurizing the fresh mixture in the crankcase volume beneath the piston and in CI engines by using a supercharger or turbocharger.

Spark ignition (SI) engine: Homogeneous charge of air-fuel mixture is compressed and ignited by a spark.

Stroke: Length of piston movement from TDC to BDC, equal to twice the crankshaft throw.

Supercharging: Pressurizing the intake of an IC engine using a compressor that is mechanically driven from the crankshaft.

Surface ignition: A source of autoignition in SI engines caused by surface hot spots.

Swirl: Circular in-cylinder air motion designed into CI engines to promote fuel-air mixing.

Swirl ratio: Ratio of rotational speed of in-cylinder air (rpm) to engine speed (rpm).

© 1999 by CRC Press LLC

Top dead center (TDC): Piston located at its uppermost position in the cylinder. Cylinder volume (above the piston) is minimum at TDC.

Turbocharging: Pressurizing the intake of an IC engine with a compressor that is driven by a turbine which extracts energy from the exhaust gas stream.

Two-stroke engine: Entire cycle completed in one revolution of the crankshaft and two strokes of the piston.

Unburned hydrocarbons (UHC): Harmful emission product from IC engines consisting of hydrocarbon compounds that remain uncombusted.

Volumetric efficiency: Ratio of the actual mass of air intake per cycle to the displacement volume mass determined at inlet temperature and pressure.

8.4 Hydraulic Turbines

Roger E. A. Arndt

Introduction

A hydraulic turbine is a mechanical device that converts the potential energy associated with a difference in water elevation **(head)** into useful work. Modern hydraulic turbines are the result of many years of gradual development. Economic incentives have resulted in the development of very large units (exceeding 800 mW in capacity) with efficiencies that are sometimes in excess of 95%.

The emphasis on the design and manufacture of very large turbines is shifting to the production of smaller units, especially in developed nations, where much of the potential for developing large-baseload plants has been realized. At the same time, the escalation in the cost of energy has made many smaller sites economically feasible and has greatly expanded the market for smaller turbines. The increased value of energy also justifies the cost of refurbishment and increasing the capacity of older facilities. Thus, a new market area is developing for updating older turbines with modern replacement **runners** having higher efficiency and greater capacity.

General Description

Typical Hydropower Installation

As shown schematically in Figure 8.4.1, the hydraulic components of a hydropower installation consist of an intake, penstock, guide vanes or distributor, turbine, and **draft tube**. Trash racks are commonly provided to prevent ingestion of debris into the turbine. Intakes usually require some type of shape transition to match the passageway to the turbine and also incorporate a gate or some other means of stopping the flow in case of an emergency or for turbine maintenance. Some types of turbines are set in an open flume; others are attached to a closed-conduit penstock.

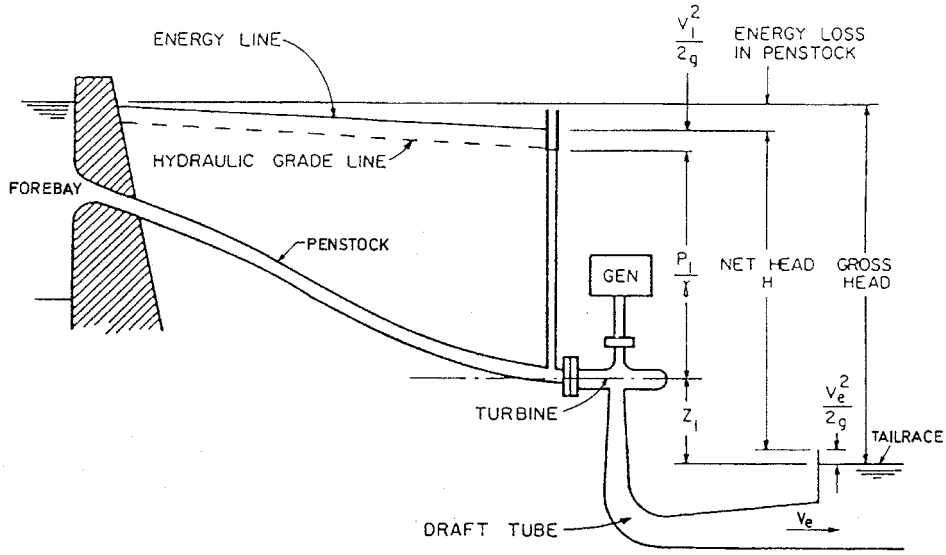

FIGURE 8.4.1 Schematic of a hydropower installation.

© 1999 by CRC Press LLC

Turbine Classification

There are two types of turbines, denoted as impulse and reaction. In an impulse turbine, the available head is converted to kinetic energy before entering the **runner**; the power available is extracted from the flow at approximately atmospheric pressure. In a reaction turbine, the runner is completely submerged and both the pressure and the velocity decrease from inlet to outlet. The velocity head in the inlet to the turbine runner is typically less than 50% of the total head available.

Impulse Turbines. Modern impulse units are generally of the Pelton type and are restricted to relatively high-head applications (Figure 8.4.2). One or more jets of water impinge on a wheel containing many curved buckets. The jet stream is directed inward, sideways, and outward, thereby producing a force on the bucket, which in turn results in a torque on the shaft. All kinetic energy leaving the runner is "lost." A draft tube is generally not used since the runner operates under approximately atmospheric pressure and the head represented by the elevation of the unit above tailwater cannot be utilized.* Since this is a high-head device, this loss in available head is relatively unimportant. As will be shown later, the Pelton wheel is a low-**specific-speed** device. Specific speed can be increased by the addition of extra nozzles, the specific speed increasing by the square root of the number of nozzles. Specific speed can also be increased by a change in the manner of inflow and outflow. Special designs such as the Turgo or cross-flow turbines are examples of relatively high specific speed impulse units (Arndt, 1991).

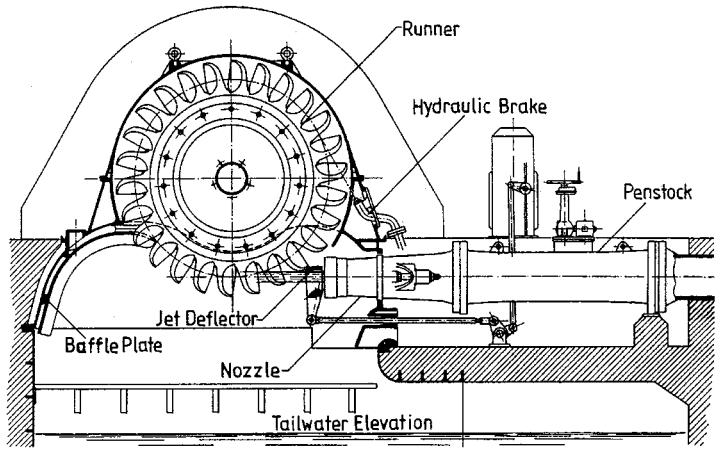

FIGURE 8.4.2 Cross section of a single wheel, single jet Pelton turbine. This is the third-highest-head pelton turbine in the world, H = 1447 m, n = 500 rpm, P = 35.2 MW, $N_s \sim 0.038$. (Courtesy of Vevey Charmilles Engineering Works, Adapted from J. Raabe, *Hydro Power: The Design, Use, and Function of Hydromechanical, Hydraulic, and Electrical Equipment*, VDI Verlag, Dusseldorf, Germany.)

Most Pelton wheels are mounted on a horizontal axis, although newer vertical-axis units have been developed. Because of physical constraints on orderly outflow from the unit, the maximum number of nozzles is generally limited to six or fewer. While the power of a reaction turbine is controlled by the **wicket gates**, the power of the Pelton wheel is controlled by varying the nozzle discharge by means of an automatically adjusted needle, as illustrated in Figure 8.4.2. Jet deflectors, or auxiliary nozzles are provided for emergency unloading of the wheel. Additional power can be obtained by connecting two wheels to a single generator or by using multiple nozzles. Since the needle valve can throttle the flow while maintaining essentially constant jet velocity, the relative velocities at entrance and exit remain unchanged, producing nearly constant efficiency over a wide range of power output.

* In principle, a draft tube could be used, which requires the runner to operate in air under reduced pressure. Attempts at operating an impulse turbine with a draft tube have not met with much success.

© 1999 by CRC Press LLC

Reaction Turbines. Reaction turbines are classified according to the variation in flow direction through the runner. In radial- and mixed-flow runners, the flow exits at a radius different than from the radius at the inlet. If the flow enters the runner with only radial and tangential components, it is a radial-flow machine. The flow enters a mixed-flow runner with both radial and axial components. Francis turbines are of the radial- and mixed-flow types, depending on the design specific speed. A Francis turbine is illustrated in Figure 8.4.3.

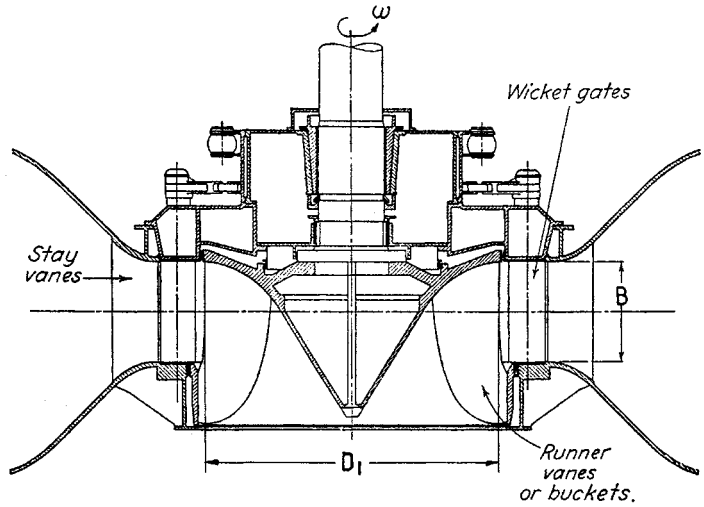

FIGURE 8.4.3 Francis turbine, $N_s \sim 0.66$. (Adapted from J.W. Daily, in *Engineering Hydraulics*, H. Rouse, Ed., New York, 1950. With permission.)

Axial-flow propeller turbines are generally either of the fixed-blade or Kaplan (adjustable-blade) variety. The "classical" propeller turbine, illustrated in Figure 8.4.4, is a vertical-axis machine with a scroll case and a radial wicket gate configuration that is very similar to the flow inlet for a Francis turbine. The flow enters radially inward and makes a right-angle turn before entering the runner in an axial direction. The Kaplan turbine has both adjustable runner blades and adjustable wicket gates. The control system is designed so that the variation in blade angle is coupled with the wicket gate setting in a manner which achieves best overall efficiency over a wide range of flow rates.

Some modern designs take full advantage of the axial-flow runner; these include the tube, bulb, and Straflo types illustrated in Figure 8.4.5. The flow enters and exits the turbine with minor changes in direction. A wide variation in civil works design is also permissible. The tubular-type can be fixed propeller, semi-Kaplan, or fully adjustable. An externally mounted generator is driven by a shaft which extends through the flow passage either upstream or downstream of the runner. The bulb turbine was originally designed as a high-output, low-head unit. In large units, the generator is housed within the bulb and is driven by a variable-pitch propeller at the trailing end of the bulb. Pit turbines are similar in principle to bulb turbines, except that the generator is not enclosed in a fully submerged compartment (the bulb). Instead, the generator is in a compartment that extends above water level. This improves access to the generator for maintenance.

Principles of Operation

Power Available, Efficiency

The power that can be developed by a turbine is a function of both the head and flow available:

$$P = \eta \rho g Q H \tag{8.4.1}$$

© 1999 by CRC Press LLC

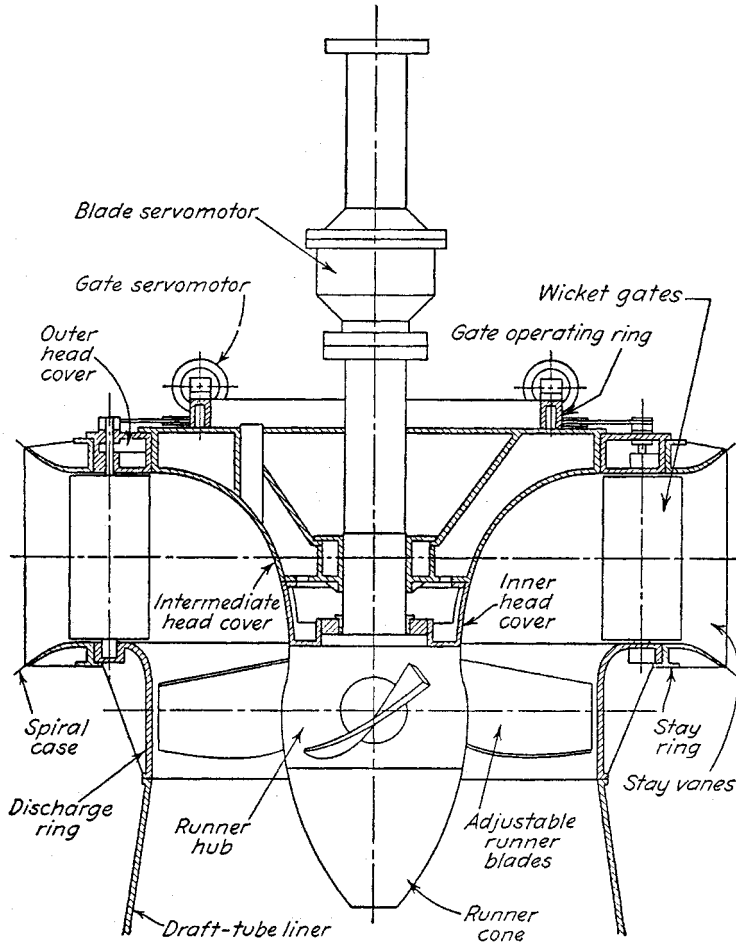

FIGURE 8.4.4 Smith-Kaplan axial flow turbine with adjustable-pitch runner blades $N_s \sim 2.0$. (From J.W. Daily, in *Engineering Hydraulics*, H. Rouse, Ed., New York, 1950. With permission.)

where η is the turbine efficiency, ρ is the density off water (kg/m^3), g is the acceleration due to gravity (m/sec^2), Q is the flow rate (m^3/sec), and H is the *net head* in meters. Net head is defined as the difference between the total head at the inlet to the turbine and the total head at the tailrace as illustrated in Figure 8.4.1. Different definitions of net head are used in practice, which depend on the value of the exit velocity head, $V_e^2/2g$, used in the calculation. The International Electrotechnical Test Code uses the velocity head at the draft tube exit.

The efficiency depends on the actual head and flow utilized by the turbine runner, flow losses in the draft tube, and the frictional resistance of mechanical components.

Similitude and Scaling Formulae

Under a given head, a turbine can operate at various combinations of speed and flow depending on the inlet settings. For reaction turbines, the flow into the turbine is controlled by the wicket gate angle, α. The flow is typically controlled by the nozzle opening in impulse units. Turbine performance can be described in terms of nondimensional variables:

© 1999 by CRC Press LLC

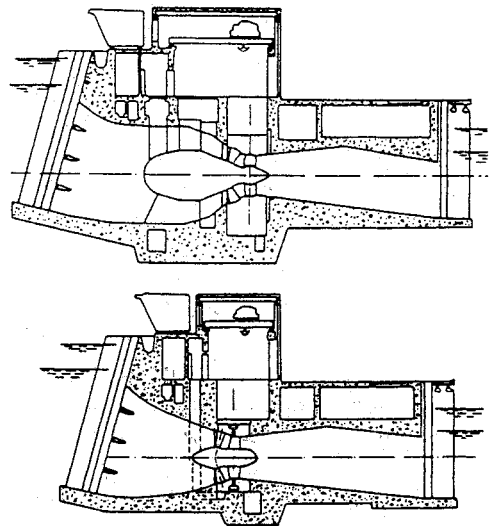

FIGURE 8.4.5 Comparison between bulb (upper) and Straflow (lower) turbines. (Courtesy of U.S. Department of Energy.)

$$\psi = \frac{2gH}{\omega^2 D^2} \tag{8.4.2}$$

$$\phi = \frac{Q}{\sqrt{2gH}D^2} \tag{8.4.3}$$

where ω is the rotational speed of the turbine in radians per second and D is the diameter of the turbine.

The hydraulic efficiency of the runner alone is given by

$$\eta_h = \frac{\phi}{\sqrt{\psi}}\left(C_1 \cos\alpha_1 - C_2 \cos\alpha_2\right) \tag{8.4.4}$$

where C_1 and C_2 are constants that depend on the specific turbine configuration and α_1 and α_2 are the inlet and outlet angles that the absolute velocity vectors make with the tangential direction. The value of $\cos\alpha_2$ is approximately zero at peak efficiency. The terms ϕ, ψ, α_1, and α_2 are interrelated. By using model test data, isocontours of efficiency can be mapped in the ϕ-ψ plane. This is typically referred to as a hill diagram as shown in Figure 8.4.6.

The specific speed is defined as

$$N_s \equiv \frac{\omega\sqrt{Q}}{(2gH)^{3/4}} = \sqrt{\frac{\phi}{\psi}} \tag{8.4.5}$$

A given specific speed describes a specific combination of operating conditions that ensures similar flow patterns and same efficiency in geometrically similar machines regardless of size and rotational speed of the machine. It is customary to define the design specific speed in terms of the value at the design head and flow where peak efficiency occurs. The value of specific speed so defined permits a classification of different turbine types.

© 1999 by CRC Press LLC

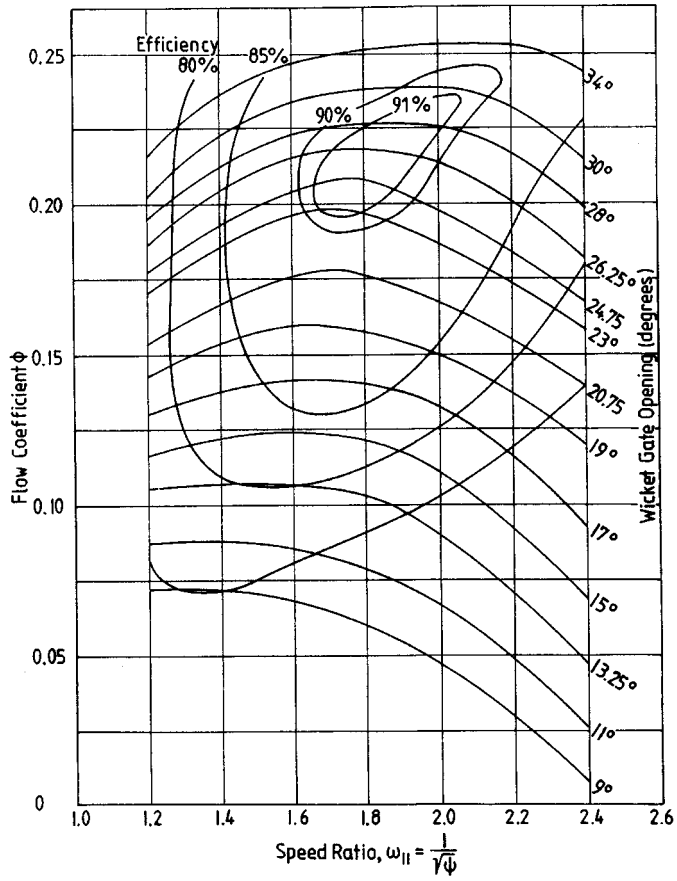

FIGURE 8.4.6 Typical hill diagram. (Adapted from T.L. Wall, Draft tube surging times two: the twin vortex problem, in *Hydro Rev.* 13(1): 60–69, 1994. With permission.)

The specific speed defined herein is dimensionless. Many other forms of specific speed exist which are dimensional and have different numerical values depending on the system of units used (Arndt, 1991).* The similarity arguments used to arrive at the concept of specific speed indicate that a given machine of diameter D operating under a head H will discharge a flow Q and produce a torque T and power P at a rotational speed ω given by

$$Q = \phi D^2 \sqrt{2gH} \tag{8.4.6}$$

$$T = T_{11} \rho D^3 2gH \tag{8.4.7}$$

$$P = P_{11} \rho D^2 (2gH)^{3/2} \tag{8.4.8}$$

$$\omega = \frac{2u_1}{D} = \omega_{11} = \frac{\sqrt{2gH}}{D} \qquad \left[\omega_{11} = \frac{1}{\sqrt{\psi}}\right] \tag{8.4.9}$$

* The literature also contains two other minor variations of the dimensionless form. One differs by a factor of $1/\pi^{1/2}$ and the other by $2^{3/4}$.

© 1999 by CRC Press LLC

with

$$P_{11} = T_{11}\omega_{11} \tag{8.4.10}$$

where T_{11}, P_{11}, and ω_{11} are also nondimensional.* In theory, these coefficients are fixed for a machine operating at a fixed value of specific speed, independent of the size of the machine. Equations 8.4.6 through 8.4.10 can be used to predict the performance of a large machine using the measured characteristics of a smaller machine or model.

Factors Involved in Selecting a Turbine

Performance Characteristics

Impulse and reaction turbines are the two basic types of turbines. They tend to operate at peak efficiency over different ranges of specific speed. This is due to geometric and operational differences.

Impulse Turbines. Of the head available at the nozzle inlet, a small portion is lost to friction in the nozzle and to friction on the buckets. The rest is available to drive the wheel. The actual utilization of this head depends on the velocity head of the flow leaving the turbine and the setting above tailwater. Optimum conditions, corresponding to maximum utilization of the head available, dictate that the flow leaves at essentially zero velocity. Under ideal conditions, this occurs when the peripheral speed of the wheel is one half the jet velocity. In practice, optimum power occurs at a speed coefficient, ω_{11}, somewhat less than 1.0. This is illustrated in Figure 8.4.7. Since the maximum efficiency occurs at fixed speed for fixed H, V_j must remain constant under varying flow conditions. Thus, the flow rate Q is regulated with an adjustable nozzle. However, maximum efficiency occurs at slightly lower values of ω_{11} under partial power settings. Present nozzle technology is such that the discharge can be regulated over a wide range at high efficiency.

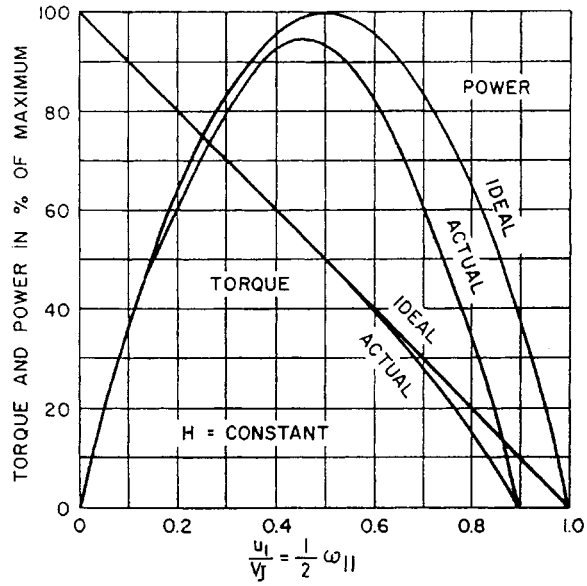

FIGURE 8.4.7 Ideal and actual variable-speed performance for an impulse turbine. (Adapted from J.W. Daily, in *Engineering Hydraulics*, H. Rouse, Ed., New York, 1950. With permission.)

* The reader is cautioned that many texts, especially in the American literature, contain dimensional forms of T_{11}, P_{11}, and ω_{11}.

© 1999 by CRC Press LLC

A given head and penstock configuration establishes the optimum jet velocity and diameter. The size of the wheel determines the speed of the machine. The design specific speed is approximately

$$N_s = 0.77\frac{d_j}{D} \quad \text{(Pelton turbines)} \tag{8.4.11}$$

Practical values of d_j/D for Pelton wheels to ensure good efficiency are in the range 0.04 to 0.1, corresponding to N_s values in the range 0.03 to 0.08. Higher specific speeds are possible with multiple-nozzle designs. The increase is proportional to the square root of the number of nozzles. In considering an impulse unit, one must remember that efficiency is based on net head; the net head for an impulse unit is generally less than the net head for a reaction turbine at the same *gross head* because of the lack of a draft tube.

Reaction Turbines. The main difference between impulse and reaction turbines is the fact that a pressure drop takes place in the rotating passages of the reaction turbine. This implies that the entire flow passage from the turbine inlet to the discharge at the tailwater must be completely filled. A major factor in the overall design of modern reaction turbines is the draft tube. It is usually desirable to reduce the overall equipment and civil construction costs by using high-specific speed runners. Under these circumstances the draft tube is extremely critical both flow-stability and efficiency viewpoints.* At higher specific speed, a substantial percentage of the available total energy is in the form of kinetic energy leaving the runner. To recover this efficiently, considerable emphasis should be placed on the draft tube design.

The practical specific speed range for reaction turbines is much broader than for impulse wheels. This is due to the wider range of variables which control the basic operation of the turbine. The pivoted guide vanes allow for control of the magnitude and direction of the inlet flow. Because there is a fixed relationship among blade angle, inlet velocity, and peripheral speed for shock-free entry, this requirement cannot be completely satisfied at partial flow without the ability to vary blade angle. This is the distinction between the efficiency of fixed-propeller and Francis-types at partial loads and the fully adjustable Kaplan design.

Referring to Equation 8.4.4, optimum hydraulic efficiency of the runner would occur when α_2 is equal to 90°. However, the overall efficiency of the turbine is dependent on the optimum performance of the draft tube as well, which occurs with a little swirl in the flow. Thus, the best overall efficiency occurs with $\alpha_2 \approx 75°$ for high-specific speed turbines.

The determination of optimum specific speed in a reaction turbine is more complicated than for an impulse unit since there are more variables. For a radial-flow machine, an approximate expression is

$$N_s = 1.64\left[C_v \sin\alpha_1 \frac{B}{D_1}\right]^{1/2} \omega_{11} \quad \text{(Francis turbines)} \tag{8.4.12}$$

where C_v is the fraction of net head that is in the form of inlet velocity head and B is the height of the inlet flow passage (Figure 8.4.3). Value of N_s for Francis units is normally found to be in the range 0.3 to 2.5.

Standardized axial-flow machines are available in the smaller sizes. These units are made up of standard components, such as shafts and blades. For such cases,

$$N_s \sim \frac{\sqrt{\tan\beta}}{n_B^{3/4}} \quad \text{(propeller turbines)} \tag{8.4.13}$$

* This should be kept in mind when retrofitting an older, low-specific-speed turbine with a new runner of higher capacity.

© 1999 by CRC Press LLC

where β is the blade pitch angle and n_B is the number of blades. The advantage of controllable pitch is also obvious from this formula, the best specific speed simply being a function of pitch angle.

It should be further noted that ω_{11} is approximately constant for Francis units and N_s is proportional to $(B/D_1)^{1/2}$. It can be also shown that velocity component based on the peripheral speed at the throat, ω_{11e}, is proportional to N_s. In the case of axial-flow machinery, ω_{11} is also proportional to N_s. For minimum cost, peripheral speed should be as high as possible, consistent with cavitation-free performance. Under these circumstances, N_s would vary inversely with the square root of head:

$$N_s = \frac{C}{\sqrt{H}} \quad (H \text{ is in meters}) \tag{8.4.14}$$

where the range of C is 21 to 30 for fixed propeller units, 21 to 32 for Kaplan units, and 16 to 25 for Francis units.

Performance Comparison. The physical characteristics of various runner configurations are summarized in Figure 8.4.8. It is obvious that the configuration changes with speed and head. Impulse turbines are efficient over a relatively narrow range of specific speed, whereas Francis and propeller turbines have a wider useful range. An important consideration is whether or not a turbine is required to operate over a wide range of load. Pelton wheels tend to operate efficiently over a wide range of power loading because of their nozzle design. In the case of reaction machines that have fixed geometry, such as Francis and propeller turbines, efficiency can vary widely with load. However, Kaplan and Deriaz* turbines can maintain high efficiency over a wide range of operating conditions. The decision of whether to select a simple configuration with a relatively "peaky" efficiency curve or go to the added expense of installing a more complex machine with a broad efficiency curve will depend on the expected operation of the plant and other economic factors.

Note in Figure 8.4.8 that there is an overlap in the range of application of various types of equipment. This means that either type of unit can be designed for good efficiency in this range, but other factors, such as generator speed and cavitation, may dictate the final selection.

Speed Regulation

The speed regulation of a turbine is an important and complicated problem. The magnitude of the problem varies with size, type of machine and installation, type of electrical load, and whether or not the plant is tied into an electrical grid. Note that runaway or no-load speed can be higher than design speed by factors as high as 2.6. This is an important design consideration for all rotating parts, including the generator.

The speed of a turbine has to be controlled to a value that matches the generator characteristics and the grid frequency:

$$n = \frac{120 f}{N_p} \tag{8.4.15}$$

where n is turbine speed in rpm, f is the required grid frequency in Hz, and N_p is the number of poles in the generator. Typically, N_p is in multiples of 4. There is a tendency to select higher speed generators to minimize weight and cost. However, consideration has to be given to speed regulation.

It is beyond the scope of this section to discuss the question of speed regulation in detail. Regulation of speed is normally accomplished through flow control. Adequate control requires sufficient rotational inertia of the rotating parts. When load is rejected, power is absorbed, accelerating the flywheel; and when load is applied, some additional power is available from deceleration of the flywheel. Response

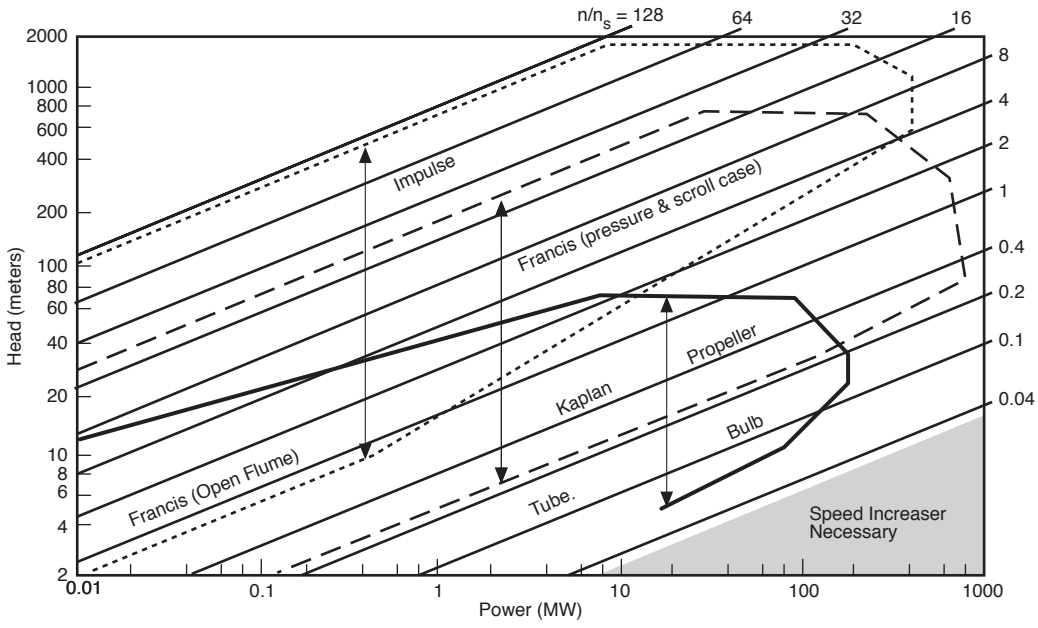

FIGURE 8.4.8 Application chart for various turbine types (n/n_S is the ratio of turbine speed in rpm, n, to specific speed defined in the metric system, $n_S = nP^{1/2}/H^{3/4}$ with P in kilowatts). (From Arndt, R.E.A., in *Hydropower Engineering Handbook*, J.S. Gulliver and R.E.A. Arndt, Eds., McGraw-Hill, New York, 1991, 4.1–4.67. With permission.)

time of the governor must be carefully selected, since rapid closing can lead to excessive pressures in the penstock.

A Francis turbine is controlled by opening and closing the wicket gates, which vary the flow of water according to the load. The actuator components of a governor are required to overcome the hydraulic and frictional forces and to maintain the wicket gates in fixed position under steady load. For this reason, most governors have hydraulic actuators. On the other hand, impulse turbines are more easily controlled, because the jet can be deflected or an auxiliary jet can by bypass flow from the power-producing jet without changing the flow rate in the penstock. This permits long delay times for adjusting the flow rate to the new flywheel; and when load is applied power conditions. The spear or needle valve controlling the flow rate can close quite slowly, say, in 30 to 60 sec, thereby minimizing pressure rise in the penstock.

Several types of governors are available, which vary with the work capacity desired and/or the degree of sophistication of control. These vary from pure mechanical to mechanical-hydraulic and electrohydraulic. Electrohydraulic units are sophisticated pieces of equipment and would not be suitable for remote regions. The precision of governing necessary will depend on whether the electrical generator is synchronous or asynchronous (induction type). There are advantages to the induction type of generator. It is less complex and therefore less expensive, but has typically slightly lower efficiency. Its frequency is controlled by the frequency of the grid it is feeding into, thereby eliminating need of an expensive the conventional governor. It cannot operate independently but can only feed into a network and does so with lagging power factor which may or may not be a disadvantage, depending on the nature of the load. Long transmission lines, for example, have a high capacitance and in this case the lagging power factor may be an advantage.

Speed regulation is a function of the flywheel effect of the rotating components and the inertia of the water column of the system. The start-up time of the rotating system is given by

© 1999 by CRC Press LLC

$$t_s = \frac{I\omega^2}{P} \tag{8.4.16}$$

where I = moment of inertia of the generator and turbine, kg · m^2 (Bureau of Reclamation, 1966).

The start-up time of the water column is given by

$$t_p = \frac{\sum LV}{gH} \tag{8.4.17}$$

where L = length of water column
V = velocity in each component of the water column

For good speed regulation, it is desirable to keep $t_s/t_p > 4$. Lower values can also be used, although special precautions are necessary in the control equipment. Higher ratios of t_s/t_p can be obtained by increasing I or decreasing t_p. Increasing I implies a larger generator, which also results in higher costs. The start-up time of the water column can be reduced by reducing the length of the flow system, by using lower velocities, or by adding **surge tanks**, which essentially reduce the effective length of the conduit. A detailed analysis should be made for each installation, since for a given length, head, and discharge the flow area must be increased to reduce t_p, which leads to associated higher construction costs.

Cavitation and Turbine Setting

Another factor that must be considered prior to equipment selection is the evaluation of the turbine with respect to tailwater elevations. Hydraulic turbines are subject to pitting due to cavitation (Arndt, 1981, 1991). For a given head, smaller, lower-cost, high-speed runner must be set lower (i.e, closer to tailwater or even below tailwater) than a larger, higher-cost, low-speed turbine runner. Also, atmospheric pressure or elevation above sea level is a factor, as are tailwater elevation ion variations and operating requirements. This is a complex concept which can only be accurately resolved by model tests. The runner design will have different cavitation characteristics. Therefore, the anticipated turbine location or setting with respect to tailwater elevations is an important consideration in turbine selection.

Cavitation is not normally a problem with impulse wheels. However, by the very nature of their operation, cavitation is an important factor in reaction turbine installations. The susceptibility for cavitation to occur is a function of the installation and the turbine design. This can be expressed conveniently in terms of Thoma's sigma defined as

$$\sigma_T = \frac{H_a - H_v - z}{H} \tag{8.4.18}$$

where H_a is the atmospheric pressure head, H_V is the vapor pressure need (generally negligible), and z is the elevation of a turbine reference plane above the tailwater (see Figure 8.4.1). Draft tube losses and the exit velocity head have been neglected.

σ_T must be above a certain value to avoid cavitation problems. The critical value of σ_T is a function of specific speed (Arndt, 1991). The Bureau of Reclamation (1966) suggests that cavitation problems can be avoided when

$$\sigma_T > 0.26 N_s^{1.64} \tag{8.4.19}$$

Equation 8.4.19 does not guarantee total elimination of cavitation, only that cavitation is within acceptable limits. Cavitation can be totally avoided only if the value σ_T at an installation is much greater than the limiting value given in Equation 8.4.19. The value of σ_T for a given installation is known as

© 1999 by CRC Press LLC

the plant sigmas, σ_p. Equation 8.4.19 should only be considered as a guide in selecting σ_p, which is normally determined by a model test in the manufacturer's laboratory. For a turbine operating under a given head, the only variable controlling σ_p is the turbine setting z. The required value of σ_p then controls the allowable setting above tailwater:

$$z_{\text{allow}} = H_a - H_v - \sigma_p H \tag{8.4.20}$$

It must be borne in mind that H_a varies with elevation. As a rule of thumb, H_a decreases from the sea-level value of 10.3 m by 1.1 m for every 1000 m above sea level.

Defining Terms

Draft tube: The outlet conduit from a turbine which normally acts as a diffuser. This is normally considered to be an integral part of the unit.

Forebay: The hydraulic structure used to withdraw water from a reservoir or river. This can be positioned a considerable distance upstream from the turbine inlet.

Head: The specific energy per unit weight of water. *Gross head* is the difference in water surface elevation between the forebay and tailrace. *Net head* is the difference between *total head* (the sum of velocity head $V^2/2g$, pressure head $p/\rho g$, and elevation head z at the inlet and outlet of a turbine. Some European texts use specific energy per unit mass, e.g., specific kinetic energy is $V^2/2$.

Runner: The rotating component of a turbine in which energy conversion takes place.

Specific speed: A universal number for a given machine design.

Spiral case: The inlet to a reaction turbine.

Surge tank: A hydraulic structure used to diminish overpressures in high-head facilities due to water hammer resulting from the sudden stoppage of a turbine

Wicket gates: Pivoted, streamlined guide vanes that control the flow of water to the turbine.

8.5 Stirling Engines

William B. Stine

Introduction

The Stirling engine was patented in 1816 by Rev. Robert Stirling, a Scottish minister (Figure 8.5.1). Early Stirling engines were coal-burning, low-pressure air engines built to compete with saturated steam engines for providing auxiliary power for manufacturing and mining. In 1987, John Ericsson built an enormous marine Stirling engine with four 4.2-m-diameter pistons. Beginning in the 1930s, the Stirling engine was brought to a high state of technology development by Philips Research Laboratory in Eindhoven, The Netherlands with the goal of producing small, quiet electrical generator sets to be used with high-power-consuming vacuum tube electronic devices. Recently, interest in Stirling engines has resurfaced, with solar electric power generation (Stine and Diver, 1994) and hybrid automotive applications in the forefront.

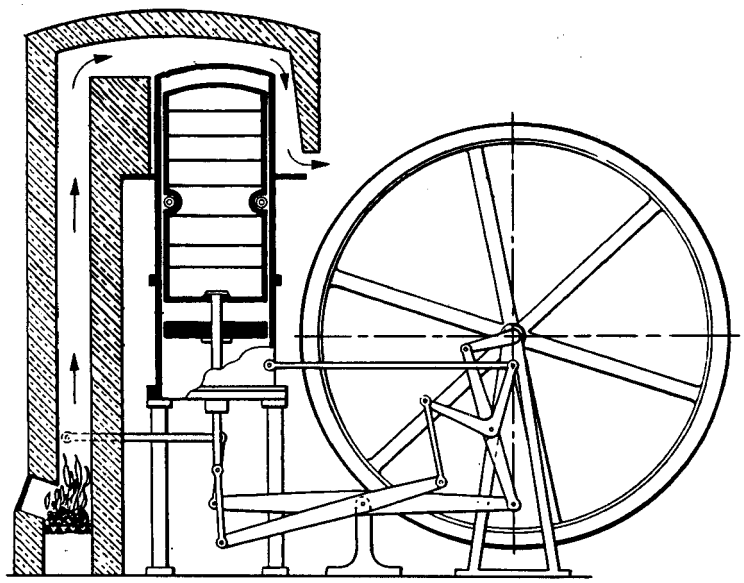

FIGURE 8.5.1 The original patent Stirling engine of Rev. Robert Stirling.

In theory, the **Stirling cycle** engine can be the most efficient device for converting heat into mechanical work with high efficiencies requiring high-temperatures. In fact, with regeneration, the efficiency of the Stirling cycle equals that of the Carnot cycle, the most efficient of all ideal thermodynamic cycles. (See West, 1986 for further discussion of the thermodynamics of Stirling cycle machines.)

Since their invention, prototype Stirling engines have been developed for automotive purposes; they have also been designed and tested for service in trucks, buses, and boats (Walker, 1973). The Stirling engine has been proposed as a propulsion engine in yachts, passenger ships, and road vehicles such as city buses (Meijer, 1992). The Stirling engine has also been developed as an underwater power unit for submarines, and the feasibility of using the Stirling for high-power space-borne systems has been explored by NASA (West, 1986). The Stirling engine is considered ideal for solar heating, and the first solar application of record was by John Ericsson, the famous British-American inventor, in 1872 (Stine and Diver, 1994).

Stirling engines are generally externally heated engines. Therefore, most sources of heat can be used to drive them, including combustion of just about anything, radioisotopes, solar energy, and exothermic

© 1999 by CRC Press LLC

chemical reactions. High-performance Stirling engines operate at the thermal limits of the materials used for their construction. Typical temperatures range fiom 650 to 800°C (1200 to 1470°F), resulting in engine conversion efficiencies of around 30 to 40%. Engine speeds of 2000 to 4000 rpm are common

Thermodynamic Implementation of the Stirling Cycle

In the ideal Stirling cycle, a **working gas** is alternately heated and cooled as it is compressed and expanded. Gases such as helium and hydrogen, which permit rapid heat transfer and do not change phase, are typically used in the high-performance Stirling engines. The ideal Stirling cycle combines four processes, two constant-temperature heat-exchange processes and two constant-volume heat-exchange processes. Because more work is done by expanding high-temperature, high-pressure gas than is required to compress low-temperature, low-pressure gas, the Stirling cycle produces net work, which can drive an electric alternator or other mechanical devices.

Working Gases

In the Stirling cycle, the working gas is alternately heated and cooled in constant-temperature and constant-volume processes. The traditional gas for Stirling engines has been air at atmospheric pressure. At this pressure, air has a reasonably high density and therefore can be used directly in the cycle with loss of working gas through seals a minor problem. However, internal component temperatures are limited because of the oxygen in air which can degrade materials rapidly.

Because of their high heat-transfer capabilities, hydrogen and helium are used for high-speed, high-performance Stirling engines. To compensate for the low density of these gases, the mean pressure of the working gas is raised by charging the gas spaces in the engine to high pressures. Compression and expansion vary above and below this **charge pressure**. Hydrogen, thermodynamically a better choice, generally results in more-efficient engines than does helium (Walker, 1980). Helium, on the other hand, has fewer material-compatibility problems and is safer to work with. To maximize power, high-performance engines typically operate at high pressure, in the range of 5 to 20 MPa (725 to 2900 psi). Operation at these high gas pressures makes sealing difficult, and seals between the high-pressure region of the engine and those parts at ambient pressure have been problematic in some engines. New designs to reduce or eliminate this problem are currently being developed.

Heat Exchange

The working gas is heated and cooled by heat exchangers that add heat from an external source, or reject heat to the surroundings. Further, in most engines, an internal heat storage unit stores and rejects heat during each cycle.

The **heater** of a Stirling engine is usually made of many small-bore tubes that are heated externally with the working gas passing through the inside. External heat transfer by direct impingement of combustion products or direct adsorption of solar irradiation is common. A trade-off between high heat-transfer rate using many small-bore tubes with resulting pumping losses, and fewer large-bore tubes and lower pumping losses drives the design. A third criterion is that the volume of gas trapped within these heat exchangers should be minimal to enhance engine performance. In an attempt to provide more uniform and constant-temperature heat transfer to the heater tubes, **reflux** heaters are being developed (Stine and Diver, 1994). Typically, by using sodium as the heat-transfer medium, liquid is evaporated at the heat source and is then condensed on the outside surfaces of the engine heater tubes.

The **cooler** is usually a tube-and-shell heat exchanger. Working gas is passed through the tubes, and cooling water is circulated around the outside. The cooling water is then cooled in an external heat exchanger. Because all of the heat rejected from the power cycle comes from the cooler, the Stirling engine is considered ideal for cogeneration applications.

Most Stirling engines incorporate an efficiency-enhancing **regenerator** that captures heat from the working gas during constant-volume cooling and replaces it when the gas is heated at constant volume. Heating and cooling of the regenerator occurs at over 60 times a second during high-speed engine operation. In the ideal cycle, all of the heat-transferred during the constant volume heating and cooling

© 1999 by CRC Press LLC

processes occurs in the regenerator, permitting the external heat addition and rejection to be efficient constant-temperature heat-transfer processes. Regenerators are typically chambers packed with fine-mesh screen wire or porous metal structures. There is enough thermal mass in the packing material to store all of the heat necessary to raise the temperature of the working gas from its low to its high temperature. The amount of heat stored by the regenerator is generally many times greater than the amount added by the heater.

Power Control

Rapid control of the output power of a Stirling engine is highly desirable for some applications such as automotive and solar electric applications. In most Stirling engine designs, rapid power control is implemented by varying the density (i.e., the mean pressure) of the working gas by bleeding gas from the cycle when less power is desired. To return to a higher power level, high-pressure gas must be reintroduced into the cycle. To accomplish this quickly and without loss of working gas, a complex system of valves, a temporary storage tank, and a compressor are used.

A novel method of controlling the power output is to change the length of stroke of the power piston. This can be accomplished using a variable-angle swash plate drive as described below. Stirling Thermal Motors, Inc., uses this method on their STM 4-120 Stirling engine (Figure 8.5.2).

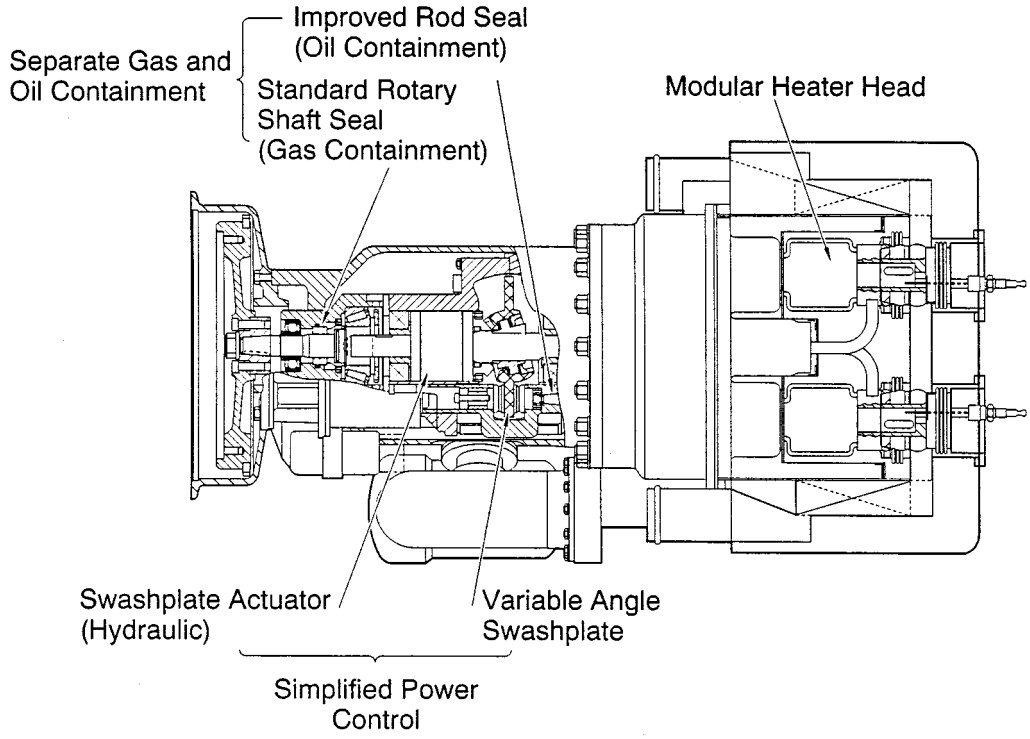

FIGURE 8.5.2 Stirling Thermal Motors 4-120 variable swash plate Rinia configuration engine. (Courtesy Stirling Thermal Motors, Ann Arbor, Michigan.)

Mechanical Implementation of the Stirling Cycle

Piston/Displacer Configurations

To implement the Stirling cycle, different combinations of machine components have been designed to provide for the constant-volume movement of the working gas between the high- and low-temperature regions of the engine, and compression and expansion during the constant-temperature heating and

© 1999 by CRC Press LLC

cooling. The compression and expansion part of the cycle generally take place in a cylinder with a piston. Movement of the working gas back and forth through the heater, regenerator, and cooler at constant volume is often implemented by a **displacer**. A displacer in this sense is a hollow plug that, when moved to the cold region, displaces the working gas from the cold region causing it to flow to the hot region and vice versa. Only a small pressure difference exists between either end of the displacer, and, therefore, sealing requirements and the force required to move it are minimal.

Three different design configurations are generally used (Figure 8.5.3). Called the alpha-, beta-, and gamma-configurations. Each has its distinct mechanical design characteristics, but the thermodynamic cycle is the same. The **alpha-configuration** uses two pistons on either side of the heater, regenerator, and the cooler. These pistons first move uniformly in the same direction to provide constant-volume processes to heat or cool the gas. When all of the gas has been moved into one cylinder, one piston remains fixed and the other moves to compress or expand the gas. Compression work is done by the **cold piston** and expansion work done on the **hot piston** The alpha-configuration does not use a displacer. The Stirling Power Systems V-160 engine (Figure 8.5.4) is an example of this configuration.

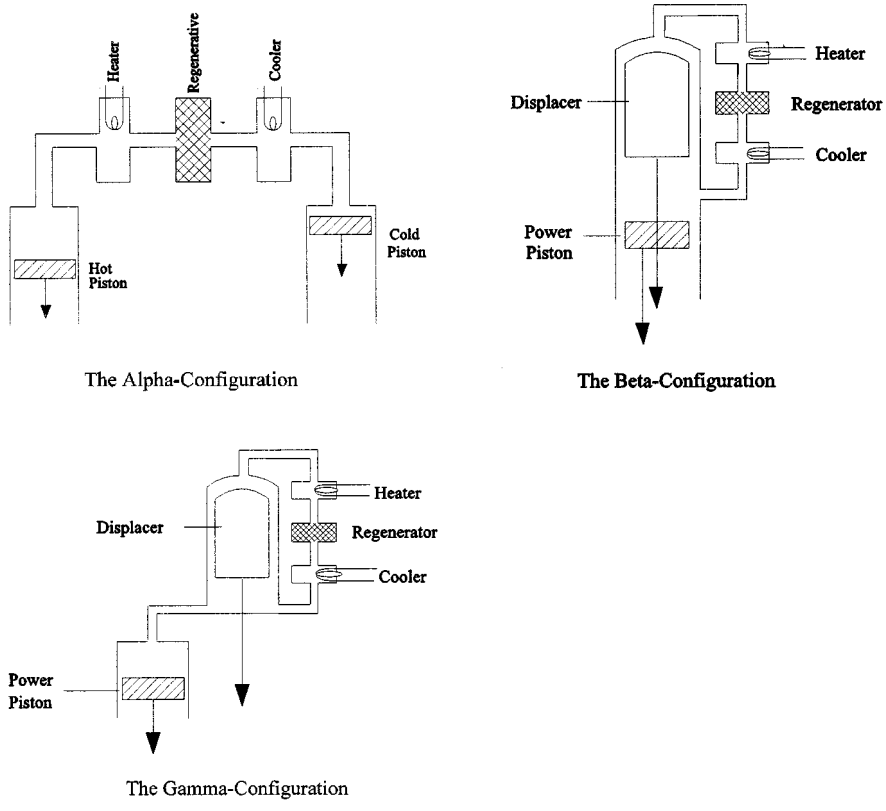

FIGURE 8.5.3 Three fundamental mechanical configurations for Stirling Engines.

A variation on using two separate pistons to implement the alpha-configuration is to use the front and back side of a single piston called a **double-acting piston**. The volume at the front side of one piston is connected, through the heater, regenerator, and cooler, to the volume at the back side of another piston. With four such double-acting pistons, each 90° out of phase with the next, the result is a four-cylinder alpha-configuration engine. This design is called the *Rinia* or *Siemens configuration* and the United Stirling 4-95 (Figure 8.5.5) and the Stirling Thermal Motors STM 4-120 (Figure 8.5.2) are current examples.

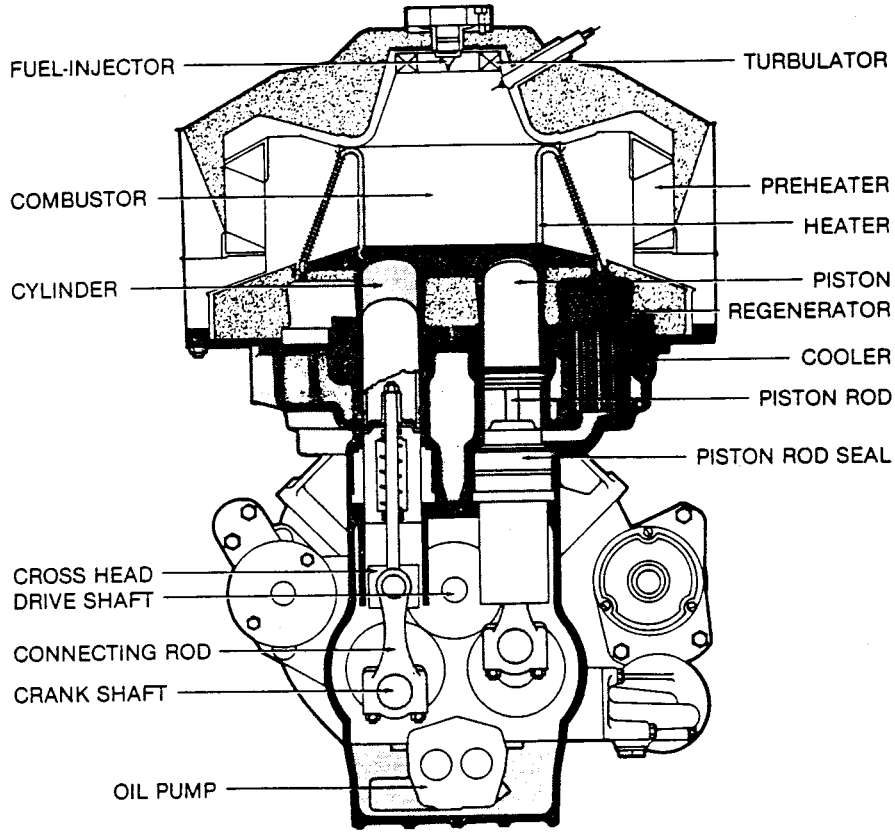

FIGURE 8.5.5 The 4-95 high-performance Siemens configuration Rinia engine by United Stirling (Malmo, Sweden).

© 1999 by CRC Press LLC

The **beta-configuration** is a design incorporating a displacer and a power piston in the same cylinder. The displacer shuttles gas between the hot end and the cold end of the cylinder through the heater, regenerator, and cooler. The power piston, usually located at the cool end of the cylinder, compresses the working gas when the gas is in the cool end and expands the working gas when the gas has been moved to the hot end. The original patent engine by Robert Stirling and most free-piston Stirling engines discussed below are of the beta-configuration.

The third configuration, using separate cylinders for the displacer and the power piston, is called the **gamma-configuration**. Here, the displacer shuttles gas between the hot end and the cold end of a cylinder through the heater, regenerator, and cooler, just as with the beta-configuration. However, the power piston is in a separate cylinder, pneumatically connected to the displacer cylinder.

Piston/Displacer Drives

Most Stirling engine designs dynamically approximate the Stirling cycle by moving the piston and displacer with **simple harmonic motion**, either through a crankshaft, or bouncing as a spring/mass second-order mechanical system. For both, a performance penalty comes from the inability of simple harmonic motion to perfectly follow the desired thermodynamic processes. A more desirable dynamic from the cycle point of view, called overdriven or **bang-bang motion**, has been implemented in some designs, most notably the **Ringbom configuration** and engines designed by Ivo Kolin (West, 1986).

Kinematic Engines. Stirling engine designs are usually categorized as either kinematic or free-piston. The power piston of a **kinematic Stirling engine** is mechanically connected to a rotating output shaft. In typical configurations, the power piston is connected to the crankshaft with a connecting rod. In order to eliminate side forces against the cylinder wall, a **cross-head** is often incorporated, where the connecting rod connects to the cross-head, which is laterally restrained so that it can only move linearly in the same direction as the piston. The power piston is connected to the cross-head and therefore experiences no lateral forces. The critical sealing between the high-pressure and low-pressure regions of the engine can now be created using a simple **linear seal** on the shaft between the cross-head and the piston. This design also keeps lubricated bearing surfaces in the low-pressure region of the engine, reducing the possibility of fouling heat-exchange surfaces in the high-pressure region of the engine. If there is a separate displacer piston as in the beta- and gamma configurations, it is also mechanically connected to the output shaft.

A variation on crankshaft/cross-head drives is the **swash plate** or **wobble-plate drive**, used with success in some Stirling engine designs. Here, a drive surface affixed to the drive shaft at an angle, pushes fixed piston **push rods** up and down as the slanted surface rotates beneath. The length of stroke for the piston depends on the angle of the plate relative to the axis of rotation. The STM 4-120 engine (Figure 8.5.2) currently being commercialized by Stirling Thermal Motors incorporates a **variable-angle swash plate drive** that permits variation in the length of stroke of the pistons.

Free-Piston Engine/Converters. An innovative way of accomplishing the Stirling cycle is employed in the free-piston engine. In this configuration, the power piston is not mechanically connected to an output shaft. It bounces alternately between the space containing the working gas and a spring (usually a gas spring). In many designs, the displacer is also free to bounce on **gas springs** or mechanical springs (Figure 8.5.6). This configuration is called the Beale free-piston Stirling engine after its inventor, William Beale. Piston stroke, frequency, and the timing between the two pistons are established by the dynamics of the spring/mass system coupled with the variations in cycle pressure. To extract power, a magnet can be attached to the power piston and electric power generated as it moves past stationary coils. These Stirling engine/alternator units are called **free-piston Stirling converters**. Other schemes for extracting power from free-piston engines, such as driving a hydraulic pump, have also been considered.

Free-piston Stirling engines have only two moving parts, and therefore the potential advantages of simplicity, low cost, and ultra-reliability. Because electricity is generated internally, there are no dynamic seals between the high-pressure region of the engine and ambient, and no oil lubrication is required. This design promises long lifetimes with minimal maintenance. A number of companies are currently

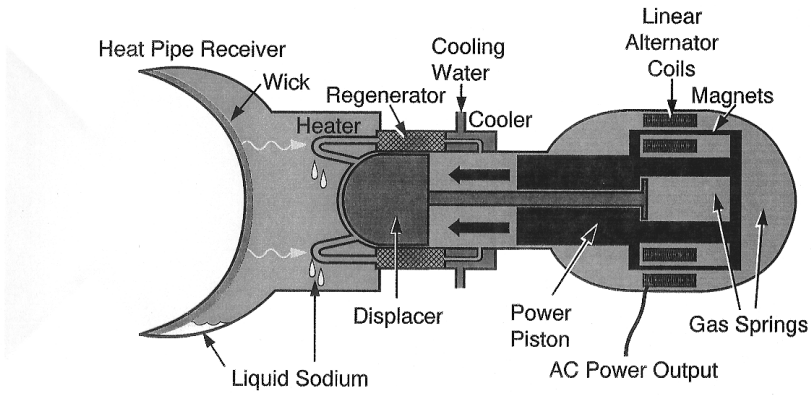

FIGURE 8.5.6 Basic components of a Beale free-piston Stirling converter incorporating a sodium heat pipe receiver for heating with concentrated solar energy.

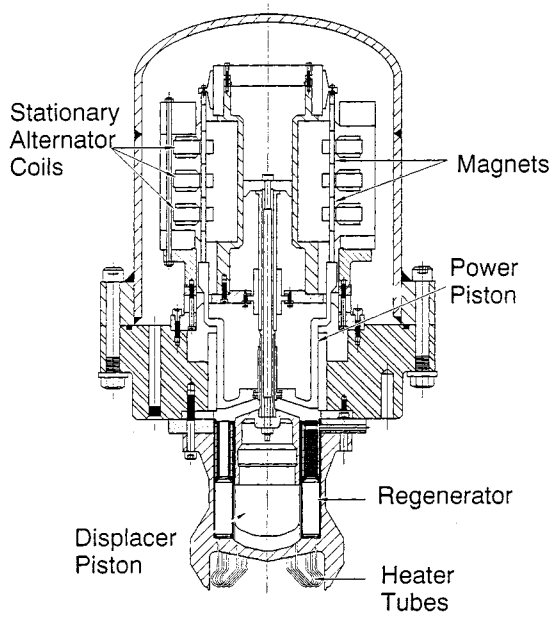

FIGURE 8.5.7 The Sunpower 9-kWe free-piston beta-configuration Stirling engine.

developing free-piston engines including Sunpower, Inc. (Figure 8.5.7), and Stirling Technology Company.

Seals and Bearings

Many proposed applications for Stirling engine systems require long-life designs. To make systems economical, a system lifetime of at least 20 years with minimum maintenance is generally required. Desired engine lifetimes for electric power production are 40,000 to 60,000 hr — approximately ten times longer than that of a typical automotive internal combustion engine. Major overhaul of engines, including replacement of seals and bearings, may be necessary within the 40,000- to 60,000-hr lifetime, which adds to the operating cost. A major challenge, therefore, in the design of Stirling engines is to reduce the potential for wear in critical components or to create novel ways for them to perform their tasks.

© 1999 by CRC Press LLC

Piston seals differ from those used in internal combustion engines in a number of ways. Sealing of the power piston is critical since **blow-by loss** of the hydrogen or helium working gas must be captured and recompressed, or replaced from a high-pressure cylinder. Displacer sealing is less critical and only necessary to force most of the working gas through the heater, regenerator, and cooler. Oil for friction reduction or sealing cannot be used because of the danger of it getting into the working gas and fouling the heat-exchange surfaces. This leads to two choices for sealing of pistons, using **polymer sealing rings** or **gas bearings** (simply close tolerance fitting between piston and wall).

Free-piston engines with gas springs have special internal sealing problems. Small leakage can change the force-position characteristics of the "spring" and rapidly upset the phase and displacement dynamics designed into the engine. In order to prevent this, *centering ports* are used to ensure that the piston stays at a certain location; however, these represent a loss of potential work from the engine.

Materials

Materials used in Stirling engines are generally normal steels with a few exceptions. Materials that can withstand continuous operation at the cycle high temperature are required for the heater, regenerator, and the hot side of the displacement volume. Because most engines operate at high pressure, thick walls are often required. In the hot regions of the engine, this can lead to *thermal creep* due to successive heating and cooling. In the cool regions, large spaces for mechanical linkages can require heavy, thick walls to contain the gas pressure. Use of composite structure technology or reducing the size of the pressurized space can eliminate these problems.

Future of the Stirling Engine

The principal advantages of the Stirling engine, external heating and high efficiency, make this the engine of the future, replacing many applications currently using internal combustion engines and providing access to the sun as an inexpensive source of energy (Figure 8.5.6). For hybrid-electric automotive applications, the Stirling engine is not only almost twice as efficient as modern spark-ignition engines, but because of the continuous combustion process, it burns fuel more cleanly and is not sensitive to the quality or type of fuel. Because of the simplicity of its design, the Stirling engine can be manufactured as an inexpensive power source for electricity generation using biomass and other fuels available in developing nations.

Most importantly, the Stirling engine will provide access to inexpensive solar energy. Because it can receive its heat from a resource 93 million miles away using concentrating solar collectors, and because its manufacture is quite similar to the gasoline or diesel engine, and because economies of scale are certain when producing thousands of units per year, the Stirling engine is considered to be the least expensive alternative for solar energy electric generation applications in the range from 1 kWe to 100 MWe.

Defining Terms

Alpha-configuration: Design of a Stirling engine where two pistons moving out of phase, and cause the working gas between them to go through the four processes of the Stirling cycle.

Beale free-piston Stirling engine: Stirling engine configuration where the power piston and displacer in a single cylinder are free to bounce back and forth along a single axis, causing the enclosed working gas to go through the four processes of the Stirling cycle. Restoration forces are provided by the varying pressure of the working gas, springs (gas or mechanical), and the external load which can be a linear alternator or a fluid pump.

Beta-configuration: Design of a Stirling engine where the displacer and power piston are located in the same cylinder and cause the enclosed working gas to go through the four processes of the Stirling cycle.

Blow-by: The gas that leaks past a seal, especially a piston-to-cylinder seal.

Charge pressure: Initial pressure of the working gas.

© 1999 by CRC Press LLC

Cooler: Heat exchanger that removes heat from the working fluid and transfers it out of the cycle.

Cross-head: A linear sliding bearing surface connected to a crankshaft by a connecting rod. It is purpose is to provide linear reciprocating motion along a single line of action.

Displacer: Closed volume 'plug' that forces the working fluid to move from one region of the engine to another by displacing it.

Double-acting piston: A piston in an enclosed cylinder where pressure can be varied on both sides of the piston, resulting a total amount of work being the sum of that done on or by both sides.

Dynamic seals: Seals that permit transfer of motion without permitting gas or oil leakage. These can be either *linear seals* permitting a shaft to move between two regions (i.e., the piston rod seals in a Stirling engine), or *rotating seals* that permit rotating motion to be transmitted from one region to another (i.e., the output shaft of a Stirling engine).

Free-piston Stirling converters: A name given to a hermetically sealed free-piston Stirling engine incorporating an internal alternator or pump.

Gamma-configuration: A design of a Stirling engine where the displacer and power piston are located in separate, connected cylinders and cause the enclosed working gas to go through the four processes of the Stirling cycle.

Gas bearing: A method of implementing the sliding seal between a piston and cylinder as opposed to using piston rings. Uses a precision-fitting piston that depends on the small clearance and long path for sealing and on the viscosity of the gas for lubrication.

Gas spring: A piston that compresses gas in a closed cylinder where the restoration force is linearly proportional to the piston displacement. This is a concept used in the design of free-piston Stirling engines.

Heater: A heat exchanger which adds heat to the working fluid from an external source.

Kinematic stirling engine: Stirling engine design that employ physical connections between the power piston, displacer, and a mechanical output shaft.

Linear seal: see **dynamic seals**.

Overdriven (bang-bang) motion: Linear motion varying with time as a square-wave function. An alternative to simple harmonic motion and considered a better motion for the displacer of a Stirling engine but difficult to implement.

Phase angle: The angle difference between displacer and power piston harmonic motion with a complete cycle representing 360°. In most Stirling engines, the harmonic motion of the power piston follows (lags) the motion of the displacer by approximately 90°.

Push rod: A thin rod connected to the back of the piston that transfers linear motion through a dynamic linear seal, between the low- and high-pressure regions of an engine.

Reflux: A constant-temperature heat-exchange process where a liquid is evaporated by heat addition and then condensed as a result of cooling.

Regenerator: A heat-transfer device that stores heat from the working gas during part of a thermodynamic cycle and returns it during another part of the cycle. In the Stirling cycle the regenerator stores heat from one constant-volume process and returns it in the other constant-volume process.

Ringbom configuration: A Stirling engine configuration where the power piston is kinematically connected to a power shaft, and the displacer is a free piston that is powered by the difference in pressure between the internal gas and atmospheric pressure.

Simple harmonic motion: Linear motion varying with time as a sine function. Approximated by a piston connected to a crankshaft or a bouncing of a spring mass system.

Stirling cycle: A thermodynamic power cycle with two constant-volume heat addition and rejection processes and two constant-temperature heat-addition and rejection processes.

Swash plate drive: A disk on a shaft, where the plane of the disk is tilted away from the axis of rotation of the shaft. Piston push rods that move parallel to the axis of rotation but are displaced from the axis of rotation, slide on the surface of the rotating swash plate and therefore move up and down.

Variable-angle swash plate drive: A swash plate drive where the tilt angle between the drive shaft and the plate can be varied, resulting in a change in the displacement of the push rods.

© 1999 by CRC Press LLC

Wobble plate drive: Another name for a swash plate drive.

Working gas: Gas within the engine that exhibits pressure and temperature change as it is heated or cooled and/or compressed or expanded.

8.6 Advanced Fossil Fuel Power Systems

Anthony F. Armor

Introduction

The generation of electric power from fossil fuels has undergone significant and, in some cases, dramatic changes over the last 20 years or so. Technology improvements in fossil fuel combustion have been largely driven by environmental issues, by the need to conserve fossil fuel resources, and by the economics of the competitive marketplace. The importance of fossil fuel-fired electric generation to the world is undeniable — more than 70% of all power in the U.S. is fossil fuel based, and worldwide the percentage is higher and growing. Today, most power plants worldwide burn coal, but increasingly generating companies are turning to natural gas, as the cost of gas-fired generation and the long-term supply of gas appear favorable. This section reviews the current status and likely future deployment of competing generation technologies based on fossil fuels.

It is likely, particularly in the developed world, that gas turbine-based plants will dominate the new generation market in the immediate future. The most advanced combustion turbines (CTs) now achieve more than 40% **lower heating value** (LHV) efficiency in simple cycle mode and greater than 50% efficiency in **combined cycle** (CC) mode. In addition, combustion turbine/combined cycle (CT/CC) plants offer siting flexibility, swift construction schedules, and capital costs between $400/kW and $800/kW. These advantages, coupled with adequate natural gas supplies and the assurance, in the longer term, of **coal gasification** backup, make this technology currently the prime choice for green field and repowered plants in the United States and in Europe.

But for the developing world, particularly China and India, there is good reason why the direct coal-fired power plant may still be the primary choice for many generation companies. Fuel is plentiful and inexpensive, and sulfur dioxide scrubbers have proved to be more reliable and effective than early plants indicated. In fact, as high as 99% SO_2 removal efficiency is now possible.

Combustion of coal can occur in three basic forms, direct combustion of pulverized coals (PC), combustion of coal in a suspended bed of coal and inert matter, and coal gasification. The pulverized coal (PC) plant, the most common form of coal combustion, has the capability for much improved efficiency even with full **flue gas desulfurization** (FGD), because materials technology has now advanced to the point where higher steam pressures and temperatures are possible. In the United States, Europe, Japan, and Russia, the advanced superficial PC plant is moving ahead commercially.

Worldwide, the application of atmospheric and pressurized fluidized bed combustion (FBC) plants has increased, and such plants offer reductions in both SO_2 and NO_x while permitting the efficient combustion of vast deposits of low-rank fuels such as lignites. In the United States, there are now over 150 large operating units for power generation, and throughout Europe, China, and the former Soviet Union countries small FBC units have been extensively deployed.

Coal gasification power plants exist at the 100 and 160 MW levels and are planned up to 450 MW. Much of the impetus is now coming from the U.S. Department of Energy (DOE) clean coal program where three gasification projects are in progress and four more are planned, and gasification plants are under construction in Europe and Japan. Gasification not only leads to minimum atmospheric and solid emissions, but also provides an opportunity to take advantage of gas turbine advances. With the rapid a, advances now being introduced in CT technology, the coal gasification option is a leading turn-of-the-century candidate for new plant construction.

Clean Coal Technology Development

At an increasing rate in the last few years, innovations have been developed and tested that are aimed at reducing emissions through improved combustion and environmental control, in the near term, and, in the longer term, through fundamental changes in the way coal is preprocessed before converting its

© 1999 by CRC Press LLC

chemical energy to electricity. Such technologies are referred to as "clean coal technologies" described as a family of precombustion, combustion/conversion, and postcombustion technologies (Torrens, 1990). They are designed to provide the coal user with added technical capabilities and flexibility and the world with an opportunity to exploit our most abundant fossil source. They can be categorized as

- *Precombustion*, where sulfur and other impurities are removed from the fuel before it is burned;
- *Combustion*, where techniques to prevent pollutant emissions are applied in the boiler while the coal burns;
- *Postcombustion*, where the flue gas released from the boiler is treated to reduce its content of pollutants;
- *Conversion*, where coal, rather than being burned, is changed into a gas or liquid that can be cleaned and used as a fuel.

Coal Cleaning

Cleaning of coal to remove sulfur and ash is well established in the United States with more than 400 operating plants, mostly at the mine. Coal cleaning removes primarily pyritic sulfur (up to 70% SO_2 reduction is possible) and in the process increases the heating value of the coal, typically about 10% but occasionally 30% or higher. Additionally, if slagging is a limiting item, increased megawatts may be possible, as occurred at one station which increased generation from 730 to 779 MW. The removal of organic sulfur, chemically part of the coal matrix, is more difficult, but may be possible using microorganisms or through chemical methods; research is underway (Couch, 1991). Finally, heavy metal trace elements can be removed also, conventional cleaning removing (typically) 30 to 80% of arsenic, mercury, lead, nickel, antimony, selenium, and chromium.

Cleaning of Low-Rank Coal

With large deposits of high-moisture, and sometimes high-ash, low-rank coals and lignites, there is interest, but as yet no large-scale activity, in cleaning these coals. Improvement in heating value and reduction of boiler **slagging and fouling** problems are outcomes. Economics will decide whether precleaning or direct combustion (perhaps in a fluidized bed) will be the future choice. Large subbituminous and lignite fields exist in the United States, the former U.S.S.R., Germany, and Eastern Europe, as Table 8.6.1 indicates.

TABLE 8.6.1 World Coal Production

Country	Total Coal Production, Mt	Bituminous, Mt	Subbituminous and Lignite, Mt	Approximate Amount Bituminous Cleaned, %

Pulverized Coal Plants

There has been a perception that the PC power plant has come to the end of the road, that advanced coal technologies will quite soon make obsolete the PC plant with a scrubber, whose efficiency hovers around 35%. This perception may be premature. In fact, the PC plant has the capability for much improved heat rate (about 8500 Btu/kWh) even with full FGD. Beyond these units, the PC-fired CC with topping turbine (Figure 8.6.1) has a projected heat rate of 7200 Btu/kWhr, which includes full scrubbing capability. The PC plant is a proven, reliable power source with unit capabilities demonstrated at more than to 1000 MW using a single-shaft steam turbine. One plant, commercially available now, uses steam at 4500 psig and 1100°F, all ferritic materials for major boiler and turbine components, leading-edge technology in environmental controls, and the latest techniques in waste heat utilization (Poe et al., 1991). It is modular, fuel flexible, and designed for **on/off cycling capability**.

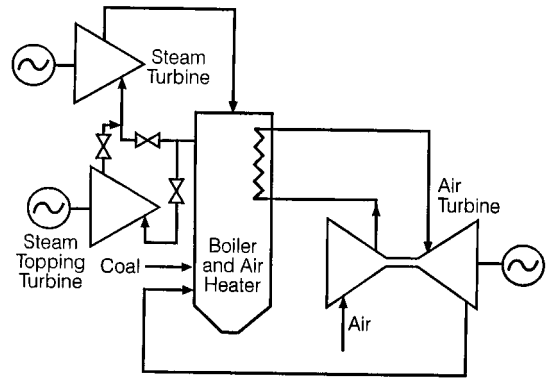

FIGURE 8.6.1 A PC CC with topping steam turbine has a projected heat rate of 7200 Btu/kWhr. The air turbine uses 1800°F air, or 2300°F air with supplemental firing. The topping turbine uses steam at 1300°F.

Higher steam temperatures (to 1150°F) and **supercritical steam pressures** are an important aspect of the modern advanced PC plant. They are possible now because of advances in ferritic materials technology that will extend life, provide greater creep and fatigue strength, and be resistant to **temper embrittlement** and, in the boiler, to coal ash corrosion (Armor et al., 1988).

Of particular note are

- **Coextruded tubing** or monotubing for superheaters and reheaters, resistant to coal ash corrosion.
- Super-9-chrome steel (P91), for steam piping, valves, headers, casings.
- Improved creep-resistant 12-chrome forgings for high-pressure/intermediate-pressure (HP/IP) turbines.
- "Superclean" 3.5 NiCrMoV rotors for low-pressure (LP) turbines, resistant to temper embrittlement.

Built in 1959, Eddystone 1 at PECO Energy was, and still is, the supercritical power unit with the highest steam conditions in the world. When constructed in the early 1960s, Eddystone 1 had a main steam pressure of 5000 psi, and main steam temperature of 1200°F. **Double reheat** of the steam was employed. PECO Energy continues to operate Eddystone 1, an impressive achievement for a prototype unit. More-recent advanced plants include the Chuba Electric Kawagoe unit in Japan, a 700-MW double-reheat supercritical with steam conditions of 4750 psi, 1050°F, and the Esbjerg unit of Elsam in Denmark, a 400-MW supercritical with steam conditions of 3700 psi, 1040°F. Both plants use advanced ferritic steels for turbine and boiler thick wall components. There are over 170 supercritical units in the United States, more than 220 in Russia (Oliker and Armor 1992), and over 60 in Japan. A number are installed in Germany, Denmark, Holland, and other European countries, and increasingly in the Far East.

Emissions Controls for Pulverized Coal Plants

Today, worldwide, about 40% of electricity is generated from coal and the total installed coal-fired generating capacity is more than 1000 GW, largely made up of 340 GW in North America; 220 GW in Western Europe, Japan, and Australia; 250 GW in Eastern Europe and the former U.S.S.R., and 200 GW in China and India. In the decade 1990 to 2000, 190 GW of new coal-fired capacity will likely be added. So the control of particulates, sulfur dioxides, and nitrogen oxides from those plants is one of the most pressing needs of today and of the future, together with the potential impact of carbon dioxide emissions, with their contribution to global warming. To combat these concerns, a worldwide move toward environmental retrofitting of older fossil-fired power plants is underway, focused largely on sulfur dioxide scrubbers and combustion or postcombustion optimization for nitrogen oxides.

Conventional Lime/Limestone Wet Scrubber

The dominant SO_2 scrubbing system is the wet limestone design, limestone being one quarter the cost of lime as a reagent. In this system (Figure 8.6.2) the limestone is ground and mixed with water in a reagent preparation area. It is then conveyed to a spray tower called an absorber, as a slurry of 90% water and 10% solids, and sprayed into the flue gas stream. The SO_2 in the flue gas is absorbed in the slurry and collected in a reaction tank where it combines with the limestone to produce water and calcium sulfate or calcium sulfate crystals. A portion of the slurry is then pumped to a thickener where these solids/crystals settle out before going to a filter for final dewatering. Mist eliminators installed in the system ductwork at the spray tower outlet collect slurry/moisture entrained in the flue gas stream. Calcium sulfate is typically mixed with fly ash (1:1) and lime (5%) and disposed of in a landfill.

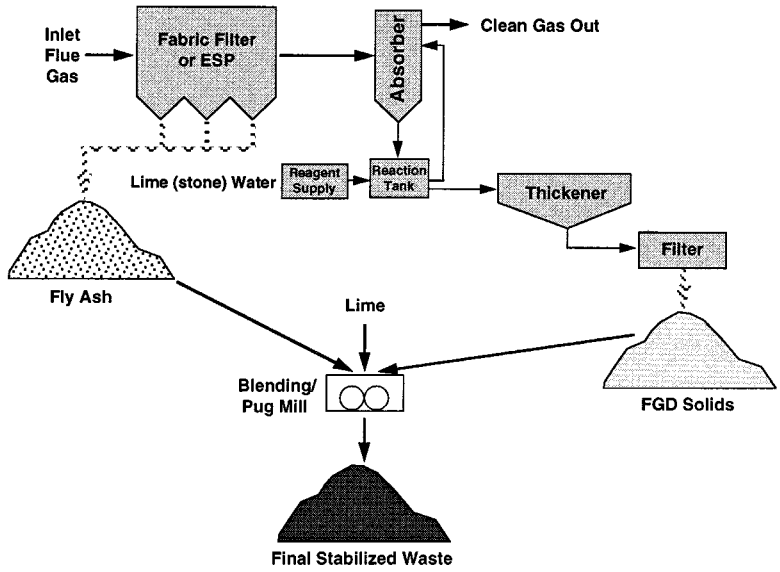

FIGURE 8.6.2 The conventional lime/limestone wet scrubber is the dominant system in operation in the United States. With recent refinements this system can be 98 to 99% effective in removing SO_2.

Various improvements can be made to this basic process, including the use of additives for performance enhancement and the use of a hydrocyclone for dewatering, replacing the thickener, and leading to a salable gypsum by-product. The Chiyoda-121 process (Figure 8.6.3) reverses the classic spray scrubber and bubbles the gas through the liquid. This eliminates the need for spray pumps, nozzle headers, separate oxidation towers, and thickeners. The Chiyoda process is being demonstrated in a DOE Clean Coal Technology (CCT) project on a 100-MW unit at the Yates plant of the Georgia Power Company.

© 1999 by CRC Press LLC

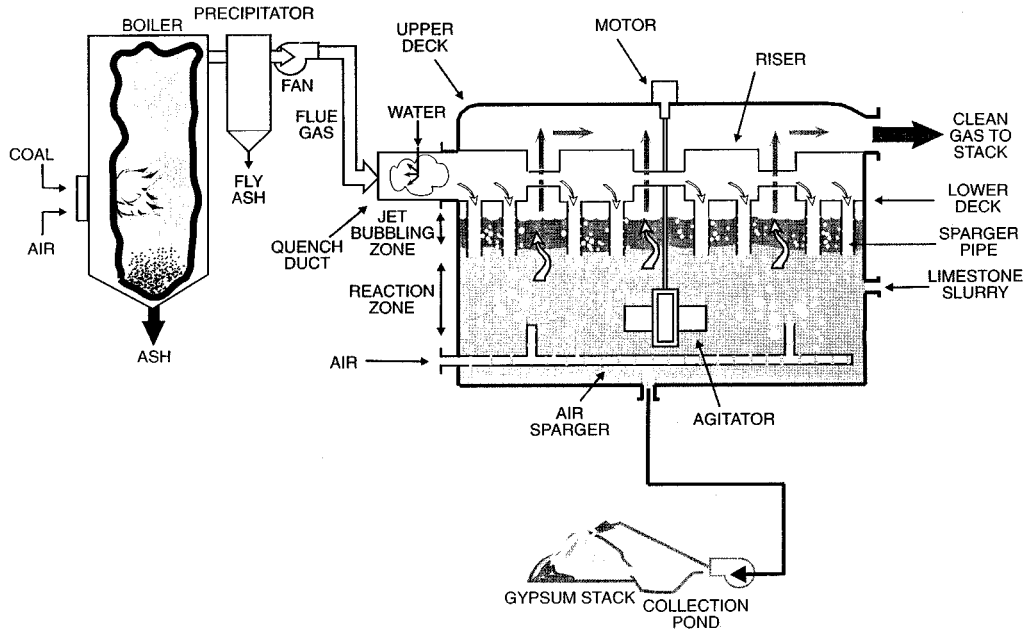

FIGURE 8.6.3 The Chioda-121 scrubber simplifies the process by bubbling the flue gas through the liquid, eliminating some equipment needs.

Spray Drying

Spray drying (Figure 8.6.4) is the most advanced form of dry SO_2 control technology. Such systems tend to be less expensive than wet FGD but remove typically a smaller percentage of the sulfur (90% compared with 98%). They are usually used when burning low-sulfur coals, and utilize fabric filters for particle collection, although recent tests have shown applicability to high-sulfur coals also.

Spray driers use a calcium oxide reagent (quicklime) which when mixed with water produces a calcium hydroxide slurry. This slurry is injected into the spray drier where it is dried by the hot flue gas. As the drying occurs, the slurry reacts to collect SO_2. The dry product is collected at the bottom of the spray tower and in the downstream particulate removal device where further SO_2 removal may take place. It may then be recycled to the spray drier to improve SO_2 removal and alkali utilization.

For small, older power plants with existing **electrostatic precipitators** (ESPs), the most cost-effective retrofit spray-dry configuration locates the spray drier and fabric filter downstream of the ESP, separating in this manner the spray drier and fly ash waste streams. The fly ash can then be sold commercially.

Control of Nitrogen Oxides

Nitrogen oxides can be removed either during or after coal combustion. The least-expensive option and the one generating the most attention in the United States is combustion control, first through adjustment of the fuel/air mixture and second through combustion hardware modifications. Postcombustion processes seek to convert NO_x to nitrogen and water vapor through reactions with amines such as ammonia and urea. Selective catalytic reduction (SCR) injects ammonia in the presence of a catalyst for greater effectiveness. So the options (Figure 8.6.5) can be summarized as

Operational changes. Reduced excess air and biased firing, including taking burners out of service;
Hardware combustion modifications. Low-NO_x burners, air staging, and fuel staging (reburning);
Postcombustion modifications. Injection of ammonia or urea into the convection pass, SCR, and wet or dry NO_x scrubbing (usually together with SO_2 scrubbing).

© 1999 by CRC Press LLC

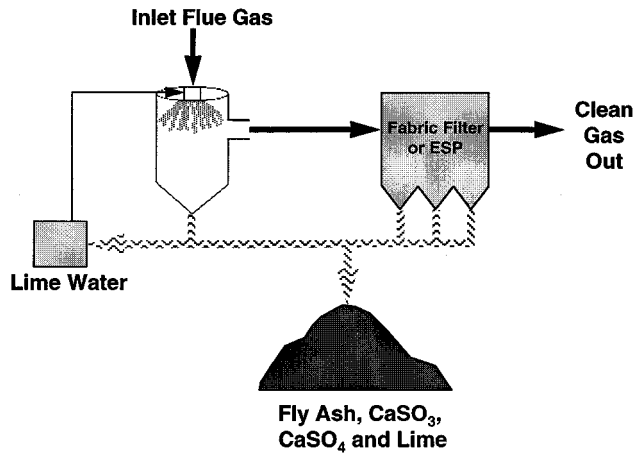

FIGURE 8.6.4 Spray driers use a calcium oxide reagent mixed with water, which is dried by the flue gas. A dry product is collected in a fabric filter.

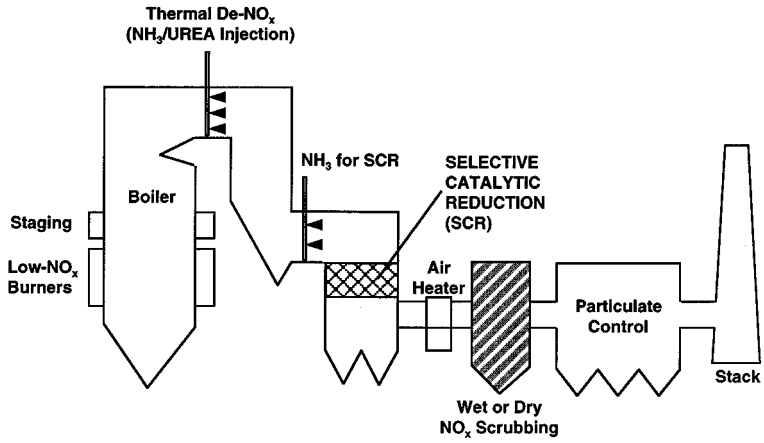

FIGURE 8.6.5 Control options for NO_x include operational, hardware, and postcombustion modifications.

Low-NO_x burners can reduce NO_x by 50% and SCR by 80%, but the low-NO_x burner option is much more cost-effective in terms of cost per ton of NO_x removed. Reburning is intermediate in cost per removed ton and can reduce NO_x 50 or 75% in conjunction with low-NO_x burners.

Fluidized Bed Plants

Introduced nearly 30 years ago, the **fluidized bed** combustion boiler has found growing application for power generation. From the first FBC boiler, generating 5000 lb/hr of steam in 1967, the technology has matured to the 250-MW-size units available today. In North America more than 170 units now

© 1999 by CRC Press LLC

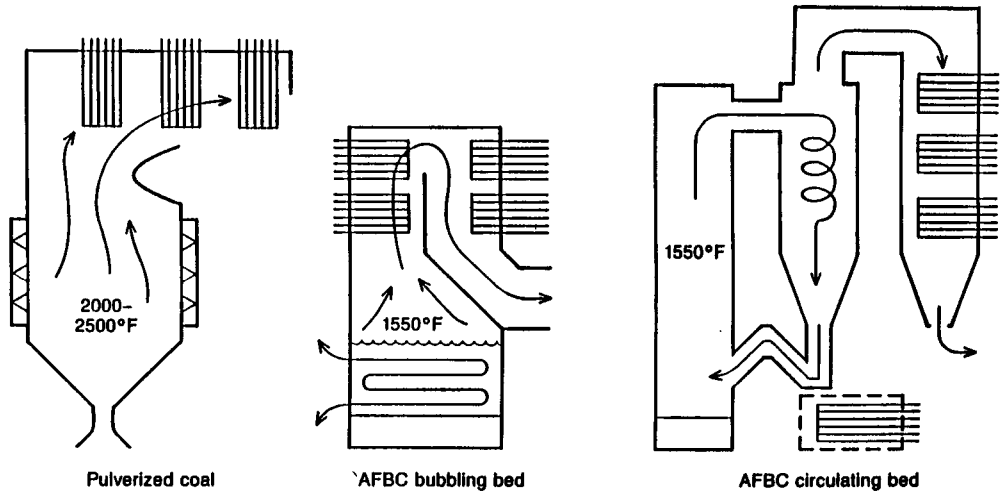

FIGURE 8.6.6 An illustration of the distinguishing features of PC and fluidized bed boilers. Noticeable in this diagram are the in-bed tubes characteristic of bubbling beds and the cyclone separator of the circulating bed.

generate in excess of 6000 MW. Burning coal in a suspended bed with limestone or dolomite permits effective capture of sulfur, and fuel flexibility allows a broad range of opportunity fuels. These fuels might include coal wastes (culm from anthracite, gob from bituminous coal), peat, petroleum coke, and a wide range of coals from bituminous to lignite. A low (1500°F) combustion temperature leads to low NO_x formation. The salient features of atmospheric fluidized bed boilers, compared with a PC boiler, are shown in Figure 8.6.6.

Utility-size demonstration projects at the Tennessee Valley Authority in 1989 (Shawnee, 160 MW) (Manaker, 1992) and Northern States Power in 1986 (Black Dog, 133 MW) (Hinrichsen, 1989) are examples of successful atmospheric bubbling bed units. The Black Dog unit has been dispatched in a daily cycling mode and has successfully fired a blend of coal and petroleum coke. But the focus of atmospheric FBC (AFBC) in the United States is now on the circulating fluid bed (CFB). In fact, more than 70% of operating fluid bed boilers in the United States are of the circulating type. The CFB unit at Nucla (Tri-State G&T Association) (Blunder, 1989) has been successful in demonstrating the technology at the 110-MW level, and commercial CFB plants have now reached 250 MW in size. Most fluidized bed units for electricity generation are being installed by independent power producers in the 50- to 100-MW-size range, where the inherent SO_2 and NO_x advantages over the unscrubbed PC plant have encouraged installations even in such traditional non-coal arenas as California (Melvin and Friedman, 1994). Worldwide, the AFBC boiler is employed largely for steam heat, with hundreds of them in operation in Russia and India, and thousands in China. The extension of the concept of fluidized beds to units where the fuel mixture is burned under several atmospheres pressure (PFBC) has now opened the way to smaller modular units with opportunities to move to efficient PFBC CCs.

Atmospheric Fluidized Bed Combustion

In the bubbling bed version of the AFBC, the fuel and inert matter, together with limestone or dolomite for SO_2 capture, is suspended through the action of fluidizing air, which flows at a velocity of 3 to 8 ft/sec in essentially a one-pass system. CFBs differ from bubbling beds in that much of the bed material passes through a cyclone separator before being circulated back to the boiler (Figure 8.6.7). In-bed tubes are generally not used for CFB units, permitting a much higher fluidizing velocity of 16 to 26 ft/sec. Since the early AFBC designs, attention has been directed toward increasing unit efficiency, and reheat designs are now usual in large units. When SO_2 capture is important, a key parameter is the ratio of calcium in the limestone to sulfur in coal. Typical calcium-to-sulfur ratios for 90% SO_2 reduction are

© 1999 by CRC Press LLC

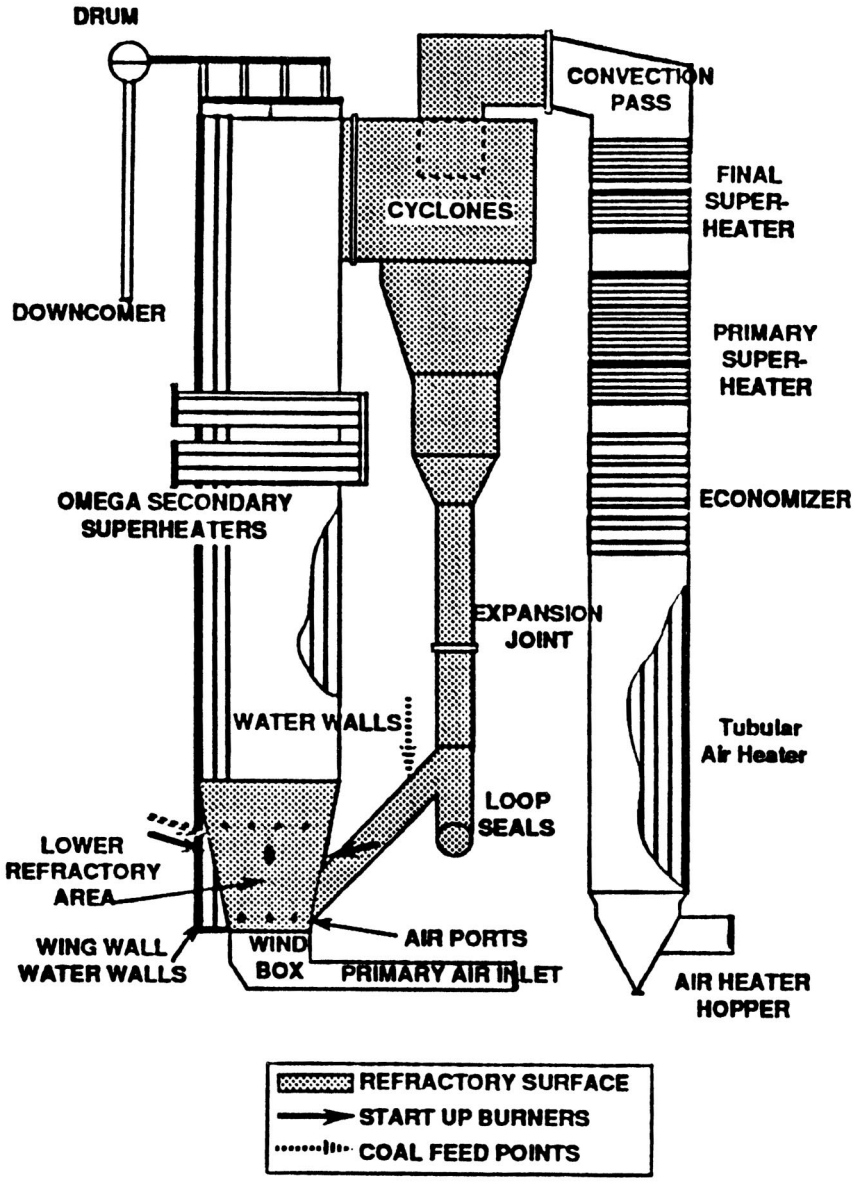

FIGURE 8.6.7 A Pyropower circulating fluid bed boiler installed at the ACE Cogeneration Company at Trona, California. This 108-MW unit burns low sulfur, western bituminous coal with limestone in a bed which circulates back to the boiler after passing through a cyclone separator.

in the range of 3.0 to 3.5 for bubbling beds and 2.0 to 2.5 for circulating beds. This depends on the fuel, however, and the 200-MW CFB units at the Conoco/Entergy plant in Lake Charles, Louisiana burning 100% **petroleum coke** (4.5% S), have a Ca/S ratio of below 1.7 for more than 90% sulfur capture. NO_x levels in AFBCs are inherently low and nominally less than 0.2 lb/MM Btu.

It is important to note that for CFBs, boiler efficiencies can be as high as a PC unit (Table 8.6.2). In fact, designs now exist for AFBCs with supercritical steam conditions, with prospects for cycles up to 4500 psia, 1100°F with **double reheat** (Skowyra et al., 1995).

Pressurized Fluidized Bed Combustion

In a PFBC CC unit (Figure 8.6.8), coal in a fluid bed is burned with dolomite or limestone in a pressurized steel chamber, raising steam for a steam turbine generator. The pressurized flue gases are expanded through a gas turbine. Commercial plants at about the 80-MW level in Sweden, the United States, and Spain have demonstrated that bubbling bed PFBC plants with a calcium-to-sulfur molar ratio of about 1.5 offer sulfur capture up to 95%, together with inherently low NO_x emissions due to low combustion temperatures. Cleanup of the flue gas before entry to the gas turbines is a key technical objective, and first-generation units have used cyclones together with gas turbines ruggedized with special blade coatings. For more-advanced, higher-efficiency PFBC systems, hot-gas cleanup technology, where the gas is directed through large ceramic filter units, will likely be needed.

To date, the 80-MW units at Vaertan (Sweden) and Escatron (Spain) and the 70-MW unit at Tidd (AEP) have operated satisfactorily, and larger units up to 350 MW are now under development. The modular aspect of the PFBC unit is a particularly attractive feature leading to short construction cycles and low-cost power. This was particularly evident in the construction of the Tidd plant, which first generated power from the CC on November 29, 1990. The heat rate and capital cost of the PFBC plant are forecast to reach very competitive levels which, when combined with shortened construction schedules, will position the technology for a role in future generation plans, particularly where modular additions have advantages.

One promising use for PFBC units is for small in-city cogeneration plants where the inherent size advantages, high efficiencies, and effective coal gas cleanup approach permit compact plants to be retrofitted in place of heating boilers, while the small steam turbines can be easily adapted to both electricity and hot water supply (Olesen, 1985).

Advanced PFBCs

In conventional PFBC plants, the overall cycle efficiency is limited to less than 42%. That is because the operating temperature of the combustor — which must be held to 1650°F (900°C) or less to avoid sintering the ash and releasing alkali metals that could foul or corrode the gas turbine — in effect sets the gas turbine inlet temperature far below the 2350°F (1290°C) or so featured in the most-efficient heavy-frame machines currently in use firing natural gas or oil.

© 1999 by CRC Press LLC

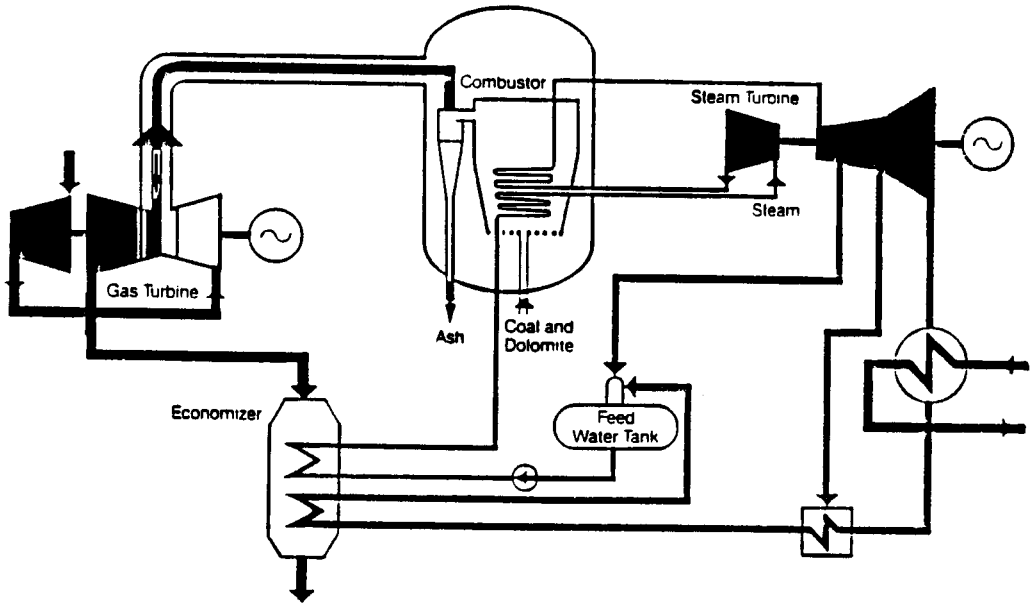

FIGURE 8.6.8 Pressurized fluidized bed with combined cycle. This 70-MW system has operated at the Tidd plant of American Electric Power.

Increasing the inlet temperature of the gas turbine, which typically provides 20 to 25% of the power in a PFBC plant, could raise the overall cycle efficiency to more than 45%. A simple means of boosting the flue gas temperature would be to fire a topping fuel, such as natural gas, ahead of the gas turbine. But 2350°F would be well above the **ash-softening temperature**, so high temperature, HP filtration systems would be essential to remove all particulate matter before firing the natural gas.

A further advance would be to use gas from coal rather than natural gas as the topping fuel. The coal would be pyrolyzed in a low-oxygen environment under pressure to produce both a low-Btu fuel gas and a residual char. The fuel gas would be passed through its own hot-gas cleanup filters before being fired in a topping combustor ahead of the gas turbine; the char would be burned in a circulating bed PFBC, from which the flue gas would also be filtered and then combined with the topping cycle gas stream. (Or the char could be simply fired in an AFBC.) With net heat rates below 7600 Btu/kWhr (45% efficiency), carbon dioxide emissions would be correspondingly low.

A U.S. DOE CCT project known as the Four Rivers Energy Modernization Project, involves building a Foster-Wheeler 95-MW advanced circulating-type PFBC unit at the Air Products chemical manufacturing facility in Calvert City, Kentucky. Steam from the unit, which will feature a coal-gas-fired topping combustor and a hot-gas cleanup system, will be used in chemical production, and the power will be sold to the Tennessee Valley Authority. The project is scheduled to begin commercial operation in October, 1998 (Carpenter and Dellefield, 1994).

Gasification Plants

One option of growing interest to coal-burning utilities is that of coal gasification. After the EPRI Cool Water demonstration in 1984 at the 100-MW level, the technology has moved ahead in the United States largely through demonstrations under the CCT program (U.S. DOE, 1994). Overseas, the 250-MW Buggenham plant in Holland is now operational, and the PSI/Destec 262-MW and TECO Energy 250-MW gasification plant demonstrations are also on-line. Beyond this, there is a 300-MW gasification unit scheduled for Endesa, Spain and a 330-MW unit for RWE in Germany (Figure 8.6.9).

© 1999 by CRC Press LLC

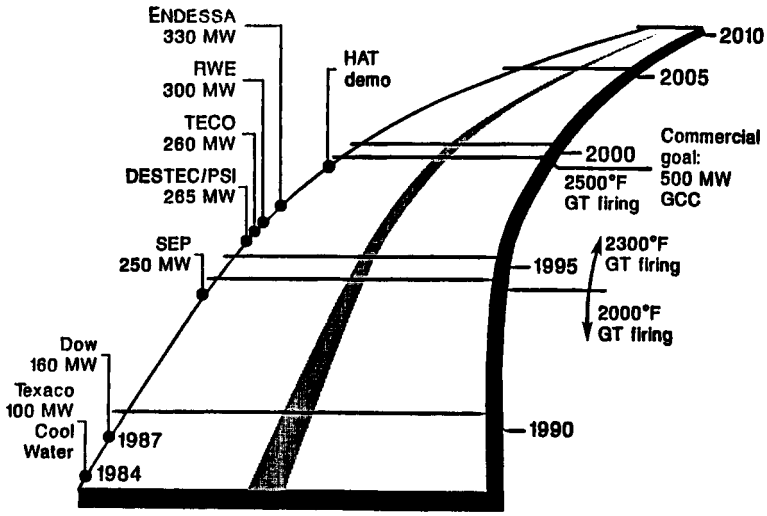

FIGURE 8.6.9 By building on the early success of the 100-MW Cool Water gasification-CC plant in California, demonstrations in the 250 to 350 MW range will be carried out in the 1995 to 2000 time frame.

Gasification-based plants have among the lowest emissions of pollutants of any central station fossil technology. Through use of the efficiency advantages of CCs, CO_2 emissions are also low. Fuel flexibility is an additional benefit since the gasifier can accommodate a wide range of coals, plus petroleum coke. Integrated gasification CC (IGCC) plants permit a hedge against long-term increases in natural gas prices since natural gas-fired CTs can be installed initially, and gasifiers at a later time when a switch to coal becomes prudent (Douglas, 1986).

The pioneering Cool Water plant, the first of its kind in the world, operated for more than 4 years, gasifying 1.1 million tons of coal and producing 2.8 million MWhr of electricity. The project was a collaborative effort of the industry involving the utility (Southern California Edison), equipment manufacturers (Texaco, General Electric), and consultants/research consortia (Bechtel, EPRI, and others). Particularly notable was the achievement of exceptionally low levels of emissions of SO_2, NO_x, and particulates, as shown in Figure 8.6.10.

Basically, IGCC plants replace the traditional coal combustor with a gasifier and gas turbine. Ultra-low emissions are realized, over 99% of the sulfur in the coal being removed before the gas is burned in the gas turbine. A gasification cycle can take advantage of all the technology advances being made in CTs and steam turbines, so as to enhance overall cycle efficiency. Net system efficiencies of 45% are expected to be demonstrated by the turn of the century, and when, in the next decade, the **fuel cell** begins to replace the gas turbine, plant efficiencies will climb to the 60% level. Major demonstrations are underway, as part of the CCT program, at Sierra Pacific Power, Pinon Pine (a KRW 99-MW air-blown, pressurized, fluidized bed coal gasifier); Tampa Electric, Polk County (a Texaco, 250-MW oxygen-blown, entrained-flow gasifier); at Tamco Power, Toms Creek (a 190-MVV joint gasification/PC plant with a Tampella Power fluidized bed gasifier); and at PSI Energy/Destec Energy, Wabash River (a 262-MW plant based on the Destec two-stage, entrained-flow, oxygen-blown gasifier). More-detailed descriptions of the Pinon Pine and Polk County gasification systems follow.

Pinon Pine IGCC

At the Sierra Pacific Power Pinon Pine plant (Figure 8.6.11), dried and crushed coal is introduced into a pressurized, air-blown, fluidized bed gasifier. Crushed limestone is added to the gasifier to capture a portion of the sulfur and to inhibit conversion of fuel nitrogen to ammonia. The sulfur reacts with the limestone to form calcium sulfide, which, after oxidation, exits along with the coal ash in the form of agglomerated particles suitable for landfill.

© 1999 by CRC Press LLC

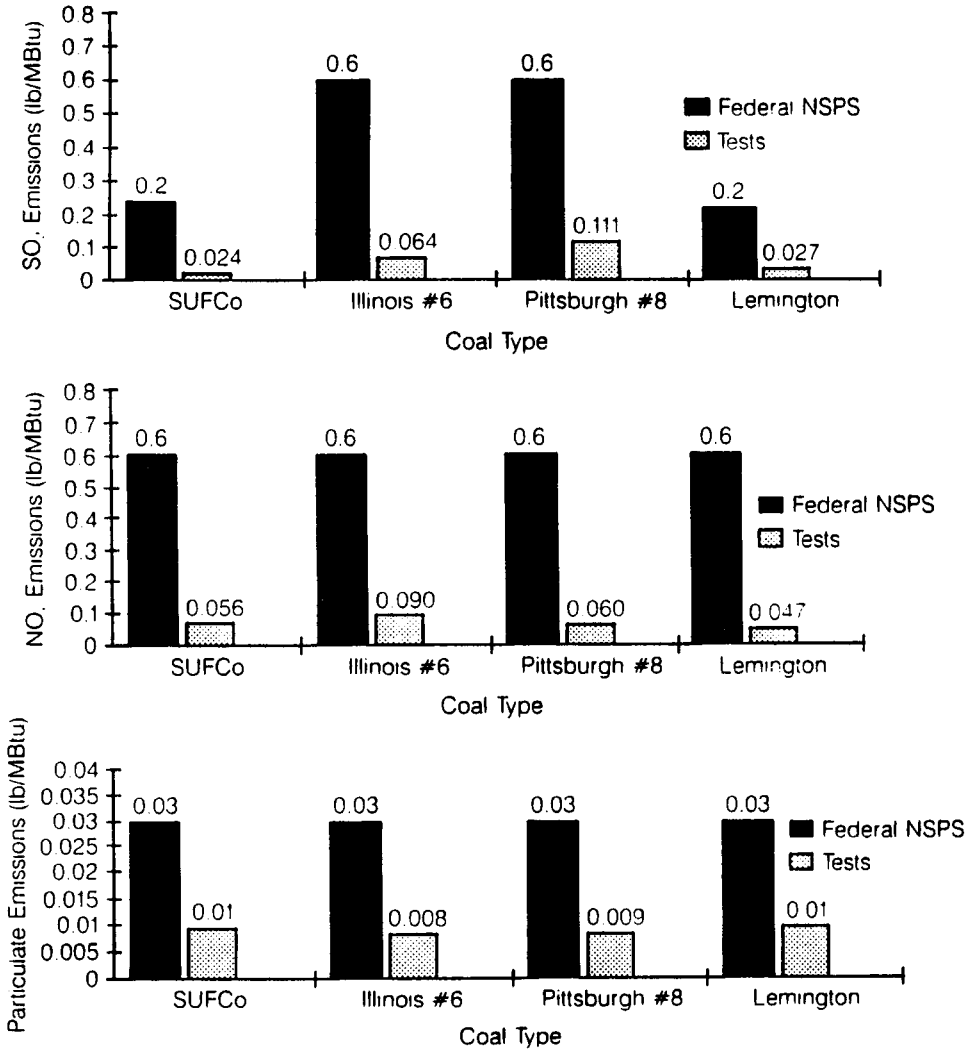

FIGURE 8.6.10 Tests at Cool Water on four coals show emissions of SO_2, NO_x, and particulates substantially below the Federal New Source Performance Standards.

Hot, low-Btu coal gas leaving the gasifier passes through cyclones, which return most of the entrained particulate matter to the gasifier. The gas, which leaves the gasifier at about 1700°F, is cooled to about 1100°F before entering the hot-gas cleanup system. During cleanup, virtually all of the remaining particulates are removed by ceramic candle filters, and final traces of sulfur are removed by reaction with metal oxide sorbent.

The hot, cleaned gas then enters the CT, which is coupled to a generator designed to produce 61 MW. Exhaust gas is used to produce steam in a heat-recovery steam generator. Superheated HP steam drives a condensing steam turbine/generator designed to produce about 46 MW.

Owing to the relatively low operating temperature of the gasifier and the injection of steam into the combustion fuel stream, the NO_x emissions are likely to be below 0.053 lb/M Btu. Because of the combination of in-bed sulfur capture and **hot-gas cleanup**, SO_2 emissions will be below 0.045 lb/M Btu (98% reduction).

© 1999 by CRC Press LLC

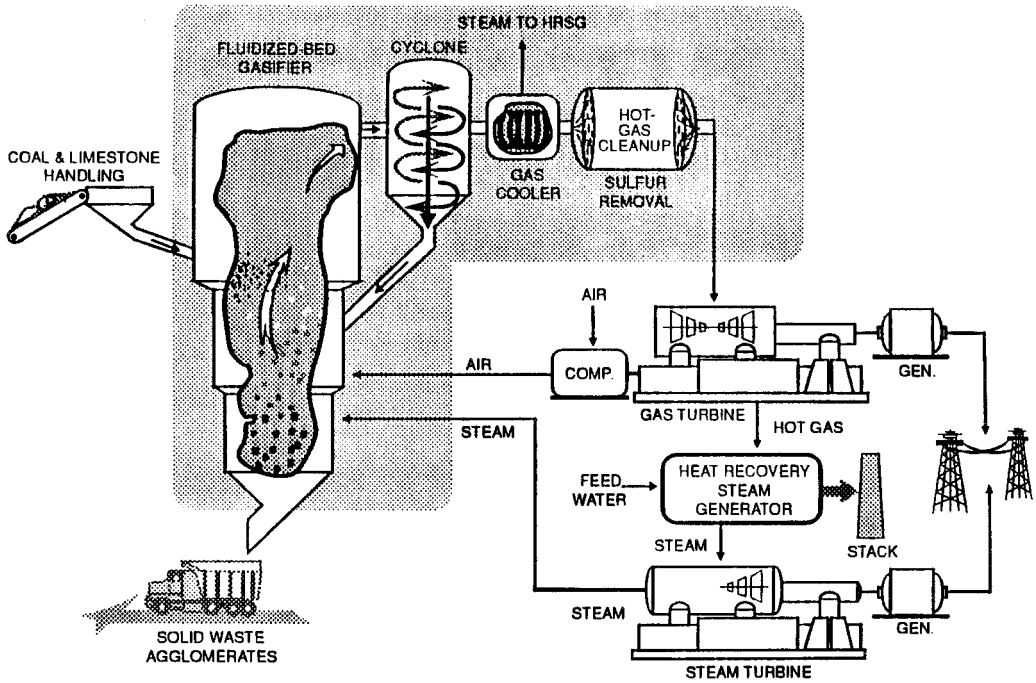

FIGURE 8.6.11 Integrated gasification CC at Sierra Pacific Power, Pinon Pine plant. This uses a KRW air-blown, pressurized fluidized bed coal gasifier, and produces 99 MW (net).

At Pinon Pine, 880 ton/day of coal are converted into 107 MW (gross), or 99 MW (net), for export to the grid. Western bituminous coal (0.5 to 0.9% sulfur) from Utah is the design coal although tests will be done using West Virginia or Pennsylvania bituminous coal containing 2 to 3% sulfur.

Polk County IGCC

The Texaco pressurized, oxygen-blown, entrained-flow gasifier will be used at the Tampa Electric Polk County plant to produce a medium-Btu fuel gas (Figure 8.6.12). Coal/water slurry and oxygen are combined at high temperature and pressure to produce a high-temperature syngas. Molten coal ash flows out of the bottom of the vessel and into a water-filled quench tank, where it is turned into a solid slag. The syngas from the gasifier moves to a high-temperature heat-recovery unit which cools the gases.

The cooled gases flow to a particulate-removal section before entering gas cleanup trains. A portion of the syngas is passed through a moving bed of metal oxide absorbent to remove sulfur. The remaining syngas is further cooled through a series of heat exchangers before entering a conventional gas cleanup train where sulfur is removed by an acid-gas removal system. These cleanup systems combined are expected to maintain sulfur levels below 0.21 lb/M Btu (96% capture). The cleaned gases are then routed to a CC system for power generation. A gas turbine generates about 192 MW. Thermally generated NO_x is controlled to below 0.27 lb/M Btu by injecting nitrogen as a diluent in the combustion section of the turbine. A heat-recovery steam generator uses heat from the gas turbine exhaust to reduce HP steam. This steam, along with the steam generated in the gasification process, is routed to the steam turbine to generate an additional 120 MW. The IGCC heat rate for this demonstration is expected to be approximately 8600 Btu/kWhr (40% efficient).

The demonstration project involves only the first 250-MW portion of the planned 1150-MW Polk County power station. Coals being used in the demonstration are Illinois 6 and Pittsburgh 8 bituminous coals having sulfur contents ranging from 2.5 to 3.5%.

© 1999 by CRC Press LLC

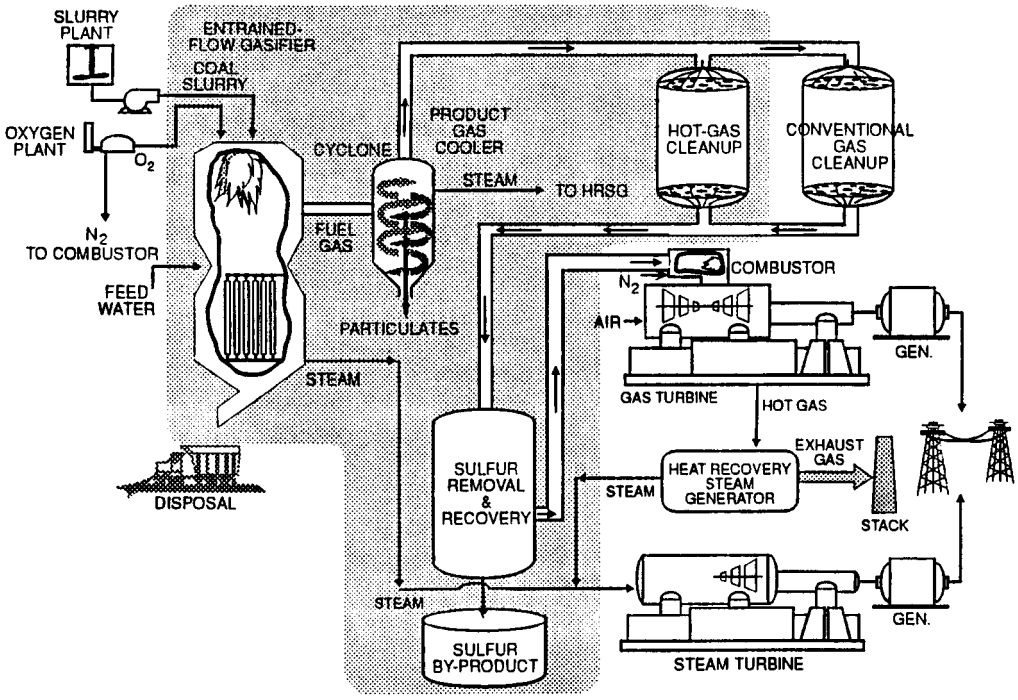

FIGURE 8.6.12 Integrated gasification CC at Tampa Electric, Polk County plant. A Texaco oxygen-blown gasifier is used. Total net generation is 250 MW.

By-products from the process — sulfuric acid and slag — can be sold commercially, sulfuric acid by-products as a raw material to make agricultural fertilizer and the nonleachable slag for use in roofing shingles and asphalt roads and as a structural fill in construction projects.

Buggenum IGCC

Meanwhile, tests are in progress on the 250-MW IGCC plant in Buggenum, Netherlands. After successful operations running on natural gas, a switch was made to coal gas using Columbia coals. Buggenum comprises a 2000-ton/day single reactor coal gasification unit and an air separation plant able to produce 1700 ton/day of 95% pure oxygen. Syngas drives a Siemens CC power unit, including a 156-MW V94.2 gas turbine and a 128-MW steam turbine. The gasifier, operating at 28 bar pressure and 2700°F is designed to produce syngas containing 42% nitrogen, 25% carbon monoxide, and 12% hydrogen, with a combustion value of 4.3 MJ/kg.

The environmental constraints are defined by permit requirements fixing upper limits of SO_2 at 0.22 g/kWhr, NO_x at 0.62g/kWhr, and particulates at 0.007 g/kWhr.

Key steps for limiting emissions include

- Removing fly ash with cyclone and candle filters after gas cooling;
- Removing halogens and other soluble pollutants with water scrubbing;
- Desulfurizing gas by catalytic and chemical processes. Sulfur is fixed in sulfinol-M solvent, which is further treated to produce elemental sulfur; and
- Desulfurized gas is mixed with nitrogen from the air separation units and saturated with water vapor to reduce its lower heating value from about 11,000 to 4300 kJ/kg greatly reducing NO_x production.

Combustion Turbine Plants

CT-based plants are the fastest growing technology in power generation. Through the turn of the century natural gas-fired CTs and CCs burning gas will account for 50 to 70% of the 900 to 1000 GW of new generation to be ordered worldwide. Almost all of these CT and CC plants will be gas fired, leading to a major expansion of gas for electricity generation (Armor et al., 1992).

It is likely that CTs and CCs will grow steadily more important in all generation regimes, peaking, midrange, and base load. If the present 2300°F firing temperature machines operate reliably and durably, CT and CC plants will begin to replace older steam plants and uneconomic nuclear plants. So until the emergence of large-scale fuel cells, CT plants will be a competitive choice for new fossil generation, and advanced CT cycles, with intercooling, reheat, possibly chemical recuperation, and most likely with humidification, will spearhead the drive to higher efficiencies and lower capital costs. Gasification, which guarantees a secure bridge to coal in the near term, will come into its own if natural gas prices rise under demand pressure, and by 2015 coal through gasification may be the economic fuel for a significant fraction of new base-load generation. The rate at which these trends develop depends in large measure on the speed of deregulation and advent of competition in the electricity industry.

Modern gas turbines for power generation are mostly heavy-frame machines, with ratings in a simple cycle configuration around 150 to 170 MW for the high firing temperatures (~2300°F) of the **"F-class" machines**. Efficiencies (LHV) are 36 to 38% in simple cycles. In CCs, the units are 220 to 350 MW in size and 53 to 55% efficient. The next generation of CTs, with efficiencies from 57 to 60% has recently been announced (Table 8.6.3). Smaller-scale aeroderivative machines have benefited from turbofan engines designed for wide-body aircraft and today are available in ratings of 35 to 65 MW and with efficiencies of 40% or more for turbine inlet temperatures around 2250°F. Beyond this, work is underway to design and build an advanced **aeroderivative turbine**, and three teams are involved: United Technologies/Fluor Daniel is looking at a humid air turbine at 200 MW and 55% efficiency; Rolls-Royce/Bechtel is studying an intercooled, regenerative design based on the Aero-Trent machine; and General Electric/Bechtel is melding the GE LM 6000 and the GE heavy-frame designs to achieve close to 60% efficiency in a 100-MW combined cycle.

Recently, General Electric announced a new concept which uses steam from the steam turbine to cool the gas turbine blades permitting a firing temperature of 2600°F. This avoids the losses due to the normal method of diverting compressor air for cooling. This "H" class turbine, it is said, will break the 60% barrier for a 400-MW CC. Comparison of the F- and H-class machines for General Electric is shown in Table 8.6.4.

Humidified Air Power Plants (Cohn, 1994)

A new class of CTs has been designed based on humidifying the combustion air. In these combustion turbine cycles the compressor exit air is highly humidified prior to combustion. This reduces the mass of dry air needed and the energy required to compress it, raising plant efficiency.

The continuous plant cycle for this concept is termed the **humid air turbine** (HAT). This cycle has been calculated to have a heat rate for natural gas about 5% better than current high-technology CCs. The HAT cycle is adaptable to coal gasification leading to the low emissions and high-efficiency characteristics of gasification CC plants but at a low capital cost since the steam turbine bottoming cycle is eliminated. A simple humidified air turbine cycle is shown in Figure 8.6.13. The addition of moisture means that perhaps 25% more mass flow goes through the turbine, than through the compressor. This suggests the use of separate spools for the turbine and compressor. By using present-day 2350°F firing temperatures it is reasonable to expect a HAT heat rate of about 6100 Btu/kWhr from this cycle.

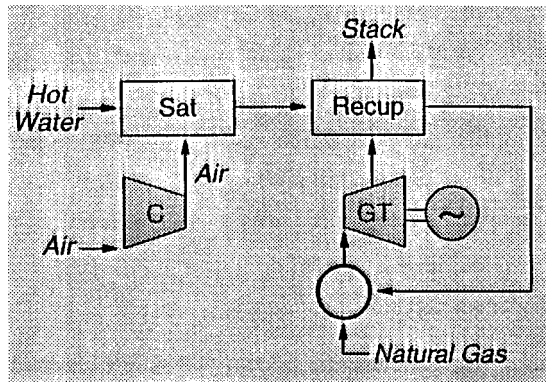

FIGURE 8.6.13 The HAT cycle adds moisture to the compressor exit air, reducing the air mass flow needed and increasing cycle efficiency.

As noted above, the ideal natural gas-fired HAT plant has been calculated to have higher efficiency (about 2 points higher) than a CC for the same turbine cooling technology. Thus, it would provide the lowest heat rate for a natural gas-fired thermal plant and would be utilized in base-load or long intermediate dispatch. The capital cost of this power plant has been calculated to be only slightly higher

© 1999 by CRC Press LLC

than that of a CC. However, the anticipated development cost for the ideal turbomachinery has been estimated to be very high, in excess of $250 million.

In contrast, the CHAT (cascaded humid air turbine) plant utilizes turbine components, which are now available, with few exceptions, in a cascade arrangement that allows them to match together. The development cost of the CHAT equipment is currently estimated to be only in the $5 to 10 million range, making its development much more practical.

The HAT and CHAT cycles can be integrated with gasification. Because these cycles directly incorporate humidification, they can make direct use of hot water generated in the gasification plant, but cannot readily utilize steam. Thus, they match well with the lower-capital-cost, but lower-efficiency, quench types of gasifier. This provides an overall power plant with efficiency about the same as an IGCC. Moreover, the capital cost of the IGHAT plant has been calculated to be about $150/kW less than an IGCC plant. These humidification cycles have yet to be offered commercially. The main obstacle is the need to demonstrate experimentally low-emission, high-efficiency, full-scale combustors utilizing very humid air.

Other Combustion Turbine Cycle Enhancements

There are several variants of the CT-based Brayton cycle which increase plant efficiency and capacity (Lukas, 1986). **Regenerative cycles** use storage-type heat exchangers, where porous or honeycomb wall structures store energy from the hot gases. This is released later to the cold gases. A **recuperative cycle** uses a heat exchanger where the hot and cold streams are separated by walls through which heat transfer occurs. This is the approach commonly used in CTs allowing gains in efficiency and reduced fuel consumption, but no specific output increase.

Intercooling between compressor stages increases useful output by about 30% for a given air mass flow, by reducing the volume flow and increasing available energy to the power turbine. It has minimal effect on efficiency, since heat removed must be added back in the combustion chamber, but is commonly used in conjunction with recuperation.

In a reheat cycle the fuel is introduced at two locations, increasing the total energy available to produce work. A combination of intercooling, reheat, and recuperation is shown in Figure 8.6.14.

Steam injection, where the steam is injected directly into the combustion chamber, increases the mass flow through the turbine and results in increased output power. Steam-injected gas turbine (SIGT) cycles have been compared from the viewpoints of efficiency, power generation, capital and operating costs, and environmental impacts with CC systems (Esposito, 1989). Above 50-MW size, it was found that CC plants were more economical and achieved significantly better heat rates, although cooling tower fog, visible plumes, and drift deposition favored SIGT plants for a flat site.

Capital and Operating Costs of Power Plants

Table 8.6.5 lists typical costs for constructing and operating fossil fuel plants as of 1993. These costs are variable depending on plant design and location; the table assumes a plant in the Northeast United States burning Pittsburgh bituminous coal. Fuel costs, not listed explicitly, will be affected by the plant efficiency, listed in the table.

Costs will vary according to type of coal burned, the size of the unit, the plant location in the United States, and the extent of environmental control employed. In this table, Pittsburgh bituminous coal is assumed, which has 7% ash, 2% sulfur, 5% moisture, and a higher heating value of 13,395 Btu/lb. Wet scrubbers for PC plants use limestone-forced oxidation. Fixed O&M costs include labor, maintenance, and overhead. Variable O&M costs are largely consumables: water, chemicals, other materials.

Summary

The preceding section has described how the future for electric power generation will increasingly be dominated by environmental control needs, putting an emphasis on the base efficiency of new generation and on heat rate recovery for existing units. The PC-fired power plant with FGD will remain a focus of

[a] Costs of new plants are likely to reduce, in real terms, over the next 10 years due to technology developments and increased worldwide competition for markets in the developing countries. New technologies (PFBC, IGCC, fuel cells) will lower capital costs as production capacity grows.

most near-term activity related to upgrades and retrofits. But new technology, based on coal gasification, is under development and being tested in a growing number of demonstration plants which promise extremely low emissions.

© 1999 by CRC Press LLC

The future for many nations will be based on exploiting the opportunities offered by clean and efficient use of coal. This implies access to the range of new technologies now being tested at large scale in the United States and other developed nations. This strategy is both timely and prudent on a global basis, as the world increasingly voices concerns related to carbon combustion.

Base-load, central generation plants will largely be focused in the immediate future on the rapidly developing areas of the world — Asia (particularly China and India) and Latin America. In these areas the fuel of choice will likely be coal, particularly in Asia, and the generating unit most often will be a conventional PC unit, but also could be an atmospheric or pressurized fluidized bed unit. In North America, Europe, and Japan, gas-fired central plants using CTs, often in a CC, will dominate through the next decade. As the cost of natural gas, relative to coal, increases, this will then encourage the installation of gasification units enabling the enormous world coal reserves to be utilized. Then, sometime after the turn of the century, smaller distributed generating sources will begin to emerge, based on gas-fired fuel cells, small CTs, or possibly photovoltaics. As the economics for the distributed option become favorable, these smaller generating units could encourage broad electrification of the developing countries of the world.

Defining Terms

Aeroderivative turbine: In the 1960s gas turbines derived from military jet engines formed a source of utility peaking capacity. Now, modern airline fan-jets are being converted to utility service. These lighter CTs are highly efficient and can have low NO_x emissions, high pressure ratios, and low capital cost.

Ash-softening temperature: The tendency for fly ash to adhere to tube banks is increased as the ash softens and melts. The point at which the ash begins to soften is dependent on the type of coal and is difficult to predict, depending on the many coal constituents. Slagging and fouling of tubes can lead to severe tube corrosion.

Coal gasification: Coal can be converted into a mixture of carbon monoxide and hydrogen by burning it with a controlled deficiency of oxygen. Use of pure oxygen produces a medium-calorific-value gas, and air a low calorific value gas. This "syngas" can then be used to power a CT.

Coextruded tubing: Tubing for superheaters and reheaters must be strong enough to withstand the pressures and temperatures expected, and also corrosion resistant to depositions of fly ash. By making tubing with a strong inner layer and corrosion-resistant outer layer through an extrusion process, both concerns can be dealt with.

Cogeneration: Cogeneration refers to the production of multiple products from a power plant. Typically, process steam, or hot water for heating, is produced in addition to electricity. This approach leads to high plant utilization, the "effective" heat rate being 70% or more.

Combined cycle: Power stations which employ both CTs (Brayton cycle) and condensing steam turbines (Rankine cycle) where the waste heat from the CTs generates steam for the steam turbines, are called *combined* cycle plants. Overall plant efficiency improves.

Electrostatic precipitators: Flue gas particles, when electrically charged in an ionized gas flow, collect on electrodes in the presence of a strong electrostatic field. Collected dust is discharged by rapping into hoppers. A collection efficiency above 99% is possible.

Double reheat: Modern designs of fossil steam-generating units remove a portion of the steam before full expansion through the turbine and reheat it in the boiler before returning it to the turbine. This enhances the thermal efficiency of the cycle by up to 5%. For supercritical cycles two stages of reheat can be justified — double reheat.

F-class machines: Recent designs of CTs have increased efficiencies resulting from increased firing temperatures. The first generation of these machines has firing temperatures of about 2300°F. They have been termed F-class machines (for example the GE 7F). Even higher temperatures have now been incorporated into "G-class" turbines.

© 1999 by CRC Press LLC

Flue gas desulfurization: Removal of sulfur dioxide, SO_2, from combustion gases is accomplished in a number of FGD methods. Most of these involve wet "scrubbing" of the gas using lime or limestone and result in a calcium sulfate waste product. A 95% removal efficiency, or higher, is possible.

Fluidized bed: A process of burning solid fuels, particularly coal, by suspending the fuel within a column of air supplied from below the furnace. This method permits effective combustion of poor-quality fuels, lowers NO_x emissions due to low combustion temperatures, and captures sulfur in the bed by mixing limestone or dolomite in with the fuel.

Fuel cell: Fuel cells convert gaseous or liquid fuels directly to electricity without any combustion process. Like a continuous battery, the fuel cell has electrodes in an electrolyte medium. Typically, hydrogen and air are supplied and DC electricity, water, and carbon dioxide are produced. They are currently high-cost, low-size devices, but with minimum environmental emissions.

Hot-gas cleanup: Cycles which use gas from the combustion of coal, typically pressurized fluidized bed or gasification cycles, need to clean up the ash particles before passing them through a gas turbine. This prevents severe erosion of the turbine blades and other components. Hot-gas cleanup can involve the application of hanging particulate traps, using ceramic filters.

Humid air turbine: A new type of CT uses humidified compressor exit air for the combustor. The mass of dry air needed is thus lessened for a given mass flow, and turbine efficiency increases. Several applications of this HAT appear attractive in gasification and compressed air storage cycles.

Intercooling: Increased output from a CT can be obtained by cooling the air between compressor stages. This reduces volume flow and increases energy to the power turbine.

Lower heating value: Fuels containing hydrogen produce water vapor as a product of combustion. The fuel heating value is said to be "lower" if the combustion process leaves all products in the gaseous state, but "higher" if the fuel heating value includes the latent heat of vaporization. Practice in the United States is to use the higher value.

On/off cycling capability: Generating units are often not required on a 24-hr basis. Some are shut down during low-demand times and started up perhaps hours later. This form of on/off cycling imposes thermal stresses on the equipment, leading to premature equipment failure unless special measures are taken to deal with this.

Petroleum coke: Petroleum coke is a residual product of the oil-refining process, and in its fuel-grade form is an almost pure carbon by-product. About 19 million tons of fuel-grade pet coke is produced each year in the United States. It is inexpensive although it may have high sulfur and vanadium content.

Recuperative cycle: Recuperative cycles for CTs use walls between the hot and cold streams through which heat is transferred. This improves efficiency and reduces fuel consumption.

Regenerative cycles: Combustion turbine cycles using heat exchangers to store and transfer heat from the hot gases to the cold gases are termed regenerative cycles.

Slagging and fouling: The mineral matter in coal can attach itself following combustion to the boiler walls and heat-exchanger surfaces. Oxides of silicon, aluminum, iron, calcium, and magnesium can foul all boiler surfaces, requiring soot blowers for cleaning. Hot ash can melt, becoming sticky and sometimes coalescing in the furnace to cause slagging problems.

Spray drying: Spray driers, for desulfurization, used typically when burning lower-sulfur coals, use a spray of quicklime which is dried by the hot flue gas and results in a dry solid product. A 90% removal efficiency is typical.

Steam injection: Injecting stream directly into the combustion chamber of a CT increases turbine mass flow and thus increases the output power.

Temper embrittlement: Tempering of steel in the manufacturing process removes some of the brittleness and is carried out by a heating and cooling process. During operation, though, it is possible that ductility can worsen close to specific tempering temperatures. The material is then said to be temper embrittled, and premature cracking may follow.

8.7 Energy Storage

Chand K. Jotshi and D. Yogi Goswami

Introduction

Energy storage is very important for utility load leveling, electrical vehicles, solar energy systems, uninterrupted power supply, and energy systems at remote locations. Two important parameters for energy storage are duration of storage and **specific energy** or **energy density**. Duration of energy storage may vary from many years to a fraction of a second. In a nuclear power plant, nuclear fuel is stored within a reactor for a year. Coal piles, gas and oil storage tanks, or pumped hydro are kept by power utilities for several days use, depending upon the need. Similarly for a solar energy system, requirement of energy storage may be on an hourly, daily, or weekly basis. Specific energy or energy density is a critical factor for the size of a storage system.

Energy can be stored as mechanical, thermal, chemical, electrical, or magnetic energy. In this section, storage of thermal, mechanical, and electrical energy are described.

Thermal Energy Storage (TES)

Thermal energy can be stored as sensible heat, latent heat, or as the heat of chemical reaction (thermochemical).

Sensible heat, Q, is stored in a material of mass m and specific heat C_p by raising the temperature of the storage material and is expressed by Equation (8.7.1):

$$Q = mc_p\Delta T \tag{8.7.1}$$

Most common sensible heat storage materials are water, organic oils, rocks, ceramics, and molten salts. Some of these materials along with their physical properties are listed in Table 8.7.1. Water has the highest specific heat value of 4190 J/kg · C.

TABLE 8.7.1 Physical Properties of Some Sensible Heat Storage Materials

Storage Medium	Temperature Range, °C	Density (ρ), kg/m³	Specific Heat (C), J/kg K	Energy Density(ρC) kWhr/m³ K	Thermal Conductivity (W/m K)
Water	0–100	1000	4190	1.16	0.63 at 38°C
Water (10 bar)	0–180	881	4190	1.03	—
50-ethylene glycol–50 water	0–100	1075	3480	0.98	—
Dowtherm A® (Dow Chemical, Co.)	12–260	867	2200	0.53	0.112 at 260°C
Therminol 66® (Monsanto Co.)	–9–343	750	2100	0.44	0.106 at 343°C
Draw salt ($50NaNO_3$-$50KNO_3$)[a]	220–540	1733	1550	0.75	0.57
Molten Salt ($53KNO_3/40NaNO_2/7NaNO_3$)[a]	142–540	1680	1560	0.72	0.61
Liquid sodium	100–760	750	1260	0.26	67.5
Cast iron	m.p. (1150–1300)	7200	540	1.08	42.0
Taconite	—	3200	800	0.71	—
Aluminum	m.p. 660	2700	920	0.69	200
Fireclay	—	2100–2600	1000	0.65	1.0–1.5

[a] Composition in percent by weight.

Thermal energy, Q, can be stored as latent heat in a material of mass, *m*, that undergoes phase transformation as given by Equation (8.7.2):

$$Q = m\lambda \tag{8.7.2}$$

where λ = heat of phase transformation.

Four types of phase transformations useful for latent heat storage are: solid $\rightleftarrows$ liquid, liquid $\rightleftarrows$ vapor, solid $\rightleftarrows$ vapor, and solid $\rightleftarrows$ solid. Since phase transformation is an isothermal process, thermal energy is stored and retrieved at a fixed temperature known as the transition temperature. Some common phase change materials (PCMs) used for thermal storage are paraffin waxes, nonparaffins, inorganic salts (both anhydrous and hydrated), and eutectics of organic and/or inorganic compounds. Table 8.7.2 lists some PCMs with their physical properties.

TABLE 8.7.2 Physical Properties of Latent Heat Storage Materials or PCMs

Storage Medium	Melting Point °C	Latent Heat, kJ/kg	Specific Heat (kJ/kg °C)		Density (kg/m³)		Energy Density (kWhr/m³ K)	Thermal Conductivity (W/m K)
			Solid	Liquid	Solid	Liquid		
$LiClO_3 \cdot 3H_2O$	8.1	253	—	—	1720	1530	108	—
$Na_2SO_4 \cdot 10H_2O$	32.4	251	1.76	3.32	1460	1330	92.7	2.25
$Na_2S_2O_3 \cdot 5H_2O$	48	200	1.47	2.39	1730	1665	92.5	0.57
$NaCH_3COO \cdot 3H_2O$	58	180	1.90	2.50	1450	1280	64	0.5
$Ba(OH)_2 \cdot 8H_2O$	78	301	0.67	1.26	2070	1937	162	0.653ℓ
$Mg(NO_3) \cdot 6H_2O$	90	163	1.56	3.68	1636	1550	70	0.611
$LiNO_3$	252	530	2.02	2.041	2310	1776	261	1.35
$LiCO_3/K_2CO_3$, (35:65)[a]	505	345	1.34	1.76	2265	1960	188	—
$LiCO_3/K_2CO_3/Na_2CO_3$ (32:35:33)[a]	397	277	1.68	1 63	2300	2140	165	—
n-Tetradecane	5.5	228	—	—	825	771	48	0.150
n-Octadecane	28	244	2.16	—	814	774	52.5	0.150
HDPE (cross-linked)	126	180	2.88	2.51	960	900	45	0.361
Steric acid	70	203	—	2.35	941	847	48	0.172ℓ

[a] Composition in percent by weight.

Note: ℓ = liquid.

Thermochemical energy can be stored as heat of reaction in reversible chemical reactions. In this mode of storage, the reaction in the forward direction is endothermic (storage of heat), while the reverse reaction is exothermic (release of heat). For example,

$$A + \Delta H \rightleftarrows B + C \tag{8.7.3}$$

The amount of heat *Q* stored in a chemical reaction depends on the heat of reaction and the extent of conversion as given by Equation (8.7.4):

$$Q = a_r m \Delta H \tag{8.7.4}$$

where a_r = fraction reacted, ΔH = heat of reaction per unit mass, and *m* = mass.

Chemical reaction is generally a highly energetic process. Therefore, a large amount of heat can be stored in a small quantity of a material. Another advantage of thermochemical storage is that the products of reaction can be stored at room temperature and need not be insulated. For sensible and latent heat storage materials, insulation is very important. Examples of reactions include decomposition of metal hydrides, oxides, peroxides, ammoniated salts, carbonates, sulfur trioxide, etc. Some useful chemical reactions are reported in Table 8.7.3.

			O_2(g)	10000	20	130	280

Note: s = solid, ℓ = liquid, g =gas.

Applications and Examples

Cool Storage has major applications in space cooling of buildings, food and medicine preservation, and transportation of items that need to be stored at low temperatures. A major application of cool storage is in the use of off-peak electricity for air-conditioning during peak hours. During off-peak hours electricity can be used to make ice or chilled water, which can be used later for air-conditioning of buildings during the peak hours. The advantage of using ice as a storage medium over chilled water is that a much larger amount of coolness can be stored in ice; 1 kg of ice stores 335 kJ, whereas 1 kg of water stores only 42 kJ for a temperature swing of 10°C. The disadvantage of ice is its lower thermal conductivity, which is responsible for lower heat-transfer rates.

Cool storage systems have been used in several buildings in the United States and Canada. The Merchandise Mart of Chicago boasts the largest ice storage system in the world: each day more than 2 million lb of ice are made and melted. For long-term cool storage, aquifers have been used for chilled water storage. Examples include cooling of buildings at the University of Alabama and the United States Postal Service in Long Island, NY, using chilled water stored in aquifers (Tomlinson and Kannberg, 1990). Other materials which have been found to have cool storage potential are PCMs like $LiClO_3 \cdot 3H_2O$, a eutectic of Glauber's salt, paraffins and their mixtures, and some gas hydrates or clatherates.

Heat Storage has major applications in space heating, crop drying, cooking, electric power generation, industrial process heat (air and steam), waste heat utilization, and solar energy utilization, etc. Heat storage in water is the most economical and well-developed technology. Epoxy-lined steel, fiberglass-reinforced polymer, concrete with plastic liner, and wood tanks are suitable containment materials for systems using water as the storage material. The storage tanks may be located above or below ground. In North America and China, aquifers have been used for long-term storage of hot water and chilled water. Pressurized water tanks are used to store heat from off-peak electricity (ASHRAE, 1995). For example, water is heated to maximum temperatures of about 138°C in a tank at a pressure of 50 psig.

Molten nitrate salt (50 wt% $NaNO_3$/50 wt% KNO_3) also known as Draw salt, which has a melting point of 222°C, has been used as a storage and a heat-transfer fluid in an experiment in Albuquerque, NM. It was the first commercial demonstration of generating power from storage (Delameter and Bergen, 1986). Solar Two, a 10-MW solar thermal power demonstration project in Barstow, CA, is also designed to use this molten salt to store solar energy (Chavez et al., 1995). Another molten nitrate salt is 40 wt% $NaNO_2$/7 wt% $NaNO_3$/53 wt% KNO_3, known as HTS (heat-transfer salt) with a melting point of 142°C. This salt has been widely used in the chemical industry.

For applications in heating and cooling of buildings the containment of PCM can become an integral part of the building. It may be part of the ceiling, wall, or floor of the building and may serve a structural or a nonstructural function. Tubes, trays, rods, panels, balls, canisters, and tiles containing PCMs have been studied in the 1970s and 1980s for space-heating applications (Moses and Lane, 1983). The PCMs used were mostly salt hydrates such as Glauber's salt ($Na_2SO_4 \cdot 10H_2O$), Hypo ($Na_2S_2O_3 \cdot 5H_2O$),

© 1999 by CRC Press LLC

$NaCH_3COO \cdot 3H_2O$, $Na_2HPO_4 \cdot 12H_2O$, $Ba(OH)_2 \cdot 8H_2O$, $MgCl_2 \cdot 6H_2O$, and $Mg(NO_3)_2 \cdot 6H_2O$. Paraffin mixtures have been used for thermal storage in wall boards. Some PCMs, such as salt hydrates, exhibit supercooling and phase segregation problems during heat removal. Low thermal conductivity and complex mechanism of heat transfer during melting and freezing introduce complexities in the design of their containment systems.

Mechanical Energy Storage

Mechanical energy may be stored as potential or kinetic energy.

Kinetic Energy

Kinetic energy can be stored in the rotating mass of a wheel, commonly known as a flywheel. Kinetic energy of a rotating body is given by Equation (8.7.5):

$$KE = \frac{1}{2} I\omega^2 \tag{8.7.5}$$

where I = moment of inertia, and ω = angular velocity.

The maximum specific energy of a flywheel is expressed by the following equation (Jenser, 1980):

$$\frac{KE_{max}}{m} = A\frac{\rho_{max}}{\rho} \tag{8.7.6}$$

where A = shape factor, and its value depends on the geometry of flywheel; $A = 1.0$ for a constant stress disk and 0.5 for a thin-rimmed flywheel. This equation shows that high tensile strength and low density are the key parameters to store maximum energy. Tensile strength, density, and specific energy of some materials are given in Table 8.7.4.

TABLE 8.7.4 Flywheel Rotor Materials

Material	Design Stress, MN/m²	Density, kg/m³	Specific Energy, Whr/kg
Composite fiber[a]/epoxy	750	1550	51.5
E-glass fiber[a]/epoxy	250	1990	14.0
S-glass fiber[a]/epoxy	350	1900	19.6
Kevlar fiber[a]/epoxy	1000	1400	76.2
Maraging steel	900	8000	24.2
Titanium alloy	650	4500	30.8

[a] 60% fiber.

Storing energy in a flywheel is one of the oldest techniques used in ancient potteries. Present-day flywheels are much more advanced as a result of superstrong/ultralight composite materials and frictionless high-performance magnetic bearings.

Potential Energy

If a body of mass m is elevated against the gravitational force g to a height Δh, the potential energy stored is given by

$$PE = mg\Delta h \tag{8.7.7}$$

From Equation (8.7.7), 1 Wh of energy can be stored in 1 kg mass of a body by raising it to a height of 367 m.

© 1999 by CRC Press LLC

Potential energy is also stored in a spring, either by compressing or expanding. Here, energy stored is given by

$$\text{PE} = (1/2)kx^2 \tag{8.7.8}$$

where k = spring constant and x is the distance to which the spring is compressed or expanded. Springs have been widely used to power toys and watches mainly because of very low values of energy density.

Pumped Hydro

Water may be pumped from a lower reservoir to a higher reservoir using electricity during off-peak hours, which may be used to generate electricity using hydraulic turbines during peak hours. Figure 8.7.1a shows a schematic diagram of an above-ground pumped hydro system. Advantages of pumped hydro units include simple operation, high reliability, low maintenance, long life, quick start from standstill, and economic generation of peaking electrical energy. In the United States a large number of such systems are in operation. Power-generating capacities of these systems vary between 5 and 2000 MW (Makansi, 1994). The overall efficiencies of these power plants vary between 65 and 90%, which includes the efficiencies of pumps, hydraulic turbines, generators, and losses from the upper reservoir. In spite of the technical and economic viability of pumped hydro, the requirement of a specific type of topography and some environmental concerns limit its application. To overcome these problems, a concept of underground pumped hydro storage as shown in Figure 8.7.1b can be used. In this case, large caverns or aquifers can be used as the lower reservoir.

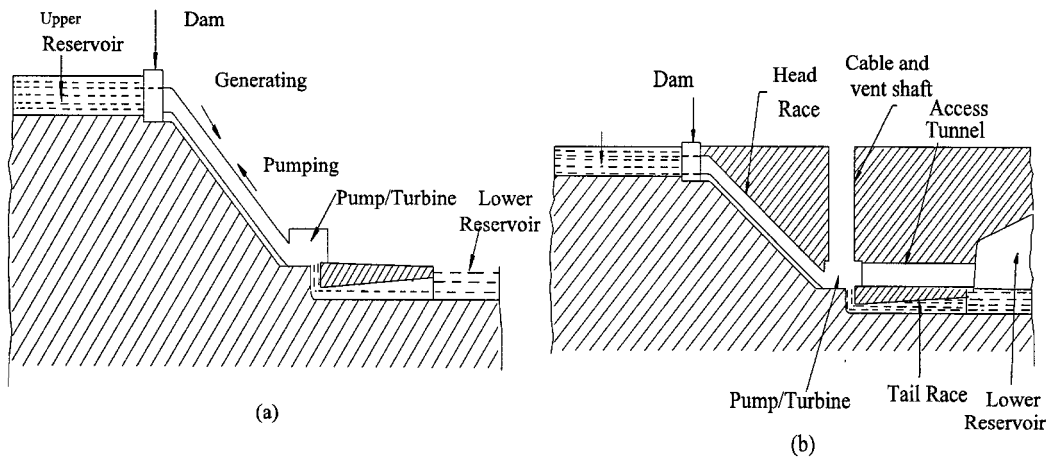

FIGURE 8.7.1 Pumped hydrostorage: (a) above ground; (b) underground.

Compressed Air Storage

In a fossil fuel power plant, approximately half of the output of a conventional gas turbine is used to drive the compressors. If the air is compressed during off-peak hours and stored, it can be used later during peak hours. Compressed air can be stored underground in abandoned mines, oil or gas fields, sealed aquifers, or natural caverns. A compressed air storage plant in Huntorf, Germany that has been in operation since 1978 is the oldest unit. A 110-MW demonstration facility at the Alabama Electric Cooperative (AEC), Inc., McIntosh, Alabama , site has been in operation since 1991. The Hunterof unit is a 4-hr facility and the AEC site is a 26-hr facility (Makansi, 1994).

© 1999 by CRC Press LLC

Electrical Energy Storage

Electrochemical energy storage, more commonly known as battery storage, stores electrical energy as chemical energy. Batteries are classified as primary and secondary batteries. Only secondary batteries are rechargeable and are therefore suitable for energy storage applications. Lead-acid and nickel-cadmium are well-known rechargeable batteries that are most commonly used. Lead-acid batteries have been used for over a century and are still the most popular batteries.

Electrochemical operation of a cell during discharge and charge is shown in Figures 8.7.2a and b. During discharge when a cell is connected to a load, electrons flow from the anode to the cathode. In this operation oxidation, or loss of electrons, takes place at the anode, and reduction, or gain of electrons, occurs at the cathode. The cell chemistry of a lead-acid battery is as follows: the anode is lead (Pb) and the cathode is lead oxide (PbO_2); the electrolyte is H_2SO_4. The cell reaction is

$$2H_2SO_4 \rightarrow 4H^+ + 2SO_4^-$$

$$\text{Anodic reaction:} \quad Pb + SO_4^{2-} = PbSO_4 + 2e^- \tag{8.7.9}$$

$$\text{Cathodic reaction:} \quad PbO_2 + SO_4^{2-} + 4H^+ + 2e^- = PbSO_4 + 2H_2O \tag{8.7.10}$$

Theoretical voltages and capacities of some known batteries are reported in Table 8.7.5.

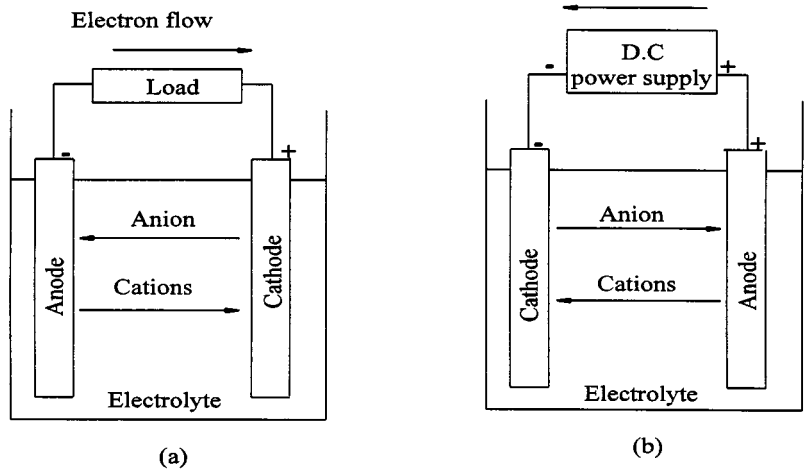

FIGURE 8.7.2 Electrochemical operation of a cell: (a) discharge; (b) charge.

TABLE 8.7.5 Properties of Some Rechargeable Batteries

No.	System	Electrolyte	Temp. °C	O.C.V. (V)	Energy Density (Theoretical), Whr/kg	Energy Density (Achievable), Whr/kg	In/Out Electrical Effciency	Cycle Life
1	Lead-Acid	H_2SO_4	20–30	2.05	171	50	75	1000
2	Nickel-Iron	KOH	20–30	1.37	267	60	55	2000
3	Zinc-Iron	KOH	50–60	1.65	1084	90	45	600
4	Sodium-Sulfur	β-Al_2O_3	300–375	1.76–2.08	664	120	75	2000
5	Lithium-Iron Sulfide	LiCl-KCl (eutectic)	400–450	1.6	869	150	75	1000

Note: O.C.V. = open cell voltage.

Applications

Battery storage is used in a wide range of applications. Currently, the main emphasis of research is on applications in vehicles and load leveling.

Electric Vehicles. For electric vehicles, the specific energy and specific power are two important parameters. The greater the specific energy, the farther a vehicle can travel. If specific power is high, a vehicle can accelerate more quickly and have a higher top speed. Other important requirements are the ability to charge and discharge a large number of times, to retain charge over an extended period of time, and to charge and discharge over a wide range of temperatures. Table 8.7.5 provides information about some rechargeable batteries.

Power Plants. Recent start-up of a commercial unit for the Puerto Rico Electric Power Authority (PREPA) is the latest development in large-scale application of lead-acid batteries. The facility stores 20 MW for 20 min, both for peaking requirement and voltage and frequency control. Maximum discharge is limited to 10 MW (Makanasi, 1994).

Defining Terms

Cool storage: The storage of thermal energy at temperatures below the nominal temperature required by the space or process.

Heat storage: The storage of thermal energy at temperatures above the nominal temperature required by the space or process.

Energy density: Amount of energy stored per unit volume, kJ/m^3 or kWhr/m^3.

Specific energy: Amount of energy stored per unit mass, kJ/kg or kWhr/kg.

8.8 Nuclear Power

Roberto Pagano and James S. Tulenko

Nuclear power refers to power generated through reactions involving atomic nuclei (i.e., nuclear reactions). These reactions fall into three broad categories — fusion reactions, fission reactions, and radioisotopes. In fusion, two light nuclei (most commonly isotopes of hydrogen) combine to form a heavier nucleus (usually helium), with energy being released in the process. Nuclear fusion is the source of energy generated in the stars (our sun). In artificial applications, the technology to induce fusion reactions has been available for several decades, but such reactions have been essentially uncontrolled (the hydrogen bomb). Once initiated, fusion reactions generate huge amounts of energy, which is subsequently released explosively. Means to produce and release energy from fusion in a sustained, controlled manner are still being developed. Extensive research is ongoing, both in the United States and abroad, on the development of nuclear fusion as a controlled source of power.

Nuclear fission, in contrast, is the basis of a mature technology applied to the generation of power. Fission is the fragmentation of a heavy nucleus into two, sometimes three, lighter nuclei. Certain nuclides found in nature fission spontaneously, that is, with no external intervention. However, spontaneous fission in naturally occurring nuclides takes place at a very slow rate. Fission can be induced through a nuclear reaction. Of primary interest here is the fissioning of several specific nuclei through interactions with neutrons. Again, the fissioning of a nucleus is accompanied by the release of energy.

At present, the element of primary importance with respect to nuclear fission power is uranium. Naturally occurring uranium consists of three isotopes — ^{238}U, ^{235}U, and ^{234}U. In a mixture of isotopes of an element, the abundance of any one is usually expressed as the number of atoms of that isotope present per 100 atoms of the mixture, abbreviated as atom percent a/o or weight percent w/o. Natural uranium consists of 99.2745 a/o ^{238}U, 0.7200 a/o ^{235}U, and 0.0055 a/o ^{234}U.

Radioisotope power is the third form of nuclear energy. When radioisotopes decay, high-energy electrons (beta particles), helium atoms (alpha particles), and gamma rays (photons) are emitted. When the energy of these radiations is stopped and converted to heat, a power source is created. Radioisotopes decay energies range from 0.01 to 10 MeV. Radioisotopes are generally separated from radioactive wastes produced from nuclear power plants. The most common radioisotopes are polonium-210 (alpha emitter of 5.3 MeV), plutonium-238 (alpha emitter of 5.46 MeV), cesium-144 (beta emitter of 1.25 MeV), and strontium-90 (beta emitter of 1.10 MeV).

The Fission Process

Consider first the fission of a nucleus of ^{235}U caused by an interaction with a neutron. A compound nucleus of ^{236}U is initially formed. If fission occurs, it does so within a very short time. Normally with thermal reaction, 85% of the interaction leads to fission. Alternatively, the compound nucleus dissipates energy by emitting a gamma photon, no fission occurs and the nucleus remains as ^{236}U. This latter process occurs in 20% of the interaction of ^{235}U with a neutron.

The fissioning of a nucleus produces fission fragments called fission products, a number of neutrons and gamma photons. Most frequently, the number of neutrons is 2 or 3, ranging in extreme cases from 0 to 8. In the fissioning of ^{235}U, the average number of neutrons released, designated by υ, has a value of 2.42. This value applies strictly if the fission is induced by a neutron of relatively low kinetic energy, called a thermal neutron.

In a nuclear reactor, which is a special material medium in which ^{235}U is dispersed for the reactor to work, one of the neutrons liberated in the fissioning of a nucleus must go on to induce a fission in another nucleus. This leads to the idea of a self-sustaining chain reaction or, more specifically, a **critical configuration** in which a self-sustaining chain reaction can be maintained indefinitely. To this end, an adequate supply of ^{235}U must be on hand and replenished as needed. Further, the configuration must be

© 1999 by CRC Press LLC

such that the likelihood that any particular neutron ultimately induces a fission is adequately high to ensure that on average one neutron will induce a fission.

The energy liberated in fission results from Einstein's equation $E = Mc^2$, which says that mass and energy are equivalent. A summation of the masses of the fission fragments and the neutrons resulting from fission shows that the combined mass of the products of a fission is less than the mass of the compound nucleus before fission occurs. It is found that the energy released is equal to $E = \Delta Mc^2$ when ΔM is the difference in the masses. This nuclear energy is traditionally expressed in units of electron volts (eV), with the equivalence of 1 eV = 1.602×10^{-19} J. The single fission of a single uranium atom releases approximately 200×10^6 eV, or 200 MeV, of energy. When one realizes that the combusion of a single carbon atom ($C + O_2 \rightarrow CO_2$) releases 4 eV, a quantity 50 million times smaller, one gets a true appreciation of the concentrated power of nuclear energy.

Most of the energy liberated in a fission appears as the kinetic energy of the fission fragments (168 MeV, or 84%) and the kinetic energy of the neutrons (5 MeV, or 2.5%). The remainder is distributed among the gamma photons appearing instantaneously with the fission and the energy associated with the radioactive decay of the fission fragments. These fragments are readily stopped in the reactor. Their range is of the order of 0.01 to 0.001 mm. Thus, the major portion of the energy from a fission is deposited within a very short distance from the site of the fission.

In the largest power reactors in operation in the United States today, heat is generated at the rate of 3800 MW. At 200 MeV per fission, fissioning in such reactors must occur at the rate of 1.2×10^{20} fissions/sec to produce the power. In terms of ^{235}U, this requires the fissioning of all the nuclei contained in 0.047 g of ^{235}U, or the fissioning of approximately 4 kg per day. Thus, as a rule of thumb, the fissioning of all the nuclei present in 1 g of ^{235}U is sufficient to generate 1 MW day of thermal energy. In contrast, the generation of the same amount of energy from coal requires the combustion of 4 tons of coal of typical heating value. With the combustion of coal there is the associated release of a large quantity of carbon dioxide (~14 tons) to the atmosphere with its effects on global warming.

Cross Sections

A measure of the probability of a particular nuclide to interact with a neutron is provided by a quantity known as a **cross section**. Numerical values of cross sections are determined experimentally and are expressed in units of barns (b), with 1 b defined as 10^{-24} cm^2, or 10^{-28} m^2.

As a quantity, a cross section may be interpreted as a target area — the larger the cross section, the more likely the interaction of the nucleus with a neutron in its vicinity. For example, the cross section for fission of ^{235}U, denoted by σ_f^{235}, has a value of 582 b if the interacting neutron is traveling at the velocity associated with thermal energy (2200 m/sec). If the neutron is traveling at high energy, the cross section may drop to a value of approximately 2 b. With respect to the radiative capture of a neutron in ^{235}U leading to the formation of ^{236}U, the cross section is given by $\sigma_c^{235} = 99$ b, if the neutron is thermal. In summary, a cross section is a property specific to a given nuclide, but it is a property whose value depends on the energy of the interacting neutron.

Cross sections are additive. Thus, the cross section for the absorption of a thermal neutron in ^{235}U — whether the absorption gives rise to a fission or a radiative capture — is given by $\alpha_a = \alpha_f + \alpha_c = 582$ b + 99 b = 681 b. Further, the probability of a fission occurring as a result of a thermal neutron being absorbed in ^{235}U is given by $\alpha_f/\alpha_a = 582$ b/681 b = 0.85. Fission is, therefore, the more likely outcome of an interaction between a ^{235}U nuclide and a thermal neutron.

On average, the neutrons arising from the fissioning of ^{235}U have a kinetic energy of 2 MeV, corresponding to a speed of 2×10^7 m/sec. These neutrons are four orders of magnitude greater than the speed at which a neutron is considered to be thermal (2200 m/sec).

© 1999 by CRC Press LLC

Categories of Nuclear Reactors

A prerequisite for a self-sustaining chain reaction is that sufficient ^{235}U be present in the medium to ensure that the absorption of a neutron in a nucleus of ^{235}U is a likely occurrence. If the population of neutrons present in the medium at any instant consists predominantly of slow neutrons, a far lesser amount of ^{235}U is needed to ensure criticality than would be the case if the population were to consist of fast neutrons. This comes about because of the difference in the values of the cross sections mentioned previously.

There is, from this particular standpoint, an incentive to slow down the neutrons originating in fission in order to reduce the inventory of ^{235}U needed to maintain criticality. In the power reactors operating today, means are provided to slow down the neutrons. The slowing down is effected through multiple elastic scatterings of the neutrons with the nuclei of light elements deliberately present in the medium acting as so-called **moderators**. Notable among such elements are hydrogen present in water, deuterium in heavy water, and carbon in the form of graphite.

All of the reactors in which substantive moderation of the neutrons occurs are categorized as **thermal reactors**. This term stems from the distinguishing feature that the neutron population is in, or near, thermal equilibrium with the nuclei of the moderator. As a consequence, there is no net exchange of energy between the neutron population and its surroundings. The neutrons are then referred to as thermal neturons.

In a population of **thermal neutrons**, the distribution of the speeds of the neutrons is characterized, adequately in many cases, by the Maxwell-Boltzmann distribution, originally formulated to apply to the molecules of an ideal gas. According to this distribution, the most probable speed of the neutrons at the reference temperature of 20°C is 2200 m/sec and the kinetic energy corresponding to the most probable speed is 0.025 eV.

Reactors that are not thermal reactors fall in the category of **fast reactors**. In these reactors, the moderation of neutrons is much reduced for reasons discussed later.

Nuclear Fuel

In light-water reactors (LWR), the type of power reactors most commonly in service today, the nuclear fuel is uranium with a content of 2 to 4% of ^{235}U. This fuel is produced by enriching natural uranium in ^{235}U by one of several technologies, principally gaseous diffusion and gaseous centrifugation (Benedict et al., 1981). Neutrons of all energies, down to and including thermal energies, can induce fission in ^{235}U. For this reason, ^{235}U is said to be fissile.

In contrast, ^{238}U, present to the extent of 96 to 98% in the fuel, can be fissioned to a significant extent by neutrons with energies in excess of a threshold of roughly 2 MeV. Fissions of ^{238}U, referred to as fast fissions, play only a slight role in the chain reaction in an LWR. However, ^{238}U absorbs neutrons radiatively to yield ^{239}U. This nuclide is radioactive and decays to ^{239}Np which, in turn, decays to ^{239}Pu, a **fissile nuclide**. Thus, in LWR fuel ^{239}Pu, produced from ^{238}U, is available for fissioning by neutrons of all energies and contributes to the chain reaction. Because of its ability to form fissile ^{239}Pu, ^{238}U is termed a **fertile nuclide**.

Conversion and Breeding

To characterize the unique capability of nuclear fuel simultaneously to produce and consume fissile material, a figure of merit known as the **conversion ratio** (CR) is informative. It is defined by the relation:

$$\text{CR} = \frac{\text{number of fissile nuclei produced from fertile nuclei}}{\text{number of fissile nuclei consumed}}$$

In fuel irradiated in an LWR, the conversion ratio typically has a value of 0.5. If the appropriate combination of materials, design, and operating parameters could be found to raise the conversion ratio

© 1999 by CRC Press LLC

to a value greater than unity, a reactor would become a breeder reactor, that is, one that produces more fissile material than it consumes in its operation.

To illustrate the possibility of breeding, consider a parameter known as the reproduction factor and given by

$$\eta = \upsilon \frac{\text{number of neutrons causing fission in fuel}}{\text{total number of neutrons absorbed in fuel}} = \nu \frac{\sigma_f^{\text{fuel}}}{\sigma_a^{\text{fuel}}}$$

In the case of ^{235}U and thermal neutrons, the value of η is given by $\eta_{235} = 2.42 \times 582/(589 + 99) = 2.42 \times 0.85 = 2.07$.

If a chain reaction is to be self-sustaining in a reactor, the condition $\eta > 1$ must apply. To achieve breeding requires that $\eta > 2$. In other words, one neutron from fission would be available to sustain the chain reaction and another to produce a fissile nucleus from a fertile nucleus. Practical considerations indicate that the value of η must be substantially greater than 2, since neutrons will be lost by absorption in structural materials, heat removal medium, fission fragments, the moderator, if present, and by escaping from the physical confines of the reactor.

As shown, ^{235}U has a value of η slightly above 2 with neutrons at thermal energies. Breeding or near-breeding conditions could arise, in principle, if very judicious choices of materials and parameters prevail. A more attractive fuel from the standpoint of breeding is ^{233}U. This isotope of uranium is produced artificially by placing the naturally occurring nuclide ^{232}Th in a reactor. A radiative capture of a neutron in ^{232}Th leads to the formation of the radioactive nuclide ^{233}Th. Two successive radioactive decays yield ^{233}U. In a thermal reactor, the value of η with ^{233}U is 2.29, approaching the level where breeding might be contemplated. Intermediate between the two fissile isotopes of uranium is ^{239}Pu, which at thermal energies yields a value of η of 2.15.

Figure 8.8.1 shows the behavior of η as the energy of the neutrons inducing fission increases. A little above thermal energies the value of η for ^{239}Pu and ^{235}U drops below 2, indicating that breeding is impossible at such energies. As energy increases, the values of η for both reach the threshold of 2 and continue to increase steadily, with ^{239}Pu clearly the more attractive fuel from the standpoint of breeding. The value of ^{239}Pu for ^{235}U is relatively insensitive to increases in energy and remains continuously above 2. Again, at higher energies, η is the more attractive fuel.

Research on the development of **breeder reactors** has focused on the ^{239}Pu fuel cycle, both in the U.S. and abroad. Representative of these reactors is the liquid metal fast breeder reactor (LMFBR) in which liquid sodium is the heat-removal fluid and provides the small amount of moderation needed. Breeder reactors with ^{233}U as fuel, represented by an adaptation of the high-temperature gas-cooled reactor (HTGCR), in which the heat-removal fluid is helium and the moderator is graphite, although less attractive, in principle, as breeders, might with further research and development prove to be viable alternatives to the LMFBR.

LWR Fuel

Nuclear fuel in light water is in the form of small cylindrical pellets of the ceramic UO_2, with the uranium enriched to 2 to 4% in ^{235}U, as mentioned previously. These pellets are stacked vertically in tubes and the ends of the tubes are sealed off. The dimensions and further details given here apply strictly to the more common type of LWR, known as the pressurized water reactor (PWR), but may be taken as generally representative of LWRs.

The tubes containing the fuel pellets are referred to as fuel rods. They are 4.3 to 4.7 m in length and 0.0095m in outside diameter. An array typically of 17 × 17 rods constitutes a fuel assembly, as shown in Figure 8.8.2. Certain fuel rods within the assembly are replaced by guide sheaths in which absorber rods can be moved vertically. These rods absorb neutrons, thus providing one of the means of controlling the chain reaction as the rods are inserted or withdrawn. Within the fuel assembly the fuel rods are placed on a pitch of 0.0127 m, leaving vertical passages through which water can flow. A total of

© 1999 by CRC Press LLC

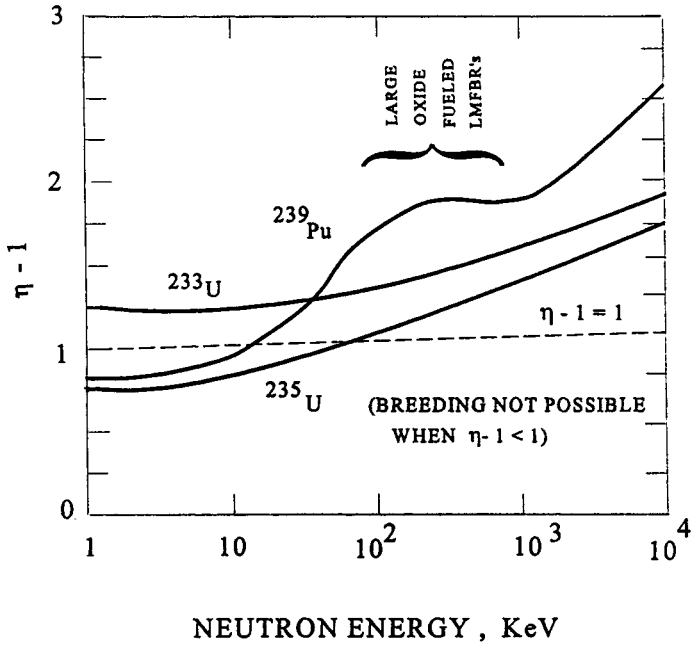

FIGURE 8.8.1 Dependence of reproduction factor of neutron energy.

approximately 200 fuel assemblies, juxtaposed to form a roughly cylindrical configuration constitute the core of the reactor. Water is circulated through the core where the water serves both to moderate the neutrons and to remove the heat generated by fissions in the nuclear fuel.

Light-Water Reactors

LWRs currently make up the largest portion of the installed nuclear generating capacity throughout the world. Among these, the PWRs are more numerous. By operating at a sufficiently high pressure, bulk boiling of the reactor coolant is suppressed in a PWR. In contrast, the coolant is allowed to boil in a boiling water reactor (BWR) and a portion of the coolant is converted to steam as it circulates through the core.

Pressurized Water Reactors

A schematic of a PWR system is shown in Figure 8.8.3. At the heart of the system is the core made up of fuel assemblies and associated control rods. The core is contained in a reactor vessel, or pressure vessel, designed to operate at a pressure typically of 15.5 mPa. Water is circulated through the core where it acts as a moderator and also removes the heat generated through fission. Typical operating temperatures at full power are 295°C at the inlet and 330°C at the outlet, an increase of 35°C as a result of the water passing through the core.

From the reactor vessel, the coolant is circulated to steam generators and returned to the reactor vessel to complete the so-called primary loop. This loop constitutes the nuclear steam supply (NSS). Steam emerging from the steam generators is directed toward the secondary loop, or balance of plant, consisting of turbine generator, condenser, and feedwater pumps. Extremely small quantities of radioactive contaminants may be present in the steam generated in PWRs, and all releases to the environment from the secondary side of the plant are carefully monitored and controlled. Otherwise, steam from the NSS differs from steam generated in fossil fueled plants only inasmuch as its grade is inferior.

© 1999 by CRC Press LLC

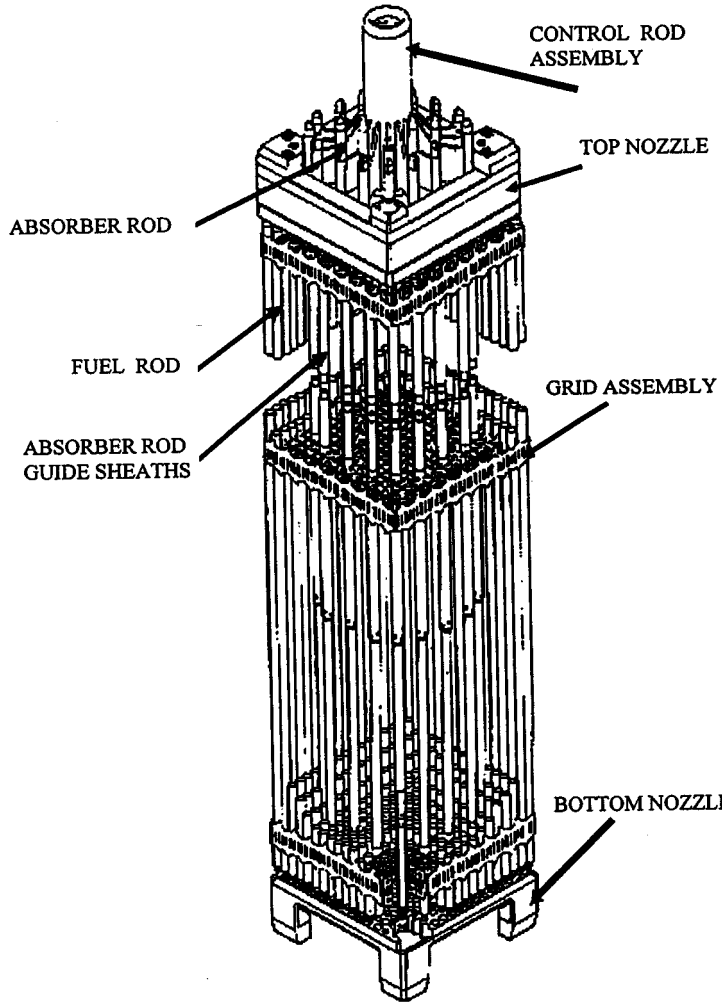

FIGURE 8.8.2 PWR fuel assembly.

Boiling Water Reactors

Figure 8.8.4 is a schematic of a BWR system. A reduced operating pressure of 7.2 MPa causes a portion of the coolant to flash to steam. Steam separators and driers allow dry steam to emerge from the reactor vessel, thus eliminating the need for separate steam generators and a secondary loop. Steam from the reactor vessel flows through a turbine generator and condenser, from which circulating pumps return the condensate to the reactor. Large quantities of radioactive contamination may be present in the steam produced by a BWR because of the direct cycle, so releases must be carefully monitored. A distinguishing feature of the BWR are the jet pumps, typically 24 in number, placed along the periphery of the core. These pumps augment the flow of coolant through the core.

Defining Terms

Breeder reactors: Reactors in which the conversion ratio is greater than unity.

Conversion ratio: The ratio of the number of fissile nuclei produced in a reactor to the number of fissile of nuclei consumed.

© 1999 by CRC Press LLC

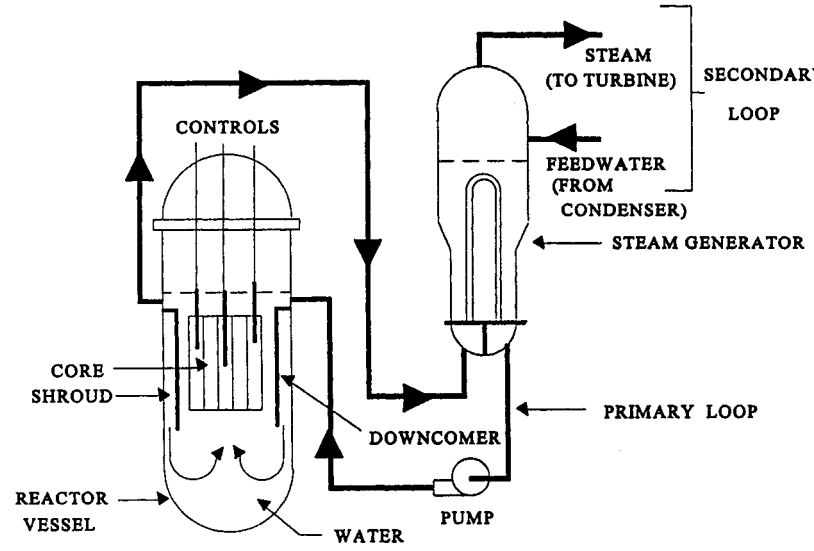

FIGURE 8.8.3 Schematic of a pressurized water reactor.

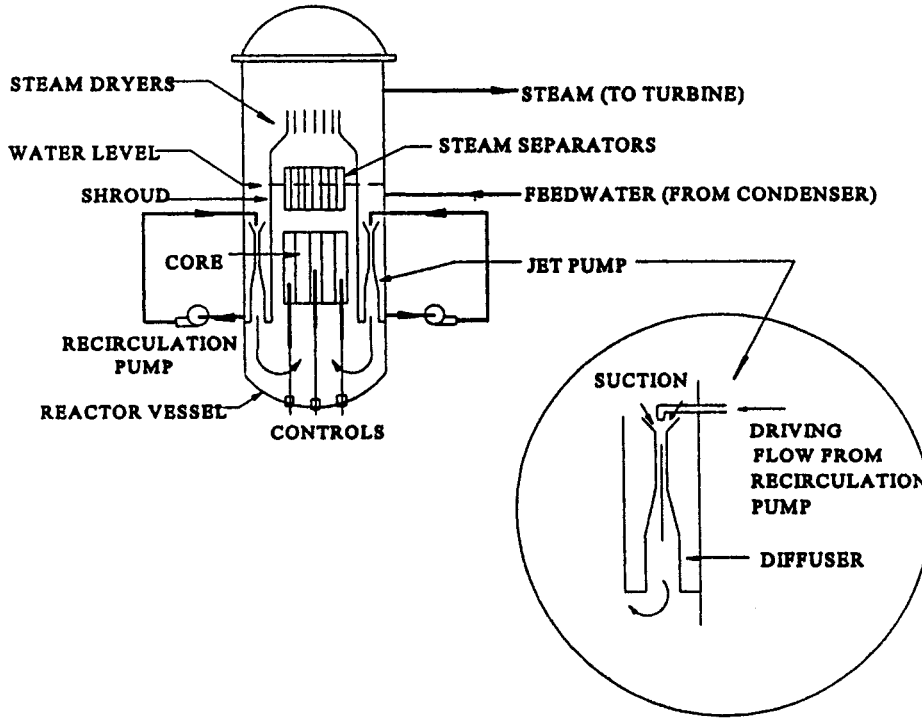

FIGURE 8.8.4 Schematic of a boiling water reactor.

Critical configuration: A medium containing nuclear fuel in which a self-sustaining chain reaction can be maintained.

Cross section: A numerical quantity, determined experimentally, related to the probability that a specific nuclide will undergo a given nuclear reaction.

© 1999 by CRC Press LLC

Fast reactors: Reactors in which little moderation of the neutrons occurs and the neutron populations consist of neutrons of relatively high speeds.

Fertile nuclide: A nuclide that, through the absorption of a neutron and subsequent radioactive decays, can produce a fissile nuclide.

Fissile nuclide: A nuclide that can be fissioned by neutrons of all energies, down to and including thermal energies.

Moderator: A component of a reactor present expressly to slow down neutrons and produce a population of thermal neutrons.

Thermal neutrons: A population of neutrons in, or near, thermal equilibrium with the nuclei of a medium in which the populations exists.

Thermal reactors: Reactors in which the neutron populations consist predominantly of thermal neutrons.

8.9 Nuclear Fusion

Thomas E. Shannon

Introduction

Nuclear fusion holds the promise of providing almost unlimited power for future generations. If the process can be commercialized as envisioned by reactor design studies (Najmabadi et al., 1994), many of the problems associated with central electric power stations could be eliminated. Fusion power plants would not produce the pollution caused by the burning of fossil fuel and would eliminate the concern for meltdown associated with nuclear fission. The amount of radioactive waste material produced by a fusion reactor will be much less than that of a fission reactor since there is essentially no radioactive ash from the fusion reaction. If **low activation advanced materials** such as silicon carbide composites can be developed for the reactor structural material, the problem of disposal of activated components can also be eliminated.

Fusion Fuel

Although a number of different atomic nuclei can combine to release net energy from fusion, the reaction of **deuterium and tritium** (D-T) is the basis of planning for the first generation of fusion reactors. This choice is based on considerations of reactor economy. The D-T reaction occurs at the lowest temperature, has the highest probability for reaction, and provides the greatest output of power per unit of cost (Shannon, 1989). The disadvantages of D-T as a fusion fuel are twofold. Tritium does not occur naturally in nature and must be bred in the fusion reactor or elsewhere. Second, tritium is a radioactive isotope of hydrogen with a relatively long **half-life** of 12.3 years. Since tritium can readily combine with air and water, special safety procedures will be required to handle the inventory necessary for a fusion reactor. There is hope that a less reactive fuel, such as deuterium alone (D-D) will eventually prove to be an economically acceptable alternative (Shannon, 1989).

Confinement Concepts

Magnetic fusion, based on the tokamak concept, has received the majority of research funding for fusion energy development. However, other magnetic fusion concepts, such as the stellarator, the spherical torus, reversed-field pinch, and field-reversed configurations, are being developed as possible alternatives to the tokamak (Sheffield, 1994). It may also be possible to develop fusion power reactors by inertial confinement concepts (Waganer et al., 1992). Research on these concepts has been done primarily in support of weapons development; therefore, the level of scientific understanding for power reactor applications is significantly less than that of magnetic fusion. The remainder of this discussion on reactor development, fusion energy conversion, and transport will consider only the tokamak magnetic fusion concept.

Tokamak Reactor Development

The tokamak device has proved to be the most effective means of producing the conditions necessary for magnetic fusion energy production. In 1994, researchers at the Princeton Plasma Physics Laboratory achieved in excess of 10 MW of D-T fusion power in a research tokamak, the Tokamak Fusion Test Reactor (TFTR). This accomplishment, coupled with worldwide progress in 40 years of magnetic fusion research, has established the scientific feasibility of the tokamak concept. The next major step, the International Thermonuclear Experimental Reactor (ITER) is being carried out under an international agreement among Europe, Japan, Russia, and the United States (Conn et al., 1992). A drawing of the ITER tokamak is shown in Figure 8.9.1. If the project is approved for construction, it will be in operation

© 1999 by CRC Press LLC

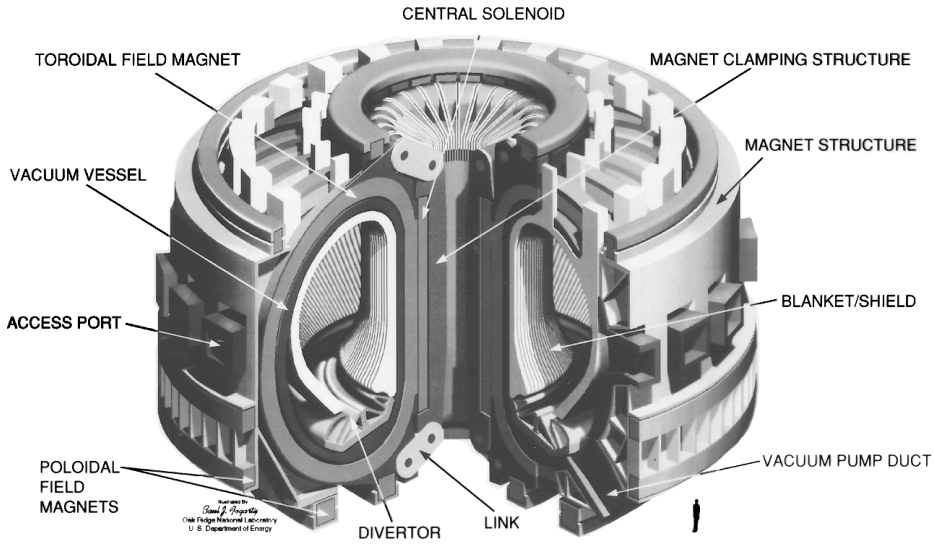

FIGURE 8.9.1 The International Thermonuclear Experimental Reactor (ITER).

around 2005. The ITER is being designed to produce a fusion power in excess of 1000 MW. This will be a significant step on the path to commercial fusion power.

The U.S. Department of Energy has proposed a strategy, shown in Figure 8.9.2, which will lead to a demonstration power reactor by the year 2025. Supporting research and development programs necessary to achieve this goal are shown in this figure.

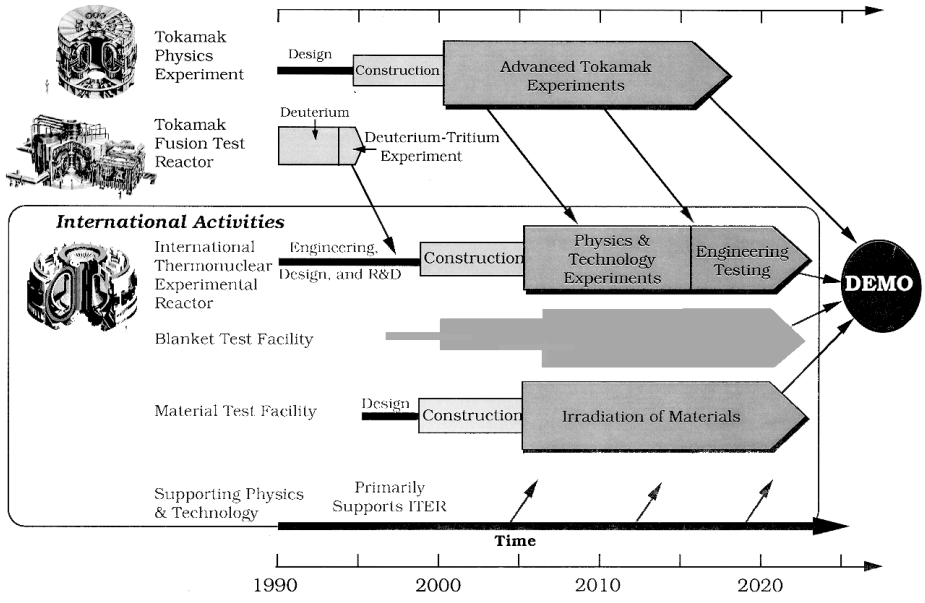

FIGURE 8.9.2 The U.S. Department of Energy magnetic fusion energy strategy.

© 1999 by CRC Press LLC

Fusion Energy Conversion and Transport

The energy from fusion is created in the form of charged particles and neutrons. The D-T reaction produces a neutron with an energy of 14.1 MeV and an alpha particle (helium) with an energy of 3.5 MeV in the reaction

$$D + T \rightarrow He^4\ (3.5\ MeV) + n(14.1\ MeV)$$

In the tokamak device, the reaction will take place in the toroidal vacuum vessel as previously shown in the ITER drawing, Figure 8.9.1. The D-T fuel, in the form of a **plasma**, will absorb energy from the positively charged alpha particles to sustain the temperature necessary for the reaction to continue. The neutron, having no charge, will escape from the plasma and pass through the wall of the vessel and penetrate into the surrounding blanket/shield structure. The kinetic energy of the alpha particles from the fusion reaction is eventually deposited on the wall of the vacuum vessel by radiation and conduction heat transfer from the plasma while the neutron deposits most of its energy within the cross section of the blanket/shield. The resulting thermal energy is transferred by a coolant such as water to a steam generator where a conventional steam to electric generator system may be used to produce electricity. An overall schematic diagram of the energy conversion and heat-transport system is shown in Figure 8.9.3.

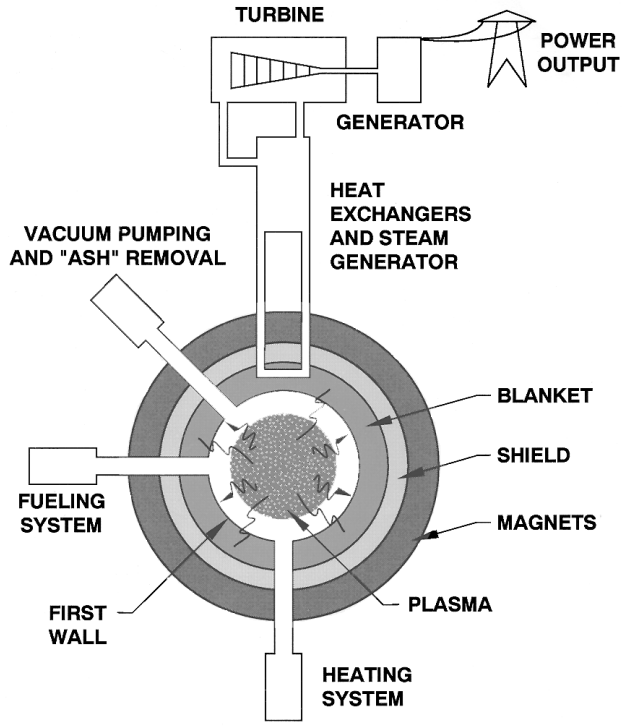

FIGURE 8.9.3 Schematic Diagram of a Magnetic Fusion Reactor Power Plant.

Defining Terms

Deuterium and tritium: Isotopes of hydrogen as the fuel for fusion reactors.
Half-life: The time required for half of the radioactive material to disintegrate.
Low activation advanced materials: Structural materials that significantly reduce the radioactivity induced by exposure to fusion neutrons.

© 1999 by CRC Press LLC

Plasma: A gas such as a mixture of deuterium and tritium raised to a very high temperature at which the electrons and the nuclei of the atoms separate. The plasma, consisting of electrons and ions, can conduct electricity and react to magnetic fields.

8.10 Solar Thermal Energy Conversion

D. Yogi Goswami

Introduction

Solar thermal energy applications such as space and water heating have been known for a long time. Researchers over the past few decades have developed a number of additional solar thermal applications, such as industrial process heat, refrigeration and air-conditioning, drying and curing of agricultural products, and electric power production by solar thermal conversion. This section will cover solar thermal energy conversion including solar thermal collectors and conversion systems.

Solar Thermal Collectors

A simple **solar thermal collector** consists of (1) an absorber surface (usually a dark, thermally conducting surface), (2) some insulation behind the surface to reduce heat loss, (3) a trap for thermal reradiation from the surface such as glass, which transmits the shorter-wavelength solar radiation but blocks the longer-wavelength radiation from the absorber, and (4) a heat-transfer medium such as air, water, etc. High-temperature collectors require reflectors of sunlight that concentrate solar radiation on the absorber. The technology of solar collectors is developed to achieve temperatures as high as 1000°C or even higher. The design of a solar collector and the choice of working fluids depend on the desired temperature and the economics of the application. Table 8.10.1 lists the types of solar thermal collectors based on their temperature range.

TABLE 8.10.1 Types of Solar Collectors and Their Typical Temperature Range

Type of Collector	Concentration Ratio	Typical Working Temperature Range (°C)
Flat plate collector	1	≤70
High-efficiency flat plate collector	1	60–120
Fixed concentrator	2–5	100–150
Parabolic trough collector	10–50	150–350
Parabolic dish collector	200–2000	250–700
Central receiver tower	200–2000	400–1000

Source: Compiled from Goswami, D.Y., *Alternative Energy in Agriculture,* Vol. 1, CRC Press, Boca Raton, FL, 1980.

Flat Plate Collectors

Flat plate collectors may be designed to use liquids (water, oil, etc.) or air as the heat-transfer fluid. Figure 8.10.1 shows a typical liquid-type flat plate collector. The choice of materials for glazing and absorber needs special attention.

Glazing. The purpose of **glazing** is to (1) transmit the shorter-wavelength solar radiation, but block the longer-wavelength reradiation from the absorber plate, and (2) reduce the heat loss by convection from the top of the absorber plate. Glass is the most widely used glazing material. Transmittance of low iron glass in the visible and near infrared wavelength range can be as much as 91%, while for the longer-wavelength radiation (>3 μm) its transmittance is almost zero. Other materials than can be used as glazings include certain plastic sheets such as polycarbonates (Lexan® and Tuffac® — transmittance ~75%), acrylics (Plexiglass® and Lucite® — transmittance ~92%), and thin plastic films such as polyethylene. A major advantage of the plastics is that they are shatterproof; however, they scratch easily and lose transparency over time.

Absorbers. Copper is the most common material used for absorber plates and tubes because of its high thermal conductivity and high corrosion resistance. For low-temperature applications such as swimming pool heating, a plastic material called ethylene propylene polymer (trade names EPDM, HCP,

© 1999 by CRC Press LLC

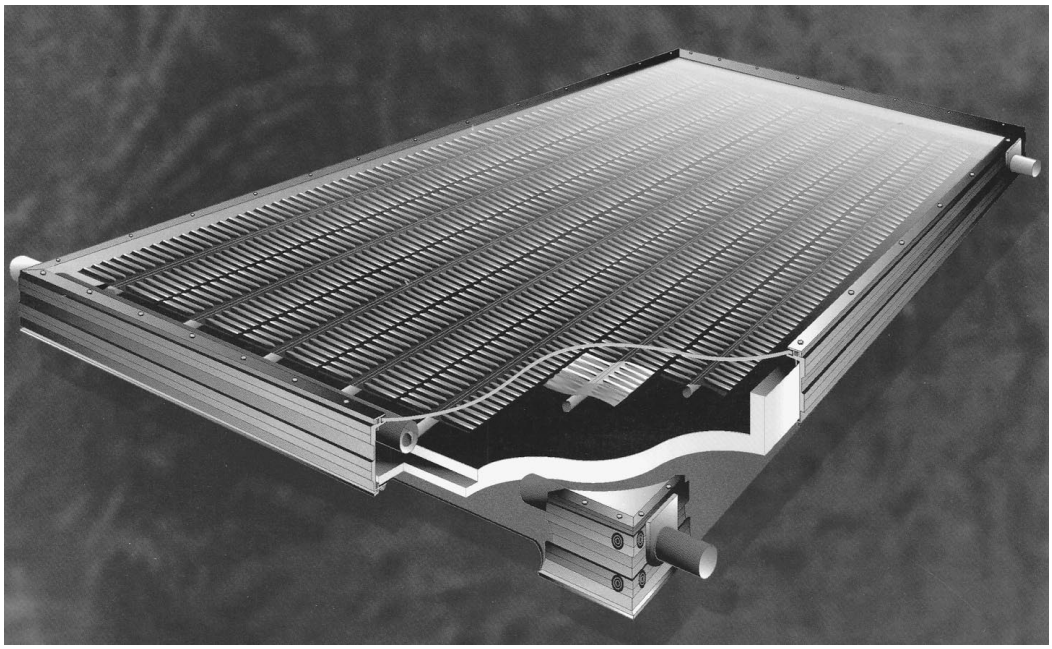

FIGURE 8.10.1 A typical liquid flat plate collector. (Courtesy of American Energy Technologies, Green Cove Springs, FL.)

etc.) can be used to provide inexpensive absorber material. To compensate for low thermal conductivity of these materials, a large surface area is provided for heat transfer. In order to increase the absorption of solar radiation and to reduce the emission from the absorber, the metallic absorber surfaces are painted or coated with flat black paint or some selective coating. Absorptivities and emissivities of some common **selective surfaces** are given in Table 8.10.2.

TABLE 8.10.2 Absorptivity and Emissivity of Common Selective Surfaces

Surface	Absorbtivity	Emissivity
Black chrome	0.95	0.1
Black nickel	0.9	0.08
Copper oxide	0.9	0.17
Lead sulfide	0.89	0.2
Flat black paint	0.98	0.98

Source: Compiled from Duffie, J.A. and Beckman, W.A., *Solar Engineering of Thermal Processes*, John Wiley and Sons, New York, 1980.

Evacuated Tube Collectors. Evacuated tube collectors have essentially a vacuum between the absorber and the glazing tube. This eliminates most of the heat loss by conduction and convection. Therefore, these collectors give a very high efficiency at higher temperatures. Evacuated tube collectors are typically used in the temperature range of 80 to 140°C

Concentrating Collectors. Concentrating collectors use reflectors or lenses to focus solar radiation from a large area onto a small area, thereby creating higher temperatures. Such collectors are usually used for temperatures higher than 100°C. Figure 8.10.2 shows schematics of some of the concentrating collectors.

Nontracking Concentrators. The simplest concentrating collector can be made by using flat wall reflectors to concentrate the solar radiation on a flat plate collector. Concentration ratios of two to three can be

© 1999 by CRC Press LLC

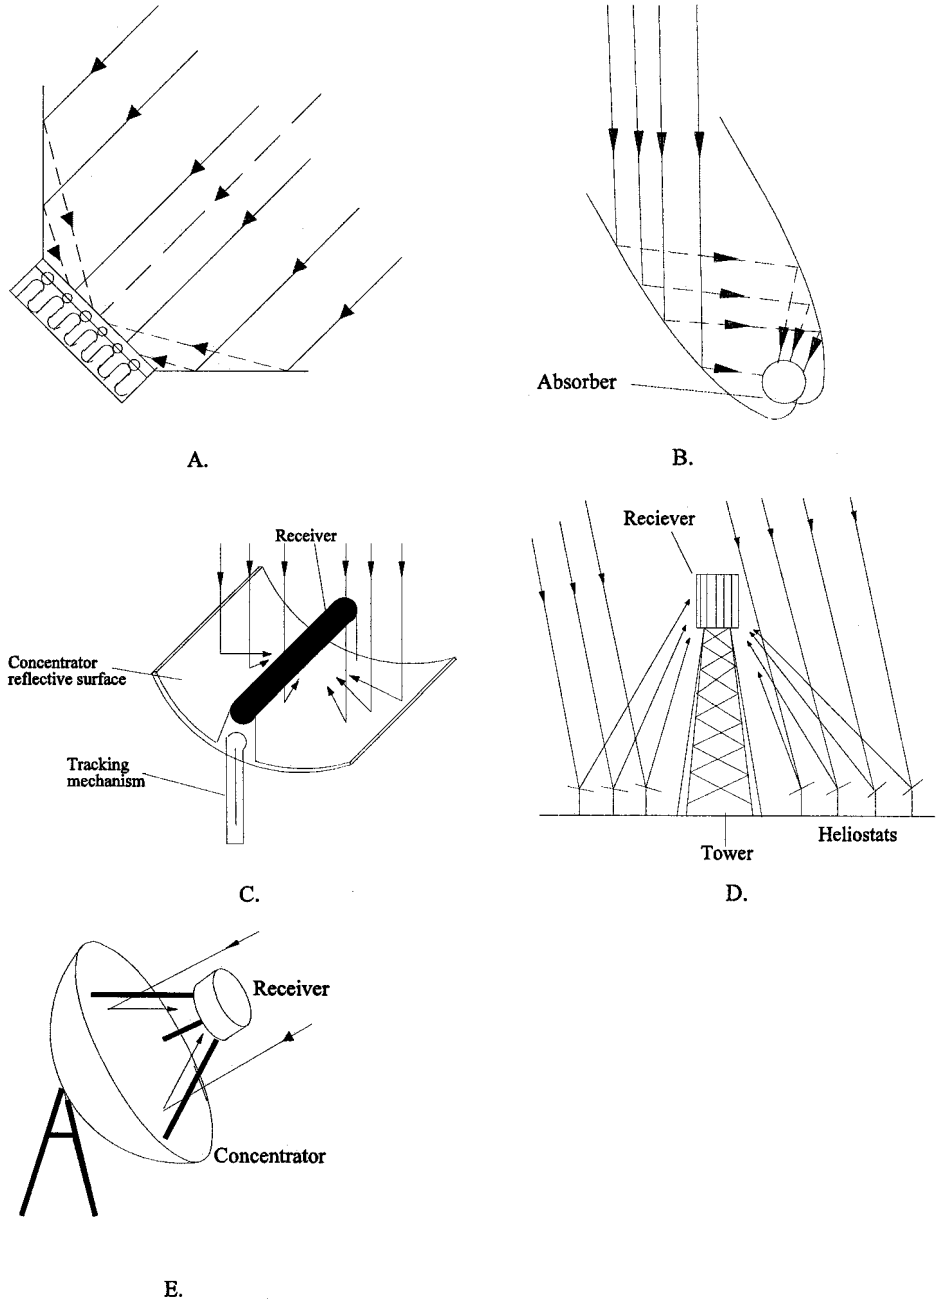

FIGURE 8.10.2 Types of concentrating collectors. (A) Flat plate collector with reflective wings; (B) Compound parabolic concentrator; (C) parabolic trough; (D) central receiver; (E) parabolic dish.

achieved this way. For slightly higher concentration ratios, a novel design, developed by Roland Winston, called a "compound parabolic concentrator" (CPC) can be used (Winston, 1974).

Tracking Concentrators. For temperatures up to 350°C, cylindrical parabolic trough collectors are used. These collectors focus solar radiation on a line focus where the absorber is located. These collectors usually require tracking on one axis only with seasonal adjustment on the other axis. A reflecting spherical or paraboloidal bowl is used when temperatures of the order of 250 to 500°C are needed. These collectors

© 1999 by CRC Press LLC

require two-axis tracking. In some cases, the dish is kept stationary while the receiver is moved to track the focus of the reflected solar radiation. Finally, for extremely high temperatures (500 to 1000°C) needed for large-scale thermal power generation, a large field of tracking flat mirrors (called heliostats) is used to concentrate solar radiation on a receiver that is located on top of a central tower.

Collector Thermal Performance

The instantaneous efficiency of a collector is given by

$$\eta = \frac{\text{Useful energy collected}}{\text{Incident solar energy}} = \frac{Q_u / A}{I} \tag{8.10.1}$$

where

$$Q_u = mC_p\left(T_o - T_i\right) \tag{8.10.2}$$

and A = area of the collector, I = incident solar energy per unit area, m, C_p, T_i, and T_o are the mass flow rate, specific heat, and inlet and outlet temperatures of the heat-transfer fluid.

The efficiency of a flat plate solar collector can also be written by the Hottel–Whillier–Bliss equation:

$$\eta = F_R(\tau\alpha)_e - F_R U_L \frac{\left(T_i - T_{\text{amb}}\right)}{I} \tag{8.10.3}$$

where F_R, called the collector heat-removal factor, is a convenient parameter that gives the ratio of the actual useful energy gain of a flat plate collector to the useful gain if the whole collector surface were at the inlet fluid temperature; $(\tau\alpha)_e$ = effective transmittance absorptance product; and U_L = collector heat-loss coefficient.

Equation 8.10.2 suggests that if the efficiency, η, is plotted against $(T_i - T_{\text{amb}})/I$, the resulting curve will have a y intercept equal to $F_R\,(\tau\alpha)_e$ and a slope of $F_R U_L$. A linear curve usually gives an adequate approximation. Figure 8.10.3 shows an example of a performance curve for a water-heating flat plate collector, which is a linear least square curve fit to the actual test data.

Solar Ponds

A solar pond combines collector and energy storage in one unit. Solar radiation that enters the pond travels some distance through the water before being totally absorbed, thus increasing the temperature of the water at that depth. The heat thus collected can be stored in the pond by creating a stagnant, transparent, insulating layer in the top part of the pond. The most common method is by the addition of a salt into the pond to increase the density of water in the lower section of the pond. This type of pond is called a **salt gradient solar pond**. Reid (1987) reviewed the progress in the design and applications of salt gradient solar ponds. Figure 8.10.4 shows a schematic of a salt gradient pond along with a density profile in the pond.

The theory of salt gradient solar ponds has been described by Tabor (1981). The most important aspect of such ponds is the creation and maintenance of the salt gradient. Theory shows that the condition for maintaining stability is

$$\frac{\partial S}{\partial Z} > -1.14\frac{\partial \rho}{\partial T} \times \frac{\partial T}{\partial Z}\frac{\partial \rho}{\partial S} \tag{8.10.4}$$

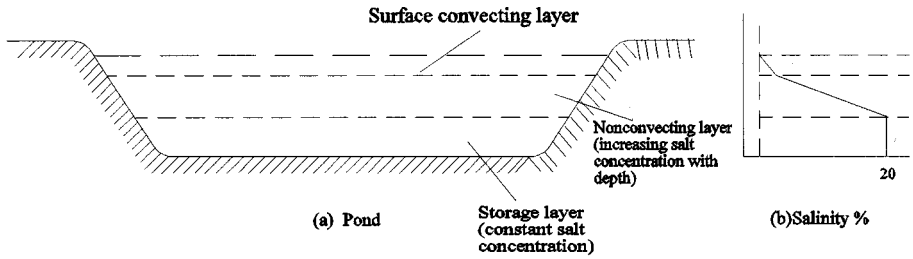

FIGURE 8.10.4 Schematic of a salt gradient solar pond.

where S is the salt concentration in kilograms per cubic meter, Z is the depth from the surface in meters, ρ is the density in kilograms per cubic meter, and T is the temperature in Kelvin. The two most common salts considered for solar pond applications are NaCl and $MgCl_2$. According to the above criteria, there is no difficulty in obtaining stability with $MgCl_2$ and it is somewhat difficult but possible to get stability with NaCl.

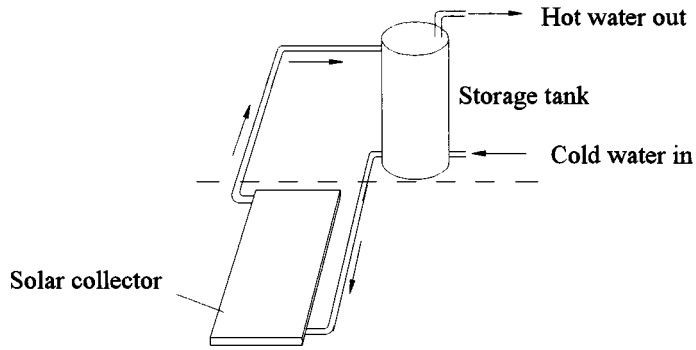
Solar Water-Heating Systems

Solar water-heating systems represent the most common application of solar energy at the present time. Small systems are used for domestic hot water applications while larger systems are used in industrial process heat applications. There are basically two types of water-heating systems: **natural circulation or passive solar system** (thermosyphon) and **forced circulation or active solar system**.

Natural Circulation

Figure 8.10.5 shows a schematic of a natural circulation solar water-heating system. It is also called a thermosyphon or passive solar water heater because it does not require a pump to circulate water. The storage tank is located above the collector. When the water in the collector gets heated, it rises into the tank, because of density change, setting up a circulation loop.

© 1999 by CRC Press LLC



FIGURES 8.10.5 Schematic of a thermosyphon solar water-heating system.

Forced Circulation

Figure 8.10.6 shows three configurations of forced circulation systems: (1) open loop, (2) closed loop, and (3) closed loop with drainback. In an open loop system, the collectors are empty when they are not providing useful heat and the storage tank is at atmospheric pressure. A disadvantage of this system is the high pumping power required to pump the water to the collectors every time the collectors get hot. This disadvantage is overcome in the pressurized closed loop system (Figure 8.10.6B) since the pump has to overcome only the resistance of the pipes. Because water always stays in the collectors of this system, antifreeze (propylene glycol or ethylene glycol) is required for locations where freezing conditions can occur. During stagnation conditions (in summer), the temperature in the collector can become very high, causing the pressure in the loop to increase. This can cause leaks in the loop unless some fluid is allowed to escape through a pressure-relief valve. In both cases, air enters the loop causing the pump to run dry. This disadvantage can be overcome in a closed loop drainback system (Figure 8.10.6C). In this system, when the pump shuts off, the water in the collectors drains back into a small holding tank, which can be located where freezing does not occur. The holding tank can be located at a high level to reduce pumping power.

Industrial Process Heat Systems

For temperatures of up to about 100°C, required for many industrial process heat applications, forced circulation water-heating systems described above can be used. The systems, however, will require a large collector area, storage and pumps, etc. For higher temperatures, evacuated tube collectors or concentrating collectors must be used.

Space-Heating Systems

Solar space-heating systems can be classified as active or passive depending on the method utilized for heat transfer. A system that uses pumps and/or blowers for fluid flow in order to transfer heat is called an *active system*. On the other hand, a system that utilizes natural phenomena for heat transfer is called a *passive system*. Examples of passive solar space-heating systems include direct gain, attached greenhouse, and storage wall (also called Trombe wall).

Active space-heating systems store solar collected heat in water or rocks. Heat from water storage can be transferred to the space by convertors or by fan-coil units. A system using a fan-coil unit can be integrated with a conventional air system as shown in Figure 8.10.7. Heat from rock storage can be transferred to air by simply blowing air over the rocks.

Solar Thermal Power

Solar thermal energy can be used to produce electrical power using conventional thermodynamic power cycles such as Rankine, Stirling, and Brayton cycles. The choice of power cycle and the working fluids depends on the temperature obtainable in the solar system, which depends on the type of solar collectors used. At present, developed solar thermal power systems include

Parabolic trough systems
Central receiver systems
Parabolic dish-Stirling engine system

Parabolic Trough Systems

Parabolic trough systems are simple in concept and, therefore, the most developed commercially. In 1984, Luz Company installed a Solar Electric Generating System (SEGS I) of 14 MW_e capacity in Southern California, utilizing parabolic trough solar collectors and natural gas fuel for superheat and backup. From 1984 to 1991, Luz Company installed eight additional plants, SEGS II to SEGS IX, with the total capacity of the nine plants being 354 MW_e. With each successive SEGS plant the technology was improved and the cost reduced. The cost of electricity was reduced from about 30¢/kWhr for the first plant to about 8¢/kWhr for the last plant. A schematic of the SEGS IX is shown in Figure 8.10.8, and some important data for the system are given in Table 8.10.3.

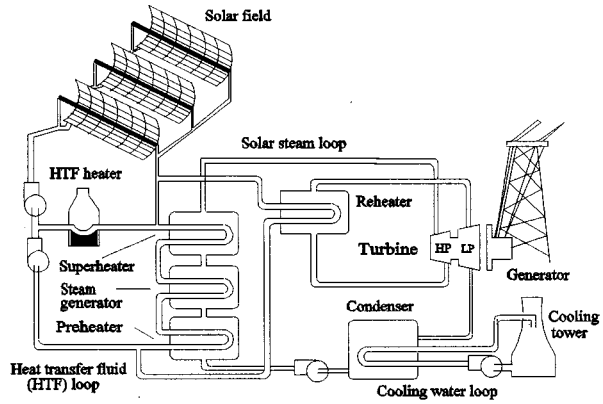

FIGURE 8.10.8 Schematic of SEGS IX power plant.

TABLE 8.10.3 Plant Characteristics — SEG IX

Power Block		Solar Field	
Gross power	88 MWe	Number of collectors	888
Net power	80 MWe	Aperature area	483,960 m^2
Steam inlet pressure	100 bar	Inlet temperature	293°C
Steam inlet temperature	371°C	Outlet temperature	390°C
Reheat pressure	17.2 bar	Annual thermal efficiency	50%
Reheat temperature	371°C	Peak optical efficiency	80%
Conversion efficiency	37.6%	Heat-transfer fluid (HTF)	Oil (VP-1)
Annual gas use	25.2×10^9 m^3	HTF volume	1289 m^3

It has been recognized that this design does not utilize the energy of the natural gas efficiently. It has been suggested that energy of natural gas can be better utilized by combining the solar system with a natural gas turbine combined-cycle power plant (DeLaquil et al., 1993; Washom et al., 1994). Such a

© 1999 by CRC Press LLC

hybrid system would use the exhaust of a natural gas turbine for superheating and preheating of water, while the solar field would be used for steam generation. Such a hybrid system can achieve conversion efficiency as high as 60%. A schematic of a **solar hybrid combined cycle** is shown in Figure 8.10.9.

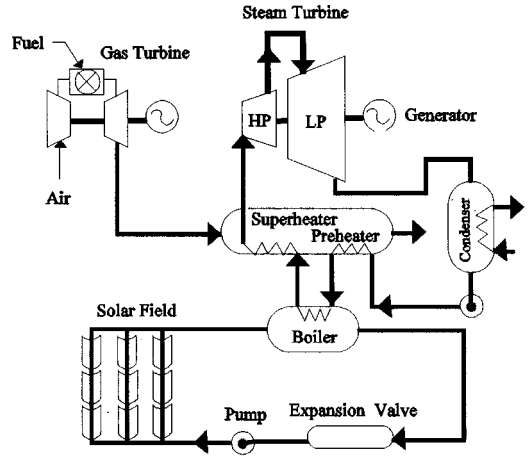

FIGURE 8.10.9 Solar hybrid combined cycle. (Adapted from Washom, B. et al., paper presented at the 1994 ASES Annual Conference, San Jose, CA, 1994.)

Central Receiver System

A central receiver system can potentially operate at very high temperature and therefore can have much higher efficiency than parabolic trough systems. However, the system can be economical only at larger capacities, such as 100 MW and above. The central receiver absorber can heat the working fluid or an intermediate fluid to a temperature as high as 600 to 1000°C which can be used to drive a Rankine cycle or Brayton cycle.

Solar One, a 10-MW_e central receiver power plant started operating in 1982 in Barstow, California. This plant generated superheated steam at 510°C and 10.3 MPa in the receiver absorber, which was used to drive a simple steam Rankine power cycle. The plant operated successfully for 6 years and provided a good learning experience. The plant has now been redesigned as Solar Two in which molten sodium nitrate is used as the heat-transfer fluid as well as for storage. Use of molten salt allows operation of the receiver absorber at much lower pressures The constraint is that the salt must always be above its melting point (220°C). Figure 8.10.10 shows a schematic of the Solar Two power plant.

Parabolic Dish Systems

Parabolic dish systems can achieve very high temperatures. The high temperatures produced by parabolic dishes can be used to drive Rankine, Stirling, and Brayton power cycles. So far, Rankine and Stirling cycles have been successfully demonstrated with parabolic dishes for electrical power production.

Early versions of parabolic dishes were made from die-stamped aluminum petals made reflective using a metallized polymer film. Later designs used simpler flat mirror facets fixed on a structure in such a way as to approximate a parabolic dish. The latest designs use a polymer film stretched on a circular frame (Mancini, 1994). The film is given a slight concave curvature by providing a vacuum behind it. These stretched polymer films are fixed on a structure to approximate a parabolic dish. Because of the low weight of the polymer film, the dish structure can be made out of light tubular members, thereby reducing the cost of the dish considerably. Parabolic dishes require two-axis tracking.

McDonnell Douglas Corporation successfully demonstrated a 25-KW_e parabolic dish system using a Stirling engine and a generator assembly fixed at the focal point of the dish in 1985 (Gupta, 1987). The concept is very attractive because it provides a modular design of stand-alone power plants for small

© 1999 by CRC Press LLC

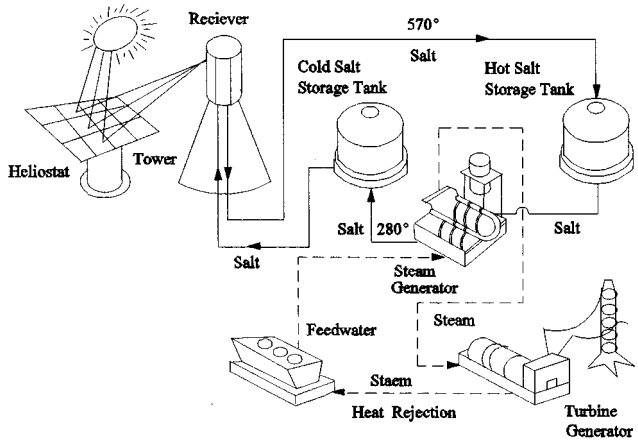

FIGURE 8.10.10 Schematic of Solar Two.

communities and independent power applications. Cummins Power Generation Company, in Indiana, has developed this concept further (Mancini, 1994). The Cummins system uses stretched polymer film facets for a parabolic dish, a heat pipe receiver absorber, a free-piston Stirling engine, and a linear alternator, resulting in a very compact power generation system. Figures 8.10.11 shows the latest version of the Cummins Dish Stirling power system. A detailed discussion of Stirling engines is given in Section 8.5.

Nomenclature

A = area of collector
C_p = specific heat
m = mass flow rate
T = temperature
I = incident solar radiation
Qn = useful heat collected
F_R = collector heat-removal factor
U_L = collector heat-loss coefficient
S = salt concentration
Z = depth

Greek Symbols

α = absorptance
τ = transmittance
η = efficiency
ρ = density

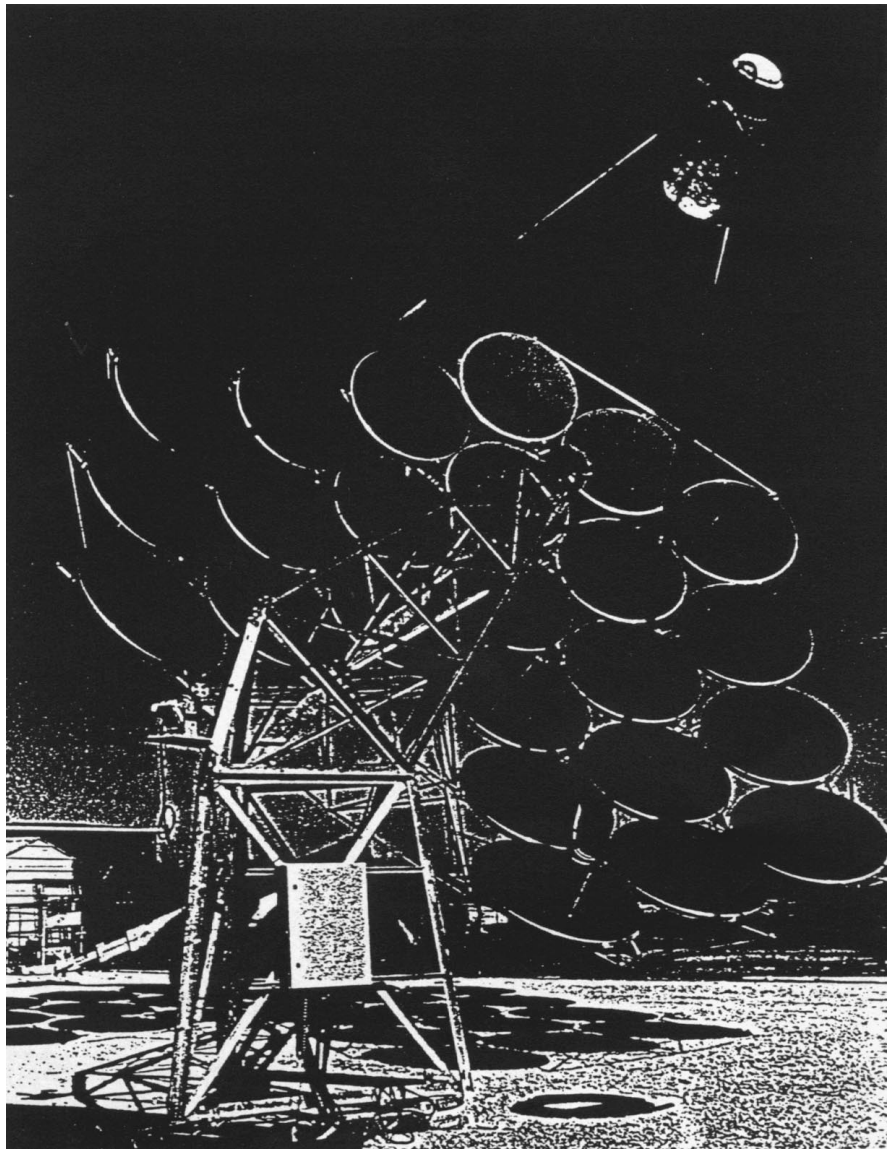
Subscripts

i = inlet
o = outlet
amb = ambient
e = effective

Defining Terms

Forced circulation or active solar system: A solar thermal system that uses active means, such as pumps, for fluid flow and heat transfer.

© 1999 by CRC Press LLC



Figures 8.10.11 A parabolic dish — Stirling Engine Power System.

Glazing: A material used in a solar collector that transmits short-wavelength solar radiation and blocks longer-wavelength reradiation from the absorber plate.

Natural circulation passive solar system: A solar thermal system that uses natural means, such as the thermosyphon effect, for fluid flow and heat transfer.

Salt gradient solar pond: A solar pond that uses high salt concentration in the lowest layer and a concentration gradient in the middle layer to make those layers nonconvective.

Selective surface: A surface that has high absorptance in short wavelengths and low emittance in longer wavelengths.

Solar hybrid combined cycle: A hybrid of solar and natural gas turbine combined cycle.

Solar thermal collector: A solar collector that absorbs sunlight and converts it to heat.

8.11 Wind Energy Conversion*

Dale E. Berg

Introduction

Wind energy conversion machines have evolved over the past 2000 years, mostly by trial and error. Although there are many different configurations of wind machines, most of them can be classified as either horizontal-axis wind turbines (HAWTs), which utilize rotors that rotate about a horizontal axis parallel to the wind, or vertical-axis wind turbines (VAWTs), which have rotors that rotate about a vertical axis. Figure 8.11.1 illustrates the main features of both HAWTs and VAWTs. Figure 8.11.2 shows both types of turbines in a wind farm in the Altamont Pass area of California. HAWTs have all of their drivetrain equipment located on a tower, which makes servicing somewhat difficult, their blades are subjected to cyclic stresses due to gravity as they rotate, and they must be oriented with respect to the wind. However, they may be placed on tall towers to access the stronger winds typically found at greater heights. VAWTs, on the other hand, have most of their drivetrain on the ground, do not experience cyclic gravitational stresses, and do not require orientation with the wind. VAWTs, however, cannot be placed on tall towers to exploit the stronger winds at greater height, and their blades are subject to severe alternating aerodynamic loading due to rotation. The most common type of modern HAWT is the propeller-type machine, and these machines are generally classified according to the rotor orientation (upwind or downwind of the tower), blade articulation (rigid or teetering), and number of blades (generally two or three). The most common types of modern VAWTs are the Darrieus, with curved blades that are fixed in pitch, and the fixed-pitch, straight-bladed machines. The following discussion will focus on these types of turbines.

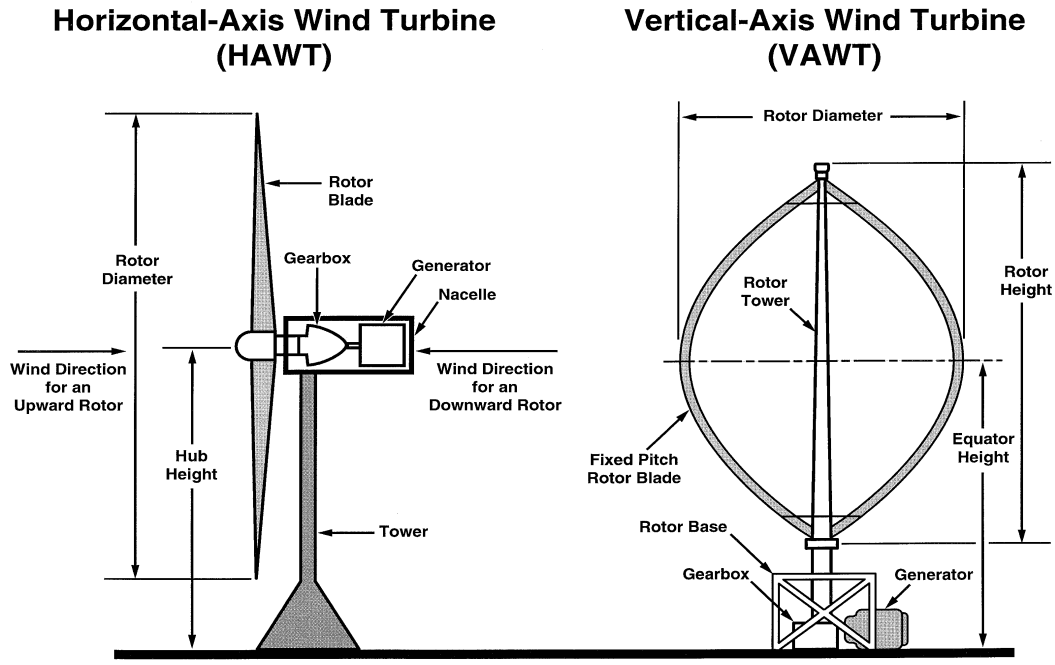

FIGURE 8.11.1 Wind turbine configurations.

FIGURE 8.11.2 Wind farm both horizontal-axis and vertical-axis turbines.

While small and even medium-sized machines have been developed primarily through trial and error, developing larger, more-complex, and highly efficient machines this way becomes very expensive and time-consuming. A large cost-effective machine can be developed at a reasonable cost only if the designers can accurately predict the performance of conceptual machines and investigate the effects of design alternatives. In the past two decades numerous techniques to predict the aerodynamic and structural dynamic performance of wind turbines have been developed. These analytical models are not, in general, amenable to simple approximations, but must be solved with the use of computer codes of varying complexity. These models and codes will be summarized in the following sections.

Wind Turbine Aerodynamics

Items exposed to the wind are subjected to both drag (in the direction of the wind) and lift (perpendicular to the wind) forces. The earliest wind machines used drag to produce power. The European and American windmills discussed in Section 7 of Chapter 7 were primarily drag devices, but they did make some use of lift. Modern wind turbines rely on airfoil-shaped blades that generate large amounts of lift to produce power more efficiently than the drag machines. Let us consider how efficient these machines are at extracting energy from the wind.

Figure 8.11.3 illustrates the flow field about a translating drag device. The drag results from the relative velocity between the wind and the device, and the power that is generated by the device (the product of the drag force and the translation velocity) is given by

$$P = Dlv = \left[0.5\rho(U - v)^2\right]C_D clv \tag{8.11.1}$$

© 1999 by CRC Press LLC

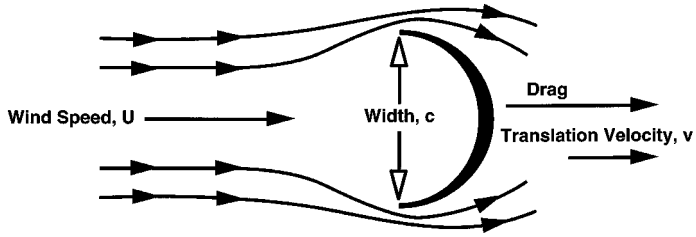

FIGURE 8.11.3 Schematic of translating drag device.

where

P = power extracted in watts
D = drag force per unit spanwise length in n/m
l = length of device (distance into the page) in m
v = translation velocity in m/sec
ρ = air density in kg/m^3
U = steady free-stream wind velocity in m/sec
C_D = drag coefficient; function of device geometry function
c = width of device (perpendicular to wind) in m

The velocity of the device must always be less than the wind velocity, or no drag is generated. The **power coefficient** (the ratio of the power extracted to the power available in the area occupied by the device) for this machine is

$$C_p = \frac{P}{0.5\rho U^3 cl} = \frac{v}{U}\left[1 - \frac{v}{U}\right]^2 C_D \tag{8.11.2}$$

Now consider a device that utilizes lift to extract power from the wind. Figure 8.11.4 illustrates an airfoil that is translating at right angles to the wind direction and is subject to both lift and drag forces. The relative velocity across this surface is the vector sum of the free-stream wind velocity and the wind speed induced by translation. The angle between the direction of the relative velocity and the chord line of the airfoil is termed the angle of attack α. In this case, the power is given by

$$P = 0.5\rho U^3 cl \frac{v}{U}\left[C_L - C_D \frac{v}{U}\right]\sqrt{1 + \left(\frac{v}{U}\right)^2} \tag{8.11.3}$$

where c = airfoil chord length in m and C_L, C_D = lift and drag coefficients, respectively; functions of airfoil shape and α. The power coefficient then is

$$C_p = \frac{v}{U}\left[C_L - C_D \frac{v}{U}\right]\sqrt{1 + \left(\frac{v}{U}\right)^2} \tag{8.11.4}$$

Figure 8.11.5 compares Equations (8.11.2) and (8.11.4) using $C_L = 1.0$ and $C_D = 0.10$ for the airfoil (easily achieved with modern airfoils) and a maximum drag coefficient of 2.0 for the drag machine. The airfoil has a maximum power coefficient of 15, compared with 0.3 for the drag device, or 50 times more power per unit of projected area. Moreover, operating a lifting device at velocities well in excess of the wind velocity is easily achieved with rotating machines.

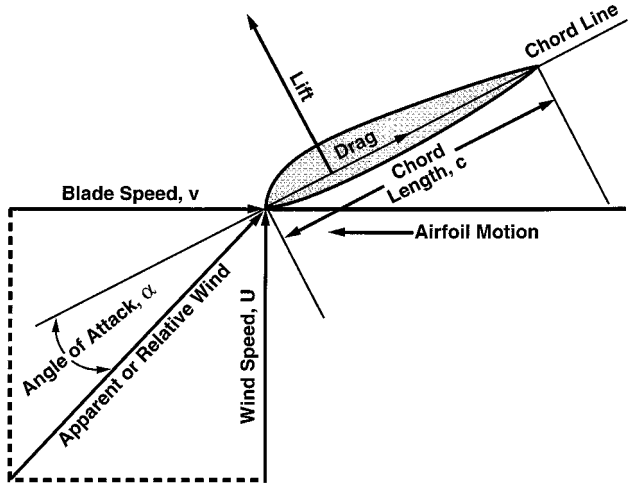

FIGURE 8.11.4 Schematic of translating lift device.

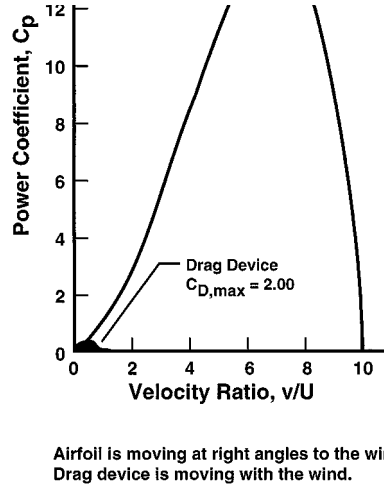

FIGURE 8.11.5 Comparison of power coefficients for a translating airfoil and a translating drag device. The airfoil is moving at right angles to the wind direction. The drag device is moving in the wind direction.

Machines discussed in this section utilize lift-producing blades to capture wind energy.

Aerodynamic Models

The aerodynamic analysis of a wind turbine has two primary objectives: (1) to predict the power produced by of the turbine and (2) to predict the detailed aerodynamic loads which will act on the turbine rotor blades. In general, the same models are used to accomplish both objectives. The aerodynamics of wind turbines are far too complex to model with simple formulas that can be solved with hand-held calculators; computer based models ranging from very simplified to very complex are required. The various models commonly used today are described below.

Momentum Models

The simplest aerodynamic model of a wind turbine is the actuator disk model or **momentum theory** in which the turbine is modeled as a single porous disk. In this model the axial force acting on the rotor or disk is equated to the time rate of change of momentum of the airstream passing through the rotor

© 1999 by CRC Press LLC

or disk. By utilizing the conservation of mass, the conservation of axial momentum, the Bernoulli equation, and the first law of thermodynamics and by assuming isothermal flow, the power produced by the turbine (the product of the axial force and the air velocity at the disk) may be found to be

$$P = 2\rho AV^3 a(1-a)^2 \tag{8.11.5}$$

where V is the freestream wind velocity, $a = (V - v)/V$ and v is the wind velocity at the disk. The power coefficient for the turbine becomes

$$C_p = 4a(1-a)^2 \tag{8.11.6}$$

This is maximized for $a = {}^1/_3$, and we get $C_{p,\max} = 16/27 = 0.593$, the **Betz limit**, as the maximum fraction of available energy that can be extracted from the wind by a turbine.

The typical performance of various types of wind machines is compared with the Betz limit in Figure 8.11.6 where the variation of the turbine power coefficients with the **tip–speed ratio** (the ratio of the speed of the blade tip to the free-stream wind speed) are presented. Even though the maximum performance of modern HAWTs and VAWTs is well above that of the older machines, it still falls more than 10% below the Betz limit.

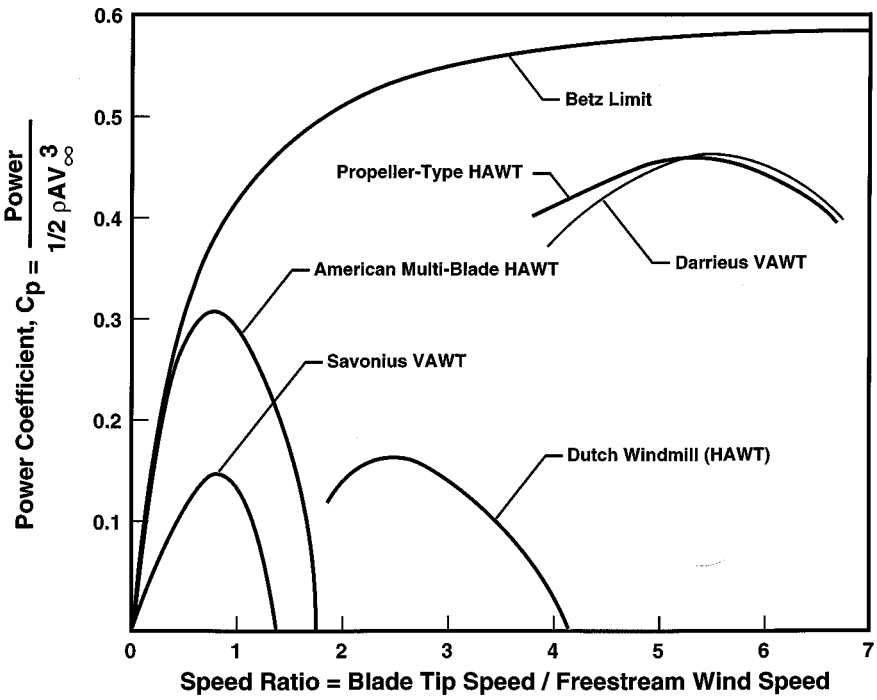

FIGURE 8.11.6 Typical performance of various types of wind turbines.

For HAWTs, momentum theory can be expanded to the blade element or strip theory, which includes the effects of blade lift and drag, wake rotation, and number and type of blades. Numerous corrections are applied to account for the three-dimensional flow near blade tips, the thick blade sections near the root, and gaps along the blade span. Additional information on these models may be found in Hansen and Butterfield (1993) and Wilson (1994).

© 1999 by CRC Press LLC

Momentum theory may also be expanded for vertical-axis turbines into the multiple streamtube and the double-multiple streamtube theories that are the VAWT equivalent of the HAWT blade element theory. Additional information on these models may be found in Touryan et al. (1987) and Wilson (1994).

Wind shear and local Reynolds number variations may be readily accounted for with both the blade element and multiple streamtube methods. These models are extremely popular with wind turbine designers because they are simple, fast, and fairly accurate for performance prediction. However, they are very approximate methods based upon the assumption of steady flow and streamtubes that are fixed in time and space. More-complex models such as vortex and local circulation models are needed for the analysis of yawed flow, unsteady aerodynamics, and other complex flows, all of which can have large impacts on turbine performance and loads.

Vortex Models

Vortex models, based on the vorticity equation, can use either lifting line or lifting surface formulations for the blades with either free-wake or fixed- (or prescribed-) wake models, although there are a number of variations of these models. The three-dimensional, lifting-surface, free-wake formulation is the most physically realistic model, but a computer program implementing such a model will require a tremendous amount of computer resources and time. The problem with vortex codes is one of finding a balance between model simplification (and limitation) and computation time. Additional information on vortex models may be found in Strickland et al. (1981) and Kocurek (1987).

Local Circulation Method

The local circulation method (LCM) utilizes a balance between the force on the blade and the change in wind momentum as it passes through the rotor, similar to what is done with the momentum models. The blade, however, is represented as a superposition of imaginary blades of different spans with elliptical circulation distributions. Unlike the streamtube models, LCM models may be formulated to analyze unsteady flow, and are able to yield detailed flow field velocity and blade-loading information. The LCM yields better answers than the momentum models, avoids the convergence problems of the vortex models, and, with an appropriate wake model, requires far less computer time than the vortex models. However, this model has not been widely used. Additional information may be found in Nasu and Azuma (1983), Masse (1986), and Oler (1989).

Common Model Limitations

All of the aerodynamic models in use today use airfoil section characteristic tables (lift and drag coefficients as functions of angle of attack and Reynolds number) to determine the blade loading and turbine performance. Static two-dimensional wind tunnel test results or two-dimensional static airfoil design code predictions are modified with empirical, semiempirical, or analytic methods and used to estimate blade loads under three-dimensional, dynamic conditions. The greatest difficulty in obtaining accurate load predictions with any performance code is the determination of the appropriate airfoil section characteristics.

Additional information and references on turbine aerodynamics may be found in Hansen and Butterfield (1993) and Wilson (1994) for HAWTs and in Touryan et al. (1987) and Wilson (1994) for VAWTs.

Wind Turbine Loads

Wind turbine aerodynamic loads are of two types — the narrowband harmonic or cyclic loads resulting from the steady atmospheric wind, wind shear, rotor rotation, and other steady effects; and the broadband random loads resulting from nonuniformity or turbulence in the wind. The prediction of these loads is more complicated than the prediction of the aerodynamic performance and requires the use of computer-based models. The harmonic loads are generally predicted with the same codes that are used to predict wind turbine performance. The random loads are typically estimated with empirical relations, although a few analysts do utilize a performance code with a nonuniform wind model to predict them. A wind

© 1999 by CRC Press LLC

turbine will experience hundreds of millions of loading cycles in a 30-year lifetime, and small errors that lead to underpredicting component loads can result in costly short-term component failure.

Accurate prediction of turbine performance does not guarantee accurate prediction of detailed aerodynamic loads — the performance predictions result from the integration of loads over the entire turbine, and significant errors may be present in the detailed loads but balance out in the performance predictions. While there is a considerable body of data showing good agreement of predicted performance with measured performance, there are very few data available against which to compare detailed aerodynamic load predictions.

Wind Turbine Dynamics

Horizontal-Axis Turbines

Horizontal-axis turbine designs usually use fairly rigid, high-aspect-ratio blades, cantilevered from a rigid hub and main shaft, although they may sometimes use relatively slender, quite flexible blades, attached to a less rigid hub and/or main shaft. This assembly rotates and yaws about a tower which may be flexible. These structures have many natural vibration modes, and some of them may be excited by the wind or the rotation frequency to cause a **resonance** condition in which the vibrations are amplified and cause large stresses in one or more components. Careful structural analysis during the design can ensure that the turbine that is built is dynamically stable under turbine operating conditions. Ignoring the structural analysis or failing to properly conduct parts of it will likely result in a machine that experiences resonances and fails very quickly. Relatively rigid systems are less likely to experience these stability problems than are very flexible, highly dynamic systems.

Detailed analysis of the structural response of a turbine is a rather daunting task requiring the formulation and solution of the full governing equations of motion, usually performed with a finite-element structural model. Those equations must account for the interaction between the blades and the steady centrifugal forces, the time-dependent gravitational forces, the steady and oscillatory aerodynamic forces, and the Coriolis forces. They must also model nonsteady airflow, the yaw motion of the nacelle, pitch control of the blades, teetering blades, the interaction between the rotor and the supporting tower, starting and braking sequences, etc. The rotor must be modeled in a rotating coordinate frame with time-dependent coefficients, while the tower must be modeled in a fixed coordinate frame, with the exciting forces arising from the nonlinear, time-dependent coupling of the rotor and the time-dependent loading of the wind.

Malcolm and Wright (1994) provide a list of some of the available HAWT dynamics codes that have been developed, together with their limitations.

Vertical-Axis Turbines

Darrieus turbine designs normally use relatively slender, high-aspect-ratio structural elements for the blades and supporting tower. The result is a very flexible, highly dynamic structure, with many natural modes of vibration which, again, must be carefully analyzed to ensure that the turbine is dynamically stable under all operating conditions. Typically, the guy cables and turbine support structure can be analyzed with conventional methods, but the tower and blades require a more refined analysis, usually performed with a finite-element structural program.

The blades and tower must be modeled in the rotating coordinate frame with time-independent coefficients. The equations of motion are determined by the steady centrifugal and gravitational forces, the steady and oscillatory aerodynamic forces, and the Coriolis forces, together with the turbine physical properties. Detailed information on the modeling may be found in Lobitz and Sullivan (1983).

Aerodynamic Loads/Blade Motion Coupling

The blades themselves are driven by aerodynamic as well as structural dynamic forces. The motion of slender, high-aspect-ratio blades may couple with the aerodynamic loads acting on them. This coupling may increase the motion of the blades, creating a potentially fatal condition known as flutter instability,

© 1999 by CRC Press LLC

or it may decrease the motion of the blades, creating a beneficial condition known as aerodynamic damping.

Stochastic Wind Effects

The wind is **stochastic** in nature, with significant short-term variations in both direction and velocity. As turbines become larger, the relative extent of these variations becomes smaller than the size of the turbine, and the effects become more pronounced. Analysis of the effect of fluctuating wind loads on the response of the turbine shows an increase in the broadband response, accompanied by a decrease in the magnitude of the dominant narrowband responses at multiples of the rotation frequency. This increase in broadband response can include excitation of turbine vibration modes that are close to a narrowband response frequency, but that are not predicted to be excited by a uniform wind (Lobitz, 1984).

Wind Turbine Controls

In general, wind turbines are designed to operate when the incident wind is high enough to generate electricity and to shut down when the wind speeds exceed 25 to 30 m/sec. In spite of the tremendous amount of power which is present in the high winds, the amount of energy that can be captured is usually more than offset by the fatigue damage that is sustained by the turbine.

Brakes

Most turbines utilize mechanical brakes, frequently in conjunction with aerodynamic brakes, to stop the rotor and to keep it from rotating when the turbine is not generating electricity. A few turbines rely solely on aerodynamic braking devices to accomplish this. Whatever type of braking system is used, it should be a fail-safe design that will automatically activate to slow or stop the rotor in the event of an electrical system failure.

Yaw Systems

Virtually all upwind and a few downwind HAWT turbines incorporate an active yaw control system, using wind-direction sensors and electric or hydraulic drive motors, to orient the rotor with respect to the wind. VAWTs do not require yaw systems.

Peak Power Regulation

All turbines incorporate some method of limiting the peak power produced. This enables the generator to operate near its design power rating, where it is most efficient, over a range of wind speeds. The increase in generator efficiency at lower wind speeds, together with the lower cost of the drivetrain, more than offset the energy that is lost as a result of power limiting. Most horizontal-axis turbines use one of three common techniques to limit peak power — stall regulation with fixed-pitch blades (passive control), full- or partial-span pitch control, or partial-span control surfaces such as ailerons and/or flaps. With stall regulation, the blades are designed so that airfoil **stall**, which creates decreased lift and increased drag, limits the power output in high winds. However, rotor drag loads continue to increase as the wind speed increases. Another disadvantage is the difficulty of controlling aerodynamic loads in deep stall. With full- or partial-span blade pitch control, peak power is controlled by decreasing blade pitch angle as wind speed increases, limiting peak power and decreasing rotor drag loads. A major disadvantage of pitch control is the poor peak power control during high-wind stochastic (or turbulent) conditions — power excursions can exceed twice the rated power levels before the pitch-control system can respond. Partial-span control surfaces limit the peak power by decreasing the lift and increasing the drag of a portion of the airfoil. They can respond to wind changes somewhat faster than full-span pitch control systems can. Sample power curves for both stall and pitch-regulated turbines are shown in Figure 8.11.7.

Several other methods of pitch control have also been used, but on a limited basis. Passive pitch-control techniques automatically adjust the blade pitch angle using cams activated by centrifugal loads or using tailored blade materials that permit the blade to twist as the aerodynamic loads increase. The

© 1999 by CRC Press LLC

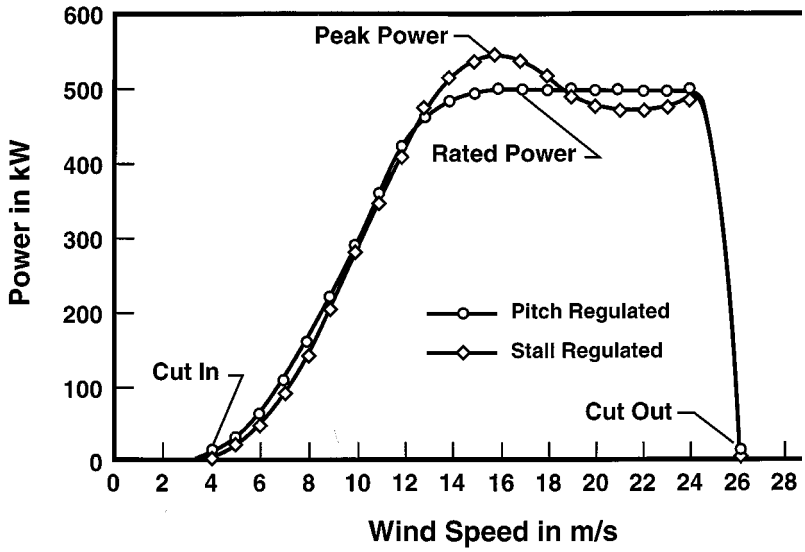

FIGURE 8.11.7 Sample power curves for stall-regulated and pitch-regulated wind turbines.

Italian Gamma 60 turbine utilizes a novel means to control peak power — it is the only large-scale turbine that yaws a fixed-pitch rotor out of the wind to limit rotor power.

Virtually all VAWTs utilize stall regulation with fixed-pitch blades to control peak power.

Controller

Every wind turbine contains a controller, usually a microprocessor-based system, to control turbine operations. The basic turbine controller will start and stop the machine and connect or disconnect the generator output lines to the grid, as needed; control the operation of the brake system; control the operation of the yaw and pitch systems, if present; perform diagnostics to monitor the operation of the machine; and perform normal or emergency shutdown of the turbine as required. However, the controller can incorporate many other functions as well, functions such as recording turbine performance characteristics and controlling the operating state of a variable-speed machine.

Wind Turbine Electrical Generators

Once a wind turbine has converted the kinetic energy in the wind into rotational mechanical energy, the energy is usually converted into electricity which can be readily transported to where it is needed. While small wind turbines may utilize permanent magnet alternators to generate electricity, most grid-connected turbines today use either synchronous or induction electrical generators. Induction machines are cheaper than synchronous machines, are easier to control, and provide some power train damping, but they require reactive power that must be supplied by the grid. This can cause problems, but those problems can be usually be solved fairly quickly and at low cost.

Generator efficiency drops off rapidly as the generated power falls below the rated generator capacity, and single-generator systems tend to be very inefficient at low wind speeds where there is little power available in the wind. Some systems address this by having a second, smaller generator which is used for low-wind operation, where it operates close to its rated power. At higher winds, the smaller generator is disconnected and the larger generator is used. Similar results can be obtained with a single generator utilizing pole switching or dual windings. The two-generator operation may yield a sizeable increase in energy capture, but the additional costs of the smaller generator or the generator modification and additional controls must be balanced against the increased energy capture to determine if this is cost-effective.

© 1999 by CRC Press LLC

While most turbines operate at a single fixed rotational speed, some operate at two or more fixed rotational speeds, and some operate anywhere within a range of speeds. Variable-speed turbine operation offers two major advantages over fixed-speed operation:

1. The aerodynamic efficiency of the rotor at low to moderate wind speeds may be improved by more closely matching the rotor speed to the short-term average wind speed. At higher wind speeds, the blades are either in stall or are pitched to control peak power, so matching rotor speed to wind speed is less important.
2. System dynamic loads are attenuated by the "flywheel" action of the rotor as it speeds up and slows down in response to wind gusts.

In addition, variable speed permits the operation of the turbine in a variety of modes, including operation at maximum efficiency for all wind speeds to maximize energy capture or operation to minimize fatigue damage. However, certain rotational speeds within the operating-speed range will likely excite turbine vibration modes, causing resonance and increased rates of fatigue damage. These rotational speeds must be avoided during operation, and turbine control can become quite a complicated issue.

Variable-speed operation, in general, generates variable-frequency power. Most applications, including interfacing with power grids, require high-quality power at a reference frequency. Sophisticated power electronics may be used to accomplish this interface (Smith, 1989).

Wind-Diesel Systems

Wind turbines are increasingly being coupled with diesel engine-powered generators to create **wind-diesel systems**. In these systems, the diesel engine provides dependable, consistent power and the wind turbines generate some of the power, reducing the engine fuel consumption and the system cost of energy. A large variety of wind-diesel systems and concepts have been investigated over the past decade (Infield, et. al., 1992). Although quite a few of these have been technically successful, very few of them have been commercially successful. While the potential market for wind-diesel systems appears to be very large, it has yet to materialize, for the reliability of the technology has not yet been well proven.

Water-Pumping Applications

The multibladed, mechanical windmill (the so-called "American" windmill) with a mechanical piston pump has been used for over a century to pump water in remote areas. Over the past few years some changes to improve operation in low wind speeds have been made to the design of these machines.

Researchers at the U.S. Department of Agriculture facility at Bushland, Texas have reported considerable success in using variable-voltage, variable-frequency electricity produced by small stand-alone wind turbines to directly power submersible water pumps. Clark (1994) compares the pumping performance of one of these wind–electric systems and that of the traditional American windmill with a piston pump. He found that the wind–electric system performed significantly better than the mechanical system, even though the price of the two systems was nearly identical. The wind–electric system offers another advantage as well — while the windmill for the mechanical pump must be mounted directly over the well, the wind turbine for a wind–electric system may be mounted some distance away, at a better wind location.

Defining Terms

Betz limit: Maximum fraction of available wind energy that can be extracted by a wind turbine rotor, according to momentum theory.
Momentum theory: A method of estimating the performance of a turbine by equating the time rate of change of air stream momentum through the turbine to the force acting on turbine blades.
Power coefficient: The ratio of captured energy to the energy available in the reference area.

© 1999 by CRC Press LLC

Resonance: A vibration of large amplitude caused by a relatively small excitation at or near a system natural frequency.

Stall: A condition in which an airfoil experiences a decrease in lift and a large increase in drag.

Stochastic: Containing variations from a smooth, uniform flow.

Tip-speed ratio: The ratio of the speed of the blade tip to the free-stream wind speed.

Wind–diesel system: An electrical-generation system that utilizes both diesel engine–powered generators and wind turbines to create a dependable, consistent power system.

8.12 Energy Conversion of the Geothermal Resource

Carl J. Bliem and Gregory L. Mines

This section discusses the uses of the geothermal resource. The primary use of the energy from geothermal resources to date has been in the production of electrical energy. Other applications, such as process heat and space conditioning, have also been made and will be discussed under the topic of direct use. This section begins with a discussion of the geothermal resource as it applies to the use of the energy. Then discussion of the three types of electrical generating facilities presently in use: — the **direct steam system**, the **flashed steam system**, and the **binary system** — is given. Finally, some discussion of direct-use applications is given.

Geothermal Resource Characteristics Applicable to Energy Conversion

Geothermal energy as defined here applies to hot fluids under pressure found at a reasonable depth (1 to 2 km) in the earth's crust. If one disregards the complex geological details relating to the formation of such naturally occurring reservoirs of hot fluids, Figures 8.12.1 and 8.12.2 present schematic representations of these reservoirs. High-temperature fluid (200 to 300°C) is created by the convection of water through the porous rock. As the water circulates, it dissolves various amounts of minerals containing sodium, potassium, calcium, silica, carbonates, and chlorides and gases such as nitrogen and carbon dioxide. In **geopressured resources** of the Gulf of Mexico, high pressures and significant amounts of dissolved methane are seen.

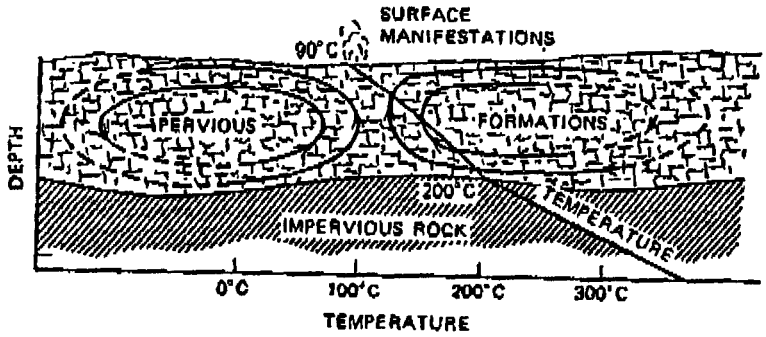

FIGURE 8.12.1 Schematic diagram of the convective cells in a geothermal reservoir. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

The convective cells operate over large horizontal distances of as much as 30 km. The time in which the transfer of energy from the magma to the water takes place is of the order of 10^5 to 10^6 years. At the present time, it is difficult to say whether or not the resource can be considered "renewable." If natural circulation or the injection of spent geothermal liquid into the reservoir can make up for the liquid extracted during the energy conversion process, the reservoir can be considered at least of a very long life. (Individual wells generally have a life of about 10 years.)

The resources considered in this section are said to be **hydrothermal**. (Work is being done on creating artificial reservoirs by injecting water into hot dry rock, but this development is in its early stages and will not be considered here. The geopressured resource will not be considered either.)

As the geofluid is extracted from a reservoir, it flows to a region of lower static pressure. If this pressure falls below the saturation pressure for the temperature of the geofluid (close to but not equal to the saturation pressure of pure water because of the presence of the dissolved solids and gases), the

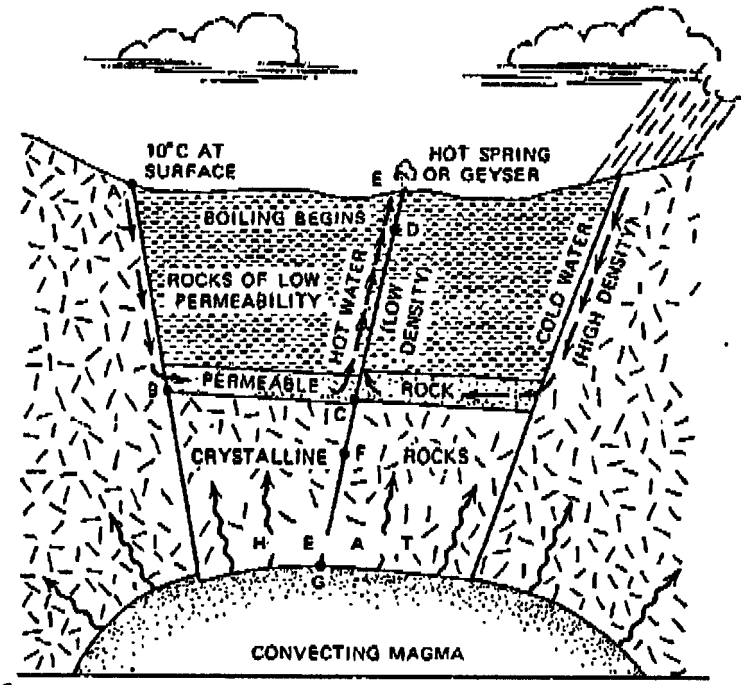

FIGURE 8.12.2 Schematic diagram of a characteristic geothermal reservoir. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

geofluid will flash into steam. Therefore, the person using this energy source may have a number of different physical forms to consider:

1. Wet steam from a *vapor-dominated resource*;
2. Superheated or saturated steam from a vapor-dominated resource;
3. Liquid at a pressure above the saturation pressure from a *liquid-dominated resource*;
4. A mixture of liquid and vapor at a relatively low quality from a liquid-dominated resource.

Electrical Energy Generation from Geothermal Resources

The type of energy conversion system used to produce electrical power depends on the type and quality (temperature) of the geothermal resource. Vapor-dominated resources use systems where steam is expanded directly through a turbine, similar to conventional fossil fuel steam plants. Liquid-dominated resources use flash steam systems and binary systems, with binary systems predominantly used for the lower-quality resources. The term **binary system** is used to describe a power cycle where the geothermal fluid provides the source of thermal energy for a closed-loop Rankine cycle using a secondary working fluid. In this closed loop, the working fluid is vaporized using the energy in the geofluid, expanded through a turbine, condensed, and pumped back to the heater completing the closed loop.

Hydrothermal resources typically contain varying amounts of numerous dissolved minerals and dissolved gases. In power cycles where steam is extracted from the geothermal resource directly (vapor dominated) or indirectly (flashing liquid dominated) and expanded through a condensing turbine, the design and operation of the power cycle must account for the removal of the noncondensable gases. If the gases are not removed from the condenser, they will accumulate in the condenser, raising the turbine back pressure and decreasing the power output. In systems where the liquid geofluid is handled (binary cycle heat exchangers and piping and flash steam flash tanks and piping), measures must be taken to

© 1999 by CRC Press LLC

prevent the precipitation of the dissolved solids and/or to provide a means of removal of the resulting scale.

Direct Steam Systems — Vapor-Dominated Resources

For a geothermal resource producing a superheated or saturated vapor steam (Case 2), the vapor from the geothermal production well is sent to a conventional steam turbine as shown in Figure 8.12.3. (This is done after appropriate removal of rocks and debris and possibly after scrubbing with water to remove corrosive substances.) Normally, the turbine is a condensing type, as shown in the figure, although in some applications a back-pressure turbine is used, exhausting the steam to the atmosphere. The back-pressure turbine is typically used for small systems with the possible later addition of another turbine and a condenser to increase the power generated by the geofluid flow from the wells.

Figure 8.12.3 shows a system with a direct-contact condenser and a wet cooling tower. In this type of system, the condensate from the condenser is more than enough to make up the evaporation and blowdown from the cooling tower. Therefore, the figure shows some of the condensate being injected into the reservoir. In many cases, direct-contact condensers are not feasible because of the hydrogen sulfide in the steam which would be released in the cooling tower exhaust. When hydrogen sulfide is in the steam, the majority of it appears as noncondensable and the noncondensable gas from the condensers must be treated. For these systems, surface condensers are normally used in conjunction with wet cooling towers. The actual hardware configuration is dictated by the process for removal of the sulfur. Again, some of the condensate can be used for cooling tower makeup if the sulfur is removed from the process. A number of processes have been developed to remove sulfur from the process.

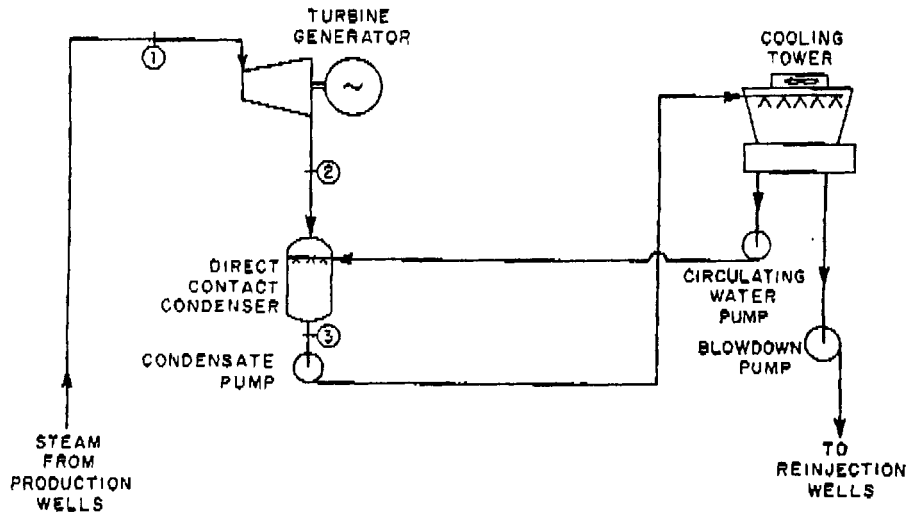

FIGURE 8.12.3 Schematic diagram of a direct dry-steam plant. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

Figure 8.12.4 depicts a system which is similar to the one described above, but one which receives wet steam (Case 1). Here, the liquid is separated from the vapor prior to the entry of the vapor into the turbine. Otherwise, the system is the same as the one in Figure 8.12.3 and the same comments apply.

Flash Steam Systems — Liquid Dominated Resources

When the geofluid is flashed before it leaves the well, flash steam systems are generally used. This indicates that the resource is at a relatively high temperature. Figures 8.12.5 and 8.12.6 depict single- and dual-flash systems schematically. The single-flash system in Figure 8.12.5 is quite similar to the system in Figure 8.12.4. The only difference is that the geofluid pressure is dropped further before the steam is separated and sent to the turbine. An optimum flash pressure exists because the lower the flash

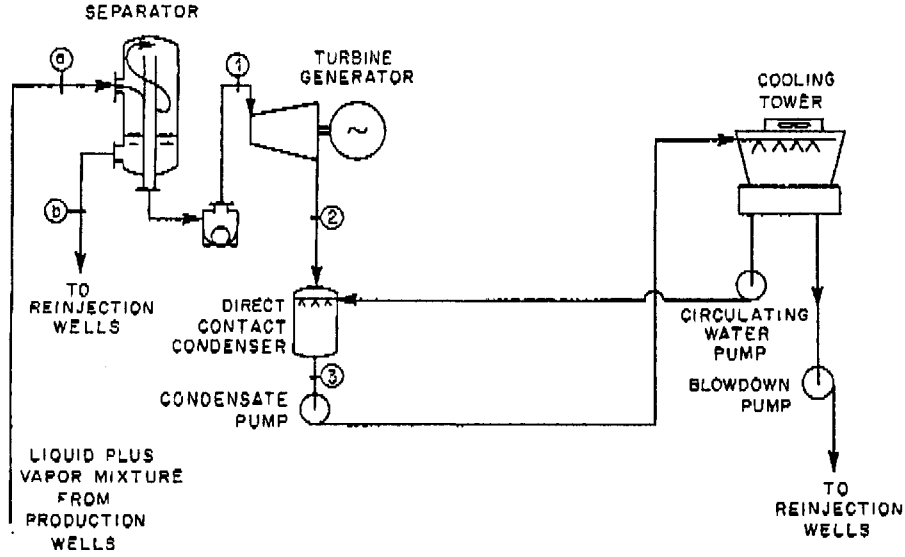

FIGURE 8.12.4 Schematic diagram of a plant using a two-phase resource. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

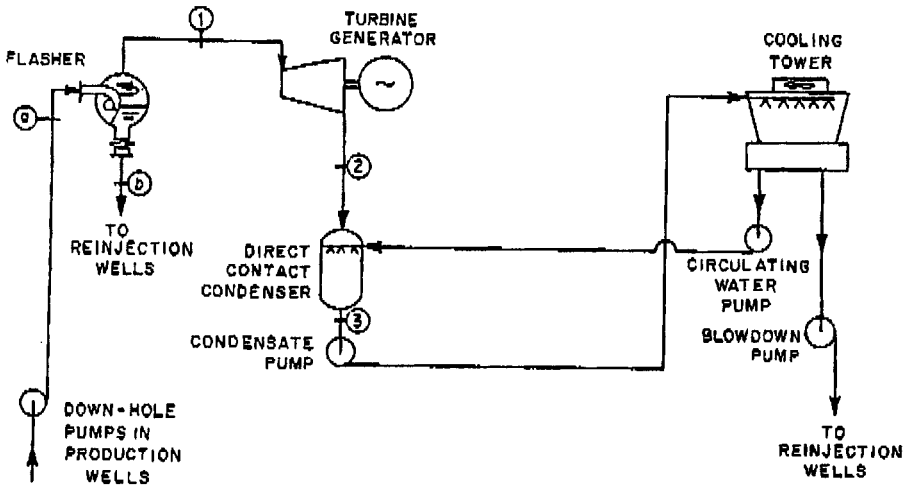

FIGURE 8.12.5 Schematic diagram of a single-flash plant. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

pressure, the more steam which is evolved. However, the work done per unit mass of steam flowing through the turbine will also decrease with the lower flash pressure. For a given set of geofluid conditions entering the plant, a flash pressure exists that will maximize the energy produced per unit mass of geofluid and also minimize the levelized energy cost (LEC). The performance and cost optima will be near, but not generally at the same pressure.

The flash steam system can also be utilized in applications where the fluid enters the plant as a liquid (single phase). In these systems, the geothermal fluid is throttled with an expansion valve to the desired flash pressure. This flashing process can be considered adiabatic, where the amount of steam evolved can be determined from energy and mass balances of a simple throttling calculation.

© 1999 by CRC Press LLC

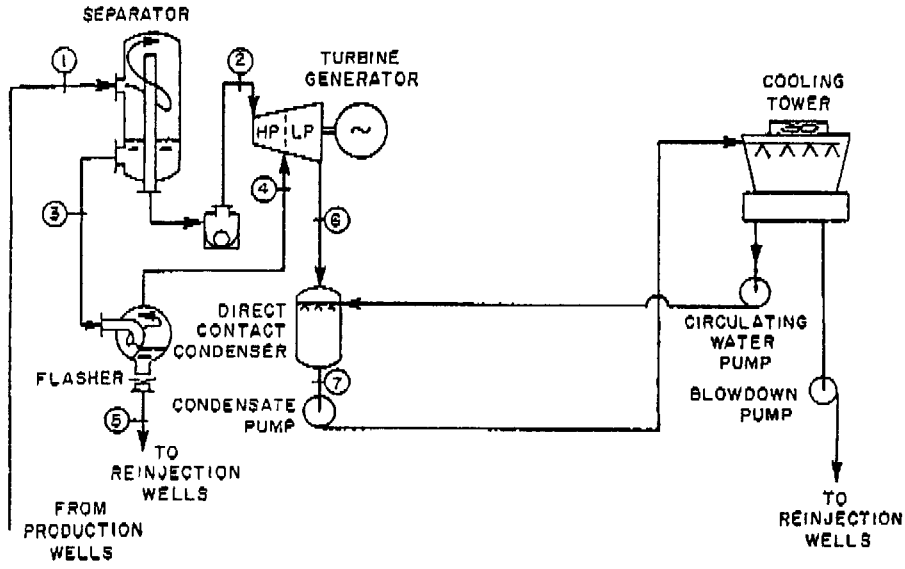

FIGURE 8.12.6 Schematic diagram of a dual-flash plant. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

Most successful flash systems are dual flash. The first flash is generally near the well-head pressure and the second flash near atmospheric pressure. The low-pressure flash is normally kept above atmospheric pressure to prohibit leakage of air into the system in the flasher. Some recent studies have indicated that for low-temperature resources, a subatmospheric second flash would produce a cost-effective system. Again, optimization of the two flash pressures is necessary to minimize the LEC. In cases in which the geofluid has a high dissolved solid content, flash crystallizers are used to remove the precipitated dissolved solids. The flashing process releases carbon dioxide dissolved in lowering the geofluid pH, which causes the precipitation of insoluble carbonates. The solubility of silica is temperature dependent; lowering the geofluid temperature causes the precipitation of silica.

None of the steam cycles depicted provides for the removal of the noncondensable gases from the condenser. This removal is typically accomplished with steam ejectors or compressors which continuously remove the small stream of vapor from the condenser. Some steam is lost in this process of removing the noncondensable gases.

Binary Systems — Liquid-Dominated Resources

Recent studies have shown that for resources below 200°C, current technology binary systems have lower LEC than flash steam plants for liquid-dominated resources. Figure 8.12.7 shows a typical binary system with an evaporative heat-rejection system. This type of heat-rejection system has been replaced by air-cooled condensers in most applications. In the areas where the geothermal resource exists, there is little excess water for makeup in the cooling tower, as shown in Figure 8.12.7. All of the cooled geofluid in a binary system is typically injected back into the reservoir. This provides an environmentally acceptable means of disposal of the fluid and, more important, provides a recharge of the reservoir to maintain the reservoir productivity.

The binary cycle is an attempt to reduce the scaling potential of the geofluid. Carbonates are precipitated when the pressure of the geofluid is reduced and carbon dioxide comes out of solution as the geofluid flashes. With downhole pumps in the wells, this can be eliminated by keeping the fluid pressurized. Some resources do not require pumps to maintain the flow and pressure necessary to eliminate flashing (artesian flow). Similarly, if the exit temperature of the geofluid remains above some minimum value, silica will not be precipitated. These two operational strategies limit the scaling in a binary plant. Any constraint imposed on the geofluid exit temperature will impact the design of the

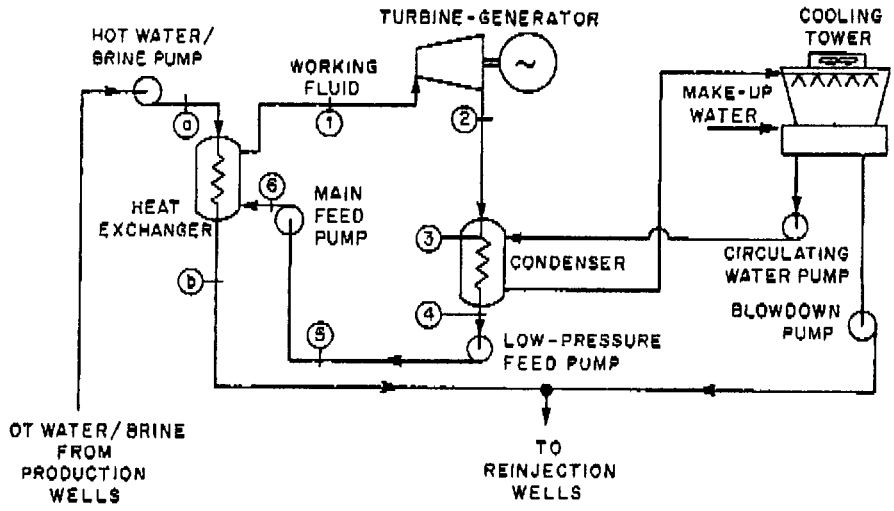

FIGURE 8.12.7 Schematic diagram of a binary plant. (From Kestin, J., Ed., Sourcebook on the Production of Electricity from Geothermal Energy, U.S. DOE, DOE/RA/4051-1, Washington, D.C., 1980).

binary plant, affecting the selection of turbine inlet conditions as well as the possible choice of working fluid.

The binary cycle consists of a closed loop of a working fluid normally performing a Rankine cycle. Most existing binary cycles use isobutane, pentane, or isopentane as working fluids. Studies have indicated that mixtures of hydrocarbons, e.g., 96% isobutane/4% hexane, will produce better utilization of a 180°C resource and in some instances lower LEC.

The performance of the binary system depends on a number of factors. Some plant designs incorporate multiple or staged boiling cycles, where the working fluid flow is split and boiling occurs at multiple pressures. In these cycles, multiple or staged turbines are required. The advantage of these cycles is the fact that the working fluid heat-addition process more closely matches the sensible cooling of the liquid geofluid (as shown on the T-Q or T-h diagram). This lowers temperature differences through the cycle, reducing cycle irreversibilities and increasing performance. The same effect can be achieved by heating the working fluid at supercritical pressures (pressures above the critical pressure). While the supercritical cycle will have higher component, material, and pumping costs because of higher operating pressures, they have fewer components because they are less complex than multiple boiling cycles. (In many cases, the maximum pressure can be kept below 600 psi with hydrocarbons such as isobutane.) Lowering the mean temperature difference in heat exchangers tends to require larger units so that capital costs are increased. In general, the LEC is reduced because the effects of increased performance more than outweigh the increase in capital cost.

The choice of the working fluid for the power cycle will also impact the cycle performance. In general, as resource temperature decreases, the more volatile fluids will produce more power per unit mass of geofluid. Power cycles using the more volatile fluids typically operate at higher pressures and have higher associated material and equipment cost. These higher costs may offset the gains in performance and produce higher LECs in some cases.

Working fluid mixtures have been shown to provide superior performance to the single component or pure working fluids. This performance improvement is due to the nonisothermal phase changes of this type of fluid at constant-pressure (both boiling and condensing), which allows the working fluid to match more closely the sensible cooling of the geofluid. More importantly in the reduction of irreversibilities, the desuperheating and condensing process more closely matches the sensible heating of cooling water or air in the heat-rejection process.

© 1999 by CRC Press LLC

One additional type of binary cycle that has been proposed uses an ammonia-water mixture for the working fluid. A great deal of recuperative preheat of the working fluid is accomplished by splitting the duty of the geofluid, turbine exhaust, and preheated liquid flows through a more complex heat-transfer train than is shown in Figure 8.12.7. These systems are known as **Kalina systems**. In general, these systems do not change the composition of the mixture in the cycle as the Kalina cycle for applications such as is the case for gas turbine bottoming.

There is some consideration of using a binary cycle as a bottoming cycle for a flash steam or direct steam system. Similarly, a binary cycle could be used to bottom another binary system, perhaps with a different working fluid.

Design Considerations

The selection of the working fluid in binary cycles imposes safety considerations to be considered in the design of the power plant. Equipment and facility designs must take into account the flammable characteristic of the hydrocarbon working fluids.

The selection of materials of construction for the piping and components exposed to the geofluid will be resource specific. Typically, carbon steel is used for piping and pressure vessels. Turbines that use the steam directly may have stainless steel components, although the use of stainless may be limited by the presence of chlorides and the potential for stress cracking. The standard design for heat exchangers in binary cycles is for the geofluid to be on the tube side. This facilitates the cleaning of the exchanger if scaling or fouling occurs on the surfaces exposed to the geofluid. If the geofluid has a high scaling potential, components and piping should be designed to allow for periodic cleaning.

Direct Use of the Geothermal Resource

A number of direct-use applications of the heat in a geothermal resource have been successfully implemented. These include

1. Space conditioning (heating with the resource or a secondary fluid and cooling with heat pumps);
2. Heating of greenhouses;
3. Aquaculture;
4. Process heating (drying vegetable products);
5. Ground coupled heat pumps.

Although the United States is one of the world leaders for the production of electrical power from geothermal energy, other nations take the lead for the direct use of this energy source. In Iceland, over 85% of the buildings are supplied with heat and domestic hot water from geothermal systems (Ragnorson, 1995).

Typical direct-use applications are either closed systems with produced fluids being injected back into the geothermal reservoir or systems where the produced water is pure enough for beneficial use or disposal to surface waterways. Experience has shown that it is usually worthwhile to inject as much of the cooled fluid as possible back into the reservoir to maintain pressure and production rates.

Defining Terms

Binary system: A binary system that uses thermal energy from the geofluid to vaporize a secondary working fluid in a Rankine cycle.

Direct steam system: A geothermal energy conversion system that utilizes steam directly from a geothermal well.

Flashed steam system: A geothermal energy conversion system that utilizes steam flashed from the liquid geofluid.

Geopressurized resource: Naturally occurring reservoirs of hot pressurized fluid created by convection of water through hot porous rock.

© 1999 by CRC Press LLC

Hydrothermal resource: Artificial reservoirs created by injecting water into hot dry rock in the earth's core.

Kalina system: A binary system using a mixture of ammonia and water as the working fluid in the power cycle.

8.13 Direct Energy Conversion

Solar Photovoltaic Cells

Kitt C. Reinhardt

Introduction

Solar photovoltaic cells convert sunlight directly into electrical energy via the collection of solar photon-generated semiconductor charge carriers. The collection of charge carriers within the cell produces a voltage across the terminals of the cell, called the **photovoltaic effect**, that can drive an external electrical circuit or charge a storage battery. Photovoltaic cells are useful in both space and terrestrial power applications. Silicon, Si, photovoltaic cells have provided the main source of electrical power to virtually all Earth-bound satellites since the advent of the space program in the late 1950s. In the early 1970s, photovoltaics generated a significant amount of interest for use in terrestrial power systems when oil supplies to the industrial world were disrupted. Today, while photovoltaic power remains the primary energy source for most communication and surveillance satellites, issues concerning system efficiency, reliability, and cost currently prevent its widespread use in residential and power utility applications. For example, in the United States the average price for conventional utility electricity is 6¢/kWhr, compared with ~35¢/kWhr for terrestrial photovoltaic electricity (Zweibel, 1995). Thus, the cost of photovoltaic power must be reduced by a factor of ~6 for it to become economically viable. At present, photovoltaic power is generally only cost-competitive for use in remotely located systems where conventional power is cost-prohibitive, such as in remote water-pumping and communications stations, signal and emergency lighting, and for village power. Factors that influence photovoltaic system energy costs include cell panel efficiency, total system lifetime, and cost per unit area. The present discussion will focus on issues concerning photovoltaic cells and panels. Detailed literature on power conditioning electronics and energy storage systems can be found elsewhere. A large number of different photovoltaic cell designs have been demonstrated by researchers over the years. However, the most common and practical cell designs are fabricated using single-crystal Si. Consequently, Si will be used to describe basic principles of semiconductors and photovoltaic cell operation.

Introduction to Semiconductors

We begin with a description of the concept of covalent bonding, valence electrons, and energy bands, which relates to conduction in semiconductors (Sze, 1981). The crystalline structure of Si is diamond, where each Si atom in the lattice is covalently bonded to four equidistant nearest neighbors that lie at the corners of a tetrahedron. Each Si atom has four electrons in its outer orbit, called valence electrons, and each atom shares these electrons with its four neighbors to form four covalent bonds. The atomic configuration of the 14 electrons of Si is $1s^2 2s^2 2p^6 3s^2 3p^2$. At practical temperatures, only the $3s^2 3p^2$ valence electrons contribute to the electrical conductivity; the $1s^2 2s^2 2p^6$ core electrons are too tightly bounded to the nucleus to participate. In a simplified model, as N Si atoms are brought together at 0 K to form a crystal, two distinct and nearly continuous bands of electronic energy levels form that are separated by an energy gap called the semiconductor **band gap, E_g**. The resulting upper **conduction band** contains 4N states, as does the lower **valence band**. The 4N electrons that come from the Si $3s^2 3p^2$ states completely fill the 4N states in the valence band at 0 K, and the conduction band states are completely empty. Since there are no unoccupied states in the valence band for electrons to move and the conduction band is empty, Si is a perfect insulator at 0 K.

As the temperature of the crystal increases, electrons in the valence band gain sufficient thermal energy ($>E_g$) to be excited across the band gap into the conduction band, leaving holes (missing electrons) behind in the valence band. When current conduction in a semiconductor is dominated by thermally generated electrons and holes, it is called intrinsic. In this case, the resulting number of electrons per unit volume in the conduction band, n, equals the number of holes per volume in the valence band, p, that is $n = p = n_i$, where n_i is called the intrinsic carrier concentration. In the presence of an electric

© 1999 by CRC Press LLC

field, intrinsic electrons and holes gain kinetic energy and conduct electricity. However, since at room temperature n_i for Si is only 1.45×10^{10} cm^{-3}, compared with a free-electron density of more than 10^{22} cm^{-3} in metals, Si behaves as a very good insulator, i.e., electrical conductivity, σ, is given by $\sigma = q(n\mu_n + p\mu_p)$, where q is the electronic charge and μ is the respective carrier mobility.

In order to increase the conductivity to values useful for solid-state devices, the level of n and p can be increased by purposely adding impurity atoms into the crystal, called doping, that liberate extra electrons or holes. In the case of Si, which is in column IV of the periodic table, and hence has four valence electrons for bonding, doping is achieved using either column III elements (boron, aluminum, gallium, or indium), which have three valence electrons, or column V elements (phosphorus, arsenic, or antimony), which have five valence electrons. When an arsenic atom with five valence electrons replaces (substitutes) an Si atom, four of its electrons are used to form covalent bonds with the four neighboring Si atoms. The fifth electron is loosely bound to the arsenic nucleus, and at room temperature is ionized and "donated" to the conduction band. Arsenic is therefore called a donor, and Si becomes an n-type (mostly electrons) semiconductor. Similarly, when a boron atom with three valence electrons substitutes for an Si atom, one of the boron four covalent bonds becomes deficient of one electron. Boron can then accept one electron from the valence band to satisfy the bond requirement, which creates a positively charged hole in the valence band. Boron is therefore called an acceptor, and Si becomes a p-type (mostly holes) semiconductor. In this way the electrical conductivity of semiconductors can be precisely controlled by varying the concentration of donor and acceptor impurities. In practical solid-state devices, typical values of n and p range between 10^{15} and 10^{19} cm^{-3}.

The p-n Junction Diode

The p-n junction is a basic structure used for solid-state device rectification, amplification, and switching, as well as for photocarrier collection in photovoltaic cells. A p-n junction is formed when a p-type semiconductor is metallurgically joined with an n-type semiconductor (Streetman, 1980). Before they are joined, the p-material has a large concentration of holes and very few electrons, whereas the converse is true for the n-material. Upon joining the two materials, holes instantaneously diffuse from the p-side into the n-side and electrons diffuse from the n-side into the p-side. The transport of these carriers constitutes a "diffusion" current from the p-side to n-side; electron current is opposite in direction to electron flow by convention. As shown in Figure 8.13.1, negative acceptor ions are left behind as holes leave the p-side of the junction, creating a negative space-charge region (SCR), and positive donor ions are left behind as electrons leave the n-side of the junction, creating a positive SCR. Consequently, an electric field directed from the positive SCR to the negative SCR results that opposes the further diffusion of electrons and holes; i.e., the electric field creates a drift component of current from the n-side to p-side that opposes the diffusion component. In the absence of any external fields a condition of equilibrium is established, and the net current flow across the junction is zero. As will be discussed, the p-n junction electric field is also responsible for separating and collecting photon-generated carriers in photovoltaic cells.

When a voltage is applied across a p-n junction, the balance between the electron and hole drift and diffusion currents is disturbed and a net current results. Under forward bias, a positive voltage is applied to the p-side relative to the n-side, and the electric field across the junction is reduced; i.e., the electric field associated with the applied voltage subtracts from the zero-bias field. The reduced field enhances hole diffusion from the p-side to the n-side and electron diffusion from the n-side to the p-side, thereby increasing the "positive" current; the transport of current from the p-side to the n-side is positive by convention. Conversely, under reverse bias a negative voltage is applied to the p-side relative to the n-side, and the electric field across the junction increases. Consequently, the diffusion component of current decreases relative to the drift component, and a net "negative" current results across the junction.

The dark current-voltage (I-V) characteristics for an Si p-n junction are generally well described by the ideal Shockley diode equation (Sze, 1981),

© 1999 by CRC Press LLC

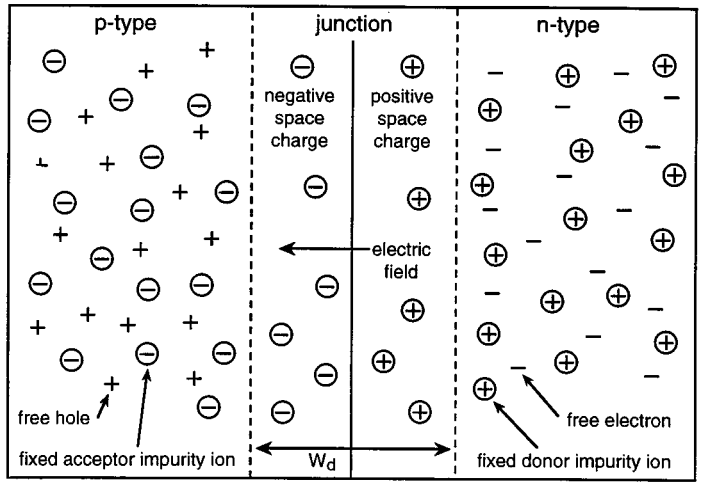

FIGURE 8.13.1 Schematic diagram illustrating an abrupt p-n junction with a unifiorm concentration of donor impurities in the n-region and acceptor impurities in the p-region.

$$I_D = I_o\left[\exp\left(qV/nkT\right) - 1\right] \tag{8.13.1}$$

where I_D is the junction dark current, I_o is the reverse saturation current, V is the forward-bias voltage, n is the diode ideality factor, and T is the absolute temperature. The value of n is ~1.0 when the current is dominated by carrier diffusion, but increases and approaches values of ~2 or greater when other current mechanisms become important, such as carrier recombination or tunneling. In high-quality Si p-n junction photovoltaic cells, the value of n is ~1.0 near the relevant operating voltage. The parameter I_o varies with T and E_g according to

$$I_o = qA\left[D_n n_p/L_n + D_p p_n/L_p\right] \propto T^3 \exp\left(-E_g/kT\right) \tag{8.13.2}$$

where A is the junction area and D_n and D_p, n_p and p_n, and L_n and L_p are the diffusion coefficients, minority carrier densities, and diffusion lengths for electrons and holes, respectively. The value of I_o decreases strongly as E_g increases, which, as will be shown, increases the photovoltage obtainable from a photovoltaic cell.

Cell Operation and Efficiency

Cell Operation. Photovoltaic energy conversion in a p-n junction is a two-step process where free electrons and holes (photocarriers) are generated in the semiconductor via the absorption of solar energy and then simultaneously collected across the junction (Fahrenbruch and Bube, 1983). Consider the schematic of a typical photovoltaic cell shown in Figure 8.13.2 which consists of a p-n junction formed very close to the top surface of the cell. Front metal ohmic contact grid fingers allow solar energy to pass into the absorber layers. The entire top surface is covered with an antireflection coating to minimize reflective losses, and the entire back surface is covered with an ohmic contact. The ohmic contacts form n and p region terminals that transfer (conduct) current from the semiconductor to the external circuit with a negligible amount of voltage drop.

When the photovoltaic cell is exposed to solar radiation, photons with energies greater than E_g (super-band-gap photons) are absorbed in the n and p layers, and free electrons and holes are generated via the breaking of covalent bonds. These electron-hole pairs, or **photocarriers**, are shown in Figure 8.13.1. The energy of the free photocarriers is converted directly into a current and voltage via photocarrier collection by the junction. The absorbed photons effectively contribute an energy E_g to the cell output,

© 1999 by CRC Press LLC

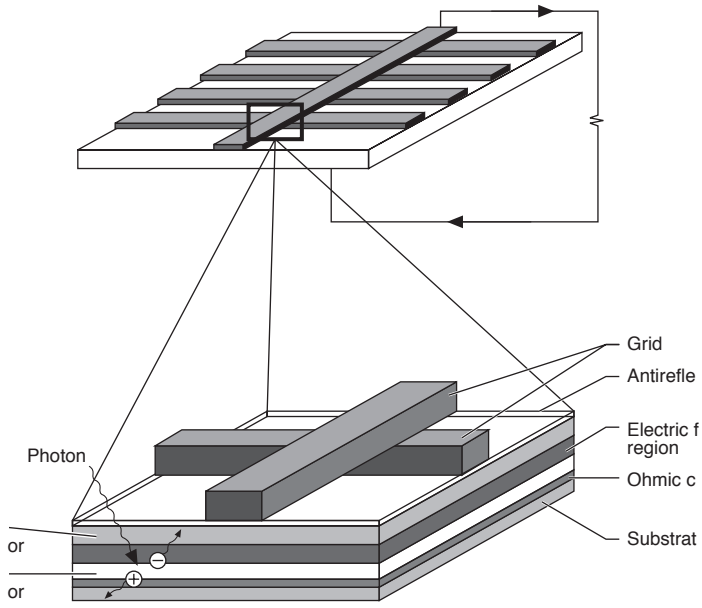

FIGURE 8.13.2 Schematic diagram of a typical p-n junction photovoltaic cell.

and energy greater than E_g is lost as heat. Photons with energies less than E_g (sub-band-gap photons) are transmitted through the cell. After generation, minority photocarriers, that is, holes on the n-side and electrons on the p-side, diffuse toward the edges of the junction due to a gradient of carriers that exists there. If the minority carriers are generated within a diffusion length, L, of the junction, they will reach it and be swept across it by the electric field of the junction. Hence, electrons are swept from the p-side to the n-side and holes from the n-side to the p-side, and thus they are separated. The minority carrier gradient present at the edges of the junction is due to the depletion of minority carriers that results from their transfer across the junction. The diffusion flux of minority carriers toward and across the junction constitutes a light-generated current, I_L, or photocurrent, that is directed from the n-side to the p-side of the cell. The build-up of positive holes on the p-side and negative electrons on the n-side gives rise to a **photovoltage** across the junction. The polarity of both the photovoltage and photocurrent is identical to that of a battery, and power is delivered from the junction to the external circuit.

Cell Efficiency. In order to derive the solar conversion efficiency, it is convenient to model the photovoltaic cell as an ideal p-n diode in parallel with a **light-generated** (constant) **current** source, I_L, as shown in the equivalent circuit of Figure 8.13.3. Parasitic series and shunt resistance losses, R_s and R_{sh}, respectively, are also shown, where R_s is due to ohmic contact and semiconductor resistances, and R_{sh} is due to defect-related carrier recombination and/or tunneling phenomena (Stirn, 1972). A qualitative expression for I_L is given by Tada et al. (1982):

$$I_L = qAG\left(L_n + W_d + L_p\right) \tag{8.13.3}$$

where G is the photocarrier generation rate in carriers/cm^3-sec due to solar photon absorption, which depends on E_g and the photon energy (wavelength) and intensity (concentration), and W_d is the sum of the negative and positive SCR widths. As mentioned, I_L is directed from the n-side to the p-side. In

© 1999 by CRC Press LLC

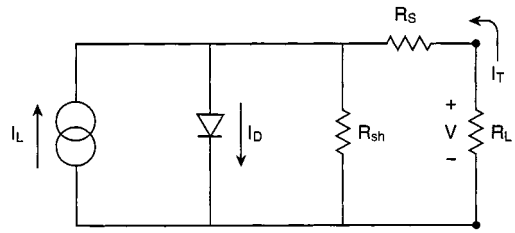

FIGURE 8.13.3 Schematic of equivalent circuit model for a p-n photovoltaic cell.

contrast, the dark diode current given by Equation (8.13.1) is directed oppositely from the p-side to the n-side. The **dark current** is due to the forward-bias photovoltage that appears across the cell p-n junction when it is illuminated. Thus, the dark current opposes the light current. In the ideal case, that is, when $R_s = 0$ and $R_{sh} = \infty$, the total forward current, I_T, is given by

$$I_T = I_D - I_L = I_o\left[\exp(qV/nkT) - 1\right] - I_L \tag{8.13.4}$$

A plot of dark and light current-voltage (I-V) curves resulting from Equations (8.13.1) and (8.13.4), respectively, is shown in Figure 8.13.4 for a typical p-n solar cell. Under illumination, the forward-bias dark I-V curve is displaced downward into the fourth quadrant by the **photocurrent**, $\boldsymbol{I_L}$. It is noted from Figure 8.13.3 that the voltage drop across the load resistance, R_L, is $V = -I_T R_L$. Under short-circuit conditions, that is, when the n and p terminals are tied to each other, R_L is negligible. The resulting voltage drop across the p-n junction will also be negligible, and from Equation (8.13.1), $I_D \approx 0$. As shown in Figure 8.13.4, the resultant current is termed the **short-circuit current**, $\boldsymbol{I_{sc}}$, or $I_T = -I_{sc} = -I_L$. As the value of R_L increases, a voltage appears across the junction, $V = -I_T R_L$, called the **photovoltage**, and I_D increases in accordance with Equation 8.13.1. Under this condition the cell is operating in the fourth quadrant of the I-V characteristic (i.e., the junction voltage is positive and the current is negative), and, consequently, the cell delivers power (product of the current and voltage) to R_L. As the value of R_L continues to increase, so too does V and I_D. When the value of R_L approaches infinity, that is, under open-circuit conditions, I_D approaches I_L and I_T goes to zero. The resulting **open-circuit voltage**, $\boldsymbol{V_{oc}}$, is shown in Figure 8.13.4. V_{oc} can be obtained by setting $I_T = 0$ in Equation (8.13.4) and solving for V. For $V \gg$ kT/q,

$$V_{oc} = nkT/q \ln\left[I_L/I_o\right] \tag{8.13.5}$$

Thus, the operating point on the I-V curve in the fourth quadrant can be swept from (I_{sc}, 0) to (0, V_{oc}) by varying the value of R_L. When the optimum load is chosen (i.e., $R_L \approx V_{oc}/I_{sc}$), approximately 80% of the product $I_{sc}V_{oc}$ can be extracted as useful power as shown by the shaded maximum-power rectangle in Figure 8.13.4. Also shown in Figure 8.13.4 are the parameters I_m and V_m, which correspond to values of current and voltage, respectively, that yield the maximum cell power, P_m, where $P_m = I_m V_m$. The knee that appears at P_m is due to the parasitic effects of R_s and R_{sh}. The curvature of the knee at P_m is described by the **fill factor**, **FF**, where

$$\text{FF} = I_m V_m / I_{sc} V_{oc} \tag{8.13.6}$$

The photovoltaic cell **conversion efficiency**, η, is defined as

$$\eta = I_m V_m / P_{in} A$$

or

© 1999 by CRC Press LLC

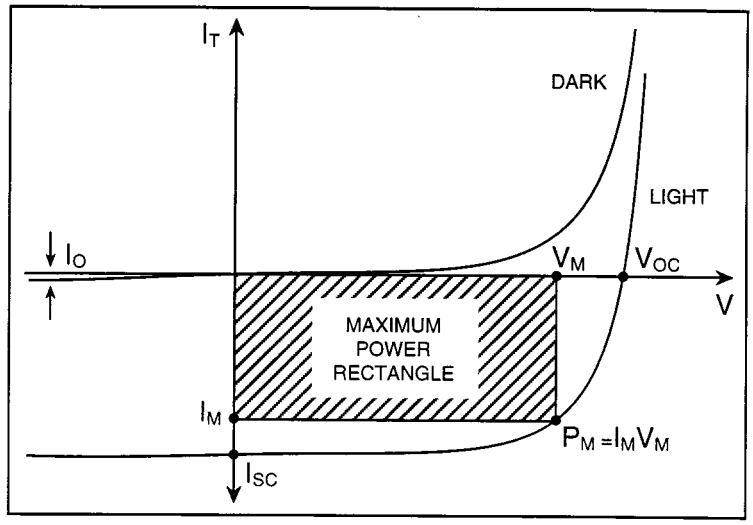

FIGURE 8.13.4 Typical dark and light current-voltage characteristics for a p-n photovoltaic cell.

$$\eta = FF\, I_{sc} V_{oc} / P_{\text{in}} \tag{8.13.7}$$

where P_{in} is the incident power in W/m^2 equal to the sum in energy of the incident photons per time per area. Values for V_{oc}, I_{sc}, FF, and η can be obtained in the laboratory under various air mass conditions from light *I-V* curves measured using a carefully controlled (calibrated) light source to illuminate the cell.

Cell Material vs. Efficiency

The optimum value of material E_g for solar photovoltaic conversion is ~1.0 to 1.5 eV. To understand how the choice of cell material affects conversion efficiency, an ideal expression can be derived using Equation 8.13.4 for the theoretical conversion efficiency. The output power can be expressed as (Henry, 1980)

$$P = IV = I_o V\left[\exp\left(qV/nkT\right) - 1\right] - I_L V \tag{8.13.8}$$

The maximum output power is obtained when $dP/dV = 0$, and an expression for I_m and V_m can be obtained from Equation (8.13.8) and multiplied to give P_m, where

$$P_m = I_m V_m \approx I_L\left[V_{oc} - kT/q \ln\left(qV_m/kT + 1\right) - kT/q\right] \tag{8.13.9}$$

In practical cells, values for V_m and V_{oc} are typically $^1/_2E_g/q$ to $^2/_3E_g/q$. Thus, for materials with $E_g \sim 1 - 2$ eV, the quantity in the large brackets of Equation (8.13.9) becomes ~V_{oc}, and the factors that determine I_L and V_{oc} also determine P_m. From Equations (8.13.2) and (8.13.5), it is clear that V_{oc} increases with E_g through the reduction in I_o. In contrast, as E_g increases, I_L decreases because a smaller portion of the solar spectrum is energetic enough to be absorbed; i.e., I_L is the product of q and the number of available photons with energy greater than E_g. Hence, for a given solar spectrum there is an optimum value of E_g that maximizes the product of V_{oc} and I_L. A plot of ideal AM1 conversion efficiency vs. E_g is shown in Figure 8.13.5 for "one sun" (925 W/m^2) and "1000 suns" (925 kW/m^2) concentrations (Henry, 1980). The efficiency curves were obtained using Equations (8.13.1) through (8.13.7) at 300 K. A maximum in efficiency occurs for $E_g \sim 1.0 - 1.5$ eV.

Manufacture of Cells and Panels

There are basically five important solar cell design concepts, and each offers a trade-off between efficiency and cost: (1) Large-area single-crystal planar cells, typically 1 × 1 cm² to 6 × 6 cm², yield high efficiencies under normal light conditions, 2) single-crystal small-area concentrator cells, typically less than 1 × 1 cm², are potentially less costly and yield higher efficiencies under concentrated light, i.e., concentration ratios of 20 to 1000 are typical; (3) more-complex single-crystal multijunction cells yield the highest efficiencies measured to date, but are substantially more expensive; (4) cells made from polycrystalline materials are less expensive than single-crystalline cells, but are less efficient; and (5) cells made from thin film amorphous materials provide the lowest-cost approach yet, but are generally less efficient than polycrystalline cells.

A typical 15% 4 × 4 cm² photovoltaic cell produces only ~0.25 W under AM1.5 conditions. Therefore, individual cells must be electrically wired together to form larger submodules or panels to increase the total output power. The cells can be connected in series to increase the total voltage or in parallel to increase the current. The modular nature of photovoltaic power allows the design of systems that can deliver electrical power from a few watts to many megawatts. In terrestrial applications the cells are typically supported and held in place with a rigid substrate, i.e., typically aluminum, Plexiglas, fiberglass, or glass, and are encapsulated with glass or a polymeric material; in space applications the support structure may be rigid or flexible, and the cells are protected from the space environment with quartz cover slides. The electrical power generated by the cells is conducted to an electrical load or storage battery. Metal interconnects soldered to the ohmic contacts of the cells conduct electrical current from one cell to the next. Current is then conducted from the network of series- and parallel-connected cells by wires to a distribution terminal "bus" that transfers the power to either the load or battery.

Single-Crystal Cells. The p-n photovoltaic cells made from **single-crystal** Si dominate in space and terrestrial applications because of their high efficiency and reliability. The formation of single-crystal p-

© 1999 by CRC Press LLC

type Si results from the selective cooling of pure molten Si to form large cylindrical crystal ingots, called boules, from which thin wafers are sliced and polished. The p-type impurities, usually boron, are added to the melt, to give the desired impurity concentration. A large-area p-n junction is then formed by diffusion of n-type impurity atoms, usually phosphorus. Front and back metal ohmic contacts and an antireflection coating are then formed using standard photolithography thermal evaporation or sputtering techniques (Sze, 1985). The resulting cell structure is shown in Figure 8.13.2, and typical cell areas range from 1 to 36 cm^2. Different semiconductors absorb sunlight more efficiently than others, described by a factor called the absorption coefficient. Si has a relatively small absorption coefficient compared with other materials, such as InP, GaAs, and amorphous-Si, and consequently requires an absorption layer thickness of ~100 μm to maximize conversion efficiency. Conventional Si cells have a thickness on the order of 250 μm, but can be chemically or mechanically polished to a thickness of 100 μm.

Single-crystal III-V photovoltaic cells, such as InP and GaAs, are made from elements in the III and V columns of the periodic table. The band gaps of these cells, 1.35 and 1.42 eV, respectively, are close to the optimum value. These materials involve the growth of single-crystal semiconductor layers upon a single-crystal semiconductor substrate. This technique is called epitaxy and it provides a method to produce both n-type and p-type layers to form the p-n junction. Epitaxial growth of n and p layers is required for InP and GaAs because diffusion of impurities at high temperatures is confounded by the high vapor pressure of the material. The formation of ohmic contacts and antireflection coating employ the same techniques as used for Si cells. The required absorption layer thickness for these cells is only a few microns because of their large absorption coefficients. However, issues concerning yield and mechanical strength limit their minimum thickness to ~100 μm The best reported efficiencies for single-crystal Si, GaAs, and InP cells under AM1.5 conditions are 24, 25, and 22%, respectively (Green et al., 1995).

Polycrystalline Cells. In the case of **polycrystalline** Si cells, molten Si is directly deposited into either cylindrical or rectangular ingots. As the material solidifies, individual crystalline regions form that are separated by grain boundaries which contain large numbers of structural defects. When the cell is illuminated, these defects capture a portion of the light-generated electron-hole pairs through recombination processes before they can reach the junction and be collected. Thus, the grain boundaries diminish the light-generated current and overall efficiency of the cell. However, polycrystalline silicon cells are sufficiently inexpensive to be commercially viable (Stone, 1993). An area that requires improvement is the slicing of polycrystalline ingots, where yields as low as 50% are common. An approach that eliminates the expense of sawing and polishing altogether is the growth of polycrystalline Si directly into the form of thin ribbons using a technique called edge-defined film-fed growth (EFG) (Fahrenbruch and Bube, 1983). In this approach, a carbon die with a slot-shaped aperture is immersed in a crucible of molten Si. The liquid Si wets the die and flows through the slot where it cools and is pulled to form a thin ribbon. This material also has high crystalline defect densities, but has good overall yields. An additional approach involves the growth of films of nearly single-crystal quality, where two parallel supporting dendrites form the boundaries of a web or ribbon pulled from a supercooled melt of Si. The best efficiency for polycrystalline Si cells under AM1.5 conditions is ~18%; that for Si cells grown by the EFG technique is 14%; and that for Si dendritic web cells is 15.5% (Stone, 1993). It is important to note that although these lower-cost films yield lower cell efficiencies compared with single-crystal cells, the cost of cells depends on the cost of the starting material and the cost per watt is more important than efficiency (Zweibel, 1995).

Thin Film Cells. Thin films cells provide an even lower-cost (and lower-efficiency) approach because they require a very small amount of semiconductor. An excellent review on thin film photovoltaic technologies, particularity on present and future cost issues, is given by Zweibel (1995). The general approach involves depositing only a few microns of material on a low-cost substrate using various vacuum deposition techniques, although a multitude of other deposition techniques have also been demonstrated. The top thin film cell candidates are amorphous Si, a-Si, cadmium telluride, CdTe, and copper indium diselenide, CIS (and related alloys). The highest reported thin film AM1.5 efficiencies

© 1999 by CRC Press LLC

are 17% for CIS, followed by 15.8% for CdTe, and ~11% for a-Si (Zweibel, 1995). However, the relative level of maturity of each design for commercial application must be put into perspective. While the best CIS cell efficiency is quite high, the best CIS square foot panel efficiency reported back in 1988 was, and still is today, only 11%. Significant manufacturing problems have plagued the CIS cell, and currently it is still not commercially available. CdTe is believed to be the easiest of the thin film cells to fabricate, and probably represents the closest to large-scale commercialization. Two U.S. companies have publicly announced CdTe manufacturing plants, and commercial efficiencies are likely to be in the range of 6 to 8% in the first plants. The future of a-Si cells is currently believed to be limited if it cannot overcome a 10% efficiency at the module level. Development problems include electrochemical instability to light that results in a 20 to 40% degradation. However, it appears that the use of multijunction thin film a-Si layers may solve the problem, and modules of 7 to 9% are expected in the near term.

Concentrator Cells. Photovoltaic modules are typically either of the flat plate or concentrator configuration. Flat plate modules can be fixed with respect to the sun or mounted to track the sun in one or two axis. Concentrator modules use large-area mirrors or lenses to concentrate sunlight onto smaller-area cells. Concentrator cells operate at higher efficiencies. However, concentrator modules require one- or two-axis tracking which adds system complexity and cost that generally offsets the module efficiency and lower area cost benefits. The increase in conversion efficiency with illumination intensity is shown in the 1000-sun concentration curve of Figure 8.13.5. Values for I_L increase linearly with concentration through the factor G in Equation (8.13.3) and V_{oc} increases logarithmically with concentration through I_L in Equation (8.13.5). Under solar concentration of "20 suns" or greater, a significant amount of cell heating can occur. While J_{sc} increases slightly with increasing temperature, values of V_{oc} and FF drop strongly. Thus, on adequate heat sink or active cooling is required at high concentrations. The reported AM1.5 efficiency for Si cells increases from 24 to 26.5% under a concentration of 255; and that for GaAs cells increases from 25 to 27.6% under a concentration of 140 (Green et al., 1995).

Multijunction Cells. Another approach to increase photovoltaic cell efficiency is through the use of multijunction tandem cells. The simplest multijunction cell is a two-junction, two-terminal device. In this design, a high-band-gap (E_{g1}) p-n junction is vertically stacked (mechanically) or epitaxially grown atop a bottom lower-band-gap (E_{g2}) p-n junction as shown in Figure 8.13.6. The top junction absorbs photons with energy $\geq E_{g1}$, and the bottom junction absorbs photons with energy E, where $E_{g1} > E \geq E_{g2}$, that passed through the top cell. This increases the utilization of the solar spectrum, since the excess energy of the high-energy photons is not wasted. The values of E_{g1} and E_{g2} must be chosen to achieve maximum solar absorption and current matching; i.e., the two cells must generate equal currents when illuminated. The band gap combinations of ~0.7 and 1.4, 1.0 and 1.4, 1.1 and 1.4, and 1.4 and 1.9 eV are current matched, where E_g for GaSb, $CuInSe_2$, Si, GaAs, AlGaAs, and $GaInP_2$ are ~0.7, 1.0, 1.1, 1.4, and 1.9 eV, respectively. Multijunction concentrator cells have reported efficiencies in excess of 30% (Green, 1995).

Design of a Photovoltaic Generating System

A schematic diagram depicting the basic components of a typical photovoltaic power generation system is shown in Figure 8.13.7 (Pulfrey, 1978). The system includes a photovoltaic array that consists of many smaller submodules, each containing many hundreds or thousands of photovoltaic cells. The DC output power from the array is controlled by a power conditioning unit that contains an inverter for developing AC power and an input power tracking device to maintain the optimal array load to achieve maximum output power. Power is directly fed to the electrical load and/or storage system by the conditioning unit. The storage system is needed to save energy when power is generated in excess of the immediate demand, or when the load demand exceeds the immediate generation level. Total photovoltaic power system efficiency is the product of the efficiencies of the individual components. Typical efficiencies for the power conditioning unit (determined by the inverter) and energy storage system are about 95% and 50-80%, respectively. Thus, an array efficiency of 10% would result in a total system

© 1999 by CRC Press LLC

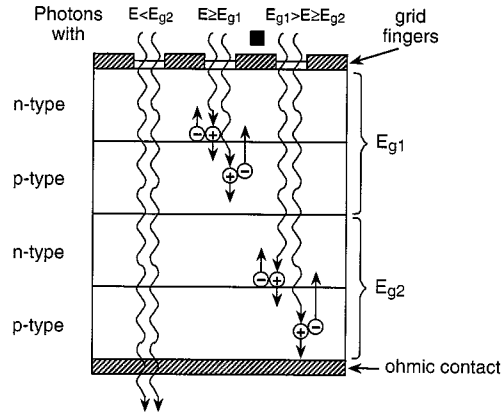

FIGURE 8.13.6 Schematic diagram of a multijunction (two-junction) photovoltaic cell under illumination.

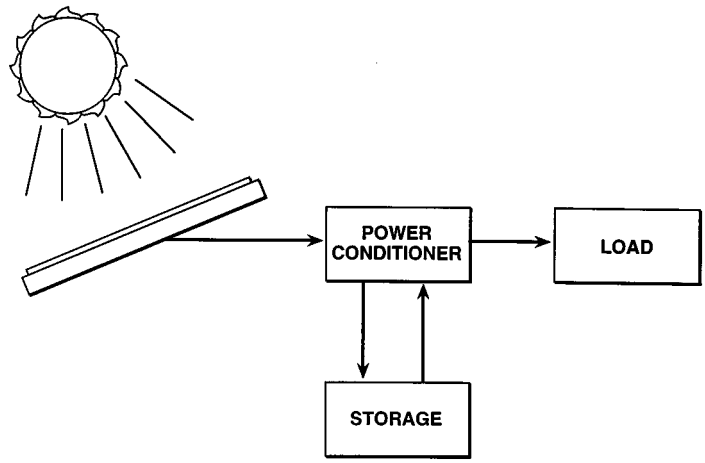

FIGURE 8.13.7 Schematic diagram depicting the basic components of a typical photovoltaic power system.

efficiency of about 5 to 8%, and a total system efficiency of 10% would require an array efficiency in excess of 13%.

Defining Terms

Band gap (E_g): The difference in energy between the energy level of the bottom of the conduction band and the energy level of the top of the valence band.

Conduction band: A range of allowable energy states in a solid in which electrons can move freely.

Conversion efficiency (η): The ratio of the available power output photovoltaic cell to the total incident radiant power.

Dark current: Any current that flows through the p-n junction in the absence of external irradiation.

Fill factor (ff): The ratio of the maximum photovoltaic cell output power to the product of the open-circuit voltage and short-circuit current.

Light-generated current (I_L): The electrical current obtained from an illuminated p-n junction resulting from the collection of photocarriers across the junction.

Open-circuit voltage (V_{oc}): The voltage obtained across the terminals of an illuminated p-n photovoltaic cell under open-circuit conditions.

© 1999 by CRC Press LLC

Photocarriers: Electrons and holes generated within a semiconductor via the absorption of photon energy.

Photocurrent: Synonymous with light-generated current.

Photovoltaic effect: The production of a voltage difference across a p-n junction resulting from the absorption of photon energy.

Photovoltage: The voltage resulting from the photovoltaic effect.

Polycrystalline: A material characterized by an array or agglomerate of small single-crystal sections of various crystal orientations separated from one another by grain boundaries, which are localized regions of very severe lattice disruptions and dislocations.

Short-circuit current (I_{sc}): The electrical current measured through the terminals of an illuminated p-n photovoltaic cell under short-circuit conditions.

Single crystal: A material characterized by a perfect periodicity of atomic structure; the basic arrangement of atoms is repeated throughout the entire solid.

Valence band: A range of allowable energy states in a solid crystal in which lie the energies of the valence electrons that bind the crystal together.

The monthly journal *Progress in Photovoltaics* documents recent results of research work conducted in photovoltaics worldwide. This journal is an excellent source for currently reported cell conversion efficiencies.

Proceedings of the conference *Space Photovoltaics Research and Technology* is an excellent source for the reader interested in the development of photovoltaics for use in space.

Fuel Cells

D. Yogi Goswami

Introduction

A *fuel cell* is an electrochemical device in which a fuel and an oxidant react in such a controlled manner that the chemical energy of reaction is converted directly into electrical energy. Ordinarily, a fuel reacts violently with an oxidant in a combustion reaction resulting in the release of heat of combustion. The heat of combustion can, then, be converted into electrical energy via mechanical work with the constraint of the second law of thermodynamics. The overall efficiency of the series of conversion processes is of the order of 40%. A fuel cell bypasses these processes resulting in potential efficiencies of the order of 80%. As an example, when hydrogen is burned in an atmosphere of oxygen it results in the following reaction:

$$H_2 + \frac{1}{2}O_2 \rightarrow H_2O + \Delta H \quad (\text{heat of reaction}) \tag{8.13.10}$$

In this reaction, two hydrogen atoms bond with an oxygen atom by sharing their electrons with the outermost orbit of oxygen, which becomes full, resulting in a stable structure.

The reactants H_2 and O_2 may be combined to form the same product (H_2O) by first stripping the electrons away from the hydrogen atoms and allowing the electrons to pass through an external circuit before combining with oxygen. Table 8.13.1 gives typical electrochemical reactions in fuel cells.

$$H_2 \rightarrow 2H^+ + 2e^- \quad (\text{electrons}) \tag{8.13.11}$$

$$2H^+ + O + 2e^- \rightarrow H_2O \tag{8.13.12}$$

Figure 8.13.8 shows a schematic of an arrangement that would allow the above reaction to proceed.

TABLE 8.13.1 Electrochemical Reactions in Fuel Cells

Fuel Cell	Anode Reaction	Cathode Reaction	Overall Reaction
Proton exchange	$H_2 \rightarrow 2H^+ + 2e^-$	$^1/_2O_2 + 2H^+ + 2e^- \rightarrow H_2O$	$H_2 + {}^1/_2O_2 \rightarrow H_2O$
Alkaline	$H_2 + 2(OH)^- \rightarrow 2H_2O + 2e^-$	$^1/_2O_2 + H_2O + 2e^- \rightarrow 2(OH)^-$	$H_2 + {}^1/_2O_2 \rightarrow H_2O$
Phosphoric acid	$H_2 \rightarrow 2H^+ + 2e^-$	$^1/_2O_2 + 2H^+ + 2e^- \rightarrow H_2O$	$H_2 + {}^1/_2O_2 \rightarrow H_2O$
Molten carbonate	$H_2 + CO_3^- \rightarrow H_2O + CO_2 + 2e^-$ $CO + CO_3^- \rightarrow 2CO_2 + 2e^-$	$^1/_2O_2 + CO_2 + 2e^- \rightarrow CO_3^-$	$H_2 + {}^1/_2O_2 + CO_2$ (cathode) $\rightarrow H_2O + CO_2$ (anode)
Solid oxide	$H_2 + O^- \rightarrow H_2O + 2e^-$ $CO + O^- \rightarrow CO_2 + 2e^-$ $CH_4 + 4O^- \rightarrow 2H_2O + CO_2 + 8e^-$	$^1/_2O_2 + 2e^- \rightarrow O^-$	$H_2 + {}^1/_2O_2 \rightarrow H_2O$ $CO + {}^1/_2O_2 \rightarrow CO_2$ $CH_4 + 2O_2 \rightarrow H_2O + CO_2$

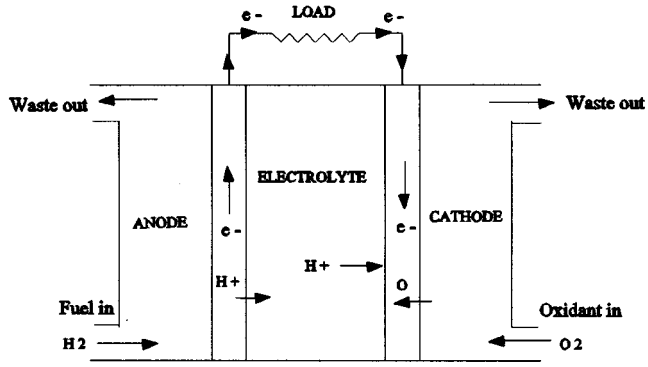

FIGURE 8.13.8 Conceptual schematic of a hydrogen fuel cell.

1. Electrodes must be porous to let the fuel and electrolyte penetrate.
2. The electrolyte must be permeable to H^+ and $(OH)^-$ ions.
3. Electrode materials must be catalysts for the reaction (Pt, Ni, etc.).

In 1839, William Grove, an English investigator, constructed a chemical battery in which he noticed that the water-forming reaction of hydrogen and oxygen generated an electrical current. However, it was not until 50 years later that two English chemists, Ludwig Mond and Carl Langer, developed a device they actually called a fuel cell (Angrist, 1982). There has been a strong resurgence in research and development of fuel cells in the last four decades.

Thermodynamic Performance

The energy released or needed in any chemical reaction (ΔH) is equal to the difference between the enthalpy of formation of the products and the reactants.

$$\Delta H = \sum (\Delta H)_{\text{products}} - \sum (\Delta H)_{\text{reactants}} \tag{8.13.13}$$

In an exothermic reaction the change in enthalpy of formation (ΔH) is negative. Table 8.13.2 gives values of ΔH for various compounds at 25°C at 1 atm. All naturally occurring elements have a ΔH value of zero.

TABLE 8.13.2 Enthalty of Formation ΔH^0 and Gibbs Free Energy ΔG^0 of Compounds at 1 atm and 298 K

Compound or Ion	Enthalpy of Formation, ΔH^0, J/kg · mol	Gibbs Free Energy ΔG^0, J/kg · mol
CO	-110.0×10^6	-137.5×10^6
CO_2	-394.0×10^6	-395.0×10^6
CH_4	-74.9×10^6	-50.8×10^6
Water	-286.0×10^6	-237.0×10^6
Steam	-241.0×10^6	-228.0×10^6
C, H_2, O_2	0	0
O(g)	$+249.2 \times 10^6$	$+231.8 \times 10^6$
H(g)	$+218.0 \times 10^6$	$+203.3 \times 10^6$

Source: Adapted from Wark, K., *Thermodynamics*, McGraw–Hill, New York, 1988. With permission.

In a combustion reaction all of the change in the enthalpy of formation (ΔH) is converted to heat and is, therefore, called the higher heating value (HHV).

© 1999 by CRC Press LLC

$$-(\Delta H)_{\text{reaction}} = \text{HHV of fuel} \tag{8.13.14}$$

For example, for complete combustion of hydrogen according to the following reaction:

$$H_2 + \frac{1}{2}O_2 \rightarrow H_2O \quad (\text{liquid}) \tag{8.13.15}$$

Change in the enthalpy of formation is

$$\Delta H = \Delta H_{H_2O} - \Delta H_{H_2} - \frac{1}{2}\left(\Delta H_{O_2}\right) = \left(-286 \times 10^6\right) - 0 - 0 = -286 \times 10^6 \ \text{J/kg} \cdot \text{mol } H_2 \tag{8.13.16}$$

In a fuel cell, most of ΔH can be converted to electricity directly. The part that cannot be converted to work directly gets converted into heat. The minimum amount that must be converted to heat is represented by reversible heat transfer $\int T\,dS$. If a fuel cell operates isothermally, the maximum amount of electrical work (W_e) produced is given by

$$W_e, \max = \Delta H - T\Delta S \tag{8.13.17}$$

In an irreversible reaction

$$W_e, \max < \Delta H - T\Delta S \tag{8.13.18}$$

Gibbs free energy, G, is given by:

$$G = H - TS \tag{8.13.19}$$

Therefore, in a reversible isothermal process

$$\Delta G = \Delta H - T\Delta S = W_e, \max \tag{8.13.20}$$

The actual electrical work in a fuel cell is given by

$$W_e \leq \Delta G \quad (\text{change in Gibbs free energy for the reaction}) \tag{8.13.21}$$

$$\Delta G_{\text{reaction}} = \sum (\Delta G)_{\text{products}} - \sum (\Delta G)_{\text{reactants}} \tag{8.13.22}$$

The electrical work, W_e, is associated with the work of electrons passing through an external resistance. 1 g · mol of electrons is equal to Avogadro's number (6.022×10^{23}) and the charge of these electrons is equal to 96,439 C which is called a **faraday** (F). If n g · mols of electrons are generated and E is the internal reversible cell voltage, then the maximum electrical work is given by

$$W_e, \max = \Delta G = -nFE \tag{8.13.23}$$

denoting values under standard conditions (25°C, 1 atm) by superscript 0, we have

$$\Delta G^0 = -nFE^0 \tag{8.13.24}$$

© 1999 by CRC Press LLC

Values of G^0 for various compounds are given in Table 8.13.2. For fuel cell reactions as below:

$$aA + bB \rightarrow cC + dD \tag{8.13.25}$$

if the reactants (A and B) and the products (C and D) are assumed to be ideal gases with partial pressures P_A, P_B, P_C, and P_D the change in Gibbs free energy ΔG and the internal reversible cell voltage, E, are given by

$$\Delta G = \Delta G^0 + RT \ln \frac{(P_C)^c (P_D)^d}{(P_A)^a (P_B)^b} \tag{8.13.26}$$

$$E = E^0 + RT \ln \frac{(P_A)^a (P_B)^b}{(P_C)^c (P_D)^d} \tag{8.13.27}$$

Equation 8.13.27 is also called the Nernst equation.

Table 8.13.3 gives Nernst equations for the electrochemical reactions listed in Table 8.13.1.

TABLE 8.13.3 Fuel Cell Reactions and the Corresponding Nernst Equations

Cell Reactions	Nernst Equation
$H_2 + {}^1/_2O_2 \rightarrow H_2O$	$E = E^0 + (RT/2F)\ln[P_{H_2}(P_{O_2})^{1/2}/P_{H_2O}]$
$H_2 + {}^1/_2O_2 + CO_2(c) \rightarrow H_2O + CO_2(a)$	$E = E^0 + (RT/2F)\ln[P_{H_2}(P_{O_2})^{1/2}(P_{CO_2})_c/(P_{H_2O}(P_{CO_2})_a]$
$CO + {}^1/_2O_2 \rightarrow CO_2$	$E = E^0 + (RT/2F)\ln[P_{CO}(P_{O_2})^{1/2}/P_{CO_2}]$
$CH_4 + 2O_2 \rightarrow H_2O + CO_2$	$E = E^0 + (RT/8F)\ln[P_{CH_4}(P_{O_2})^2/P^2_{H_2O}P_{CO_2}]$

Note: (a) = anode; (c) = cathode; E = equilibrium potential.

Source: Hirschenhofer, J.H. et al., *Fuel Cells, A Handbook,* Gilbert/Commonwealth, Morgantown, WV, 1994. With permission.

The maximum conversion efficiency of a fuel cell is given by

$$\eta_{max} = \frac{W_e,\max}{\Delta H} = \frac{\Delta G}{\Delta H} = 1 - \frac{T\Delta S}{\Delta H} = \frac{-nFE}{\Delta H} \tag{8.13.28}$$

As current is drawn through an external circuit, the actual voltage drop (V) will be less than the internal cell voltage (E). Therefore, the actual conversion efficiency of a fuel cell will be lower than above and may be calculated as

$$\eta_{actual} = \frac{-nFV}{\Delta H} = \frac{ItV}{\Delta H} \tag{8.13.29}$$

where I is the current drawn through an external circuit for a period of time, t.

Types of Fuel Cells

Fuel cells are primarily classified by type of electrolyte, since many other characteristics, particularly operating temperatures, are limited by the electrolyte properties (Hirschenhofer et al., 1994). Major fuel cells under active development at this time are the **phosphoric acid fuel cell (PAFC)**, the **molten carbonate fuel cell** (**MCFC**), the **solid oxide fuel cell** (**SOFC**), the **polymer electrolyte fuel cell** (**PEFC**), and the **alkaline fuel cell** (**AFC**).

© 1999 by CRC Press LLC

Phosphoric Acid Fuel Cell. PAFC uses concentrated phosphoric acid (H_3PO_4) as the electrolyte, hydrogen as the fuel, and oxygen (from air) as the oxidant. Table 8.13.4 provides information on the electrodes and other materials for PAFC as well as other fuel cells.

The reactions take place at the porous electrodes on highly dispersed electrocatalyst Pt particles supported on carbon black and a polymeric binder, usually polytetrafluoroethylene (PTFE) (about 30 to 50% by weight) (Kinoshita et al., 1988; Hirschenhofer et al., 1994). A porous carbon paper substrate provides structural support for the electrocatalyst and serves as the current collector. A typical carbon paper electrode impregnated with the electrocatalyst has a porosity of about 60%, consisting of micropores of about 34 Å diameter and macropores of 3 to 50 μm diameter.

Dipolar plates (usually graphite) are used to separate the individual cells and electrically connect them in series in a fuel cell stack. In PAFC stacks, provisions are included to remove the waste heat, by liquids (usually water) or gases (usually air) which flow through channels provided in the cell stack.

Molten Carbonate Fuel Cells. MCFCs use as electrolytes mixtures of molten carbonates of lithium (Li_2CO_3), potassium (K_2CO_3), and sodium (Na_2CO_3) in proportions as shown in Table 8.13.4. The operating temperature of the cell (~650°C) is higher than the melting temperature of the carbonate electrolytes. Besides H_2 (fuel) and O_2 (oxidant from air) the cell uses CO_2 which transfers from the cathode to the anode according to the reactions in Table 8.13.1.

According to the reactions, 1 g · mol of CO_2 is transferred along with 2 g · mol of electrons ($2F$). The reversible potential for an MCFC, taking into account the transfer of CO_2, is given by the Nernst equation in Table 8.13.3.

It is usual practice to recycle the CO_2 generated at the anode to the cathode where it is consumed. An early process used to fabricate electrolyte structures involved hot processing mixtures of $LiAlO_2$ and alkali carbonates at temperatures slightly below the melting point of carbonates. These electrolyte structures had problems of void spaces, nonuniformity of microstructure, poor mechanical strength, and high iR drop. To overcome these problems, processes have been developed recently that include tape casting (Man et al., 1984; Hirschenhofer et al., 1994) and electrophoretic deposition (Baumgartner et al., 1985; Hirschenhofer et al., 1994).

Increasing the operating pressures results in enhanced cell voltages. Increasing the operating temperature above 550°C also enhances the cell performance. However, beyond 650°C the gains are diminished and the electrolyte loss and material corrosion are increased. Therefore, 650°C is about the optimum operating temperature.

Solid Oxide Fuel Cell. SOFCs offer a number of advantages over MCFCs for high-temperature operation, since there is no liquid electrolyte. Solid electrolyte allows flexibility in cell shape design based on application. Cells of several shapes, as shown in Figure 8.13.9, are being developed. Because of the high temperature of operation (~1000°C) carbon monoxide (CO) and hydrocarbons such as methane (CH_4) can be used as fuels. At 1000°C, these fuels can easily produce H_2 that is used at the anode by steam reforming and water-gas reactions as

$$CO + H_2O \rightarrow CO_2 + H_2 \quad (\text{water-gas}) \tag{8.13.30}$$

$$CH_4 + H_2O \rightarrow CO + 3H_2 \quad (\text{steam reforming}) \tag{8.13.31}$$

Because of very high operating temperatures the choice of cell materials is limited by (1) chemical stability in oxidizing and reducing atmosphere; (2) chemical stability of contacting materials; and (3) conductivity and thermomechanical compatibility. A detailed description of the current status is given by Minh (1991; 1993) and Appleby and Foulkes (1989). Present SOFC designs make use of thin film wall concepts where films of electrodes, electrolyte, and interconnect material are deposited on each other and sintered to form cell structure. Electrochemical vapor deposition (EVD) is now used to deposit thin layers.

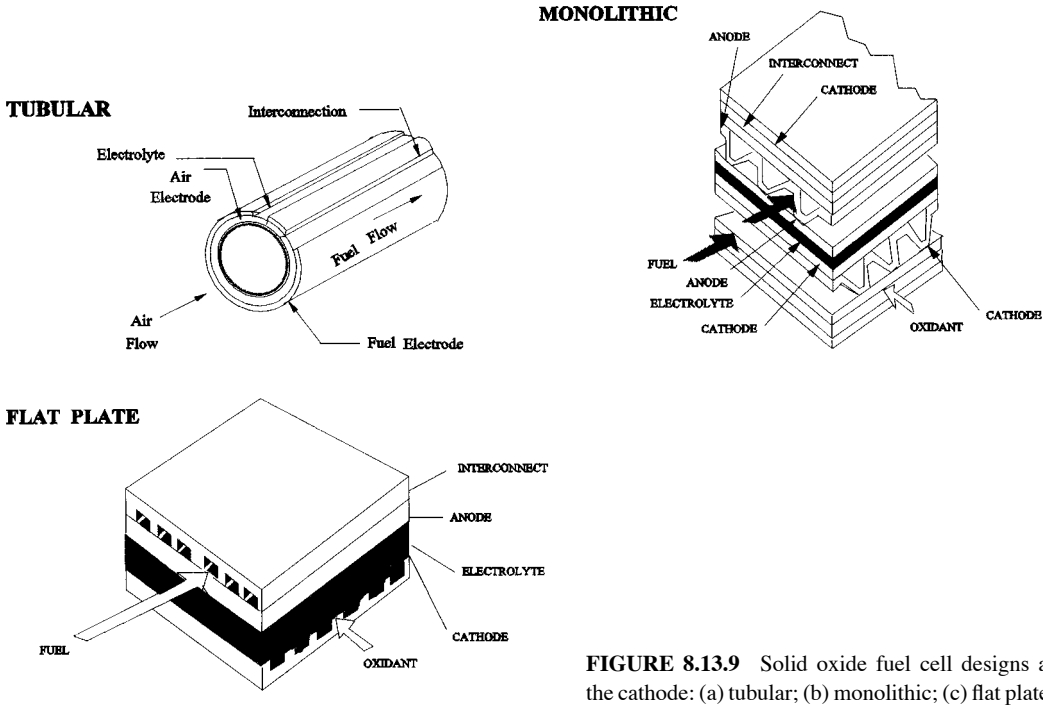

FIGURE 8.13.9 Solid oxide fuel cell designs at the cathode: (a) tubular; (b) monolithic; (c) flat plate.

Increasing pressure and temperature enhances the performance of SOFC.

Polymer Electrolyte Fuel Cell. The basic cell consists of a proton-conducting membrane such as perfluoro sulfonic acid polymer sandwiched between two Pt-impregnated porous electrodes. The backs of the electrodes are made hydrophobic by coating with Teflon®, which provides a path for gas to diffuse to the catalyst layer.

The electrochemical reactions for PEFC are similar to PAFC as given in Table 8.13.1.

The protons from the anode diffuse through the membrane with the help of water molecules soaked in the membrane. The cell operates at low temperature (80°C) and can have very high current densities. Therefore, the cell can be made very compact and can have fast start. There are no corrosive fluids (acids or alkalis) in the cell. Because of these attributes the cell is particularly suited for vehicle-power operation. Present research includes investigation of using methanol and natural gas as the fuel for the cell.

Alkaline Fuel Cell. Alkaline electrolytes have faster kinetics, which allows the use of non-noble metal electrocatalysts. However, AFCs suffer a drastic performance loss if CO_2 is present in the fuel or the oxidant, for example, air. Therefore, AFCs are restricted for use where pure H_2 and O_2 can be used. They have been used in the past in the space program.

Fuel Cell Performance

The performance of fuel cells is affected by the operating variables (e.g., temperature, pressure, gas composition, reactant utilization, and current density) and other factors that influence the reversible cell potential (impurities) and the magnitude of the irreversible voltage losses (polarization, contact resistance, exchange current).

The cell voltage (V_{cell}) is given by

$$V_{cell} = E - iR - \mu_p \tag{8.13.32}$$

where i is the current through the cell, R is the cell resistance, and μ_p is the polarization loss.

© 1999 by CRC Press LLC

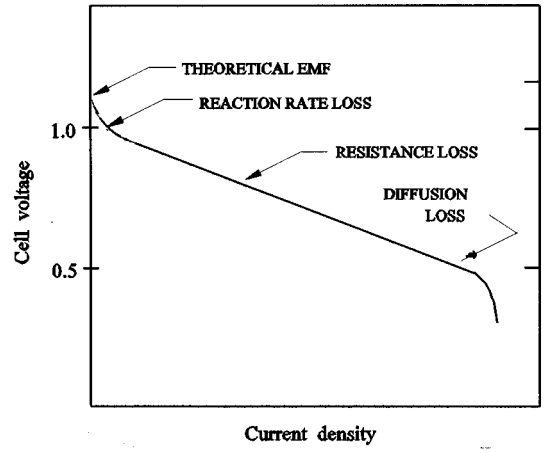

FIGURE 8.13.10 Losses affecting current-voltage characteristics.

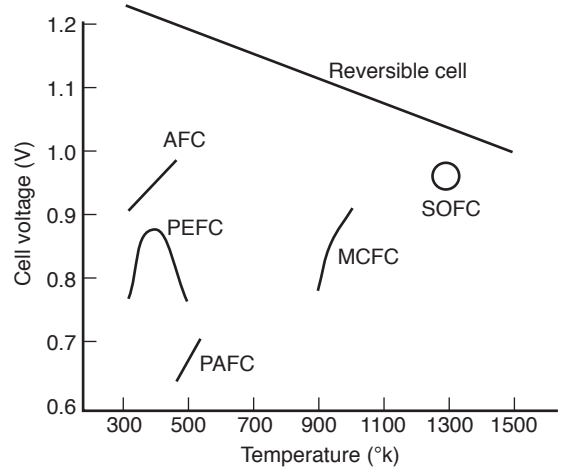

FIGURE 8.13.11 Dependence of the initial operating cell voltage of typical fuel cells on temperature. .

Current Density. Current density has a major impact on the cell voltage. Figure 8.13.10 shows how various losses affect the current-voltage characteristics.

Temperature and Pressure. Increase in pressure generally has a beneficial effect on the cell performance. Increased reactant pressure increases gas solubility and mass transfer rates. In addition, electrolyte loss due to evaporation is decreased.

Theoretically, the reversible potential of an H_2/O_2 fuel cell decreases with an increase in temperature. The practical effect of temperature is mixed, as shown in Figure 8.13.11.

Fuel Cell Power Systems

A general fuel cell power system consists of a fuel processor, fuel cell stack, power conditioner, and possibly a cogeneration or bottoming system to utilize the rejected heat. A schematic of a basic system is shown in Figure 8.13.12.

© 1999 by CRC Press LLC

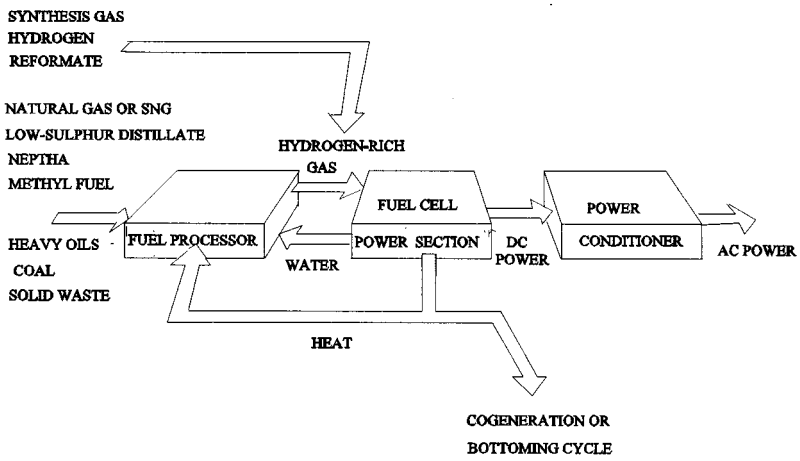

FIGURE 8.13.12 Basic fuel cell power system.

Fuel Processors. If pure hydrogen is available, no additional fuel processor is needed. However, in most applications hydrogen needs to be generated from other fuels, such as natural gas, methane, methanol, etc.

Natural Gas Processing. Natural gas is mostly methane (CH_4) with small amounts of other hydrocarbons. It can be converted to H_2 and CO in a steam-reforming reactor according to Equation (8.13.31). Fuels are typically steam reformed at temperatures of 760 to 980°C.

Liquid Fuel Processing. Liquid fuels such as distillate, naphtha, diesel oil, and fuel oil can be reformed by noncatalytic partial oxidation of the fuel by oxygen in the presence of steam with flame temperatures of 1300 to 1500°C.

Nomenclature

E = internal cell voltage
F = faraday, charge of 1 g-mol of electrons
G = Gibbs free energy
H = enthalpy
ΔH = heat of reaction, enthalpy of formation
I = current
n = number of g-mol
P = Pressure
R = gas constant
S = entropy
t = time
T = temperature
V = voltage drop
W_e = electrical work

Superscript

0 = values under standard conditions — 25°C, 1 atm

Defining Terms

Alkaline fuel cell (AFC): A fuel cell using KOH as the electrolyte.
Faraday: Change of 1 g · mol of electrons, which equals 96,439 C.
Molten carbonate fuel cell (MCFC): A fuel cell using molten carbonate as the electrolyte.

© 1999 by CRC Press LLC

Phosphoric acid fuel cell (PAFC): A fuel cell using phosphoric acid as the electrolyte.
Polymer electrolyte fuel cell (PEFC): A fuel cell using Zerconia as the electrolyte.
Solid oxide fuel cell (SOFC): A fuel cell using potassium as the electrolyte.

Thermionic Energy Conversion

Mysore L. Ramalingam

Introduction

Thermionic energy conversion (TEC) is the process of converting heat directly to useful electrical work by the phenomenon of thermionic electron emission. This fundamental concept can be applied to a cylindrical version of the planar converter, considered the building block for space nuclear power systems (SNPS) at any power level. Space nuclear reactors based on TEC can produce power in the range of 5 kWe to 5 MWe, a spectrum that serves the needs of current users such as National Aeronautics and Space Administration (NASA), United States Air Force (USAF), United States Department of Energy (USDOE), and Ballistic Missile Defense Organization (BMDO). Electrical power in this range is currently being considered for commercial telecommunication satellites, navigation, propulsion, and planetary exploration missions.

The history of thermionic emission dates back to the mid-1700s when Charles Dufay observed that electricity is conducted in the space near a red-hot body. Although Thomas Edison requested a patent in the late 1800s, indicating that he had observed thermionic electron emission while perfecting his electric light system, it was not until the 1960s that the phenomenon of TEC was adequately described theoretically and experimentally (Hatsopoulos and Gryftopoulos, 1973). These pioneering activities have led to the development of thermionic SNPS that could potentially be augmented by Brayton and Stirling

© 1999 by CRC Press LLC

cycle generators to produce additional power from waste heat in NASA manned lunar and martian exploration missions (Ramalingam and Young, 1993).

Principles of Thermionic Energy Conversion

Figure 8.13.13 represents a schematic of the essential components and processes in an elementary thermionic converter (TC). Electrons "boil-off" from the emitter material surface, a refractory metal such as tungsten, when heated to high temperatures (2000 K) by a **heat source**. The electrons then traverse the small interelectrode gap, to a colder (1000 K) collector surface where they condense, producing an output voltage that drives the current through the electrical load and back to the emitter. The flow of electrons through the electrical load is sustained by the temperature difference and the difference in **surface work functions** of the electrodes.

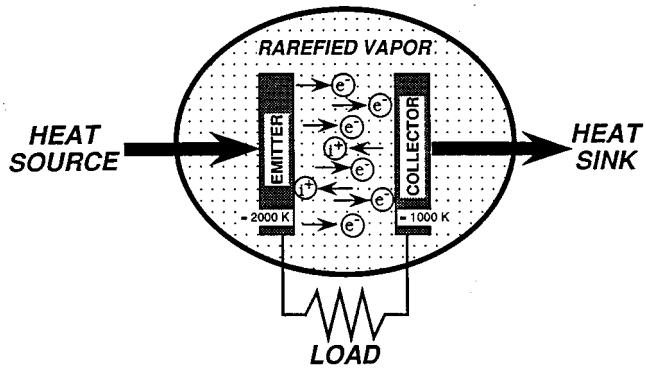

FIGURE 8.13.13 Schematic of an Elementary TEC.

Surface Work Function. In a simple form, the energy required to separate an electron from a metal surface atom and take it to infinity outside the surface is termed the electron work function or the work function of the metal surface. The force experienced by an electron as it crosses an interface between a metal and a rarefied vapor can be represented by the **electron motive**, Ψ, which is defined as a scalar quantity whose negative gradient at any point is a measure of the force exerted on the electron at that point (Langmuir and Kingdon, 1925). At absolute zero the kinetic energy of the **free electrons** would occupy quantum energy levels from zero to some maximum value called the Fermi level. Each energy level contains a limited number of free electrons, similar to the electrons contained in each electron orbit surrounding the nucleus of an atom. Fermi energy, μ, corresponds to the highest energy of all free electrons at absolute zero. At temperatures other than absolute zero some of the free electrons begin to experience energies greater than that at the Fermi level. Thus, the electron work function Φ, would be defined as

$$\Phi = \Psi_T - \mu \tag{8.13.33}$$

where Ψ_T represents the electron motive or energy at some temperature, T, above absolute zero.

Interelectrode Motive Distribution. Figure 8.13.14 provides a schematic representation of the electron motive distribution in the interelectrode space of a thermionic converter. Under ideal conditions of particle transport, the motive varies linearly from Ψ_{EM}, the motive just outside the emitter, to Ψ_{CO}, the motive outside the collector surface. The magnitudes of the Fermi energies of the emitter and collector relative to Ψ_{EM} and Ψ_{CO} are clearly indicated. The internal voltage drop of the converter is defined as;

$$\Delta V = \left(\Psi_{EM} - \Psi_{CO}\right)/e \tag{8.13.34}$$

© 1999 by CRC Press LLC

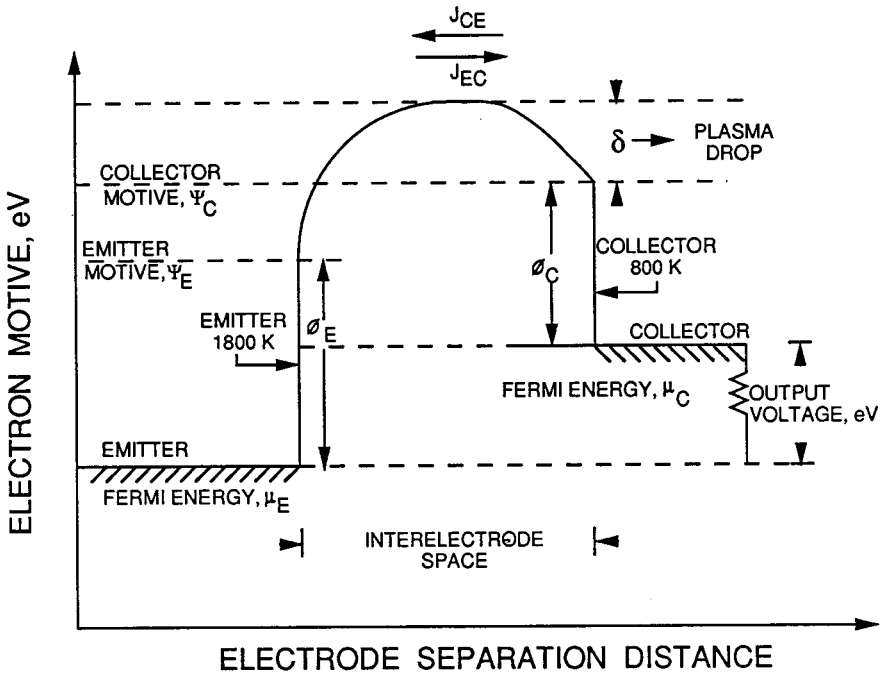

FIGURE 8.13.14 Electron motive distribution in the interelectrode gap.

In a conventional thermionic converter, the emitter and collector are not at the same temperature, but to a good approximation, the output voltage, neglecting **lead losses** and **particle interaction losses**, can be represented by the relationship.

$$V = \left(\mu_{CO} - \mu_{EM}\right)/e \tag{8.13.35}$$

Since a real thermionic converter has an ionizing medium to improve its performance, a similar motive distribution can be defined for the ions. It is sufficient to state that the ion interelectrode motive has a slope equal and opposite to the corresponding electron interelectrode motive. The ions are, therefore, decelerated when the electrons are accelerated and vice versa.

Electron Saturation Current. In the absence of a strong influence from an external electrical source, the electron current ejected from a hot metal at the emitter surface into the vacuum ionizing medium is termed the *electron saturation current*. As this quantity depends on the number of free electrons $N(\varepsilon_x)$, Fermi-Dirac statistics provide the means to compute the number of free electrons, $N(\varepsilon_x)\, d\varepsilon_x$, incident on a unit area within the metal in unit time with energies corresponding to the motion normal to the area, between ε_x and $\varepsilon_x + d\varepsilon_x$. For energies greater than the Fermi energy, the functional dependence of $N(\varepsilon_x)$ on ε_x is given by (Fowler, 1955)

$$N\left(\varepsilon_x\right) \approx \left[4\pi m_e kT/h^3\right]\left[\exp\left\{-\varepsilon_x - \mu/kT\right\}\right] \tag{8.13.36}$$

where m_e is the mass of the electron = 9.108×10^{-28} g and h is Planck's constant = 4.140×10^{-15} eV · sec.

The electron saturation current density, J_{sat}, for a uniform surface, is found by integrating $N(\varepsilon_x)$ in the range of ε_x from Ψ_T to infinity for all $\Psi_T - \mu > kT$, which is the case for almost all materials and practical temperatures. The result of the integration yields

© 1999 by CRC Press LLC

$$J_{sat} = AT^2 \exp\left[-\left(\Psi_T - \mu\right)/kT\right] \tag{8.13.37}$$

or

$$J_{sat} = AT^2 \exp\left[-\left(\Phi\right)/kT\right] \tag{8.13.38}$$

where A is the Richardson constant ≈ 120 A/cm$^2 \cdot$ K^2.

Equation (8.13.38), which is the most fundamental and important relationship for the design of a thermionic converter, is called the Richardson-Dushmann equation (Richardson, 1912). On similar lines, the ion saturation current density for a converter with an ionizing medium is given by the relationship (Taylor and Langmuir, 1933):

$$f_{iSat} = ep_g \Big/ \left[\left(2\pi m_g kT_g\right)^{0.5}\left(1 + 2\exp\left\{\left(V_i - \Phi/kT\right)\right\}\right)\right] \tag{8.13.39}$$

where p_g, T_g, m_g, and V_i are the pressure, temperature, mass, and first ionization energy, respectively, of the ionizing medium.

Types of Thermionic Converters

Thermionic converters can be broadly classified as vacuum thermionic converters and vapor thermionic converters, depending on the presence of an ionizing medium in the interelectrode gap. In vacuum thermionic converters the interelectrode space is evacuated so that the space is free of particles other than electrons and the two electrodes are placed very close together, thereby neutralizing the negative space charge buildup on the electrode surface and reducing the total number of electrons in transit. Due to machining limitations, vacuum converters have been all but completely replaced by vapor-filled thermionic converters. In vapor-filled thermionic converters, the interelectrode space is filled with a rarefied ionizing medium at a vapor pressure generally on the order of 1 to 10 torr. The vapor generally used is cesium as it is the most easily ionized of all stable gases and this can be provided through an external two-phase reservoir or an internal graphite reservoir (Young et al., 1993). The vapor neutralizes the negative space charge effect by producing positive ions at the electrode surfaces and gets adsorbed on the surfaces, thereby altering the work function characteristics.

Converter Output Characteristics

Figure 8.13.15 represents the output current-voltage characteristics for various modes of operation of the vacuum and vapor-filled thermionic converters. Characteristics obtained by not considering particle interactions in the interelectrode gap are generally considered ideal output characteristics. The figure essentially displays three types of converter output current-voltage characteristics, an ideal characteristic, an ignited mode characteristic, and an unignited mode characteristic. For an ideal converter in the interelectrode space the net output current density consists of the electron current density, J_{EMCO} flowing from emitter to collector diminished by the electron current density J_{COEM} flowing from collector to emitter and the ion-current density f_{iEMCO} flowing from emitter to collector. Thus,

$$J_{net} = J_{EMCO} - J_{COEM} - f_{iEMCO} \tag{8.13.40}$$

By expressing the individual terms as functions of ϕ, T, and V,

$$\begin{aligned} J_{net} = {} & AT_{EM}^2 \exp\left[-\left(\Phi_{EM}/kT_{EM}\right)\right] - AT_{CO}^2 \exp\left[-\left(\Phi_{EM} - eV\right)/kT_{CO}\right] \\ & - f_{EMS} \exp\left[-\left(\Psi_{EM} - \Psi_{CO}\right)kT_{EM}\right] \end{aligned} \tag{8.13.41}$$

© 1999 by CRC Press LLC

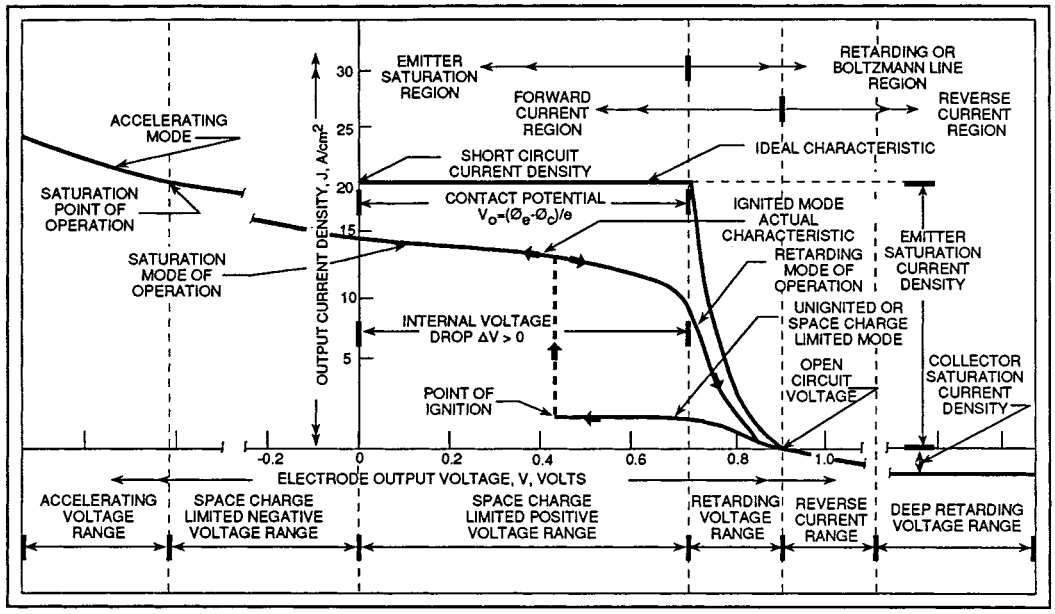

FIGURE 8.13.15 Thermionic diode output current density characteristics and nomenclature.

$$\text{for} \quad eV < \Phi_{EM} - \Phi_{CO}$$

Similar relationships can be generated for various types of thermionic converters.

Thermodynamic Analysis

In thermodynamic terms a thermionic converter is a heat engine that receives heat at high temperature, rejects heat at a lower temperature, and produces useful electrical work while operating in a cycle analogous to a simple vapor cycle engine. Based on the application of the first law of thermodynamics to the control volumes around the emitter (Houston, 1959; Angrist, 1976),

$$\text{Energy In} = \text{Energy Out} \tag{8.13.42}$$

i.e.,

$$q_{CB} + q_{JH} + q_{HS} = q_{EC} + q_{WB} + q_{CD} + q_{RA} \tag{8.13.43}$$

where, by using the terminology in Figure 8.13.14, each of the terms in Equation (8.13.43) can be elaborated as follows:

(a) Energy supplied by back emission of the collector:

$$q_{CB} = J_{COEM}\left[\Phi_{CO} + \delta + V + \left(2kT_{CO}/e\right)\right] \tag{8.13.44}$$

(b) Energy supplied by joule heating of lead wires and plasma:

$$q_{JH} = 0.5\left[J_{EMCO} - J_{COEM}\right]^2\left(R_{LW} + R_{PL}\right) \tag{8.13.45}$$

© 1999 by CRC Press LLC

(c) Energy dissipated by electron cooling:

$$q_{EC} = J_{EMCO}\left[\Phi_{CO} + \delta + V - \Phi_{EM} + \left(2kT_{EM}\right)/e\right] \tag{8.13.46}$$

(d) Energy dissipated due to phase change by electron evaporation:

$$q_{WB} = J_{EM}\Phi_{EM} \tag{8.13.47}$$

(e) Energy dissipated by conduction through the lead wires and plasma:

$$q_{CD} = \Delta T\left[\left(K_{LW}A_{LW}/A_eL_{LW}\right) + \left(K_{PL}A_{PL}/A_eL_{IG}\right)\right] \tag{8.13.48}$$

Here, K represents thermal conductivity, LW = lead wires, PL = plasma, and IG = interelectrode gap.

(f) Energy dissipated by radiation from emitter to collector:

$$q_{RA} = 5.67 \times 10^{-12}\left(T_{EM}^2 - T_{CO}^4\right)\left(\varepsilon_{EM}^{-1} + \varepsilon_{CO}^{-1} - 1\right)^{-1} \tag{8.13.49}$$

Substitution for the various terms in Equation (8.13.42) yields q_{Hs}, the energy supplied to the emitter from the heat source.

The thermal efficiency of the thermionic converter is now expressed as

$$\eta_{TH} = \left[V\left(J_{EMCO} - J_{COEM}\right)/q_{HS}\right] \tag{8.13.50}$$

Design Transition to Space Reactors — Concluding Remarks

All the fundamentals discussed so far for a planar thermionic converter can be applied to a cylindrical version which then becomes the building block for space power systems at any power level. In a thermionic reactor, heat from the nuclear fission process produces the temperatures needed for thermionic emission to occur. The design of a thermionic SNPS is a user-defined compromise between the required output power and the need to operate reliably for a specified lifetime. Based on the type of contact the emitter has with the nuclear fuel, the power systems can be categorized as "in-core" or "out-of-core" power systems. At this stage it suffices to state that the emitter design for in-core systems is extremely complex because of its direct contact with the hot nuclear fuel.

Defining Terms

Electron motive: A scalar quantity whose negative gradient at any point is a measure of the force exerted on an electron at that point.

Free electrons: Electrons available to be extracted from the emitter for thermionic emission.

Heat source: Electron bombardment heating of the emitter.

Lead losses: Voltage drop as a result of the built-in resistance of the leads and joints.

Particle interaction losses: Voltage drop in the interelectrode gap as a result of particle collisions and other interactions.

Surface work function: A measure of the electron-emitting capacity of the surface.

Thermionic energy conversion: Energy conversion from heat energy to useful electrical energy by thermionic electron emission.

Thermoelectric Power Conversion

Jean-Pierre Fleurial

Introduction

The advances in materials science and solid-state physics during the 1940s and 1950s resulted in intensive studies of thermoelectric effects and related applications in the late 1950s and through the mid-1960s (Rowe and Bhandari, 1983). The development of semiconductors with good thermoelectric properties made possible the fabrication of thermoelectric generators and refrigerators. Being solid-state devices, thermoelectric systems offer some unique advantages, such as high reliability, long life, small-size and no-vibrations refrigerators, and can be used in a wide temperature range, from 200 to 1300 K. However, because of their limited conversion efficiencies, these devices have remained confined to specialized applications. As the following sections will emphasize, the performance of those devices is closely associated with the magnitude of the **dimensionless figure of merit**, *ZT*, of the thermoelectric semiconductor.

ZT represents the relative magnitude of electrical and thermal cross-effect transport in materials. State-of-the-art thermoelectric materials, known since the early 1960s, have been extensively developed. Although significant improvements of the thermoelectric properties of these materials have been achieved, a maximum *ZT* value close to 1 is the current approximate limit over the whole 100 to 1500 K temperature range (Figure 8.13.16). To expand the use of thermoelectric devices to a wide range of applications will require improving *ZT* by a factor of two to three. There is no theoretical limitation on

© 1999 by CRC Press LLC

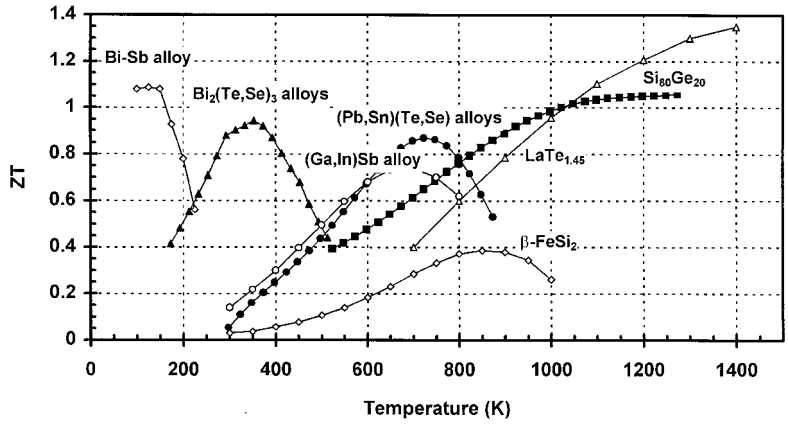

FIGURE 8.13.16 Typical temperature variations of *ZT* of state-of-the-art n-type thermoelectric alloys.

the value of *ZT*, and new promising approaches are now focusing on the investigation of totally different materials and the development of novel thin film heterostructure.

Thermoelectric Effects

Thermoelectric devices are based on two transport phenomena: the Seebeck effect for power generation and the Peltier effect for electronic refrigeration. If a steady temperature gradient is applied along a conducting sample, the initially uniform charge carrier distribution is disturbed as the free carriers located at the high-temperature end diffuse to the low-temperature end. This results in the generation of a back emf which opposes any further diffusion current. The open-circuit voltage when no current flows is the Seebeck voltage. When the junctions of a circuit formed from two dissimilar conductors (n- and p-type semiconductors) connected electrically in series but thermally in parallel are maintained at different temperatures T_1 and T_2, the open-circuit voltage V developed is given by $V = S_{pn}(T_1 - T_2)$, where S_{pn} is the Seebeck coefficient expressed in $\mu V \cdot K^{-1}$.

The complementary Peltier effect arises when an electrical current I passes through the junction. A temperature gradient is then established across the junctions and the corresponding rate of reversible heat absorption $\dot{Q}$ is given by $\dot{Q} = \Pi_{pn} I$, where Π_{pn} is the Peltier coefficient expressed in $W \cdot A^{-1}$ or V. There is actually a third, less-important phenomenon, the Thomson effect, which is produced when an electrical current passes along a single conducting sample over which a temperature gradient is maintained. The rate of reversible heat absorption is given by $\dot{Q} = \beta I(T_1 - T_2)$, where β is the Thomson coefficient expressed in $V \cdot K^{-1}$. The three coefficients are related by the Kelvin relationships:

$$S_{pn} = \frac{\Pi_{pn}}{T} \quad \text{and} \quad \frac{dS_{pn}}{dT} = \frac{\beta_p - \beta_n}{T} \tag{8.13.51}$$

Thermoelectric Applications

The schematic of a thermoelectric device, or module, on Figure 8.13.17, illustrates the three different modes of operation: power generation, cooling, and heating. The *thermoelectric module* is a standardized device consisting of several p- and n-type legs connected electrically in series and thermally in parallel, and bonded to a ceramic plate on each side (typically alumina). The modules are fabricated in a great variety of sizes, shapes, and number of thermoelectric couples and can operate in a wide range of currents, voltages, powers, and efficiencies. Complex, large-scale thermoelectric systems can be easily designed and built by assembling various numbers of these modules connected in series or in parallel depending on the type of applications.

© 1999 by CRC Press LLC

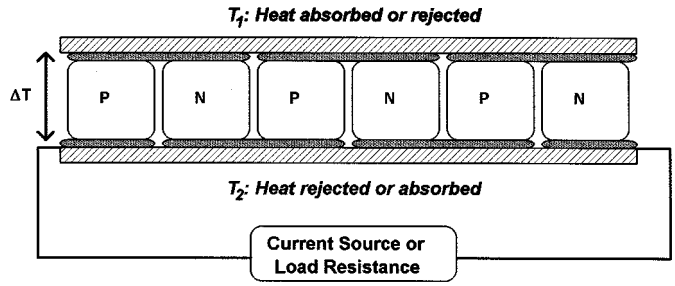

FIGURE 8.13.17 Schematic of a thermoelectric module.

Power Generation. When a temperature gradient is applied across the thermoelectric device, the heat absorbed at the hot junction (Figure 8.13.17, hot side $T_h - T_1$ and cold side, $T_c - T_2$) will generate a current through the circuit and deliver electrical power to the load resistance R_L (Harman and Honig, 1967). The conversion efficiency η of a thermoelectric generator is determined by the ratio of the electrical energy, supplied to the load resistance, to the thermal energy, absorbed at the hot junction, and is given by

$$\eta = \frac{R_L I^2}{S_{\text{pn}} I T_h + K\left(T_h - T_c\right) - \frac{1}{2} RI^2} \tag{8.13.52}$$

where K is the thermal conductance in parallel and R is the electrical series resistance of one p-n thermoelectric couple. The electrical power P_L generated can be written as

$$P_L = \frac{S_{\text{pn}}\left(T_h - T_c\right)^2 R_L}{\left(R_L + R\right)^2} \tag{8.13.53}$$

The thermoelectric generator can be designed to operate at maximum power output, by matching the load and couple resistances, $R_L = R$. The corresponding conversion efficiency is

$$\eta_P = \frac{T_h - T_c}{\frac{3}{2} T_h + \frac{1}{2} T_c + \frac{1}{4} Z_{\text{pn}}^{-1}} \tag{8.13.54}$$

where Z_{pn} is the figure of merit of the p-n couple given by

$$Z_{\text{pn}} = \frac{S_{\text{pn}}^2}{RK} \tag{8.13.55}$$

The figure of merit can be optimized by adjusting the device geometry and minimizing the RK product. This results in Z_{pn} becoming independent of the dimensions of the **thermoelectric legs**. Moreover, if the p- and n-type legs have similar transport properties, the figure of merit, $Z_{\text{pn}} = Z$, can be directly related to the Seebeck coefficient S, electrical conductivity σ or resistivity ρ, and thermal conductivity λ of the thermoelectric material:

$$Z = \frac{S^2}{\rho\lambda} = \frac{S^2\sigma}{\lambda} \tag{8.13.56}$$

© 1999 by CRC Press LLC

The maximum performance η_{max} of the generator is obtained by optimizing the load-to-couple-resistance ratio, leading to the maximum energy conversion efficiency expressed as

$$\eta_{max} = \frac{T_h - T_c}{T_h} \frac{\sqrt{1 + Z_{pn} T_{av}} - 1}{\sqrt{1 + Z_{pn} T_{av}} + \frac{T_c}{T_h}} \tag{8.13.57}$$

It must be noted that the maximum efficiency is thus the product of the Carnot efficiency, less than unity, and of a material-related efficiency, increasing with increasing Z_{pn} values as illustrated in Figure 8.13.18.

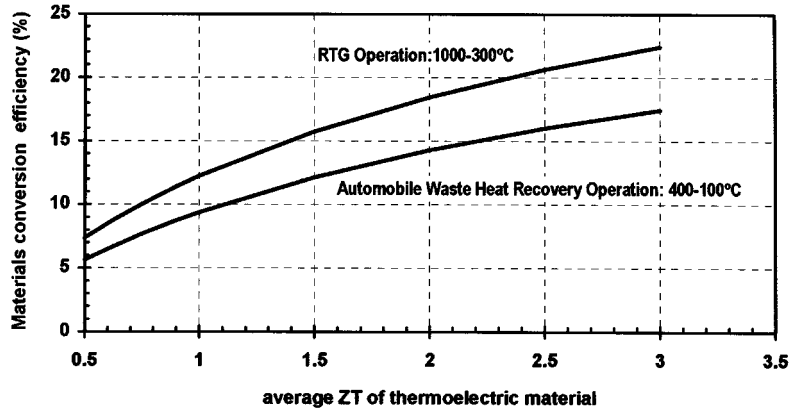

FIGURE 8.13.18 Maximum conversion efficiency η_{max} as a function of the average material figure of merit *ZT,* calculated using Equation (8.13.57) for two systems operating in different temperature ranges: the radioisotope generator (RTG) used for deep space missions and an automobile waste heat recovery generator.

Refrigeration. When a current source is used to deliver electrical power to a thermoelectric device, heat can be pumped from T_1 to T_2 and the device thus operates as a refrigerator (Figure 8.13.17, hot side $T_h = T_2$ and cold side, $T_c = T_1$). As in the case of a thermoelectric generator the operation of a thermoelectric cooler depends solely upon the properties of the p-n thermocouple materials expressed in terms of the figure of merit Z_{pn} and the two temperatures T_c and T_h (Goldsmid, 1986). The conversion efficiency or **coefficient of performance**, COP, of a thermoelectric refrigerator is determined by the ratio of the cooling power pumped at the cold junction to the electrical power input from the current source and is given by

$$\text{COP} = \frac{S_{pn} T_c I - \frac{1}{2} RI^2 - K(T_h - T_c)}{S_{pn}(T_h - T_c) I + RI^2} \tag{8.13.58}$$

There are three different modes of operation which are of interest to thermoelectric coolers. A thermoelectric cooler be designed to operate at maximum cooling power, Qc_{max}, by optimizing the value of the current:

$$I_{Qc_{max}} = \frac{S_{pn} T_c}{R} \quad \text{and} \quad Qc_{max} = \frac{1}{2} \frac{(ST_c)^2}{R} - K(T_h - T_c) \tag{8.13.59}$$

© 1999 by CRC Press LLC

Similarly, the conditions required for operating at maximum efficiency, COP_{max}, across a constant temperature gradient, are determined by differentiating Equation (8.13.58) with respect to I, with the solution:

$$I_{COP_{max}} = \frac{K(T_h - T_c)_c}{S_{pn} T_{av}} \left(1 + \sqrt{1 + Z_{pn} T_{av}}\right) \tag{8.13.60}$$

$$COP_{max} = \frac{T_c}{T_h - T_c} \frac{\sqrt{1 + Z_{pn} T_{av}} - \frac{T_h}{T_c}}{\sqrt{1 + Z_{pn} T_{av}} + 1} \tag{8.13.61}$$

By reversing the input current to the device, the thermoelectric refrigerator can become a heat pump, with T_1 being the hot junction temperature. The expression of the maximum conversion efficiency of the heat pump is very similar to Equation (8.13.61) because of the following relationship:

$$\left(COP_{max}\right)^{\text{heat pump}} = 1 + \left(COP_{max}\right)^{\text{refrigerator}} \tag{8.13.62}$$

The maximum COP expression in Equation (8.13.61) is similar to the one derived for the conversion efficiency η of a thermoelectric generator in Equation (8.13.57). However, there is a major difference between the COP_{max} and η_{max} parameters. Clearly, η_{max} increases with increasing ΔT values but is limited by the Carnot efficiency (Equation 8.13.54) which is less than 1, while COP_{max} in Equation (8.13.52) increases with decreasing ΔT values and can reach values much larger than 1. Figure 8.13.19 represents the variations of the COP_{max} of a thermoelectric cooling device optimized for working voltage and geometry as a function of average ZT values and temperature differences (hot junction temperature at 300 K). The average ZT value for current state-of-the-art commercially available materials (Bi_2Te_3-based alloys) is about 0.8. For example, it can be seen that a COP_{max} of 4 is obtained for a $(T_h - T_c)$ difference of 10 K, meaning that to pump 8 W of thermal power only 2 W of electrical power needs to be provided to the thermoelectric cooling device. This also means that 10 W of thermal power will be rejected at the hot side of the cooler.

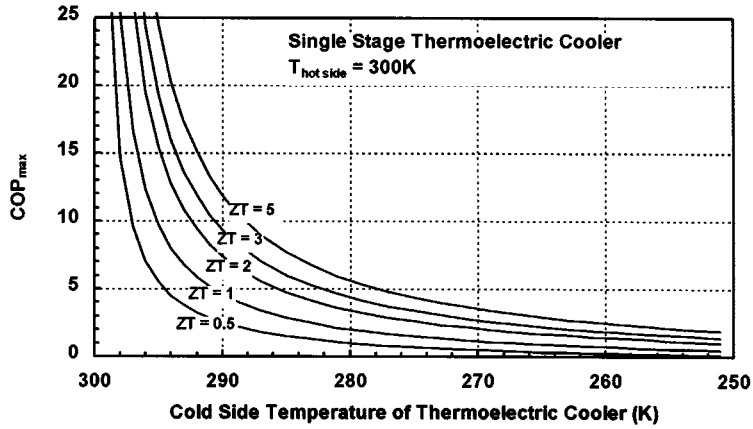

FIGURE 8.13.19 Maximum material coefficient of performance COP_{max} of a single-stage thermoelectric cooler calculated using Equation (8.13.61) as a function of the cold-side temperature (hot-side temperature of 300 K). Curves corresponding to various values of the average material figure of merit are displayed.

© 1999 by CRC Press LLC

The operation of a thermoelectric refrigerator at maximum cooling power necessitates a substantially higher input current than the operation at maximum efficiency. This is illustrated by calculating the variations of the maximum COP and cooling power with the input current and temperature difference which have been plotted in Figures 8.13.20 and 8.13.21. The calculation was based on the properties of a thermoelectric cooler using state-of-the-art Bi_2Te_3-based alloys, and the arbitrary units are the same for both graphs. It can be seen that $I_{COP_{max}}$ increases while $I_{Qc_{max}}$ decreases with increasing ΔT. Also, it is possible to operate at the same cooling power with two different current values.

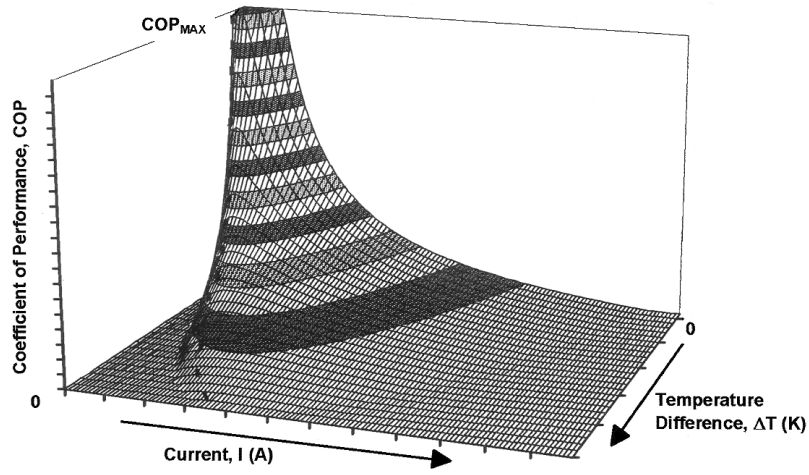

FIGURE 8.13.20 Three-dimensional plot of the variations of the COP of a thermoelectric cooler as a function of the operating current and the temperature difference.

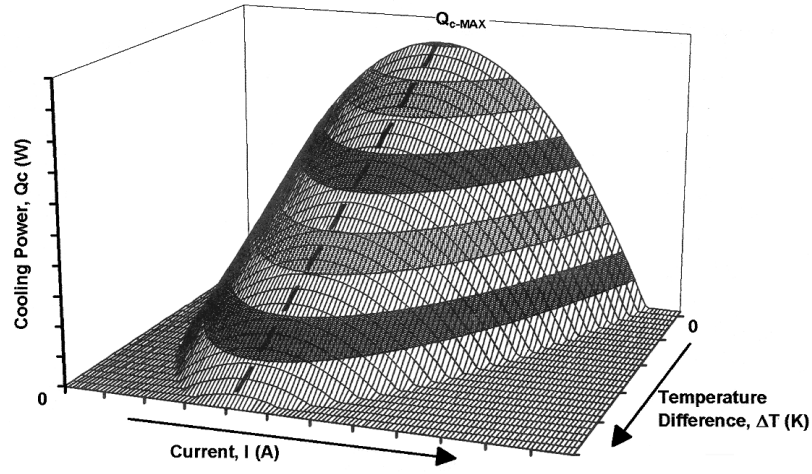

FIGURE 8.13.21 Three-dimensional plot of the variations of the cooling power of a thermoelectric cooler as a function of the operating current and the temperature difference.

Finally, the third problem of interest for thermoelectric coolers is to determine the maximum temperature difference, ΔT_{max}, that can be achieved across the device. As shown on Figure 8.13.21, by operating at maximum cooling power and extrapolating Equation (8.13.59) to $Qc_{max} = 0$, ΔT_{max} is given by

© 1999 by CRC Press LLC

$$\Delta T_{\max} = \frac{1}{2} Z_{\text{pn}} T_c^2 \quad \text{and} \quad T_{c\,\min} = \frac{\sqrt{1 + 2Z_{\text{pn}} T_h} - 1}{Z_{\text{pn}}} \tag{8.13.63}$$

where $T_{c\,\min}$ corresponds to the lowest cold-side temperature achievable. If the cooler operates at a ΔT close to $\Delta T_{\max}$ or higher, it becomes necessary to consider a cascade arrangement with several **stages**. The COP of an n-stage thermoelectric cooler is optimized if the COP of each stage, COP_i, is the same, which requires $\Delta T_i / T_{i-1}$ to be the same for each stage. The overall maximum COP is then expressed as

$$\text{COP}_{\max} = \frac{1}{\left(\prod_{i=1}^{n} \left(1 + \frac{1}{\text{COP}_i} \right) - 1 \right)} \tag{8.13.64}$$

Additional Considerations

When considering the operation of an actual thermoelectric device, several other important parameters must be considered. The thermal and electrical contact resistances can substantially degrade the device performance, in particular for short lengths of the thermoelectric legs. For example, the conversion efficiency of a radioisotope generator system is about 20% lower than the value calculated in Figure 8.13.18 for the thermoelectric materials only. The electrical contact resistance arises from the connection (see Figure 8.13.17) of all the legs in series. Typical values obtained for actual generators and coolers are 10 to 25 $\mu\Omega \cdot \text{cm}^2$. The thermal contact resistance is generated by the heat-transfer characteristics of the ceramic plates and contact layers used to build the thermoelectric module. The heat exchangers and corresponding heat losses should also be taken into account.

In addition, the transport properties of the thermoelectric materials vary with temperature, as illustrated in Figure 8.13.16. When a thermoelectric device is operating across a wide temperature range, these variations should be factored in the calculation of its performance.

Nomenclature

COP	coefficient of performance
$\text{COP}_{\max}$	maximum coefficient of performance
COP_i	coefficient of performance of the *i*th stage of a multistage thermoelectric cooler
I	current intensity
$I_{\text{COP}_{\max}}$	current intensity required to operate a thermoelectric cooler at maximum conversion efficiency
$I_{Qc_{\max}}$	current intensity required to operate a thermoelectric cooler at maximum cooling power
K	thermal conductance
Q	rate of reversible heat absorption
R	electrical resistance
R_L	load resistance
P_L	electrical power delivered to the load resistance
S	Seebeck coefficient
S_{pn}	Seebeck coefficient of a p-n couple of thermoelements
T_1	temperature
T_2	temperature
T_{av}	average temperature across the thermoelectric device
T_c	cold-side temperature of a thermoelectric device
$T_{c\,\min}$	minimum cold-side temperature which can be achieved by a thermoelectric cooler
T_h	hot-side temperature of a thermoelectric device
V	voltage; open-circuit voltage
Z	thermoelectric figure of merit

© 1999 by CRC Press LLC

Z_{pn} thermoelectric figure of merit of a p-n couple of thermoelements
ZT dimensionless thermoelectric figure of merit
β Thomson coefficient
β_p Thomson coefficient for the p-type thermoelement
β_n Thomson coefficient for the n-type thermoelement
ΔT temperature difference across a thermoelectric device
ΔT_{max} maximum temperature difference which can be achieved across a thermoelectric cooler
η thermoelectric conversion efficiency
η_{max} maximum thermoelectric conversion efficiency
λ thermal conductivity
Π_{pr} Peltier coefficient
ρ electrical resistivity

Defining Terms

Coefficient of performance: Electrical to thermal energy conversion efficiency of a thermoelectric refrigerator, determined by the ratio of the cooling power pumped at the cold junction to the electrical power input from the current source.

Dimensionless figure of merit: The performance of a thermoelectric device depends solely upon the properties of the thermoelectric material, expressed in terms of the dimensionless figure of merit *ZT*, and the hot-side and cold-side temperatures. *ZT* is calculated as the square of the Seebeck coefficient times the absolute temperature divided by the product of the electrical resistivity to the thermal conductivity. The best *ZT* values are obtained in heavily doped semiconductors, such as Bi_2Te_3 alloys, PbTe alloys, and Si-Ge alloys.

Stage: Multistage thermoelectric coolers are used to achieve larger temperature differences than possible with a single-stage cooler composed of only one module.

Thermoelectric leg: Single thermoelectric element made of n-type or p-type thermoelectric material used in fabricating a thermoelectric couple, the building block of thermoelectric modules. The geometry of the leg (cross-section-to-length ratio) must be optimized to maximize the performance of the device.

Thermoelectric module: Standardized device consisting of several p- and n-type legs connected electrically in series and thermally in parallel, and bonded to a ceramic plate on each. The modules are fabricated in a great variety of sizes, shapes, and number of thermoelectric couples.

Magnetohydrodynamic Power Generation

William D. Jackson

Introduction

The discipline known as magnetohydrodynamics (MHD) deals with the interactions between electrically conducting fluids and electromagnetic fields. First investigated experimentally by Michael Faraday in 1832 during his efforts to establish the principles of electromagnetic induction, application to energy conversion yields a heat engine which has its output in electrical form and, therefore, qualifies as a direct converter. This is generally referred to as an MHD generator, but could be better described as an electromagnetic turbine as it operates on a thermodynamic cycle similar to that of a gas turbine.

The operating principle is elegantly simple, as shown in Figure 8.13.22. A pressurized, electrically conducting fluid flows through a transverse magnetic field in a channel or duct. Electrodes located on the channel walls parallel to the magnetic field and connected through an external circuit enable the motionally induced "Faraday electromotive force" to drive an electric current through the circuit and thus deliver power to a load connected into it. Taking the fluid velocity as **u** and the magnetic flux density as **B**, the intensity of the motionally induced field is $\mathbf{u} \times \mathbf{B}$. The current density, **J**, in the channel for a scalar conductivity σ is then given by Ohm's law for a moving conductor as

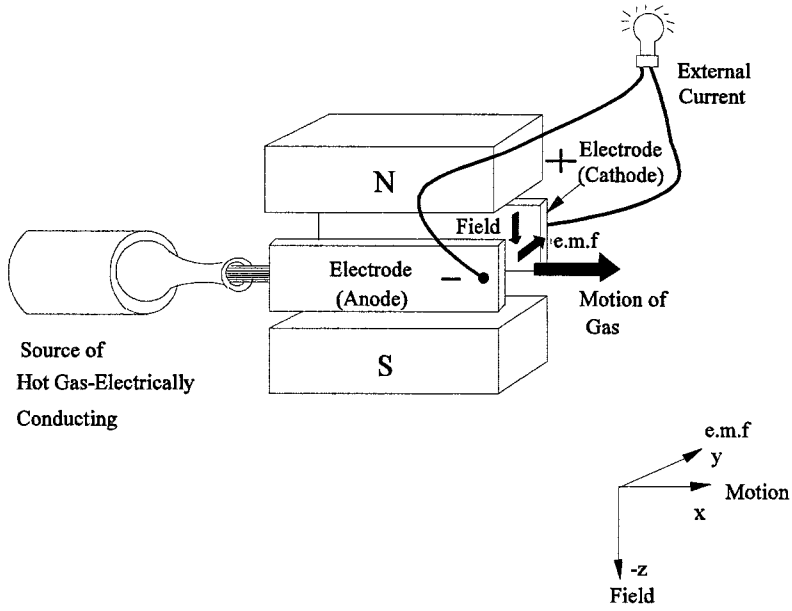

FIGURE 8.13.22 Principle of electromagnetic turbine or MHD generator.

$$\mathbf{J} = \sigma\left[\mathbf{E} + \mathbf{u} \times \mathbf{B}\right]$$

By taking the coordinates of Figure 8.13.22 and assuming that the quantities are constant, the power density flow from the MHD generator is, using $\mathbf{E} \cdot \mathbf{J}$

$$w_e = \sigma u_x^2 B^2 k(1-k)$$

© 1999 by CRC Press LLC

where $k = Ez/u \times B$ is the "loading factor" relating loaded electric field to open circuit induction and is used in the same manner as the regulation of an electrical machine is applied to its terminal voltage.

It is instructive at this point to determine the power density of an MHD generator using values representative of the most commonly considered type of MHD generator. Combustion gas with $\sigma = 10$ S/m, a flow velocity of 800 m/sec and an applied field of 5 T for maximum power transfer ($k = 0.5$) yields w_e as 40 MW/m^3. This value is sufficiently attractive to qualify MHD generators for bulk power applications. An intensive, worldwide development effort to utilize this and other MHD generator properties has been conducted since the late 1950s. However, this has not yet led to any significant application of MHD generators. To understand how this has come about and what still needs to be accomplished to make MHD attractive will now be summarized.

Electrical Conductivity Considerations

Two approaches have been followed to obtain adequate ionization and, therefore, conductivity in the working fluid. What may be termed the mainline approach to achieving electrical conductivity is to add a readily ionizable material to "seed" the working fluid. Alkali metals with ionization potentials around 4 V are obvious candidates, although a lower value would be highly desirable. A potassium salt with an ionization potential of 4.09 eV has been widely used because of low cost but cesium with a 3.89-eV value is the preferred seed material when the running time is short or the working fluid is recycled. There are two methods of ionization:

1. Thermal ionization in which recombination ensures a common temperature for electrons, ions, and neutrals; the mass action law (Saha equation) is followed; and the heat of ionization in electron volts is the ionization potential; and
2. Extrathermal or nonequilibrium ionization where electrons and heavy particles are at different temperatures and the concept of entwined fluids (electron, ion, and neutral gases) is involved.

The former is applicable to diatomic combustion gases while the latter occurs in monatomic (noble) gases but is also observed in hydrogen. Only a small amount of seed material is required and is typically around 1% of the total mass flow for maximum conductivity.

The existence of mutually perpendicular **E** and **B** fields in an MHD generator is of major significance in that the electrons are now subjected to the Hall effect. This causes electrons and, therefore, electric currents to flow at an angle with respect to the **E** field in the collision-dominated environment of the MHD generator. The presence of a significant Hall effect requires that the electrical boundary conditions on the channel be carefully selected and also introduces the possibility of working fluid instabilities driven by force fluctuations of electrical origin. A further source of fluctuations and consequent loss of conductivity occurs when nonequilibrium ionization is employed due to current concentration by Joule heating. This latter effect is controlled by operating only in a regime where, throughout the channel, complete ionization of the seed material is achieved.

Generator Configurations and Loading

The basic consequence of the Hall effect is to set up **E** fields in both transverse and axial directions in the generator channel and these are generally referred to as the Faraday and Hall fields, respectively. The direction of the Faraday field depends on the magnetic field; the Hall field depends on the Hall parameter and is always directed toward the upstream end of the channel. These considerations, in turn, lead to the MHD generator having the characteristics of a gyrator — a two-terminal pair power-producing device in which one terminal pair (Faraday) is a voltage source and the other (Hall) is a current source dependent in this case on the Hall parameter. Electric power can be extracted from either the Faraday or Hall terminals, or both.

This has resulted in several electrical boundary conditions being utilized with the axial flow channel as shown in Figure 8.13.23. These are most readily understood by treating each anode-cathode pair as a generating cell. The segmented Faraday configuration (Figure 8.13.23a) is then simply a parallel operation of cells which leads to the apparently inconvenient requirement of separate loading of individual

© 1999 by CRC Press LLC

cells: the Hall connection (Figure 8.13.23b) utilizes a single load by series connection but depends on the Hall parameter for its performance; and the diagonal connection (Figure 8.13.23c) connects the cells in series-parallel and so avoids Hall parameter dependence while retaining the single load feature. In all three linear configurations, the channel walls are electrically segmented to support the Hall field, and experience has shown that this must be sufficiently finely graded so that no more than 50 V is supported by the interelectrode gaps to avoid electrical breakdown.

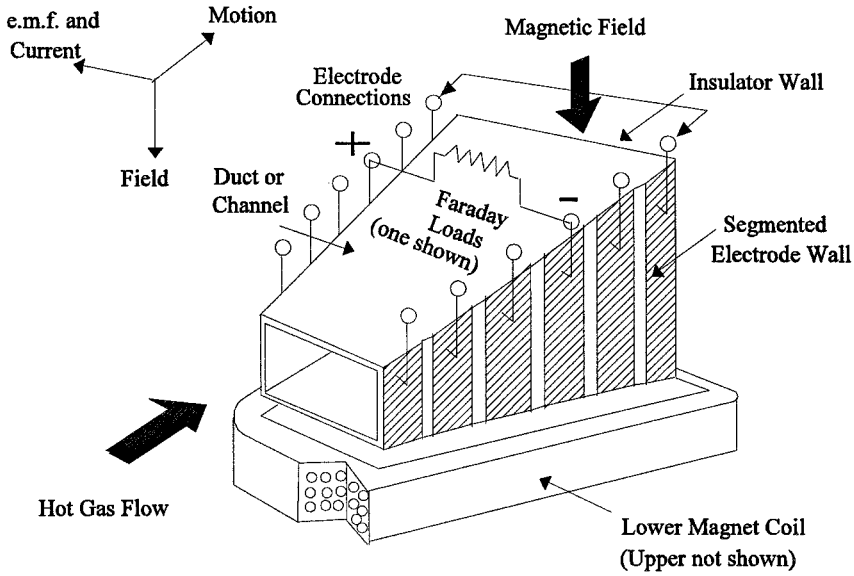

FIGURE 8.13.23 Basic Faraday linear MHD generator.

The MHD generator is a linear version of the homopolar machine originally demonstrated by Faraday and is, as a practical matter, confined to DC generation. Accordingly, some form of DC-AC conversion using power electronics is required for the vast majority of applications. The single load feature loses significance in this situation as the "power conditioning" can readily be arranged to combine (consolidate) the individual cell outputs before conversion to the required AC system conditions. Indeed, to maximize power extraction while limiting interelectrode voltages and controlling electrode currents (to ensure adequate lifetime), the power conditioning is arranged to extract power from both Faraday and Hall terminal pairs.

An alternative geometry is to set up a radial flow (usually but not necessarily outward) with the disk configuration of Figure 8.13.23d. The result is a Hall generator, which is generally favored for nonequilibrium ionization as it avoids the inevitable nonuniformities associated with electrode segmentation with their proclivity for promoting ionization instabilities. A measure of Faraday performance is achievable through the introduction of swirl, and additional ring electrodes enable power conditioning to control (and optimize) the radial electric field.

Components

An MHD generator per se requires several components to make up a complete powertrain. In addition to the power conditioning needed for DC-AC conversion these include a magnet, seed injector, combustor with fuel and oxidizer supply or an input heat exchanger, nozzle, compressor, diffuser, exhaust gas-cleaning system (for once-through systems), and controls. The need to accommodate a channel between the poles of a magnet qualifies the MHD generator as a large-air-gap machine.

© 1999 by CRC Press LLC

Systems

Power systems incorporating MHD generators are either of the once-through (open-cycle) or working fluid recycle (closed-cycle) type, and the complete MHD system described in the previous section can either be stand-alone or incorporated into a more complex configuration such as a binary cycle. In the latter case, the high-temperature operation of the MHD unit makes it a topping cycle candidate and it is in this mode that MHD has received most system consideration. An MHD generator operated directly on ionized combustion gas is usually associated with an open cycle while nonequilibrium ionization with seeded noble gases and LMMHD are invariably considered for closed-cycle operation. An exception is nonequilibrium ionization in cesium-seeded hydrogen which has received some attention for open-cycle operation.

Heat Sources, Applications, and Environmental Considerations

A heat source capable of providing from 1000 K for LMMHD to over 3000 K for open-cycle systems for power production is a candidate. Rocket motor fuels, all fossil fuels, high-temperature nuclear reactors cooled with hydrogen and biomass are suitable for open cycles, while closed cycles can be driven through a heat exchanger by any of these combustion sources. A high-temperature nuclear reactor, probably helium cooled, is also a feasible source for MHD and in the early stages of development of the process received much attention. With the abandonment of efforts to develop commercial reactors to operate at temperatures above 1200 K, attention has focused on high-energy fuels for pulse power (few seconds) operation and coal for utility power generation.

While the debate over the role of fossil energy in the long-term electricity generation scenario continues, it is established that coal is a major resource which must be utilized at maximim efficiency to limit CO_2 production and must be combusted in a manner which reduces SO_2 and NO_x effluents to acceptable levels. The use of MHD generators significantly advances all of these objectives. Briefly, it was first observed that the "electromagnetic turbine" has the major advantage that it cannot only provide the highest efficiency of any known converter from the Carnot viewpoint but that its operation is not adversely affected by coal slag and ash. Indeed, slag provides an excellent renewable coating for the channel walls and increases lifetime.

System calculations have shown that, when coupled as a topping cycle to the best available steam plant technology, a thermal efficiency with coal and full environmental control is 52.5%. When coupled into a ternary cycle with either a gas turbine or fuel cells and a steam turbine, efficiencies upward of 60% are possible.

Technology Status

A pulse-type MHD generator was successfully built and operated by Avco (now Textron Defense Industries) in 1963 and a complete natural gas-fired pilot plant with a nominal 20-MW MHD generator was commissioned in the U.S.S.R. on the northern outskirts of Moscow in 1971. In the decade of the 1980s, development was focused on coal firing as a result of the oil crises of the 1970s and in the U.S. progressed to the point where the technology base was developed for a demonstration plant with a 15-MW MHD generator.

Future Prospects

The two particular attributes of the MHD generator are its rapid start-up to multimegawatt power levels for pulse power applications and its ability to provide a very high overall thermal efficiency for power plants using coal while meeting the most stringent environmental standards. The first has already been utilized in crustal exploration, and the second must surely be utilized when coal is the fuel of choice for electric power production. In the meantime, MHD has been established as a viable technology on which further development work will be conducted for advanced applications such as the conversion system for thermonuclear fusion reactors.

8.14 Ocean Energy Technology

Desikan Bharathan and Federica Zangrando

The ocean contains a vast renewable energy potential in its waves and tides, in the temperature difference between cold, deep waters and warm surface waters, and in the salinity differences at river mouths (SERI, 1990; WEC, 1993; Cavanagh et al., 1993). Waves offer a power source for which numerous systems have been conceived. Tides are a result of the gravity of the sun, the moon, and the rotation of the Earth working together. The ocean also acts as a gigantic solar collector, capturing the energy of the sun in its surface water as heat. The temperature difference between warm surface waters and cold water from the ocean depths provides a potential source of energy. Other sources of ocean energy include ocean currents, salinity gradients, and ocean-grown biomass.

The following sections briefly describe the status and potential of the various ocean energy technologies, with emphasis placed on those with a near-term applicability.

Ocean Thermal Energy Conversion

Ocean thermal energy conversion (OTEC) technology is based on the principle that energy can be extracted from two reservoirs at different temperatures (SERI, 1989). A temperature difference as little as 20°C can be exploited effectively to produce usable energy. Temperature differences of this magnitude prevail between ocean waters at the surface and at depths up to 1000 m in many areas of the world, particularly in tropical and subtropical latitudes between 24° north and south of the equator. Here, surface water temperatures typically range from 22 to 29°C, while temperatures at a depth of 1000 m range from 4 to 6°C. This constitutes a vast, renewable resource, estimated at 10^{13} W, for potential baseload power generation.

Recent research has been concentrated on two OTEC power cycles, namely, **closed-cycle** and **open-cycle**, for converting this thermal energy to electrical energy (Avery and Wu, 1994). Both cycles have been demonstrated, but no commercial system is yet in operation. In a closed-cycle system, warm seawater is used to vaporize a working fluid such as ammonia flowing through a heat exchanger (evaporator). The vapor expands at moderate pressures and turns a turbine. The vapor is condensed in another heat exchanger (condenser) using cold seawater pumped from the ocean depths through a cold-water pipe. The condensed working fluid is pumped back to the evaporator to repeat the cycle. The working fluid remains in a closed system and is continuously circulated. In an open cycle system, the warm seawater is "flash" evaporated in a vacuum chamber to make steam at an absolute pressure of about 2.4 kPa. The steam expands through a low-pressure turbine coupled to a generator to produce electricity. The steam exiting the turbine is condensed by using cold seawater pumped from the ocean depths through a cold-water pipe. If a surface condenser is used, condensed steam provides desalinated water.

Effluent from either a closed cycle or an open cycle system can be further processed to enhance production of desalinated water through a flash evaporator/condenser system in a second stage.

For combined production of power and water, these systems are estimated to be competitive with conventional systems in several coastal markets.

Tidal Power

The energy from tides is derived from the kinetic energy of water moving from a higher to a lower elevation, as for hydroelectric plants. High tide can provide the potential energy for seawater to flow into an enclosed basin or estuary that is then discharged at low tide (Ryan, 1980). Electricity is produced from the gravity-driven inflow or outflow (or both) through a turbogenerator. The tidal resource is variable but quite predictable, and there are no significant technical barriers for deployment of this technology. Because costs are strongly driven by the civil works required to dam the reservoir, only a few sites around the world have the proper conditions of tides and landscape to lend themselves to this technology.

© 1999 by CRC Press LLC

Although it has benefited from some recent developments in marine and offshore construction that significantly reduce construction time and costs, the economics of tidal power production still does not make it competitive with conventional energy systems.

The highest tides in the world can reach above 17 m, as in the Bay of Fundy between Maine and Nova Scotia, where it is projected that up to 10,000 MW could be produced by tidal systems in this bay alone. A minimum tidal range (difference between mean high and low tides) of 5 m is required for plants using conventional hydroelectric equipment (horizontal axial-flow water turbines housed in underwater bulbs or Straflo turbines). More recently, low-head hydroelectric power equipment has proved adaptable to tidal power and new systems for 2-m heads have been proposed.

There are a few tidal power stations operating in France, the former U.S.S.R., China, and Canada. The largest and longest-operating plant is the 240-MW tidal power station on the Rance River estuary in northern France (Banal and Bichon, 1981), which has operated with 95% availability since 1968. The 400-kW tidal plant in Kislaya Bay on the Barents Sea in the former U.S.S.R. has been operating since 1968; at this favorable site only a 50-m-wide dam was needed to close the reservoir. The 20-MW Canadian plant at Annapolis on the Bay of Fundy uses a Straflo turbine generator and has operated reliably since 1984. A number of small-bulb and Straflo turbine generator plants of up to 4 MW are also installed on the China coastline.

Wave Power

Waves contain significant power which can be harnessed by shore-mounted or offshore systems, the latter having larger incident power on the device but requiring more costly installations. A myriad of wave-energy converter concepts have been devised, transforming wave energy into other forms of mechanical (rotative, oscillating, or relative motion), potential, or pneumatic energy, and ultimately into electricity; very few have been tested at sea.

The power per unit frontal length of the wave is proportional to wave height squared and to wave period, with their representative values on the order of 2 m and 10 sec. The strong dependence on wave height makes the resource quite variable, even on a seasonal and a yearly average basis. The northeastern Pacific and Atlantic coasts have average yearly incident wave power of about 50 kW/m, while near the tip of South America the average power can reach 100 kW/m. Japan, on the other hand, receives an average of 15 kW/m. Waves during storms can reach 200 kW/m, but these large waves are unsafe for operation because of their severity, and they impose significant constraints and additional costs on the system. Overall, the amount of power that could be harvested from waves breaking against world coastlines is estimated to be on the order of the current global consumption of energy. However, total installed capacity amounts to less than 1 MW worldwide.

A commonly deployed device is the oscillating water column (OWC), which has so far been mounted on shore but is also proposed for floating plants. It consists of an air chamber in contact with the sea so that the water column in the chamber oscillates with the waves. This motion compresses the air in the chamber, which flows in and out of a Wells turbine. This turbine can be self-rectifying, i.e., it uses the airflow in both directions, and it consists of a simple rotor, with symmetrical airfoil blades attached tangentially to a central disk. Inertial energy storage (flywheels) is often used to even out the variable pneumatic energy delivered by the air.

Two of the largest wave-energy power plants were built at Toftestallen, near Bergen, Norway. A Norwegian company, Norwave A.S., built a 350-kW tapered channel (Tapchan) device in 1984, which survived a severe storm in 1989 (the 500 kW multi-resonant OWC plant built by Kvaerner Brug A.S. did not). The channel takes advantage of the rocky coastline to funnel waves through a 60-m-wide opening into a coastal reservoir of 5500 m^2, while maintaining civil engineering costs to a minimum. Wave height increases as the channel narrows over its 60-m length, and the rising waves spill over the 3-m-high channel walls, filling the reservoir. Continuous wave action maintains the reservoir level at a relatively constant elevation above sea level, providing potential energy for a low-head hydroelectric Kaplan turbogenerator. Estimates by Norwave to rebuild an identical plant at this site suggested capital

© 1999 by CRC Press LLC

costs of $3500/kW installed, and energy costs of 8¢/kWhr, at a plant capacity factor of 25% (ASCE, 1992). In recent efforts, the National Institute of Ocean Technology has installed a 150-kW wave-energy conversion device in the southern tip of India.

Concluding Remarks

Among the many ocean energy prospects, OTEC, tides, and tapered channel wave-energy converters offer the most near-term potential and possess applicability for a large variety of sites. To realize their potential, additional research and development is required.

Defining Terms

Ocean thermal energy conversion (OTEC): A system that utilizes the temperature difference between the seawater at the surface and at depths.

Closed-cycle OTEC: Uses a working fluid in a closed cycle.

Open-cycle OTEC: Uses steam flashed from the warm seawater as the working fluid which is condensed and exhausted.

In the past two decades, several cycles which combine the gas turbine and the steam turbine have become available with good fuel utilization compared with other available power plants. The first ones in the 1970s had net plant efficiencies of about 40% with the most recent ones achieving net plant efficiencies of over 55%.

One way to utilize the energy available in gas turbine exhaust gases is as the energy source for a steam power plant. This is called a *combined cycle* and uses components from two systems which have independently proved themselves. The combined cycle power plant usually consists of one or more gas turbine engines exhausting into a heat-recovery steam generator (HRSG) where the energy is transferred from the exhaust gases to the water in the steam power plant.

The simplest arrangement for a combined cycle power plant is the single-pressure system as illustrated in Figure 8.15.1. It consists of the HRSG, a turbine, condenser, and pump. In this simplified configuration, it is assumed that no additional fuel is burned between the gas turbine and the HRSG.

The gases leaving the gas turbine engine enter the HRSG at state 4 and leave the HRSG at state 5. The water in the steam cycle portion of the combined cycle enters the HRSG economizer as a subcooler liquid (state a). The temperature of the water is increased in the economizer until it is a saturated liquid (state m). This is the point where the minimum temperature difference between the water in the steam cycle and the exhaust gases occurs and is called the *pinch point*. Typical pinch point values range from 10 to 30°C; the smaller the pinch point difference, the larger the required heat-transfer surface area. From state m to state v, the water is changed from a saturated liquid to a saturated vapor. From state v to state d, the water is superheated where it has its maximum temperature. A typical temperature-heat transfer diagram for this single-pressure steam turbine combined cycle is illustrated in Figure 8.15.2.

One should note that there is a significant difference between the desired feedwater conditions of a combined cycle power plant and a conventional steam power plant. In a combined cycle power plant, it is desirable to have the temperature of the water at as low a temperature as possible as it enters the HRSG to permit the maximum amount of energy to be transferred from the exhaust gases to the water

© 1999 by CRC Press LLC

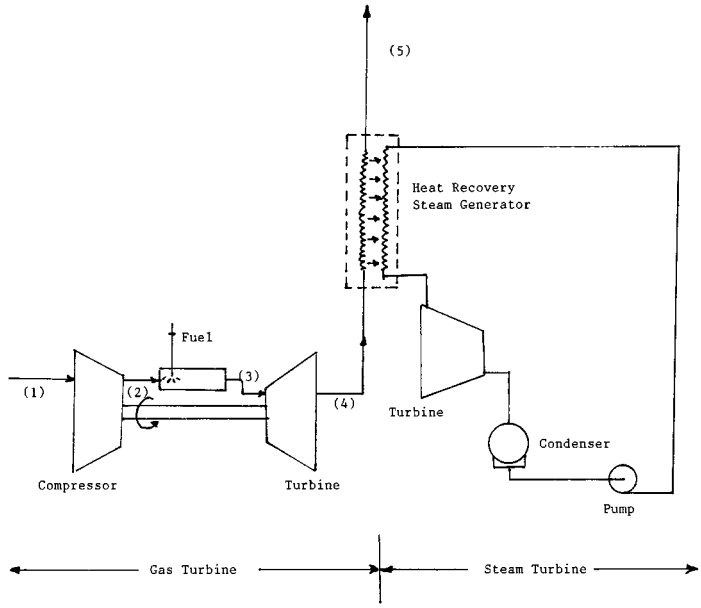

FIGURE 8.15.1 Combined cycle power plant with no supplementary firing.

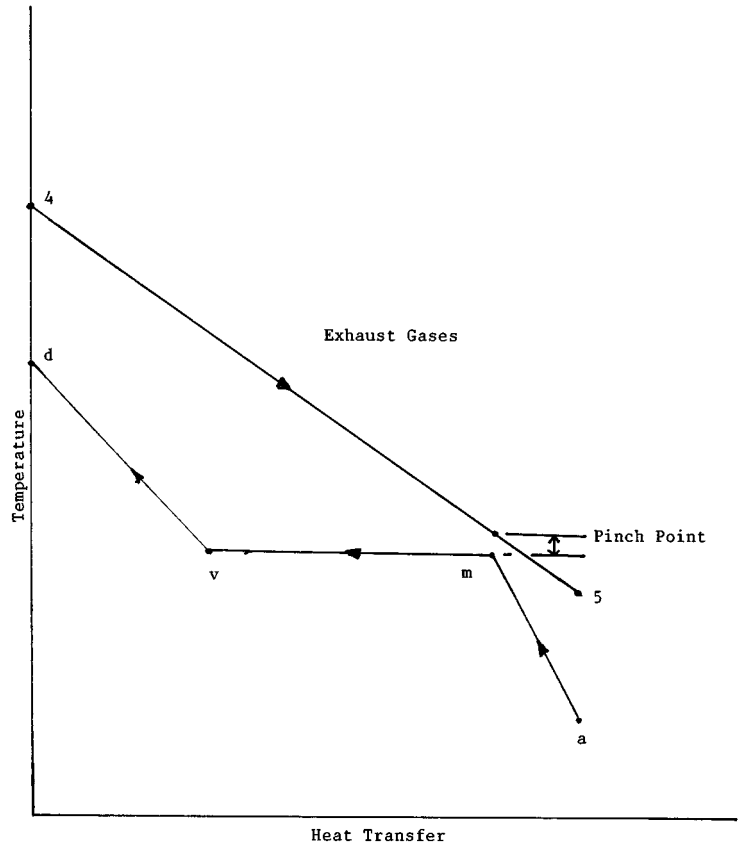

FIGURE 8.15.2 Typical temperature-heat transfer diagram for a single-pressure combined cycle power plant.

© 1999 by CRC Press LLC

since the more energy transferred, the greater the amount of power produced by the steam turbine and the higher the combined cycle thermal efficiency or the lower the heat rate. In a conventional steam cycle power plant, the higher the feedwater temperature as it enters the steam generator (boiler), the higher the cycle thermal efficiency. Conventional steam cycle power plants achieve the higher feedwater temperature by the use of feedwater heaters.

Table 8.15.2 lists net plant output, heat rate, and net plant efficiency values for several combined cycles. One should observe for the units listed in Table 8.15.2 that

1. The size varies widely from a low of 22,800 kW to a high of 711,000 kW;
2. The heat rates vary from 7880 to 5885 Btu/kWhr. These compare with heat rate values for the gas turbines listed in Table 8.15.1 that vary from a high of 12,544 Btu/kWhr to a low of 8980 Btu/kWhr.
3. The net plant efficiency varies from a low of 42.8% to a high of 57.0%;
4. The fraction of the total net plant output from the steam turbine power plant in most cases ranges from 35 to 39%.

TABLE 8.15.2 Net Plant Output, Heat Rate, and Net Plant Efficiency for Several Combined Cycles

Source: 1995 Handbook, Gas Turbine World, Southport, CT, 1995. With permission.

One should keep in mind that only a few of the combined cycle plants currently available are listed in Table 8.15.2. The ones listed are intended to illustrate the range in net plant output and heat rate values and should not be interpreted as a list of all units currently available.

The amount of energy transferred in the HRSG is dependent on the steam pressure. This is illustrated in Figure 8.15.3. In this comparison, it is assumed in both cases that the steam exit temperature is the same and that the exhaust gas HRSG inlet temperature and flow rate are the same. One observes that the pressure of the water dictates the temperature at which evaporation occurs. The higher the evaporation temperature (and therefore steam pressure), the lower the mass flow rate of the steam, and therefore the lower the power generated by the steam power plant. It is obvious that the lower the steam pressure, the lower the flue gas temperature.

The output of an unfired single-pressure combined cycle power plant is determined by the gas turbine selected since this fixes the temperature and mass flow rate of the exhaust gases. One way to increase the steam cycle output is to introduce supplementary firing in the exhaust duct between the gas turbine exit and HRSG inlet. This is shown schematically in Figure 8.15.4. The advantages of adding supplementary firing are

© 1999 by CRC Press LLC

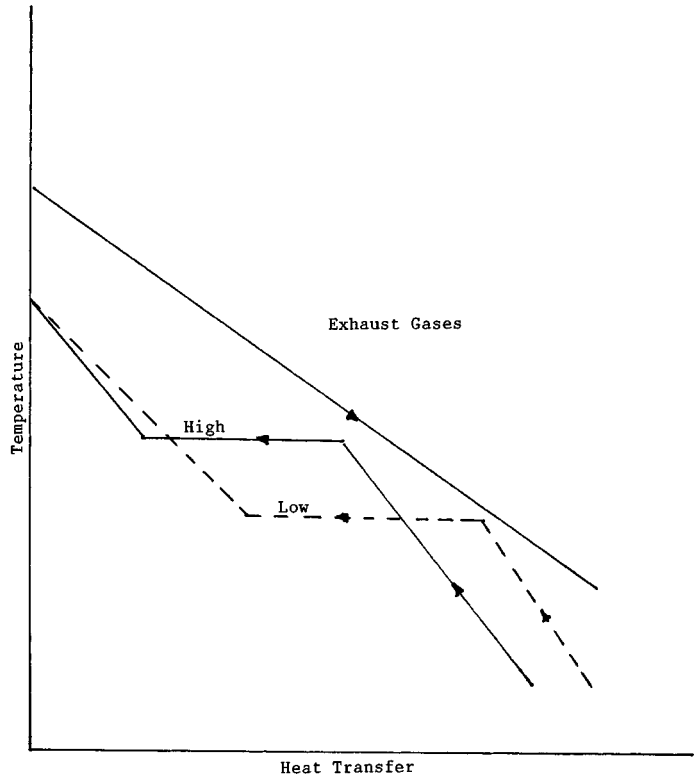

FIGURE 8.15.3 Effect of steam cycle pressure on energy transferred for a single-pressure combined cycle power plant.

1. The total output from the combined cycle will increase with a higher fraction of the output coming from the steam turbine cycle;
2. The temperature at the inlet to the HRSG can be controlled. This is important since the temperature and mass flow rate at the exit from the gas turbine are very dependent on the ambient temperature.

Figure 8.15.5 illustrates the effect on the temperature of the exhaust gases at the exit from the HRSG for unfired and supplementary fired combined cycles with the same pinch point temperature.

Combined cycle power plants with a single-pressure steam turbine do not maximize utilization of the energy in the exhaust gases. The ideal temperature-heat transfer diagram would be one where the temperature difference in the HRSG between the water (steam) and the exhaust gases is a constant.

One way to approach this constant temperature difference and improve the utilization of the energy in the exhaust gases is to use multipressures in the steam power plant cycle. Systems which have been used are

1. A dual pressure nonreheat cycle;
2. A dual-pressure reheat cycle; and
3. A triple-pressure reheat cycle.

Each system listed above has advantages and disadvantages. As new gas turbine engines enter the market with increased turbine inlet temperatures and component efficiencies, exhaust temperature from the gas turbine increases. This allows for higher superheated steam temperatures and improved combined cycle power plant efficiencies. This means that each design must be analyzed so that the selected design yields the most economical system.

8.16 EMERGY Evaluation and Transformity

Howard T. Odum

EMERGY (spelled with an "m") evaluation is a method of energy analysis that puts all inputs and products on a common basis of what was previously required directly and indirectly to make each from one form of energy.

> EMERGY is the available energy of one kind previously used up directly and indirectly to make a service or product.

Its unit is the *emjoule,* defined to measure availability already used up. If average solar insolation at the earth's surface is chosen as the common base for the convenience of evaluating environmental and technological energy flows, then evaluations are made in units of solar emjoules, abbreviated sej.

In every energy transformation, available energy is used up to produce a smaller amount of energy of another kind. The EMERGY of one kind required directly and indirectly to make one unit of energy of another kind is defined as *transformity* (Odum, 1988).

> Solar transformity is the solar EMERGY of the inputs divided by the energy of the output.

$$\text{energy (J)} \times \text{transformity (sej/J)} = \text{EMERGY (sej)}$$

If all energy flows are expressed in solar EMERGY, then all kinds of energy may be compared according to their solar transformity. The more successive energy transformations there are, the higher the transformity. The higher the transformity, the more energy flows have converged in the process. Since many energy flows of one kind are usually required to support a smaller energy flow of another type, it is appropriate to describe the converging process as an *energy hierarchy.* The more transformations there are, the higher the transformity and the higher the position in a universal energy hierarchy. Figure 8.16.1 shows an environmental food chain with more energy flow but lower quality units (lower transformity) on the left and small total energy flow through high transformity units on the right. A land example is sunlight-grass-sheep-people. An aquatic series is sunlight-phytoplankton-zooplankton-small fish-large fish.

In environment, engineering, and economics the selective process of self organization generates higher quality energy capable of amplifying other processes. Thus observed transformitites are a measure of energy quality. Tables of solar transformity have been prepared based on previous EMERGY analysis (Odum, 1996). See sample in Table 8.16.1

Empower is the EMERGY used per unit time, for the United States about 8.5 E24 solar emjoules per year, a measure of the nation's processing of real wealth. By dividing the gross economic product ($6.5 trillion per year) the *EMERGY/money ratio* results (1.3 trillion solar emjoules per dollar). This is real wealth buying power of a dollar.

After an EMERGY evaluation is made, the solar EMERGY of each item can be divided by the *EMERGY*/money ratio to determine the *emdollars*, the buying power contributed by that item.

> *Emdollars are defined as the dollars of gross economic product due to that much real wealth measured as EMERGY.*

Because it puts all forms of available energy on a common basis, EMERGY may be the correct way to evaluate useful work. If real wealth comes from work, maximizing EMERGY production and use maximizes the real wealth of an economy. Selecting alternatives to maximize empower and emdollars is a new tool for engineering design and public policy.

Many energy analysis procedures add available energy as an exergy sum. However, EMERGY evaluation recognizes that each form of energy is different in its quality and the quantity of energy of other kinds required to make it. As shown in the EMERGY evaluation example (Table 8.16.2), each energy value is multiplied by its transformity so as to convert all items to solar EMERGY.

				6.2	477
7	Sum of inputs			10.8	830
8	Lignite yield	2.0 E14 J	3.68 E4/J	73.6	5661

[*] Analysis of Big Brown Plant, Fairfield, Texas (Odum et al., 1987, revised).

[#] Solar empower in Column 5 divided by 1.3 E12 sej/$ for U.S.A., 1995. Net EMERGY ratio = Yield/Inputs = 73.6/10.8 = 6.8

An Example of EMERGY Evaluation, Lignite

The evaluation procedure starts with an aggregated systems diagram to relate inputs, outputs, and main processes. This is used to identify line items in an evaluation table. An example is the analysis of lignite processing at the Big Brown Mine in Fairfield, Texas. Line items for the EMERGY evaluation in Table 8.16.2 were identified from the summarizing systems diagram in Figure 8.16.2. The net EMERGY ratio relates the EMERGY yield to the EMERGY required for the processing. The net EMERGY ratio of 6.8 (Table 8.16.2) means that 6.8 times more real wealth was contributed to the economy than required in the processing. The operation contributed 5.6 million emdollars per day to the economy as lignite yield, almost 12 times more than the economic value of $477,000 dollars per day.

Defining Terms

EMERGY: Available energy of one kind previously required directly and indirectly to make a product or service (unit: emjoules). Example: solar emjoules (abbreviation: sej).

Transformity: EMERGY per unit available energy (units: emjoules per joule). Example: solar emjoules per joule (abbreviation: sej/J).

Empower: EMERGY flow per unit time (units: emjoules per time). Example: solar emjoules per year (abbreviation: sej/yr).

Emdollars: EMERGY divided by EMERGY/money ratio. (abbreviation Em$).

Net EMERGY ratio: Yield EMERGY/EMERGY of purchased inputs.

9.1 Introduction

Air-Conditioning

Air-conditioning is a process that simultaneously conditions air; distributes it combined with the outdoor air to the conditioned space; and at the same time controls and maintains the required space's temperature, humidity, air movement, air cleanliness, sound level, and pressure differential within predetermined limits for the health and comfort of the occupants, for product processing, or both.

The acronym HVAC&R stands for heating, ventilating, air-conditioning, and refrigerating. The combination of these processes is equivalent to the functions performed by air-conditioning.

Because I-P units are widely used in the HVAC&R industry in the U.S., I-P units are used in this chapter. A table for converting I-P units to SI units is available in Appendix X of this handbook.

Air-Conditioning Systems

An *air-conditioning* or *HVAC&R system* consists of components and equipment arranged in sequential order to heat or cool, humidify or dehumidify, clean and purify, attenuate objectionable equipment noise, transport the conditioned outdoor air and recirculate air to the conditioned space, and control and maintain an indoor or enclosed environment at optimum energy use.

The types of buildings which the air-conditioning system serves can be classified as:

- Institutional buildings, such as hospitals and nursing homes
- Commercial buildings, such as offices, stores, and shopping centers

© 1999 by CRC Press LLC

- Residential buildings, including single-family and multifamily low-rise buildings of three or fewer stories above grade
- Manufacturing buildings, which manufacture and store products

Types of Air-Conditioning Systems

In institutional, commercial, and residential buildings, air-conditioning systems are mainly for the occupants' health and comfort. They are often called *comfort air-conditioning systems*. In manufacturing buildings, air-conditioning systems are provided for product processing, or for the health and comfort of workers as well as processing, and are called *processing air-conditioning systems*.

Based on their size, construction, and operating characteristics, air-conditioning systems can be classified as the following.

Individual Room or Individual Systems. An individual air-conditioning system normally employs either a single, self-contained, packaged room air conditioner (installed in a window or through a wall) or separate indoor and outdoor units to serve an individual room, as shown in Figure 9.1.1. "Self-contained, packaged" means factory assembled in one package and ready for use.

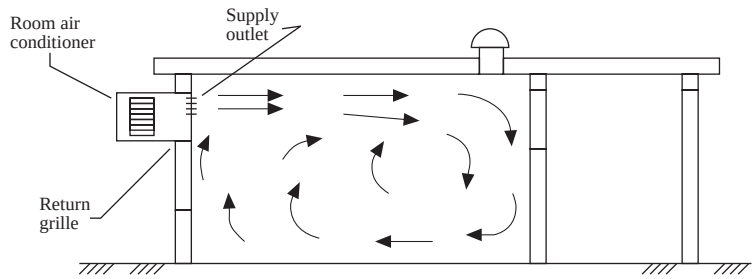

FIGURE 9.1.1 An individual room air-conditioning system.

Space-Conditioning Systems or Space Systems. These systems have their air-conditioning—cooling, heating, and filtration—performed predominantly in or above the conditioned space, as shown in Figure 9.1.2. Outdoor air is supplied by a separate outdoor ventilation system.

Unitary Packaged Systems or Packaged Systems. These systems are installed with either a single self-contained, factory-assembled packaged unit (PU) or two split units: an indoor air handler, normally with ductwork, and an outdoor condensing unit with refrigeration compressor(s) and condenser, as shown in Figure 9.1.3. In a packaged system, air is cooled mainly by direct expansion of refrigerant in coils called DX coils and heated by gas furnace, electric heating, or a heat pump effect, which is the reverse of a refrigeration cycle.

Central Hydronic or Central Systems. A central system uses chilled water or hot water from a central plant to cool and heat the air at the coils in an air handling unit (AHU) as shown in Figure 9.1.4. For energy transport, the heat capacity of water is about 3400 times greater than that of air. Central systems are built-up systems assembled and installed on the site.

Packaged systems are comprised of only air system, refrigeration, heating, and control systems. Both central and space-conditioning systems consist of the following.

Air Systems. An air system is also called an air handling system or the air side of an air-conditioning or HVAC&R system. Its function is to condition the air, distribute it, and control the indoor environment according to requirements. The primary equipment in an air system is an AHU or air handler; both of these include fan, coils, filters, dampers, humidifiers (optional), supply and return ductwork, supply outlets and return inlets, and controls.

© 1999 by CRC Press LLC

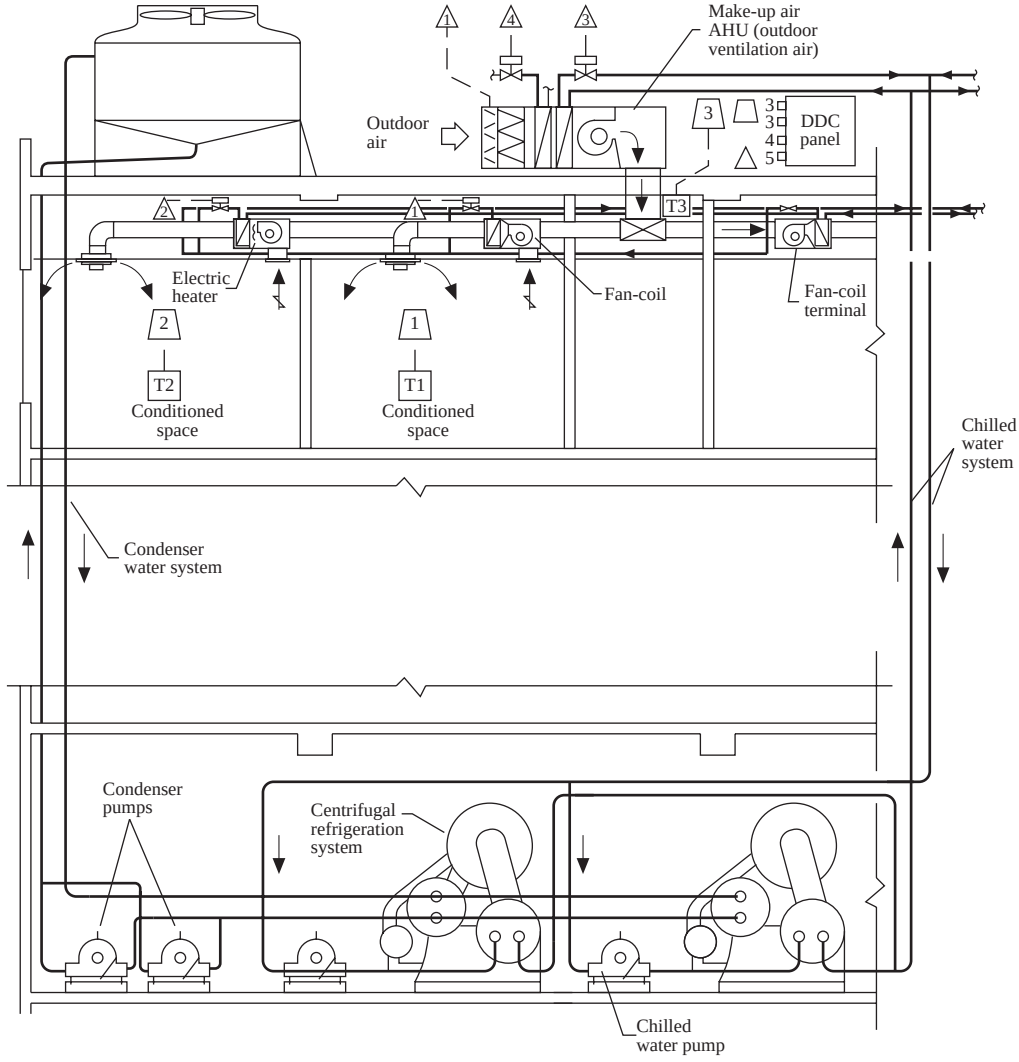

FIGURE 9.1.2 A space-conditioning air-conditioning system (fan-coil system).

Water Systems. These systems include chilled water, hot water, and condenser water systems. A water system consists of pumps, piping work, and accessories. The water system is sometimes called the water side of a central or space-conditioning system.

Central Plant Refrigeration and Heating Systems. The refrigeration system in the central plant of a central system is usually in the form of a chiller package with an outdoor condensing unit. The refrigeration system is also called the refrigeration side of a central system. A boiler and accessories make up the heating system in a central plant for a central system, and a direct-fired gas furnace is often the heating system in the air handler of a rooftop packaged system.

Control Systems. Control systems usually consist of sensors, a microprocessor-based direct digital controller (DDC), a control device, control elements, personal computer (PC), and communication network.

Based on Commercial Buildings Characteristics 1992, Energy Information Administration (EIA) of the Department of Energy of United States in 1992, for commercial buildings having a total floor area

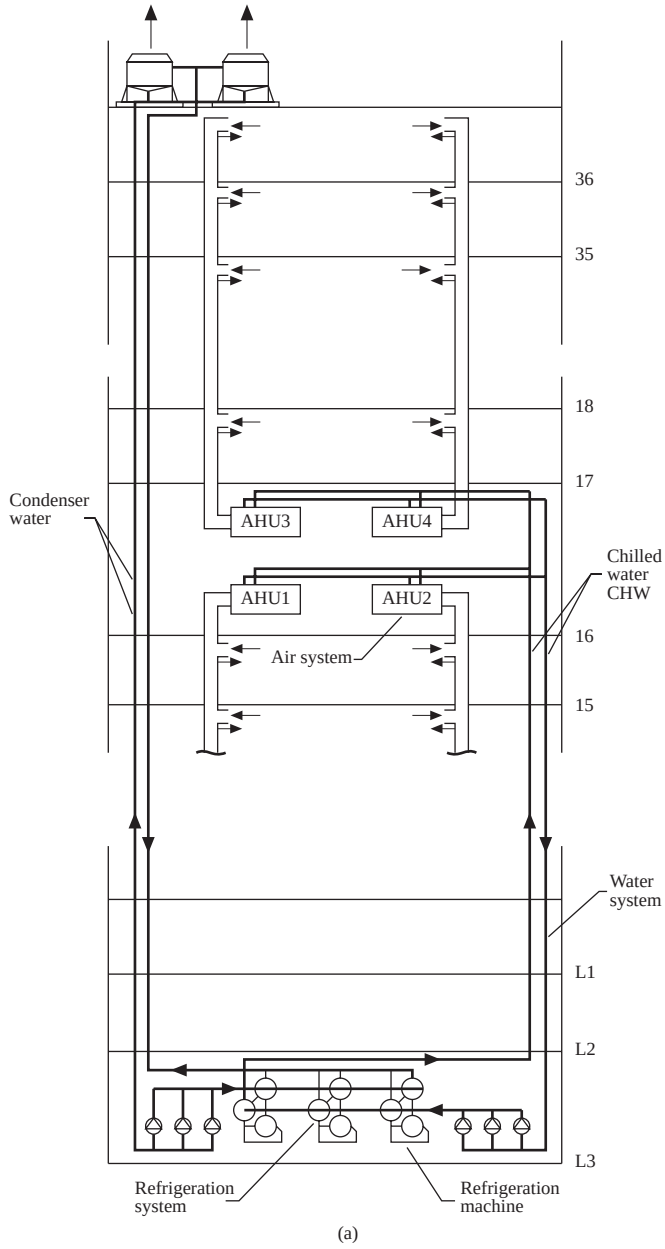

FIGURE 9.1.4a A central air-conditioning system: schematic diagram.

of 67,876 million ft², of which 57,041 million ft² or 84% is cooled and 61,996 million ft² or 91% is heated, the air-conditioning systems for cooling include:

Individual systems	19,239 million ft²	(25%)
Packaged systems	34,753 million ft²	(49%)
Central systems	14,048 million ft²	(26%)

Space-conditioning systems are included in central systems. Part of the cooled floor area has been counted for both individual and packaged systems. The sum of the floor areas for these three systems therefore exceeds the total cooled area of 57,041 million ft².

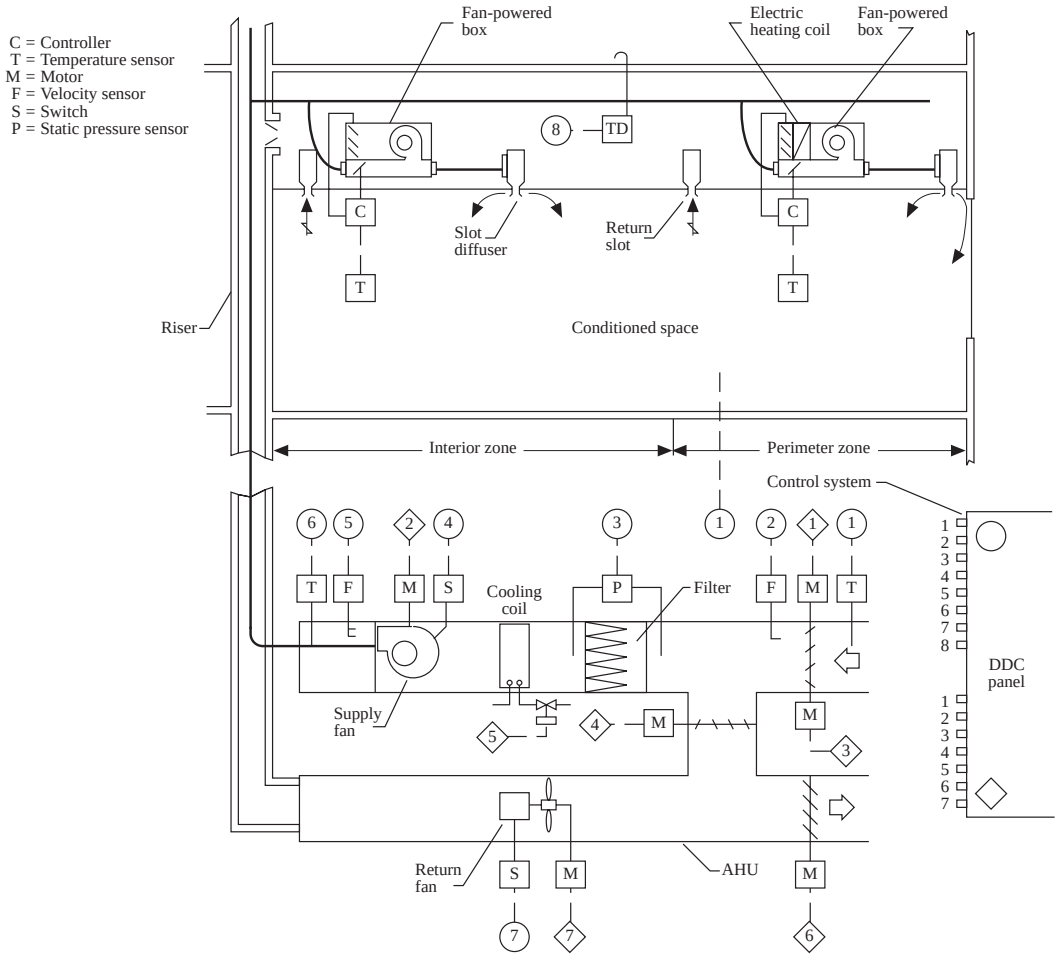

FIGURE 9.1.4b A central air-conditioning system: air and control systems for a typical floor.

Air-Conditioning Project Development and System Design

The goal of an air-conditioning/HVAC&R system is to provide a healthy and comfortable indoor environment with acceptable indoor air quality, while being energy efficient and cost effective.

ASHRAE Standard 62-1989 defines *acceptable indoor air quality* as "air in which there are no known contaminants at harmful concentrations as determined by cognizant authorities and with which a substantial majority (80% or more) of the people exposed do not express dissatisfaction."

The basic steps in the development and use of an air-conditioning project are design, installation, commissioning, operation, and maintenance. There are two types of air-conditioning projects: *design-bid* and *design-build*. A design-bid project separates the design (engineering consultant) and installation (contractors) responsibilities. In a design-build project, the design is also done by the installation contractor. A design-build project is usually a small project or a project having insufficient time to go through normal bidding procedures.

In the building construction industry, air-conditioning or HVAC&R is one of the *mechanical services*; these also include plumbing, fire protection, and escalators.

Air-conditioning design is a process of selecting the optimum system, subsystem, equipment, and components from various alternatives and preparing the drawings and specifications. Haines (1994) summarized this process in four phases: gather information, develop alternatives, evaluate alternatives,

© 1999 by CRC Press LLC

and sell the best solution. Design determines the basic operating characteristics of a system. After an air-conditioning system is designed and constructed, it is difficult and expensive to change its basic characteristics.

The foundation of a successful project is teamwork and coordination between designer, contractor, and operator and between mechanical engineer, electrical engineer, facility operator, architect, and structural engineer.

Field experience is helpful to the designer. Before beginning the design process it is advisable to visit similar projects that have operated for more than 2 years and talk with the operator to investigate actual performance.

Mechanical Engineer's Responsibilities

The normal procedure in a design-bid construction project and the mechanical engineer's responsibilities are

1. Initiation of a project by owner or developer
2. Organizing a design team
3. Determining the design criteria and indoor environmental parameters
4. Calculation of cooling and heating loads
5. Selection of systems, subsystems, and their components
6. Preparation of schematic layouts; sizing of piping and ductwork
7. Preparation of contract documents: drawings and specifications
8. Competitive biddings by various contractors; evaluation of bids; negotiations and modifications
9. Advice on awarding of contract
10. Monitoring, supervision, and inspection of installation; reviewing shop drawings
11. Supervision of commissioning
12. Modification of drawings to the as-built condition; preparation of the operation and maintenance manual
13. Handing over to the property management for operation

Design Documents

Drawings and *specifications* are legal documents of a construction contract. The designer conveys the owner's or developer's requirements to the contractor through these documents. Drawings and specifications complement each other.

Drawings should clearly and completely show, define, and present the work. Adequate plan and sectional views should be drawn. More often, isometric drawings are used to show the flow diagrams for water or the supply, return, and exhaust air.

Specifications include the legal contract between the owner and the contractor, installer, or vendor and the technical specifications, which describe in detail what kind of material and equipment should be used and how they are to be installed.

Most projects now use a format developed by the Construction Specifications Institute (CSI) called the Masterformat for Specifications. It includes 16 divisions. The 15000 Mechanical division is divided into the following:

Section No.	Title
15050	Basic Mechanical Materials and Methods
15250	Mechanical Insulation
15300	Fire Protection
15400	Plumbing
15500	Heating, Ventilating, and Air-Conditioning
15550	Heat Generation
15650	Refrigeration
15750	Heat Transfer
15850	Air Handling

© 1999 by CRC Press LLC

Section No.	Title
15880	Air Distribution
15950	Controls
15990	Testing, Adjusting, and Balancing

Each section includes general considerations, equipment and material, and field installation. Design criteria and selected indoor environmental parameters that indicate the performance of the HVAC&R system must be clearly specified in the general consideration of Section 15500.

There are two types of specifications: the performance specification, which depends mainly on the required performance criteria, and the or-equal specification, which specifies the wanted vendor. Specifications should be written in simple, direct, and clear language without repetition.

Computer-Aided Design and Drafting

With the wide acceptance of the PC and the availability of numerous types of engineering software, the use of *computer-aided drafting* (CAD) and *computer-aided design and drafting* (CADD) has increased greatly in recent years. According to the 1994 CADD Application and User Survey of design firms reported in *Engineering Systems* (1994[6]), "15% of the design firms now have a computer on every desk" and "Firms with high productivity reported that they perform 95% on CADD." Word processing software is widely used to prepare specifications.

Drafting software used to reproduce architectural drawings is the foundation of CADD. Automated CAD (AutoCAD) is the leading personal computer-based drafting tool software used in architectural and engineering design firms.

In "Software Review" by Amistadi (1993), duct design was the first HVAC&R application to be integrated with CAD.

- Carrier Corp. DuctLINK and Softdesk HVAC 12.0 are the two most widely used duct design software. Both of them convert the single-line duct layout drawn with CAD to two-dimensional (2D) double-line drawings with fittings, terminals, and diffusers.
- Tags and schedules of HVAC&R equipment, ductwork, and duct fittings can be produced as well.
- DuctLINK and Softdesk can also interface with architectural, electrical, and plumbing drawings through AutoCAD software.

Software for piping system design and analysis can also be integrated with CAD. The software developed at the University of Kentucky, KYCAD/KYPIPE, is intended for the design and diagnosis of large water piping systems, has extensive hydraulic modeling capacities, and is the most widely used. Softdesk AdCADD Piping is relative new software; it is intended for drafting in 2D and 3D, linking to AutoCAD through design information databases.

Currently, software for CADD for air-conditioning and HVAC&R falls into two categories: engineering and product. The engineering category includes CAD (AutoCAD integrated with duct and piping system), load calculations and energy analysis, etc. The most widely used software for load calculations and energy analysis is Department of Energy DOE-2.1D, Trane Company's TRACE 600, and Carrier Corporation's softwares for load calculation, E20-II Loads.

Product categories include selection, configuration, performance, price, and maintenance schedule. Product manufacturers provide software including data and CAD drawings for their specific product.

Codes and Standards

Codes are federal, state, or city laws that require the designer to perform the design without violating people's (including occupants and the public) safety and welfare. Federal and local codes must be followed. The designer should be thoroughly familiar with relevant codes. HVAC&R design codes are definitive concerning structural and electrical safety, fire prevention and protection (particularly for gas- or oil-fired systems), environmental concerns, indoor air quality, and energy conservation.

© 1999 by CRC Press LLC

Conformance with *ASHRAE Standards* is voluntary. However, for design criteria or performance that has not been covered in the codes, whether the ASHRAE Standard is followed or violated is the vital criterion, as was the case in a recent indoor air quality lawsuit against a designer and contractor.

For the purpose of performing an effective, energy-efficient, safe, and cost-effective air-conditioning system design, the following ASHRAE Standards should be referred to from time to time:

- ASHRAE/IES Standard 90.1-1989, Energy Efficient Design of New Buildings Except New Low-Rise Residential Buildings
- ANSI/ASHRAE Standard 62-1989, Ventilation for Acceptable Indoor Air Quality
- ANSI/ASHRAE Standard 55-1992, Thermal Environmental Conditions for Human Occupancy
- ASHRAE Standard 15-1992, Safety Code for Mechanical Refrigeration

© 1999 by CRC Press LLC

9.2 Psychrometrics

Moist Air

Above the surface of the earth is a layer of air called the *atmosphere*, or *atmospheric air*. The lower atmosphere, or homosphere, is composed of moist air, that is, a mixture of dry air and water vapor.

Psychrometrics is the science of studying the thermodynamic properties of moist air. It is widely used to illustrate and analyze the change in properties and the thermal characteristics of the air-conditioning process and cycles.

The composition of dry air varies slightly at different geographic locations and from time to time. The approximate composition of dry air by volume is nitrogen, 79.08%; oxygen, 20.95%; argon, 0.93%; carbon dioxide, 0.03%; other gases (e.g., neon, sulfur dioxide), 0.01%.

The amount of water vapor contained in the moist air within the temperature range 0 to 100°F changes from 0.05 to 3% by mass. The variation of water vapor has a critical influence on the characteristics of moist air.

The equation of state for an ideal gas that describes the relationship between its thermodynamic properties covered in Chapter 2 is

$$pv = RT_R \tag{9.2.1}$$

or

$$pV = mRT_R \tag{9.2.2}$$

where p = pressure of the gas, psf (1 psf = 144 psi)
v = specific volume of the gas, ft^3/lb
R = gas constant, $ftlb_f/lb_m$ °R
T_R = absolute temperature of the gas, °R
V = volume of the gas, ft^3
m = mass of the gas, lb

The most exact calculation of the thermodynamic properties of moist air is based on the formulations recommended by Hyland and Wexler (1983) of the U.S. National Bureau of Standards. The psychrometric charts and tables developed by ASHRAE are calculated and plotted from these formulations. According to Nelson et al. (1986), at a temperature between 0 and 100°F, enthalpy and specific volume calculations using ideal gas Equations (9.2.1) and (9.2.2) show a maximum deviation of 0.5% from the results of Hyland and Wexler's exact formulations. Therefore, ideal gas equations are used in the development and calculation of psychrometric formulations in this handbook.

Although air contaminants may seriously affect human health, they have little effect on the thermodynamic properties of moist air. For thermal analysis, moist air may be treated as a binary mixture of dry air and water vapor.

Applying Dalton's law to moist air:

$$p_{at} = p_a + p_w \tag{9.2.3}$$

where p_{at} = atmospheric pressure of the moist air, psia
p_a = partial pressure of dry air, psia
p_w = partial pressure of water vapor, psia

Dalton's law is summarized from the experimental results and is more accurate at low gas pressure. Dalton's law can also be extended, as the Gibbs-Dalton law, to describe the relationship of internal energy, enthalpy, and entropy of the gaseous constituents in a mixture.

© 1999 by CRC Press LLC

Humidity and Enthalpy

The *humidity ratio* of moist air, *w*, in lb/lb is defined as the ratio of the mass of the water vapor, m_w to the mass of dry air, m_a, or

$$w = m_w / m_a = 0.62198 p_w / \left(p_{at} - p_w\right) \tag{9.2.4}$$

The *relative humidity* of moist air, φ, or RH, is defined as the ratio of the mole fraction of water vapor, x_w, to the mole fraction of saturated moist air at the same temperature and pressure, x_{ws}. Using the ideal gas equations, this relationship can be expressed as:

$$\varphi = x_w / x_{ws}\big|_{T,p} = p_w / p_{ws}\big|_{T,p} \tag{9.2.5}$$

and

$$x_w = n_w / \left(n_a + n_w\right); \quad x_{ws} = n_{ws} / \left(n_a + n_{ws}\right)$$

$$x_a + x_w = 1 \tag{9.2.6}$$

where p_{ws} = pressure of saturated water vapor, psia
T = temperature, °F
n_a, n_w, n_{ws} = number of moles of dry air, water vapor, and saturated water vapor, mol

Degree of saturation μ is defined as the ratio of the humidity ratio of moist air, *w*, to the humidity ratio of saturated moist air, w_s, at the same temperature and pressure:

$$\mu = w / w_s\big|_{T,p} \tag{9.2.7}$$

The difference between φ and μ is small, usually less than 2%.

At constant pressure, the difference in specific enthalpy of an ideal gas, in Btu/lb, is $\Delta h = c_p \Delta T$. Here c_p represents the specific heat at constant pressure, in Btu/lb. For simplicity, the following assumptions are made during the calculation of the *enthalpy* of moist air:

1. At 0°F, the enthalpy of dry air is equal to zero.
2. All water vapor is vaporized at 0°F.
3. The enthalpy of saturated water vapor at 0°F is 1061 Btu/lb.
4. The unit of the enthalpy of the moist air is Btu per pound of dry air and the associated water vapor, or Btu/lb.

Then, within the temperature range 0 to 100°F, the enthalpy of the moist air can be calculated as:

$$\begin{aligned} h &= c_{pd} T + w\left(h_{g0} + c_{ps} T\right) \\ &= 0.240 T + w(1061 + 0.444 T) \end{aligned} \tag{9.2.8}$$

where c_{pd}, c_{ps} = specific heat of dry air and water vapor at constant pressure, Btu/lb°F. Their mean values can be taken as 0.240 and 0.444 Btu/lb°F, respectively.
h_{g0} = specific enthalpy of saturated water vapor at 0°F.

© 1999 by CRC Press LLC

Moist Volume, Density, Specific Heat, and Dew Point

The specific *moist volume v*, in ft^3/lb, is defined as the volume of the mixture of dry air and the associated water vapor when the mass of the dry air is exactly 1 lb:

$$v = V/m_a \tag{9.2.9}$$

where V = total volume of the moist air, ft^3. Since moist air, dry air, and water vapor occupy the same volume,

$$v = R_a T_R / p_{at}(1 + 1.6078w) \tag{9.2.10}$$

where R_a = gas constant for dry air.

Moist air density, often called *air density* ρ, in lb/ft^3, is defined as the ratio of the mass of dry air to the total volume of the mixture, or the reciprocal of the moist volume:

$$\rho = m_a/V = 1/v \tag{9.2.11}$$

The *sensible heat of moist air* is the thermal energy associated with the change of air temperature between two state points. In Equation (9.2.8), $(c_{pd} + wc_{ps})T$ indicates the sensible heat of moist air, which depends on its temperature T above the datum 0°F. *Latent heat of moist air*, often represented by wh_{fg0}, is the thermal energy associated with the change of state of water vapor. Both of them are in Btu/lb. Within the temperature range 0 to 100°F, if the average humidity ratio w is taken as 0.0075 lb/lb, the *specific heat of moist air* c_{pa} can be calculated as:

$$c_{pa} = c_{pd} + wc_{ps} = 0.240 + 0.0075 \times 0.444 = 0.243 \text{ Btu/lb °F} \tag{9.2.12}$$

The *dew point temperature* T_{dew}, in °F, is the temperature of saturated moist air of the moist air sample having the same humidity ratio at the same atmospheric pressure. Two moist air samples of similar dew points T_{dew} at the same atmospheric pressure have the same humidity ratio w and the same partial pressure of water vapor p_w.

Thermodynamic Wet Bulb Temperature and Wet Bulb Temperature

The *thermodynamic wet bulb temperature* of moist air, T^*, is equal to the saturated state of a moist air sample at the end of a constant-pressure, ideal adiabatic saturation process:

$$h_1 + \left(w_s^* - w_1\right)h_w^* = h_s^* \tag{9.2.13}$$

where h_1, h_s^* = enthalpy of moist air at the initial state and enthalpy of saturated air at the end of the constant-pressure, ideal adiabatic saturation process, Btu/lb

w_1, w_s^* = humidity ratio of moist air at the initial state and humidity ratio of saturated air at the end of the constant-pressure, ideal adiabatic saturation process, lb/lb

h_w^* = enthalpy of water added to the adiabatic saturation process at temperature T^*, Btu/lb

An *ideal adiabatic saturation process* is a hypothetical process in which moist air at initial temperature T_1, humidity ratio w_1, enthalpy h_1, and pressure p flows over a water surface of infinite length through a well-insulated channel. Liquid water is therefore evaporated into water vapor at the expense of the sensible heat of the moist air. The result is an increase of humidity ratio and a drop of temperature until the moist air is saturated at the thermodynamic wet bulb temperature T^* during the end of the ideal adiabatic saturation process.

© 1999 by CRC Press LLC

The thermodynamic wet bulb temperature T^* is a unique fictitious property of moist air that depends only on its initial properties, T_1, w_1, or h_1.

A sling-type *psychrometer*, as shown in Figure 9.2.1, is an instrument that determines the temperature, relative humidity, and thus the state of the moist air by measuring its dry bulb and wet bulb temperatures. It consists of two mercury-in-glass thermometers. The sensing bulb of one of them is dry and is called the dry bulb. Another sensing bulb is wrapped with a piece of cotton wick, one end of which dips into a water tube. This wetted sensing bulb is called the wet bulb and the temperature measured by it is called the *wet bulb temperature* T'.

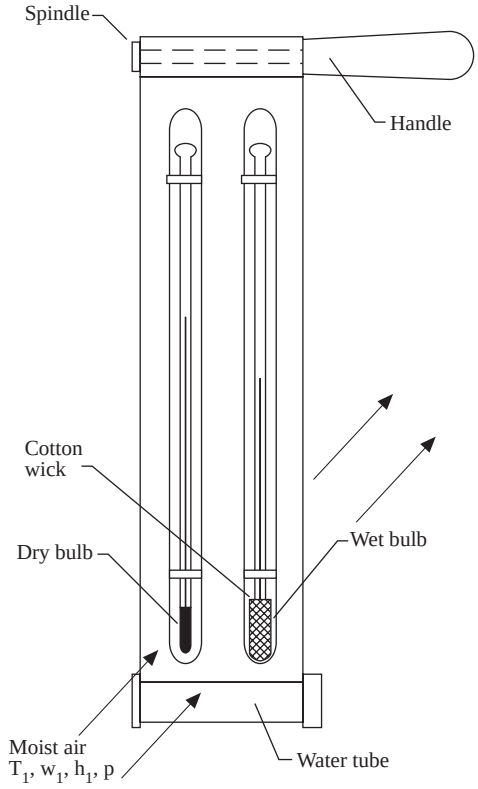

FIGURE 9.2.1 A sling psychrometer.

When unsaturated moist air flows over the surface of the wetted cotton wick, liquid water evaporates from its surface. As it absorbs sensible heat, mainly from the surrounding air, the wet bulb temperature drops. The difference between the dry and wet bulb temperatures is called *wet bulb depression* $(T - T')$. Turning the handle forces the surrounding air to flow over the dry and wet bulbs at an air velocity between 300 to 600 fpm. Distilled water must be used to wet the cotton wick.

At steady state, if heat conduction along the thermometer stems is neglected and the temperature of the wetted cotton wick is equal to the wet bulb temperature of the moist air, as the sensible heat transfer from the surrounding moist air to the cotton wick exactly equals the latent heat required for evaporation, the heat and mass transfer per unit area of the wet bulb surface can be evaluated as:

$$h_c(T - T') + h_r(T_{ra} - T) = h_d(w'_s - w_1) \tag{9.2.14}$$

where h_c, h_r = mean conductive and radiative heat transfer coefficient, Btu/hr ft²°F
h_d = mean convective mass transfer coefficient, lb/hr ft²

© 1999 by CRC Press LLC

T = temperature of undisturbed moist air at a distance from the wet bulb, °F
T_{ra} = mean radiant temperature (covered later), °F
w_1, w'_s = humidity ratio of the moist air and the saturated film at the interface of cotton wick and surrounding air, lb/lb
h'_{fg} = latent heat of vaporization at the wet bulb temperature, Btu/lb

The humidity ratio of the moist air is given by:

$$w_1 = w'_s - K'(T - T')\left(1 + \left\{h_r(T_{ra} - T')/\left[h_c(T - T')\right]\right\}\right)$$

$$K' = c_{pa}\,\mathrm{Le}^{0.6667}/h'_{fg} \tag{9.2.15}$$

where K' = wet bulb constant, which for a sling psychrometer = 0.00218 1/°F
Le = Lewis number

The wet bulb temperature T' depends not only on its initial state but also on the rate of heat and mass transfer at the wet bulb. Therefore, the thermodynamic wet bulb temperature is used in ASHRAE psychrometric charts.

According to Threlkeld (1970), for a sling psychrometer whose wet bulb diameter is 1 in. and for air flowing at a velocity of 400 fpm over the wet bulb, if the dry bulb temperature is 90°F and the measured wet bulb temperature is 70°F, the difference between the measured wet bulb and the thermodynamic wet bulb $(T' - T^*)/(T^* - T')$ is less than 1%.

Psychrometric Charts

A *psychrometric chart* is a graphical presentation of the thermodynamic properties of moist air and various air-conditioning processes and air-conditioning cycles. A psychrometric chart also helps in calculating and analyzing the work and energy transfer of various air-conditioning processes and cycles.

Psychrometric charts currently use two kinds of basic coordinates:

1. *h*-*w* charts. In *h*-*w* charts, enthalpy *h*, representing energy, and humidity ratio *w*, representing mass, are the basic coordinates. Psychrometric charts published by ASHRAE and the Charted Institution of Building Services Engineering (CIBSE) are *h*-*w* charts.
2. *T*-*w* charts. In *T*-*w* charts, temperature *T* and humidity ratio *w* are basic coordinates. Psychrometric charts published by Carrier Corporation, the Trane Company, etc. are *T*-*w* charts.

Figure 9.2.2 shows an abridged ASHRAE psychrometric chart. In the ASHRAE chart:

- A normal temperature chart has a temperature range of 32 to 120°F, a high-temperature chart 60 to 250°F, and a low-temperature chart –40 to 50°F. Since enthalpy is the basic coordinate, temperature lines are not parallel to each other. Only the 120°F line is truly vertical.
- Thermodynamic properties of moist air are affected by atmospheric pressure. The standard atmospheric pressure is 29.92 in. Hg at sea level. ASHRAE also published charts for high altitudes of 5000 ft, 24.89 in. Hg, and 7500 ft, 22.65 in. Hg. Both of them are in the normal temperature range.
- Enthalpy *h*-lines incline downward to the right-hand side (negative slope) at an angle of 23.5° to the horizontal line and have a range of 12 to 54 Btu/lb.
- Humidity ratio *w*-lines are horizontal lines. They range from 0 to 0.28 lb/lb.
- Relative humidity φ-lines are curves of relative humidity 10%, 20%, ... 90% and a saturation curve. A saturation curve is a curve of the locus of state points of saturated moist air, that is, φ = 100%. On a saturation curve, temperature *T*, thermodynamic wet temperature bulb T^*, and dew point temperature T_{dew} have the same value.

© 1999 by CRC Press LLC

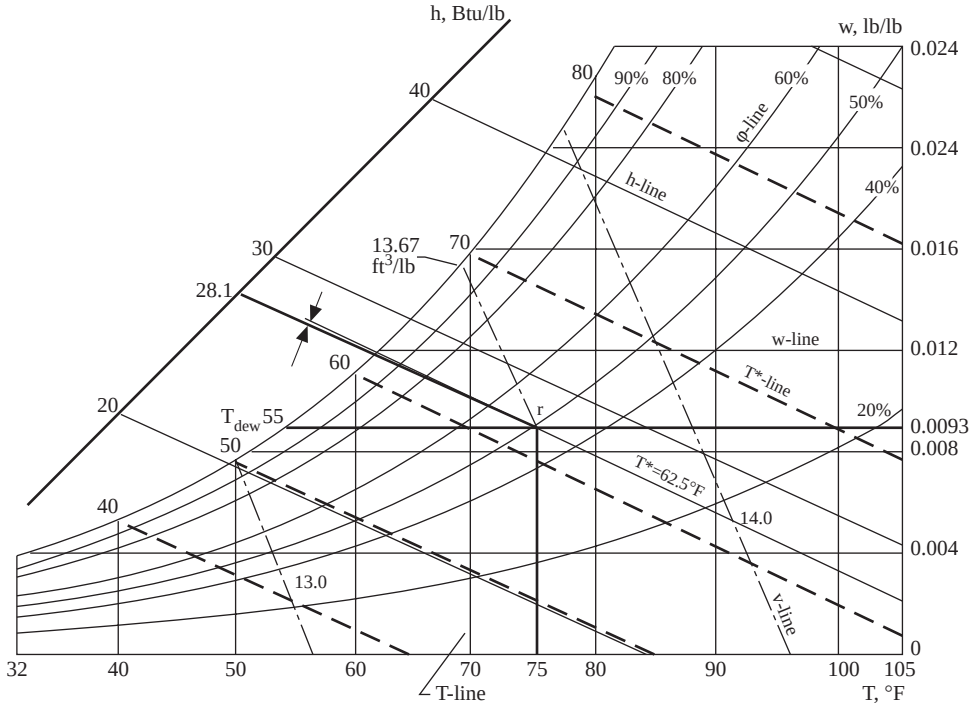

FIGURE 9.2.2 The abridged ASHRAE psychrometric chart and the determination of properties as in Example 9.2.1.

- Thermodynamic wet bulb T^*-lines have a negative slope slightly greater than that of the h-lines. A T^*-line meets the T-line of the same magnitude on the saturation curve.
- Moist volume v-lines have a far greater negative slope than h-lines and T^*-lines. The moist volume ranges from 12.5 to 15 ft^3/lb.

Moist air has seven independent thermodynamic properties or property groups: h, T, φ, T^*, p_{at}, $\rho - v$, and $w - p_w - T_{dew}$. When p_{at} is given, any additional two of the independent properties determine the state of moist air on the psychrometric chart and the remaining properties.

Software using AutoCAD to construct the psychrometric chart and calculate the thermodynamic properties of moist air is available. It can also be linked to the load calculation and energy programs to analyze the characteristics of air-conditioning cycles.

Refer to Wang's *Handbook of Air Conditioning and Refrigeration* (1993) and *ASHRAE Handbook, Fundamentals* (1993) for details of psychrometric charts and psychrometric tables that list thermodynamic properties of moist air.

Example 9.2.1

An air-conditioned room at sea level has an indoor design temperature of 75°F and a relative humidity of 50%. Determine the humidity ratio, enthalpy, density, dew point, and thermodynamic wet bulb temperature of the indoor air at design condition.

Solution

1. Since the air-conditioned room is at sea level, a psychrometric chart of standard atmospheric pressure of 14.697 psi should be used to find the required properties.
2. Plot the state point of the room air at design condition r on the psychrometric chart. First, find the room temperature 75°F on the horizontal temperature scale. Draw a line parallel to the 75°F

© 1999 by CRC Press LLC

temperature line. This line meets the relative humidity curve of 50% at point *r*, which denotes the state point of room air as shown in Figure 9.2.2.

3. Draw a horizontal line toward the humidity ratio scale from point *r*. This line meets the ordinate and thus determines the room air humidity ratio $\varphi_r = 0.0093$ lb/lb.
4. Draw a line from point *r* parallel to the enthalpy line. This line determines the enthalpy of room air on the enthalpy scale, $h_r = 28.1$ Btu/lb.
5. Draw a line through point *r* parallel to the moist volume line. The perpendicular scale of this line indicates $v_r = 13.67$ ft^3/lb.
6. Draw a horizontal line to the left from point *r*. This line meets the saturation curve and determines the dew point temperature, $T_{dew} = 55$°F.
7. Draw a line through point *r* parallel to the thermodynamic wet bulb line. The perpendicular scale to this line indicates that the thermodynamic wet bulb temperature $T^* = 62.5$°F.

9.3 Air-Conditioning Processes and Cycles

Air-Conditioning Processes

An *air-conditioning process* describes the change in thermodynamic properties of moist air between the initial and final stages of conditioning as well as the corresponding energy and mass transfers between the moist air and a medium, such as water, refrigerant, absorbent or adsorbent, or moist air itself. The energy balance and conservation of mass are the two principles used for the analysis and the calculation of the thermodynamic properties of the moist air.

Generally, for a single air-conditioning process, heat transfer or mass transfer is positive. However, for calculations that involve several air-conditioning processes, heat supplied to the moist air is taken as positive and heat rejected is negative.

The *sensible heat ratio* (SHR) of an air-conditioning process is defined as the ratio of the change in absolute value of sensible heat to the change in absolute value of total heat, both in Btu/hr:

$$\text{SHR} = \left|q_{\text{sen}}\right| \Big/ \left|q_{\text{total}}\right| = \left|q_{\text{sen}}\right| \Big/ \left(\left|q_{\text{sen}}\right| + \left|q_{1}\right|\right) \tag{9.3.1}$$

For any air-conditioning process, the sensible heat change

$$q_{\text{sen}} = 60\,\mathring{V}_{\text{s}}\,\rho_{\text{s}}\,c_{\text{pa}}\left(T_2 - T_1\right) = 60\,\mathring{m}_{\text{a}}\,c_{\text{pa}}\left(T_2 - T_1\right) \tag{9.3.2}$$

where $\mathring{V}_{\text{s}}$ = volume flow rate of supply air, cfm
ρ_{s} = density of supply air, lb/ft^3
T_2, T_1 = moist air temperature at final and initial states of an air-conditioning process, °F

and the mass flow rate of supply air

$$\mathring{m}_{\text{s}} = \mathring{V}_{\text{s}}\,\rho_{\text{s}} \tag{9.3.3}$$

The latent heat change is

$$q_{1} \approx 60\,\mathring{V}_{\text{s}}\,\rho_{\text{s}}\left(w_2 - w_1\right)h_{\text{fg.58}} = 1060 \times 60\,\mathring{V}_{\text{s}}\,\rho_{\text{s}}\left(w_2 - w_1\right) \tag{9.3.4}$$

where w_2,w_1 = humidity ratio at final and initial states of an air-conditioning process, lb/lb.

In Equation (9.3.4), $h_{\text{fg58}} \approx 1060$ Btu/lb represents the latent heat of vaporization or condensation of water at an estimated temperature of 58°F, where vaporization or condensation occurs in an air-handling unit or packaged unit. Therefore

$$\text{SHR} = \mathring{m}_{\text{a}}\,c_{\text{pa}}\left(T_2 - T_1\right) \Big/ \left[\mathring{m}_{\text{a}}\,c_{\text{pa}}\left(T_2 - T_1\right) + \mathring{m}_{\text{a}}\left(w_2 - w_1\right)h_{\text{fg.58}}\right] \tag{9.3.5}$$

Space Conditioning, Sensible Cooling, and Sensible Heating Processes

In a *space conditioning process*, heat and moisture are absorbed by the supply air at state *s* and then removed from the conditioned space at the state of space air *r* during summer, as shown by line *sr* in Figure 9.3.1, or heat or moisture is supplied to the space to compensate for the transmission and infiltration losses through the building envelope as shown by line *s′r′*. Both processes are aimed at maintaining a desirable space temperature and relative humidity.

The space cooling load q_{rc}, in Btu/hr, can be calculated as:

© 1999 by CRC Press LLC

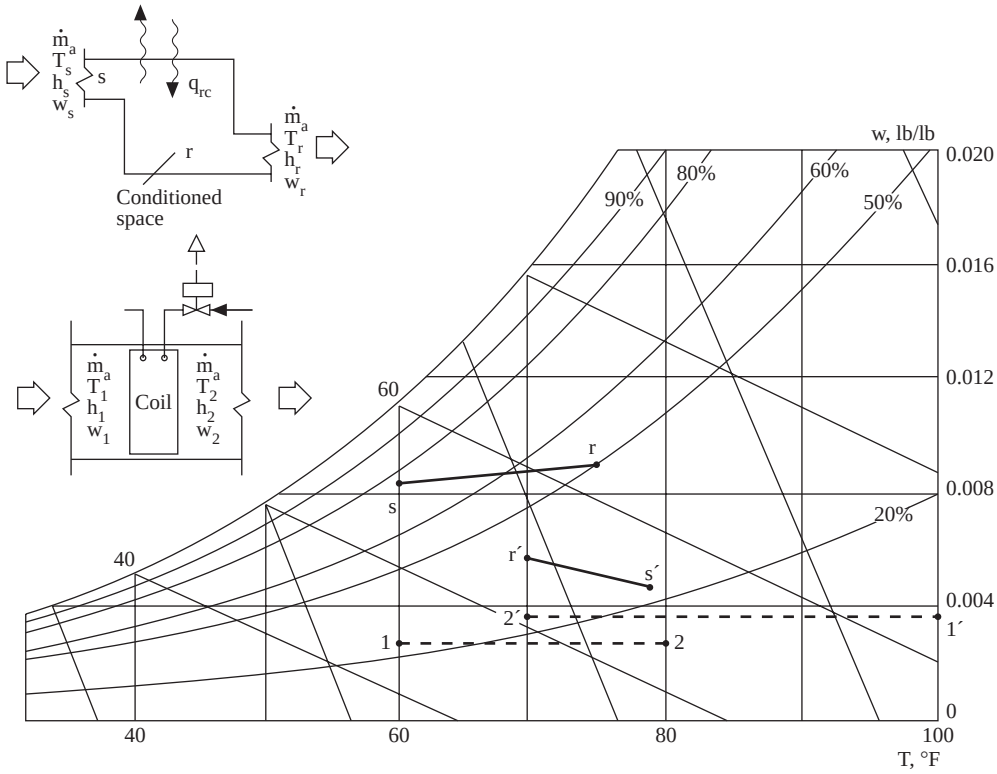

FIGURE 9.3.1 Supply conditioning, sensible heating, and sensible cooling processes.

$$q_{rc} = 60\dot{m}_a\left(h_r - h_s\right) = 60\mathring{V}_s\rho_s\left(h_r - h_s\right) \tag{9.3.6}$$

where h_r, h_s = enthalpy of space air and supply air, Btu/lb.

The space sensible cooling load q_{rs}, in Btu/hr, can be calculated from Equation (9.3.2) and the space latent load q_{rl}, in Btu/hr, from Equation (9.3.1). In Equation (9.3.4), T_2 should be replaced by T_r and T_1 by T_s. Also in Equation (9.3.1), w_2 should be replaced by w_r and w_1 by w_s. The space heating load q_{rh} is always a sensible load, in Btu/hr, and can be calculated as:

$$q_{rh} = 60\mathring{m}_a c_{pa}\left(T_s - T_r\right) = 60\mathring{V}_s\rho_s c_{pa}\left(T_s - T_r\right) \tag{9.3.7}$$

where T_s, T_r = temperature of supply and space air, °F.

A *sensible heating process* adds heat to the moist air in order to increase its temperature; its humidity ratio remains constant, as shown by line 12 in Figure 9.3.1. A sensible heating process occurs when moist air flows over a heating coil. Heat is transferred from the hot water inside the tubes to the moist air. The rate of heat transfer from the hot water to the colder moist air is often called the heating coil load q_{rh}, in Btu/hr, and is calculated from Equation (9.3.2).

A *sensible cooling process* removes heat from the moist air, resulting in a drop of its temperature; its humidity ratio remains constant, as shown by line 1′2′ in Figure 9.3.1. The sensible cooling process occurs when moist air flows through a cooling coil containing chilled water at a temperature equal to or greater than the dew point of the entering moist air. The sensible cooling load can also be calculated from Equation (9.3.2). T_2 is replaced by T_1 and T_1 by $T_{2'}$.

© 1999 by CRC Press LLC

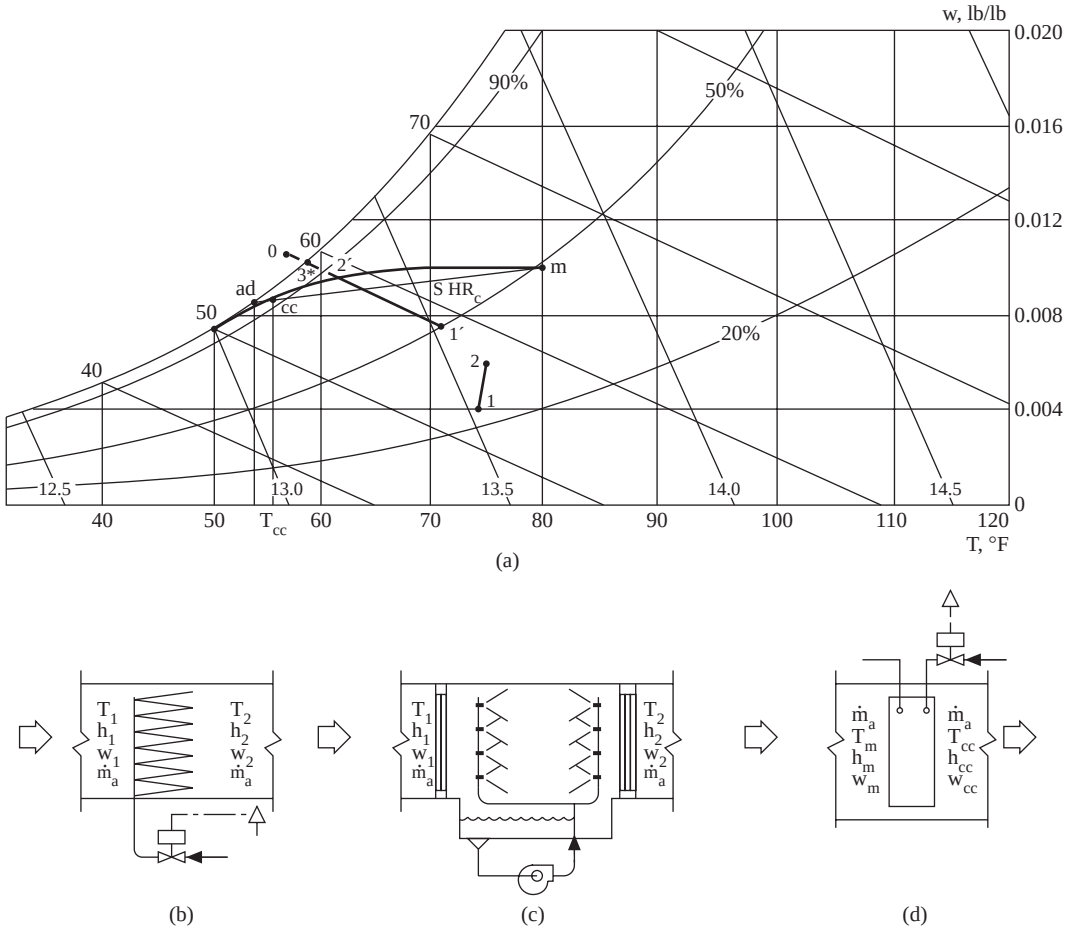

FIGURE 9.3.2 Humidifying and cooling and dehumidifying processes: (a) process on psychrometric chart, (b) steam humidifier, (c) air washer, and (d) water cooling or DX coil.

Humidifying and Cooling and Dehumidifying Processes

In a *humidifying process*, water vapor is added to moist air and increases the humidity ratio of the moist air entering the humidifier if the moist air is not saturated. Large-scale humidification of moist air is usually performed by steam injection, evaporation from a water spray, atomizing water, a wetted medium, or submerged heating elements. Some details of their construction and characteristics are covered in a later section. Dry steam in a steam injection humidifying process is often supplied from the main steam line to a grid-type humidifier and injected into the moist air directly through small holes at a pressure slightly above atmospheric, as shown by line 12 in Figure 9.3.2(a) and (b). The humidifying capacity $\mathring{m}_{hu}$, in lb/min, is given by:

$$\mathring{m}_{hu} = \mathring{V}_s \rho_s \left(w_{hl} - w_{he}\right) \tag{9.3.8}$$

where w_{hl},w_{he} = humidity ratio of moist air leaving and entering the humidifier, lb/lb. The slight inclination at the top of line 12 is due to the high temperature of the steam. The increase in temperature of the moist air due to steam injection can be calculated as:

© 1999 by CRC Press LLC

$$\left(T_2 - T_1\right) = w_{sm} c_{ps} T_s \Big/ \left(c_{pd} + w_{12} c_{ps}\right) \tag{9.3.9}$$

where T_2, T_1 = temperature of moist air at initial and final states, °F
w_{sm} = ratio of mass flow rate of injected steam to moist air, $\mathring{m}_s / \mathring{m}_a$
T_s = temperature of injected steam, °F
w_{12} = average humidity ratio of moist air, lb/lb

An *air washer* is a device that sprays water into moist air in order to humidify, to cool and dehumidify, and to clean the air, as shown in Figure 9.3.2(c). When moist air flows through an air washer, the moist air is humidified and approaches saturation. This actual adiabatic saturation process approximately follows the thermodynamic wet bulb line on the psychrometric chart as shown by line 1′2′. The humidity ratio of the moist air is increased while its temperature is reduced. The cooling effect of this adiabatic saturation process is called *evaporative cooling*.

Oversaturation occurs when the amount of water present in the moist air w_{os}, in lb/lb, exceeds the saturated humidity ratio at thermodynamic wet bulb temperature w_s^*, as shown in Figure 9.3.2(a). When moist air leaves the air washer, atomizing humidifier, or centrifugal humidifier after humidification, it often contains unevaporated water droplets at state point 2′, w_w, in lb/lb. Because of the fan power heat gain, duct heat gain, and other heat gains providing the latent heat of vaporization, some evaporation takes place due to the heat transfer to the water drops, and the humidity ratio increases further. Such evaporation of oversaturated drops is often a process with an increase of both humidity ratio and enthalpy of moist air. Oversaturation can be expressed as:

$$w_{os} = w_o - w_s^* = \left(w_{2'} + w_w\right) - w_s^* \tag{9.3.10}$$

where $w_{2'}$ = humidity ratio at state point 2′, lb/lb
w_o = sum of $w_{2'}$ and w_w, lb/lb

The magnitude of w_w depends mainly on the construction of the humidifier and water eliminator, if any. For an air washer, w_w may vary from 0.0002 to 0.001 lb/lb. For a pulverizing fan without an eliminator, w_w may be up to 0.00135 lb/lb.

Cooling and Dehumidifying Process

In a cooling and dehumidifying process, both the humidity ratio and temperature of moist air decrease. Some water vapor is condensed in the form of liquid water, called a *condensate*. This process is shown by curve m cc on the psychrometric chart in Figure 9.3.2(a). Here m represents the entering mixture of outdoor and recirculating air and cc the conditioned air leaving the cooling coil.

Three types of heat exchangers are used in a cooling and dehumidifying process: (1) water cooling coil as shown in Figure 9.3.2(d); (2) direct expansion DX coil, where refrigerant evaporates directly inside the coil's tubes; and (3) air washer, in which chilled water spraying contacts condition air directly.

The temperature of chilled water entering the cooling coil or air washer T_{we}, in °F, determines whether it is a sensible cooling or a cooling and dehumidifying process. If T_{we} is smaller than the dew point of the entering air T_{ae}'' in the air washer, or T_{we} makes the outer surface of the water cooling coil $T_{s.t} < T_{ae}''$, it is a cooling and dehumidifying process. If $T_{we} \geq T_{ae}''$, or $T_{s.t} \geq T_{ae}''$, sensible cooling occurs. The cooling coil's load or the cooling capacity of the air washer q_{cc}, in Btu/hr, is

$$q_{cc} = 60 \mathring{V}_s \rho_s \left(h_{ae} - h_{cc}\right) - 60 \mathring{m}_w h_w \tag{9.3.11a}$$

where h_{ae}, h_{cc} = enthalpy of moist air entering and leaving the coil or washer, Btu/lb
$\mathring{m}_w$ = mass flow rate of the condensate, lb/min
h_w = enthalpy of the condensate, Btu/lb

© 1999 by CRC Press LLC

Since the thermal energy of the condensate is small compared with q_{cc}, in practical calculations the term $60\dot{m}_w h_w$ is often neglected, and

$$q_{cc} = 60\dot{V}_s \rho_s (h_{ae} - h_{cc}) \tag{9.3.11b}$$

The sensible heat ratio of the cooling and dehumidifying process SHR_c can be calculated from

$$SHR_c = q_{cs}/q_{cc} \tag{9.3.12}$$

where q_{cs} = sensible heat removed during the cooling and dehumidifying process, Btu/hr. SHR_c is shown by the slope of the straight line joining points m and cc.

The relative humidity of moist air leaving the water cooling coil or DX coil depends mainly on the outer surface area of the coil including pipe and fins. For coils with ten or more fins per inch, if the entering moist air is around 80°F dry bulb and 68°F wet bulb, the relative humidity of air leaving the coil (off-coil) may be estimated as:

Four-row coil	90 to 95%
Six-row and eight-row coils	96 to 98%

Two-Stream Mixing Process and Bypass Mixing Process

For a *two-stream adiabatic mixing process*, two moist air streams, 1 and 2, are mixed together adiabatically and a mixture *m* is formed in a mixing chamber as shown by line 1 m1 2 in Figure 9.3.3. Since the AHU or PU is well insulated, the heat transfer between the mixing chamber and ambient air is small and is usually neglected. Based on the principle of heat balance and conservation of mass:

$$\begin{aligned} \dot{m}_1 h_1 + \dot{m}_2 h_2 &= \dot{m}_m h_m \\ \dot{m}_1 w_1 + \dot{m}_2 w_2 &= \dot{m}_m w_m \\ \dot{m}_1 T_1 + \dot{m}_2 T_2 &= \dot{m}_m T_m \end{aligned} \tag{9.3.13}$$

In Equation (9.3.13), $\dot{m}$ represents the mass flow rate of air, lb/min; *h* the enthalpy, in Btu/lb; w the humidity ratio, in lb/lb; and *T* the temperature, in °F. Subscripts 1 and 2 indicate air streams 1 and 2 and m the mixture; also,

$$\begin{aligned} \dot{m}_1/\dot{m}_m &= (h_2 - h_m)/(h_2 - h_1) = (w_2 - w_m)/(w_2 - w_1) \\ &= (\text{line segment m1 2})/(\text{line segment 12}) \end{aligned} \tag{9.3.14}$$

Similarly,

$$\begin{aligned} \dot{m}_2/\dot{m}_m &= (h_m - h_1)/(h_2 - h_1) = (w_m - w_1)/(w_2 - w_1) \\ &= (\text{line segment 1 m1})/(\text{line segment 12}) \end{aligned} \tag{9.3.15}$$

Mixing point *m* must lie on the line that joins points 1 and 2 as shown in Figure 9.3.3.

If the differences between the density of air streams 1 and 2 and the density of the mixture are neglected,

© 1999 by CRC Press LLC

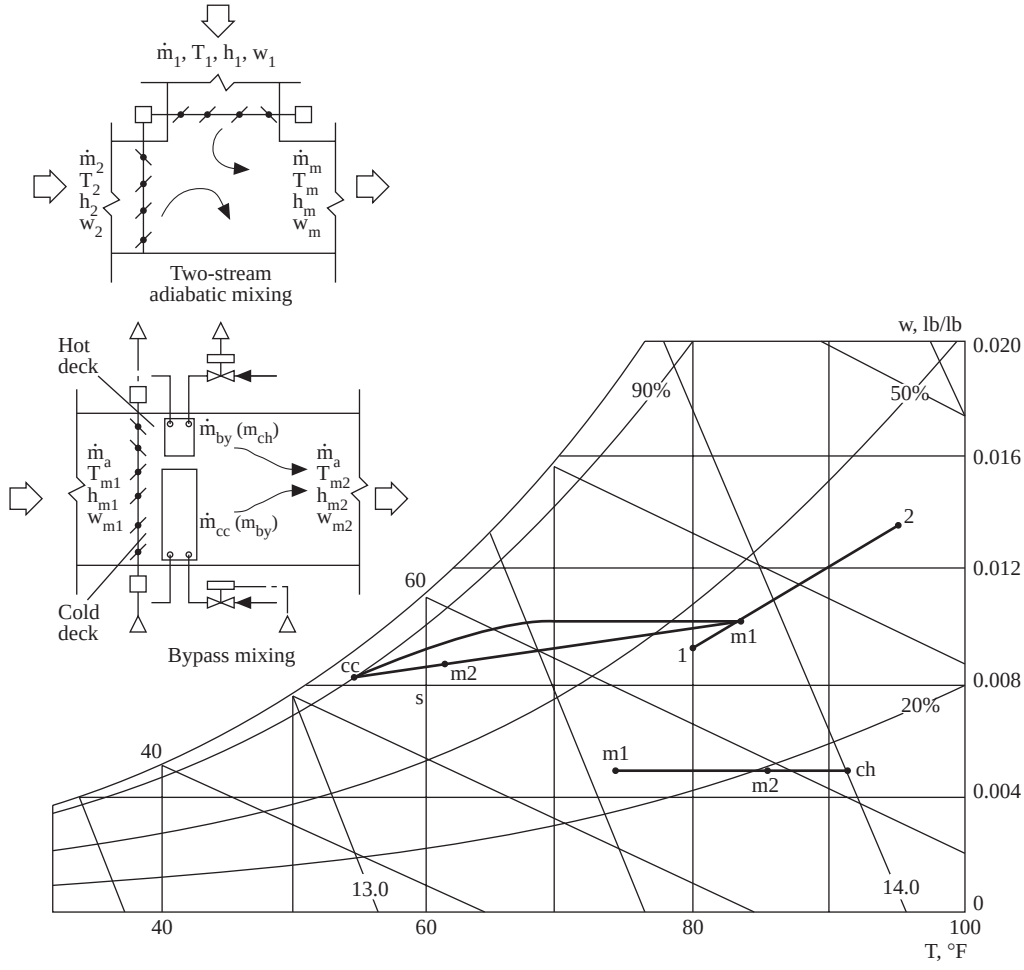

FIGURE 9.3.3 Mixing processes.

$$\mathring{V}_1 h_1 + \mathring{V}_2 h_2 = \mathring{V}_m h_m$$

$$\mathring{V}_1 w_1 + \mathring{V}_2 w_2 = \mathring{V}_m w_m \tag{9.3.16}$$

$$\mathring{V}_1 T_1 + \mathring{V}_2 T_2 = \mathring{V}_m T_m$$

$$\mathring{V}_1 + \mathring{V}_2 = \mathring{V}_m \tag{9.3.17}$$

In a *bypass mixing process*, a conditioned air stream is mixed with a bypass air stream that is not conditioned. The cold conditioned air is denoted by subscript cc, the heated air ch, and the bypass air by.

Equations (9.3.14) and (9.3.17) can still be used but subscript 1 should be replaced by cc or ch and subscript 2 by "by" (bypass).

Let $K_{cc} = \mathring{m}_{cc}/\mathring{m}_m$ and $K_{ch} = \mathring{m}_{ch}/\mathring{m}_m$; then the cooling coil's load q_{cc} and heating coil's load q_{ch}, both in Btu/hr, for a bypass mixing process are

© 1999 by CRC Press LLC

$$q_{cc} = K_{cc} \dot{V}_s \rho_s (h_m - h_{cc})$$
$$q_{ch} = K_{ch} \dot{V}_s \rho_s (h_2 - h_1) \quad (9.3.18)$$

In Equation (9.3.18), subscript s denotes the supply air and m the mixture air stream.

Air-Conditioning Cycle and Operating Modes

An *air-conditioning cycle* comprises several air-conditioning processes that are connected in a sequential order. An air-conditioning cycle determines the operating performance of the air system in an air-conditioning system. The *working substance* to condition air may be chilled or hot water, refrigerant, desiccant, etc.

Each type of air system has its own air-conditioning cycle. Psychrometric analysis of an air-conditioning cycle is an important tool in determining its operating characteristics and the state of moist air at various system components, including the volume flow rate of supply air, the coil's load, and the humidifying and dehumidifying capacity.

According to the cycle performance, air-conditioning cycles can be grouped into two categories:

- *Open cycle*, in which the moist air at its end state does not resume its original state. An air-conditioning cycle with all outdoor air is an open cycle.
- *Closed cycle*, in which moist air resumes its original state at its end state. An air-conditioning cycle that conditions the mixture of recirculating and outdoor air, supplies it, recirculates part of the return air, and mixes it again with outdoor air is a closed cycle.

Based on the outdoor weather and indoor operating conditions, the operating modes of air-conditioning cycles can be classified as:

- *Summer mode*: when outdoor and indoor operating parameters are in summer conditions.
- *Winter mode*: when outdoor and indoor operating parameters are in winter conditions.
- *Air economizer mode*: when all outdoor air or an amount of outdoor air that exceeds the minimum amount of outdoor air required for the occupants is taken into the AHU or PU for cooling. The air economizer mode saves energy use for refrigeration.

Continuous modes operate 24 hr a day and 7 days a week. Examples are systems that serve hospital wards and refrigerated warehouses. An *intermittently operated mode* usually shuts down once or several times within a 24-hr operating cycle. Such systems serve offices, class rooms, retail stores, etc. The 24-hr day-and-night cycle of an intermittently operated system can again be divided into:

1. *Cool-down or warm-up period.* When the space is not occupied and the space air temperature is higher or lower than the predetermined value, the space air should be cooled down or warmed up before the space is occupied.
2. *Conditioning period*. The air-conditioning system is operated during the occupied period to maintain the required indoor environment.
3. *Nighttime shut-down period.* The air system or terminal is shut down or only partly operating to maintain a set-back temperature.

Summer, winter, air economizer, and continuously operating modes consist of *full-load* (design load) and part-load operations. *Part load* occurs when the system load is less than the design load. The capacity of the equipment is selected to meet summer and winter system design loads as well as system loads in all operating modes.

© 1999 by CRC Press LLC

Basic Air-Conditioning Cycle — Summer Mode

A *basic air-conditioning system* is a packaged system of supply air at a constant volume flow rate, serving a single zone, equipped with only a single supply/return duct. A *single zone* is a conditioned space for which a single controller is used to maintain a unique indoor operating parameter, probably indoor temperature. A *basic air-conditioning cycle* is the operating cycle of a basic air-conditioning system. Figure 9.1.3 shows a basic air-conditioning system. Figure 9.3.4 shows the basic air-conditioning cycle of this system. In summer mode at design load, recirculating air from the conditioned space, a worship hall, enters the packaged unit through the return grill at point ru. It is mixed with the required minimum amount of outdoor air at point o for acceptable indoor air quality and energy saving. The mixture *m* is then cooled and dehumidified to point cc at the DX coil, and the conditioned air is supplied to the hall through the supply fan, supply duct, and ceiling diffuser. Supply air then absorbs the sensible and latent load from the space, becoming the space air r. Recirculating air enters the packaged unit again and forms a closed cycle. *Return air* is the air returned from the space. Part of the return air is exhausted to balance the outdoor air intake and infiltration. The remaining part is the *recirculating air* that enters the PU or AHU.

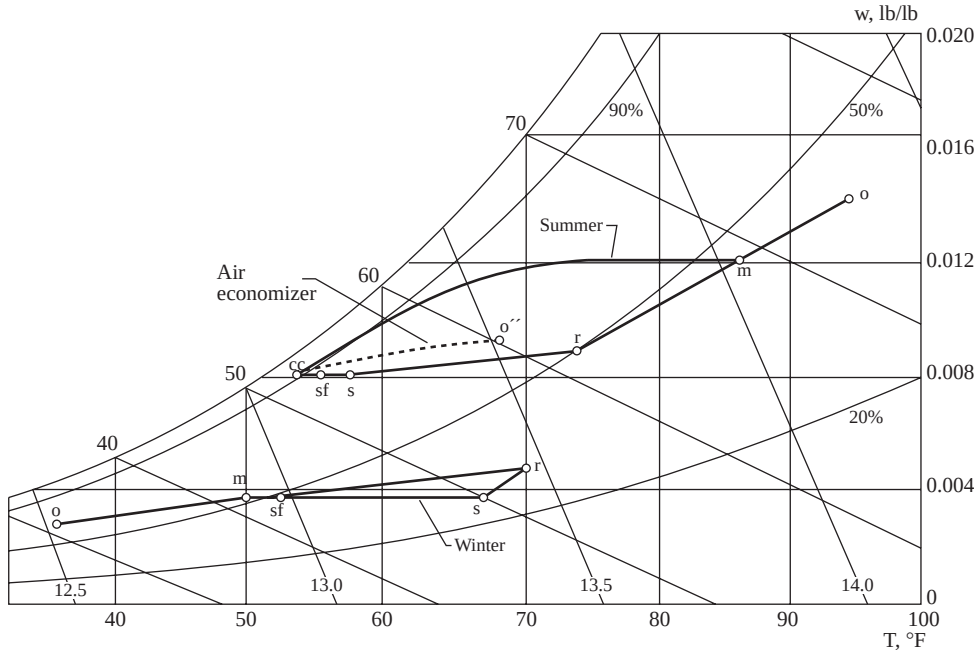

FIGURE 9.3.4 Basic air-conditioning cycle — summer, winter, and air economizer mode.

The summer mode operating cycle consists of the following processes:

1. Sensible heating process, represented by line r ru, due to the return system gain $q_{r.s}$, in Btu/hr, when recirculating air flows through the return duct, ceiling plenum, and return fan, if any. In this packaged system, the return system heat gain is small and neglected.
2. Adiabatic mixing process of recirculating air at point ru and outdoor air at point o in the mixing box, represented by line ru m o.
3. Cooling and dehumidifying process m cc at the DX coil whose coil load determines the cooling capacity of the system calculated from Equation (9.3.11).
4. Sensible heating process related to the supply system heat gain $q_{s.s}$, in Btu/hr, represented by line cc sf s. $q_{s.s}$ consists of the fan power heat gain q_{sf}, line cc sf, and duct heat gain q_{sd}, line sf s, that is:

© 1999 by CRC Press LLC

$$q_{s.s} = q_{sf} + q_{sd} = \mathring{V}_s \rho_s c_{pa} \Delta T_{s.s} \tag{9.3.19}$$

It is more convenient to use the temperature rise of the supply system $\Delta T_{s.s}$ in psychrometric analysis.

5. Supply conditioning process line sr.

Design Supply Volume Flow Rate

Design supply volume flow rate and cooling and heating capacities are primary characteristics of an air-conditioning system. Design supply volume flow rate is used to determine the size of fans, grills, outlets, air-handling units, and packaged units. For most comfort systems and many processing air-conditioning systems, *design supply volume flow rate* $\mathring{V}_{s.d}$, in cfm, is calculated on the basis of the capacity to remove the space cooling load at summer design conditions to maintain a required space temperature T_r:

$$\mathring{V}_{s.d} = q_{rc.d} \Big/ \left[60\rho_s \left(h_r - h_s\right)\right] = q_{rs.d} \Big/ \left[60\rho_s c_{pa} \left(T_r - T_s\right)\right] \tag{9.3.20}$$

where $q_{rc.d}$, $q_{rs.d}$ = design space cooling load and design sensible cooling load, Btu/hr. In Equation (9.3.20), the greater the $q_{rs.d}$, the higher $\mathring{V}_s$ will be. Specific heat c_{pa} is usually considered constant. Air density ρ_s may vary with the various types of air systems used. A greater ρ_s means a smaller $\mathring{V}_{s.d}$ for a given supply mass flow rate. For a given $q_{rs.d}$, the supply temperature differential $\Delta T_s = (T_r - T_s)$ is an important parameter that affects $\mathring{V}_{s.d}$. Conventionally, a 15 to 20°F ΔT_s is used for comfort air-conditioning systems. Recently, a 28 to 34°F ΔT_s has been adopted for cold air distribution in ice-storage central systems. When ΔT_s has a nearly twofold increase, there is a considerable reduction in $\mathring{V}_s$ and fan energy use and saving in investment on ducts, terminals, and outlets.

The summer cooling load is often greater than the winter heating load, and this is why q_{rc} or $q_{rs.d}$ is used to determine $\mathring{V}_{s.d}$, except in locations where the outdoor climate is very cold.

Sometimes the supply volume flow rate may be determined from the following requirements:

- To dilute the concentration of air contaminants in the conditioned space C_i, in mg/m^3, the design supply volume flow rate is

$$\mathring{V}_{s.d} = 2118 \mathring{m}_{par} \Big/ \left(C_1 - C_s\right) \tag{9.3.21}$$

where C_s = concentration of air contaminants in supply air, mg/m^3
$\mathring{m}_{par}$ = rate of contaminant generation in the space, mg/sec

- To maintain a required space relative humidity φ_r and a humidity ratio w_r at a specific temperature, the design supply volume flow rate is

$$\mathring{V}_{s.d} = q_{rl.d} \Big/ \left[60\rho_s \left(w_r - w_s\right) h_{fg.58}\right] \tag{9.3.22}$$

where $q_{rl.d}$ = design space latent load, Btu/hr.

- To provide a required air velocity v_r, in fpm, within the working area of a clean room, the supply volume flow rate is given by

$$\mathring{V}_{s.d} = A_r v_r \tag{9.3.23a}$$

where A_r = cross-sectional area perpendicular to the air flow in the working area, ft^2.

© 1999 by CRC Press LLC

- To exceed the outdoor air requirement for acceptable air quality for occupants, the supply volume flow rate must be equal to or greater than

$$\mathring{V}_s \geq n\mathring{V}_{oc} \tag{9.3.23b}$$

where n = number of occupants
$\mathring{V}_{oc}$ = outdoor air requirement per person, cfm/person

- To exceed the sum of the volume flow rate of exhaust air $\mathring{V}_{ex}$ and the exfiltrated or relief air $\mathring{V}_{ef}$, both in cfm,

$$\mathring{V}_s \geq \mathring{V}_{ex} + \mathring{V}_{ef} \tag{9.3.24}$$

The design supply volume flow rate should be the largest of any of the foregoing requirements.

Rated Supply Volume Flow Rate

For an air system at atmospheric pressure, since the required mass flow rate of the supply air is a function of air density and remains constant along the air flow,

$$\begin{aligned} \mathring{m}_a &= \mathring{V}_{cc}\rho_{cc} = \mathring{V}_s\rho_s = \mathring{V}_{sf}\rho_{sf} \\ \mathring{V}_{sf} &= \mathring{V}_s\rho_s/\rho_{sf} \end{aligned} \tag{9.3.25}$$

where $\mathring{V}_{sf}$ = volume flow rate at supply fan outlet, cfm
ρ_{sf} = air density at supply fan outlet, lb/ft^3

A supply fan is rated at *standard air conditions*, that is, dry air at a temperature of 70°F, an atmospheric pressure of 29.92 in. Hg (14.697 psia), and an air density of 0.075 lb/ft^3. However, a fan is a constant-volume machine at a given fan size and speed; that is, $\mathring{V}_{sf} = \mathring{V}_{sf.r}$. Here $\mathring{V}_{sf.r}$ represents the rated volume flow rate of a fan at standard air conditions. Therefore,

$$\mathring{V}_{sf.r} = \mathring{V}_{sf} = q_{rs.d}/\left[60\rho_{sf}c_{pa}\left(T_r - T_s\right)\right] \tag{9.3.26}$$

- For conditioned air leaving the cooling coil at T_{cc} = 55°F with a relative humidity of 92% and T_{sf} of 57°F, $\rho_{sf.r} = 1/v_{sf} = 1/13.20 = 0.0758$ lb/ft^3. From Equation (9.3.26):

$$\mathring{V}_{sf.r} = q_{rs.d}/\left[60\times 0.0758\times 0.243\left(T_r - T_s\right)\right] = q_{rs.d}/\left[1.1\left(T_r - T_s\right)\right] \tag{9.3.26a}$$

Equation (9.3.26a) is widely used in calculating the supply volume flow rate of comfort air-conditioning systems.

- For cold air distribution, T_{cc} = 40°F and φ_{cc} = 98%, if T_{sf} = 42°F, then v_{sf} = 12.80 ft^3/lb, and the rated supply volume flow rate:

$$\mathring{V}_{sf.r} = 12.80q_{rs.d}/\left[60\times 0.243\left(T_r - T_s\right)\right] = q_{rs.d}/\left[1.14\left(T_r - T_s\right)\right] \tag{9.3.26b}$$

- For a blow-through fan in which the fan is located upstream of the coil, if T_{sf} = 82°F and φ_{sf} = 43%, then v_{sf} = 13.87 ft^3/lb, and the rated supply volume flow rate:

© 1999 by CRC Press LLC

$$\mathring{V}_{\text{sf.r}} = 13.87 q_{\text{rs.d}} / \left[60 \times 0.243 \left(T_{\text{r}} - T_{\text{s}}\right)\right] = q_{\text{rs.d}} / \left[1.05 \left(T_{\text{r}} - T_{\text{s}}\right)\right] \quad (9.3.26c)$$

Effect of the Altitude

The higher the altitude, the lower the atmospheric pressure and the air density. In order to provide the required mass flow rate of supply air, a greater $\mathring{V}_{\text{sf.r}}$ is needed. For an air temperature of 70°F:

$$\mathring{V}_{\text{x.ft}} = \mathring{V}_{\text{sf.r}} \left(p_{\text{sea}} / p_{\text{x.ft}}\right) = \mathring{V}_{\text{sf.r}} \left(\rho_{\text{sea}} / \rho_{\text{x.ft}}\right) \quad (9.3.27)$$

where $\mathring{V}_{\text{x.ft}}$ = supply volume flow rate at an altitude of x ft, cfm
p_{sea}, $p_{\text{x.ft}}$ = atmospheric pressure at sea level and an altitude of x ft, psia
ρ_{sea}, $\rho_{\text{x.ft}}$ = air density at sea level and an altitude of x ft, psia

Following are the pressure or air density ratios at various altitudes. At 2000 ft above sea level, the rated supply volume flow rate $\mathring{V}_{\text{r.2000}} = \mathring{V}_{\text{sf.r}} (p_{\text{sea}}/p_{\text{x.ft}}) = 1.076\ \mathring{V}_{\text{sf.r}}$ cfm instead of $\mathring{V}_{\text{sf.r}}$ cfm at sea level.

Altitude, ft	p_{at}, psia	ρ, lb/ft^3	$(p_{\text{sea}}/p_{\text{x,ft}})$
0	14.697	0.075	1.000
1000	14.19	0.0722	1.039
2000	13.58	0.0697	1.076
3000	13.20	0.0672	1.116
5000	12.23	0.0625	1.200

Off-Coil and Supply Air Temperature

For a given design indoor air temperature T_{r}, space sensible cooling load q_{rs}, and supply system heat gain $q_{\text{s.s}}$, a lower air off-coil temperature T_{cc} as well as supply temperature T_{s} means a greater supply temperature differential ΔT_{s} and a lower space relative humidity φ_{r} and vice versa. A greater ΔT_{s} decreases the supply volume flow rate $\mathring{V}_{\text{s}}$ and then the fan and terminal sizes, duct sizes, and fan energy use. The result is a lower investment and energy cost.

A lower T_{cc} and a greater ΔT_{s} require a lower chilled water temperature entering the coil T_{we}, a lower evaporating temperature T_{ev} in the DX coil or refrigerating plant, and therefore a greater power input to the refrigerating compressors. When an air-conditioning system serves a conditioned space of a single zone, optimum T_{cc}, T_{s}, and T_{we} can be selected. For a conditioned space of multizones, T_{cc}, T_{s}, and T_{we} should be selected to satisfy the lowest requirement. In practice, T_{s} and T_{we} are often determined according to previous experience with similar projects.

In general, the temperature rise due to the supply fan power system heat gain q_{sf} can be taken as 1 to 3°F depending on the fan total pressure. The temperature rise due to the supply duct system heat gain at design flow can be estimated as 1°F/100 ft insulated main duct length based on 1-in. thickness of duct insulation.

Outside Surface Condensation

The outside surface temperature of the ducts, terminals, and supply outlets T_{sur} in the ceiling plenum in contact with the return air should not be lower than the dew point of the space air T_r'', in °F. The temperature rise due to the fan power heat gain is about 2°F. According to Dorgan (1988), the temperature difference between the conditioned air inside the terminal and the outside surface of the terminal with insulation wrap is about 3°F. For a space air temperature of 75°F and a relative humidity of 50%, its dew point temperature is 55°F. If the outside surface temperature $T_{\text{s}} = (T_{\text{cc}} + 2 + 3) \le 55$°F, condensation may occur on the outside surface of the terminal. Three methods are often used to prevent condensation:

1. Increase the thickness of the insulation layer on the outside surface.
2. Adopt a supply outlet that induces more space air.

© 1999 by CRC Press LLC

3. Equip with a terminal that mixes the supply air with the space air or air from the ceiling plenum.

During the cool-down period, due to the high dew point temperature of the plenum air when the air system is started, the supply air temperature must be controlled to prevent condensation.

Example 9.3.1

The worship hall of a church uses a package system with a basic air system. The summer space sensible cooling load is 75,000 Btu/hr with a latent load of 15,000 Btu/hr. Other design data for summer are as follows:

Outdoor summer design temperature: dry bulb 95°F and wet bulb 75°F
Summer indoor temperature: 75°F with a space relative humidity of 50%:
Temperature rise: fan power 2°F
supply duct 2°F
Relative humidity of air leaving cooling coil: 93%
Outdoor air requirement: 1800 cfm

Determine the

1. Temperature of supply air at summer design conditions
2. Rated volume flow rate of the supply fan
3. Cooling coil load
4. Possibility of condensation at the outside surface of the insulated branch duct to the supply outlet

Solution

1. From Equation 9.3.1 the sensible heat ratio of the space conditioning line is

$$\mathrm{SHR}_s = |q_{rs}| / (|q_{rs}| + |q_{rl}|) = 60{,}000/(60{,}000 + 15{,}000) = 0.8$$

   On the psychrometric chart, from given T_r = 75°F and φ_r = 50%, plot space point r. Draw a space conditioning line sr from point r with SHR_s = 0.8.
   Since $\Delta T_{s.s}$ = 2 + 2 = 4°F, move line segment cc s (4°F) up and down until point s lies on line sr and point cc lies on the φ_{cc} = 93% line. The state points s and cc are then determined as shown in Figure 9.3.4:

   T_s = 57.5°F, φ_s = 82%, and w_s = 0.0082 lb/lb
   T_{cc} = 53.5°F, φ_{cc} = 93%, h_{cc} = 21.8 Btu/lb, and w_{cc} = 0.0082 lb/lb

2. Since T_{sf} = 53.5 + 2 = 55.5°F and w_{sf} = 0.0082 lb/lb, $\rho_{sf} = 1/v_{sf}$ = 1/13.15 = 0.076 lb/ft^3. From Equation 9.4.2, the required rated supply volume flow rate is

$$\dot{V}_{sf.r} = q_{rs.d} / [60 \rho_{sf} c_{pa} (T_r - T_s)]$$

$$= 60{,}000/[60 \times 0.076 \times 0.243(75 - 57.5)] = 3094 \text{ cfm}$$

3. Plot outdoor air state point o on the psychrometric chart from given dry bulb 95°F and wet bulb 75°F. Connect line ro. Neglect the density differences between points r, m, and o; then

$$\mathrm{rm}/\mathrm{ro} = 1800/3094 = 0.58$$

   From the psychrometric chart, the length of line ro is 2.438 in. As shown in Figure 9.3.4, point m is then determined as:

© 1999 by CRC Press LLC

$$T_m = 86.7°F, \qquad h_m = 35 \text{ Btu/lb}$$

From Equation (9.3.11), the cooling coil load is

$$q_{cc} = 60\mathring{V}_s\rho_s(h_m - h_{cc}) = 60 \times 3094 \times 0.076(35 - 21.8) = 186{,}234 \text{ Btu/lb}$$

4. From the psychrometric chart, since the dew point of the space air $T_r'' = 55°F$ and is equal to that of the plenum air, the outside surface temperature of the branch duct $T_s = 53.5 + 2 + 3 = 58°F$ which is higher than $T_r'' = 55°F$. Condensation will not occur at the outside surface of the branch duct.

Basic Air-Conditioning Cycle — Winter Mode

When the basic air-conditioning systems are operated in winter mode, their air-conditioning cycles can be classified into the following four categories:

Cold Air Supply without Space Humidity Control. In winter, for a fully occupied worship hall, if the heat loss is less than the space sensible cooling load, a cold air supply is required to offset the space sensible cooling load and maintain a desirable indoor environment as shown by the lower cycle in Figure 9.3.4. Usually, a humidifier is not used.

The winter cycle of a cold air supply without humidity control consists of the following air-conditioning processes:

1. Adiabatic mixing process of outdoor air and recirculating air o m r.
2. Sensible heating process due to supply fan power heat gain m sf. Because of the smaller temperature difference between the air in the ceiling plenum and the supply air inside the supply duct, heat transfer through duct wall in winter can be neglected.
3. Supply conditioning line sr.

For a winter-mode basic air-conditioning cycle with a cold air supply without space humidity control, the space relative humidity depends on the space latent load, the humidity ratio of the outdoor air, and the amount of outdoor air intake. In order to determine the space humidity ratio w_r, in lb/lb, and the space relative humidity φ_r, in %, Equations (9.3.15) and (9.3.22) should be used to give the following relationships:

$$\begin{aligned} (w_r - w_m)/(w_r - w_o) &= \mathring{V}_o/\mathring{V}_s \\ (w_r - w_s) &= q_{rl}/\left(60\mathring{V}_s\rho_s h_{fg.58}\right) \\ w_s &= w_m \end{aligned} \tag{9.3.28}$$

For a cold air supply, if there is a high space sensible cooling load, the amount of outdoor air must be sufficient, and the mixture must be cold enough to satisfy the following relationships:

$$\begin{aligned} (T_r - T_s) &= q_{rs}/\left(60\mathring{V}_s\rho_s c_{pa}\right) \\ (T_r - T_s)/(T_r - T_o) &= \mathring{V}_o/\mathring{V}_s \end{aligned} \tag{9.3.29}$$

The heating coil load for heating of the outdoor air can be calculated using Equation (9.3.7).

© 1999 by CRC Press LLC

Example 9.3.2

For the same packaged air-conditioning system using a basic air system to serve the worship hall in a church as in Example 9.3.1, the space heating load at winter design condition is 10,000 Btu/hr and the latent load is 12,000 Btu/hr. Other winter design data are as follows:

Winter outdoor design temperature	35°F
Winter outdoor design humidity ratio	0.00035 lb/lb
Winter indoor design temperature	70°F
Temperature rise due to supply fan heat gain	2°F
Outdoor air requirement	1800 cfm

Determine (1) the space relative humidity at winter design temperature and (2) the heating coil load.

Solution

1. Assume that the supply air density $\rho_{sf} = 1/v_{sf} = 1/13.0 = 0.0769$ lb/ft^3, and the mass flow rate of the supply air is the same as in summer mode. Then from Equation 9.3.28 the humidity ratio difference is

$$\left(w_r - w_s\right) = q_{rl} \Big/ \left(60\,\mathring{V}_{sf.r}\,\rho_{sf}\,h_{fg.58}\right) = 12{,}000/(60 \times 3094 \times 0.0769 \times 1060) = 0.00079 \text{ lb/lb}$$

   From Equation 9.3.29, the supply air temperature differential is

$$\left(T_r - T_s\right) = q_{rs.d} \Big/ \left(60\,\mathring{V}_{sf.r}\,\rho_{sf}\,c_{pa}\right) = 10{,}000/(60 \times 3094 \times 0.0769 \times 0.243) = 2.88°\text{F}$$

   Since $\mathring{V}_o/\mathring{V}_s = 1800/3094 = 0.58$ and $w_s = w_m$,

$$\left(w_r - w_s\right)/\left(w_r - w_o\right) = 0.00079/\left(w_r - w_o\right) = \mathring{V}_o/\mathring{V}_s = 0.58$$

$$\left(w_r - w_o\right) = 0.00079/0.58 = 0.00136 \text{ lb/lb}$$

   And from given information,

$$w_r = 0.00136 + w_o = 0.00136 + 0.0035 = 0.00486 \text{ lb/lb}$$

   From the psychrometric chart, for $T_r = 70°$F and $w_r = 0.00486$ lb/lb, point r can be plotted, and φ_r is about 32% (see Figure 9.3.4).
2. Since mr/or = 0.58, point m can be determined, and from the psychrometric chart $T_m = 50.0°$F. As $T_s = 70 - 2.88 = 67.12°$F and $T_{sf} = T_m + 2 = 50.0 + 2 = 52.0°$F, from Equation 9.3.7 the heating coil's load is

$$q_{ch} = 60\,\mathring{V}_s\,\rho_s c_{pa}\left(T_s - T_{sf}\right) = 60 \times 3094 \times 0.0769 \times 0.243(67.12 - 52.0) = 52{,}451 \text{ Btu/hr}$$

Warm Air Supply without Space Humidity Control

When the sum of space heat losses is greater than the sum of the internal heat gains in winter, a warm air supply is needed. For many comfort systems such as those in offices and stores, in locations where winter is not very cold, humidification is usually not necessary. The basic air-conditioning cycle for a warm air supply without space humidity control is shown in Figure 9.3.5(a). This cycle is similar to the

© 1999 by CRC Press LLC

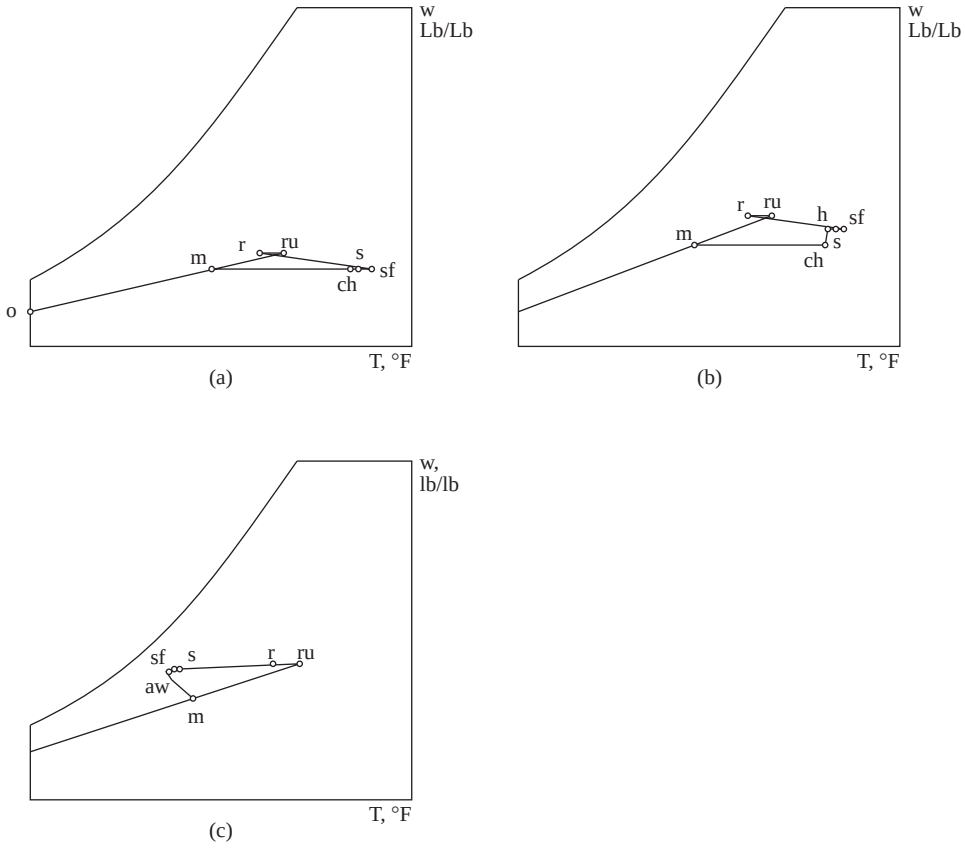

FIGURE 9.3.5 Basic air-conditioning cycle — winter modes: (a) warm air supply without space humidity control, (b) cold air supply without space humidity control, and (c) cold air supply with space humidity control. ch = air leaving heating coil, h = air leaving humidifer, and aw = air leaving air washer.

winter mode cycle of a cold air supply without space humidity control shown in Figure 9.3.4 except that the supply air temperature is higher than space temperature, that is, $T_s > T_r$. To prevent stratification, with the warm supply air staying at a higher level, $(T_s - T_r) > 20°F$ is not recommended.

Warm Air Supply with Space Humidity Control

This operating cycle (see Figure 9.3.5[b]) is often used for hospitals, nurseries, etc. or in locations where winter is very cold. The state point of supply air must be determined first by drawing a space conditioning line with known SHR_s and then from the calculated supply temperature differential ΔT_s. The difference in humidity ratio $(w_s - w_{ch})$ is the water vapor must be added at the humidifier. Humidifying capacity can be calculated from Equation 9.3.8.

Cold Air Supply with Space Humidity Control

This operating cycle (shown in Figure 9.3.5[c]) is widely used in industrial applications such as textile mills where a cold air supply is needed to remove machine load in winter and maintains the space relative humidity required for the manufacturing process. An outdoor air and recirculating air mixture is often used for the required cold air supply. An air washer is adopted for winter humidification.

© 1999 by CRC Press LLC

Air Economizer Mode

In the *air economizer* mode, as shown by the middle dotted line cycle o″-cc-sf-s-r in Figure 9.3.4, all outdoor air or an outdoor air-recirculating air mixture is used to reduce the refrigeration capacity and improve the indoor air quality during spring, fall, or winter.

When all outdoor air is admitted, it is an open cycle. Outdoor air is cooled and often dehumidified to point cc. After absorbing fan and duct heat gains, it is supplied to the conditioned space. Space air is exhausted entirely through openings, relief dampers, or relief/exhaust fans to the outside. An all-outdoor air-operating mode before the space is occupied is often called an *air purge* operation, used to dilute space air contaminants.

Cool-Down and Warm-Up Modes

In summer, when an air system is shut down during an unoccupied period at night, the space temperature and relative humidity often tend to increase because of infiltration of hot and humid air and heat transfer through the building envelope. The air system is usually started before the space is occupied in cool-down mode to cool the space air until the space temperature falls within predetermined limits.

In winter, the air system is also started before the occupied period to warm up the space air to compensate for the nighttime space temperature setback to 55 to 60°F for energy saving or the drop of space temperature due to heat loss and infiltration.

If dilution of indoor air contaminants is not necessary, only recirculating space air is used during cool-down or warm-up periods in order to save energy.

9.4 Refrigerants and Refrigeration Cycles

Refrigeration and Refrigeration Systems

Refrigeration is the cooling effect of the process of extracting heat from a lower temperature heat source, a substance or cooling medium, and transferring it to a higher temperature heat sink, probably atmospheric air and surface water, to maintain the temperature of the heat source below that of the surroundings.

A *refrigeration system* is a combination of components, equipment, and piping, connected in a sequential order to produce the refrigeration effect. Refrigeration systems that provide cooling for air-conditioning are classified mainly into the following categories:

1. *Vapor compression systems.* In these systems, a compressor(s) compresses the refrigerant to a higher pressure and temperature from an evaporated vapor at low pressure and temperature. The compressed refrigerant is condensed into liquid form by releasing the latent heat of condensation to the condenser water. Liquid refrigerant is then throttled to a low-pressure, low-temperature vapor, producing the refrigeration effect during evaporation. Vapor compression is often called *mechanical refrigeration*, that is, refrigeration by mechanical compression.
2. *Absorption systems*. In an absorption system, the refrigeration effect is produced by means of thermal energy input. After liquid refrigerant produces refrigeration during evaporation at very low pressure, the vapor is absorbed by an aqueous absorbent. The solution is heated by a direct-fired gas furnace or waste heat, and the refrigerant is again vaporized and then condensed into liquid form. The liquid refrigerant is throttled to a very low pressure and is ready to produce the refrigeration effect again.
3. *Gas expansion systems.* In an air or other gas expansion system, air or gas is compressed to a high pressure by compressors. It is then cooled by surface water or atmospheric air and expanded to a low pressure. Because the temperature of air or gas decreases during expansion, a refrigeration effect is produced.

Refrigerants, Cooling Mediums, and Absorbents

A *refrigerant* is a primary working fluid used to produce refrigeration in a refrigeration system. All refrigerants extract heat at low temperature and low pressure during evaporation and reject heat at high temperature and pressure during condensation.

A *cooling medium* is a working fluid cooled by the refrigerant during evaporation to transport refrigeration from a central plant to remote cooling equipment and terminals. In a large, centralized air-conditioning system, it is more economical to pump the cooling medium to the remote locations where cooling is required. Chilled water and brine are cooling media. They are often called secondary refrigerants to distinguish them from the primary refrigerants.

A *liquid absorbent* is a working fluid used to absorb the vaporized refrigerant (water) after evaporation in an absorption refrigeration system. The solution that contains the absorbed vapor is then heated. The refrigerant vaporizes, and the solution is restored to its original concentration to absorb water vapor again.

A numbering system for refrigerants was developed for hydrocarbons and halocarbons. According to ANSI/ASHRAE Standard 34-1992, the first digit is the number of unsaturated carbon–carbon bonds in the compound. This digit is omitted if the number is zero. The second digit is the number of carbon atoms minus one. This is also omitted if the number is zero. The third digit denotes the number of hydrogen atoms plus one. The last digit indicates the number of fluorine atoms. For example, the chemical formula for refrigerant R-123 is $CHCl_2CF_3$. In this compound:

No unsaturated carbon–carbon bonds, first digit is 0
There are two carbon atoms, second digit is $2 - 1 = 1$
There is one hydrogen atom, third digit is $1 + 1 = 2$

© 1999 by CRC Press LLC

There are three fluorine atoms, last digit is 3

To compare the relative ozone depletion of various refrigerants, an index called the *ozone depletion potential* (ODP) has been introduced. ODP is defined as the ratio of the rate of ozone depletion of 1 lb of any halocarbon to that of 1 lb of refrigerant R-11. For R-11, ODP = 1.

Similar to the ODP, halocarbon global warming potential (HGWP) is an index used to compare the global warming effect of a halocarbon refrigerant with the effect of refrigerant R-11.

Classification of Refrigerants

Nontoxic and nonflammable synthetic chemical compounds called *halogenated hydrocarbons*, or simply *halocarbons*, were used almost exclusively in vapor compression refrigeration systems for comfort air-conditioning until 1986. Because chlorofluorocarbons (CFCs) cause ozone depletion and global warming, they must be replaced. A classification of refrigerants based on ozone depletion follows (see Table 9.4.1):

Hydrofluorocarbons (HFCs)

HFCs contain only hydrogen, fluorine, and carbon atoms and cause no ozone depletion. HFCs group include R-134a, R-32, R-125, and R-245ca.

HFC's Azeotropic Blends or Simply HFC's Azeotropic

An azeotropic is a mixture of multiple components of volatilities (refrigerants) that evaporate and condense as a single substance and do not change in volumetric composition or saturation temperature when they evaporate or condense at constant pressure. HFC's azeotropics are blends of refrigerant with HFCs. ASHRAE assigned numbers between 500 and 599 for azeotropic. HFC's azeotropic R-507, a blend of R-125/R-143, is the commonly used refrigerant for low-temperature vapor compression refrigeration systems.

HFC's Near Azeotropic

A near azeotropic is a mixture of refrigerants whose characteristics are near those of an azeotropic. Because the change in volumetric composition or saturation temperature is rather small for a near azeotropic, such as, 1 to 2°F, it is thus named. ASHRAE assigned numbers between 400 and 499 for zeotropic. R-404A (R-125/R-134a/R-143a) and R-407B (R-32/R-125/R134a) are HFC's near azeotropic. R-32 is flammable; therefore, its composition is usually less than 30% in the mixture. HFC's near azeotropic are widely used for vapor compression refrigeration systems.

Zeotropic or nonazeotropic, including near azeotropic, shows a change in composition due to the difference between liquid and vapor phases, leaks, and the difference between charge and circulation. A shift in composition causes the change in evaporating and condensing temperature/pressure. The difference in dew point and bubble point during evaporation and condensation is called glide, expressed in °F. Near azeotropic has a smaller glide than zeotropic. The midpoint between the dew point and bubble point is often taken as the evaporating and condensing temperature for refrigerant blends.

Hydrochlorofluorocarbons (HCFCs) and Their Zeotropics

HCFCs contain hydrogen, chlorine, fluorine, and carbon atoms and are not fully halogenated. HCFCs have a much shorter lifetime in the atmosphere (in decades) than CFCs and cause far less ozone depletion (ODP 0.02 to 0.1). R-22, R-123, R-124, etc. are HCFCs. HCFCs are the most widely used refrigerants today.

HCFC's near azeotropic and *HCFC's zeotropic* are blends of HCFCs with HFCs. They are transitional or interim refrigerants and are scheduled for a restriction in production starting in 2004.

Inorganic Compounds

These compounds include refrigerants used before 1931, like ammonia R-717, water R-718, and air R-729. They are still in use because they do not deplete the ozone layer. Because ammonia is toxic and

flammable, it is used in industrial applications. Inorganic compounds are assigned numbers between 700 and 799 by ASHRAE.

Chlorofluorocarbons, Halons, and Their Azeotropic

CFCs contain only chlorine, fluorine, and carbon atoms. CFCs have an atmospheric lifetime of centuries and cause ozone depletion (ODP from 0.6 to 1). R-11, R-12, R-113, R-114, R-115… are all CFCs.

Halons or BFCs contain bromide, fluorine, and carbon atoms. R-13B1 and R-12B1 are BFCs. They cause very high ozone depletion (ODP for R-13B1 = 10). Until 1995, R-13B1 was used for very low temperature vapor compression refrigeration systems.

Phaseout of CFCs, BFCs, HCFCs, and Their Blends

On September 16, 1987, the European Economic Community and 24 nations, including the United States, signed a document called the Montreal Protocol. It is an agreement to restrict the production and consumption of CFCs and BFCs in the 1990s because of ozone depletion.

The Clean Air Act amendments, signed into law in the United States on November 15, 1990, concern two important issues: the phaseout of CFCs and the prohibition of deliberate venting of CFCs and HCFCs.

In February 1992, President Bush called for an accelerated ban of CFCs in the United States. In late November 1992, representatives of 93 nations meeting in Copenhagen agreed to phase out CFCs beginning January 1, 1996. Restriction on the use of HCFCs will start in 2004, with a complete phaseout by 2030.

In the earlier 1990s, R-11 was widely used for centrifugal chillers, R-12 for small and medium-size vapor compression systems, R-22 for all vapor compression systems, and CFC/HCFC blend R-502 for low-temperature vapor compression systems. Because of the phaseout of CFCs and BFCs before 1996 and HCFCs in the early years of the next century, alternative refrigerants have been developed to replace them:

- R-123 (an HCFC of ODP = 0.02) to replace R-11 is a short-term replacement that causes a slight reduction in capacity and efficiency. R-245ca (ODP = 0) may be the long-term alternative to R-11.
- R-134a (an HFC with ODP = 0) to replace R-12 in broad applications. R-134a is not miscible with mineral oil; therefore, a synthetic lubricant of polyolester is used.
- R-404A (R-125/R-134a/143a) and R-407C (R-32/R-125/R-134a) are both HFCs near azeotropic of ODP = 0. They are long-term alternatives to R-22. For R-407C, the composition of R-32 in the mixture is usually less than 30% so that the blend will not be flammable. R-407C has a drop of only 1 to 2% in capacity compared with R-22.
- R-507 (R-125/R-143a), an HFC's azeotropic with ODP = 0, is a long-term alternative to R-502. Synthetic polyolester lubricant oil will be used for R-507. There is no major performance difference between R-507 and R-502. R-402A (R-22/R-125/R-290), an HCFC's near azeotropic, is a short-term immediate replacement, and drop-in of R-502 requires minimum change of existing equipment except for reset of a higher condensing pressure.

Required Properties of Refrigerants

A refrigerant should not cause ozone depletion. A low global warming potential is required. Additional considerations for refrigerant selection are

1. *Safety*, including toxicity and flammability. ANSI/ASHRAE Standard 34-1992 classifies the *toxicity* of refrigerants as Class A and Class B. Class A refrigerants are of low toxicity. No toxicity was identified when their time-weighted average concentration was less than or equal to 400 ppm, to which workers can be exposed for an 8-hr workday and 40-hr work week without adverse effect. Class B refrigerants are of higher toxicity and produce evidence of toxicity.

ANSI/ASHRAE Standard 34-1982 classifies the *flammability* of refrigerants as Class 1, no flame propagation; Class 2, lower flammability; and Class 3, higher flammability.

© 1999 by CRC Press LLC

The safety classification of refrigerants is based on the combination of toxicity and flammability: A1, A2, A3, B1, B2, and B3. R-134a and R-22 are in the A1 group, lower toxicity and nonflammable; R-123 in the B1 group, higher toxicity and nonflammable; and R-717 (ammonia) in the B2 group, higher toxicity and lower flammability.

2. *Effectiveness of refrigeration cycle.* High effectiveness is a desired property. The power consumed per ton of refrigeration produced, hp/ton or kW/ton, is an index for this assessment. Table 9.4.1 gives values for an ideal single-stage vapor compression cycle.
3. *Oil miscibility.* Refrigerant should be miscible with mineral lubricant oil because a mixture of refrigerant and oil helps to lubricate pistons and discharge valves, bearings, and other moving parts of a compressor. Oil should also be returned from the condenser and evaporator for continuous lubrication. R-22 is partially miscible. R-134a is hardly miscible with mineral oil; therefore, synthetic lubricant of polyolester will be used.
4. *Compressor displacement.* Compressor displacement per ton of refrigeration produced, in cfm/ton, directly affects the size of the positive displacement compressor and therefore its compactness. Ammonia R-717 requires the lowest compressor displacement (1.70 cfm/ton) and R-22 the second lowest (1.91 cfm/ton).
5. Desired properties:
   - Evaporating pressure p_{ev} should be higher than atmospheric. Then noncondensable gas will not leak into the system.
   - Lower condensing pressure for lighter construction of compressor, condenser, piping, etc.
   - A high thermal conductivity and therefore a high heat transfer coefficient in the evaporator and condenser.
   - Dielectric constant should be compatible with air when the refrigerant is in direct contact with motor windings in hermetic compressors.
   - An inert refrigerant that does not react chemically with material will avoid corrosion, erosion, or damage to system components. Halocarbons are compatible with all containment materials except magnesium alloys. Ammonia, in the presence of moisture, is corrosive to copper and brass.
   - Refrigerant leakage can be easily detected. Halide torch, electronic detector, and bubble detection are often used.

Ideal Single-Stage Vapor Compression Cycle

Refrigeration Process

A refrigeration process shows the change of the thermodynamic properties of the refrigerant and the energy and work transfer between the refrigerant and surroundings.

Energy and work transfer is expressed in British thermal units per hour, or Btu/hr. Another unit in wide use is ton of refrigeration, or ton. A ton = 12,000 Btu/hr of heat removed; i.e., 1 ton of ice melting in 24 hr = 12,000 Btu/hr.

Refrigeration Cycles

When a refrigerant undergoes a series of processes like evaporation, compression, condensation, throttling, and expansion, absorbing heat from a low-temperature source and rejecting it to a higher temperature sink, it is said to have undergone a refrigeration cycle. If its final state is equal to its initial state, it is a *closed cycle*; if the final state does not equal the initial state, it is an *open cycle*. Vapor compression refrigeration cycles can be classified as single stage, multistage, compound, and cascade cycles.

A *pressure-enthalpy diagram* or *p-h* diagram is often used to calculate the energy transfer and to analyze the performance of a refrigeration cycle, as shown in Figure 9.4.1. In a *p-h* diagram, pressure *p*, in psia or psig logarithmic scale, is the ordinate, and enthalpy *h*, in Btu/lb, is the abscissa. The saturated liquid and saturated vapor line encloses a two-phase region in which vapor and liquid coexist. The two-phase region separates the subcooling liquid and superheated vapor regions. The constant-temperature

© 1999 by CRC Press LLC

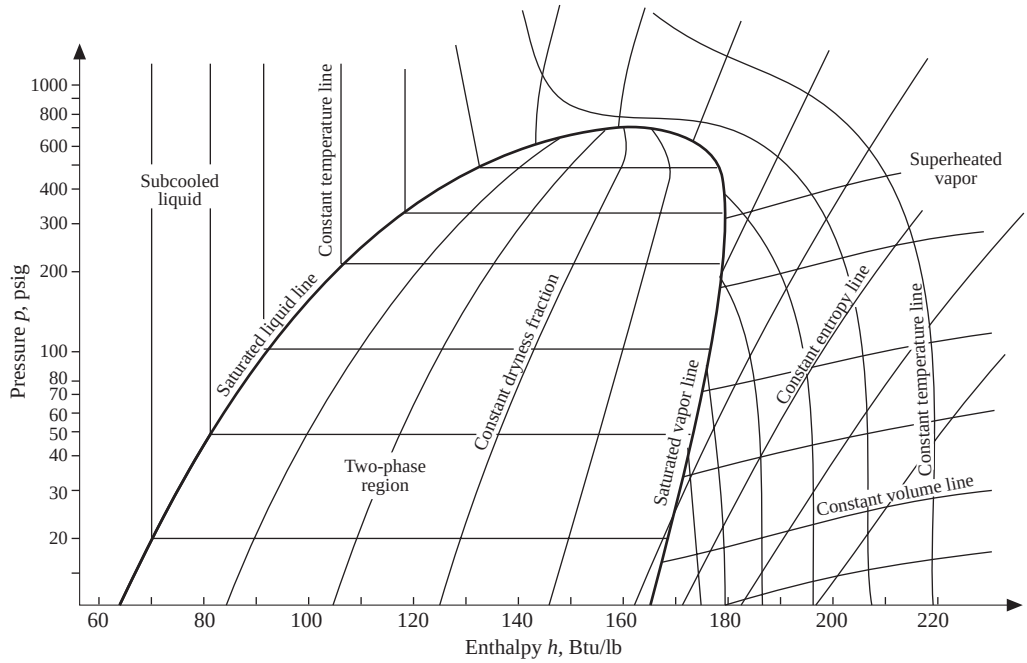

FIGURE 9.4.1 Skeleton of pressure-enthalpy diagram for R-22.

line is nearly vertical in the subcooling region, horizontal in the two-phase region, and curved down sharply in the superheated region.

In the two-phase region, a given saturated pressure determines the saturated temperature and vice versa. The constant-entropy line is curved upward to the right-hand side in the superheated region. Each kind of refrigerant has its own *p-h* diagram.

Refrigeration Processes in an Ideal Single-Stage Cycle

An *ideal cycle* has isentropic compression, and pressure losses in the pipeline, valves, and other components are neglected. All refrigeration cycles covered in this section are ideal. Single stage means a single stage of compression.

There are four refrigeration processes in an ideal single-stage vapor compression cycle, as shown in Figure 9.4.2(a) and (b):

1. Isothermal evaporation process 4–1 — The refrigerant evaporates completely in the evaporator and produces refrigeration effect q_{rf}, in Btu/lb:

$$q_{rf} = (h_1 - h_4) \tag{9.4.1}$$

   where h_1,h_4 = enthalpy of refrigerant at state points 1 and 4, respectively, Btu/lb.
2. Isentropic compression process 1–2 — Vapor refrigerant is extracted by the compressor and compressed isentropically from point 1 to 2. The work input to the compressor W_{in}, in Btu/lb, is

$$W_{in} = (h_2 - h_1) \tag{9.4.2}$$

   where h_2 = enthalpy of refrigerant at state point 2, Btu/lb.
   The greater the difference in temperature/pressure between the condensing pressure p_{con} and evaporating pressure p_{ev}, the higher will be the work input to the compressor.

© 1999 by CRC Press LLC

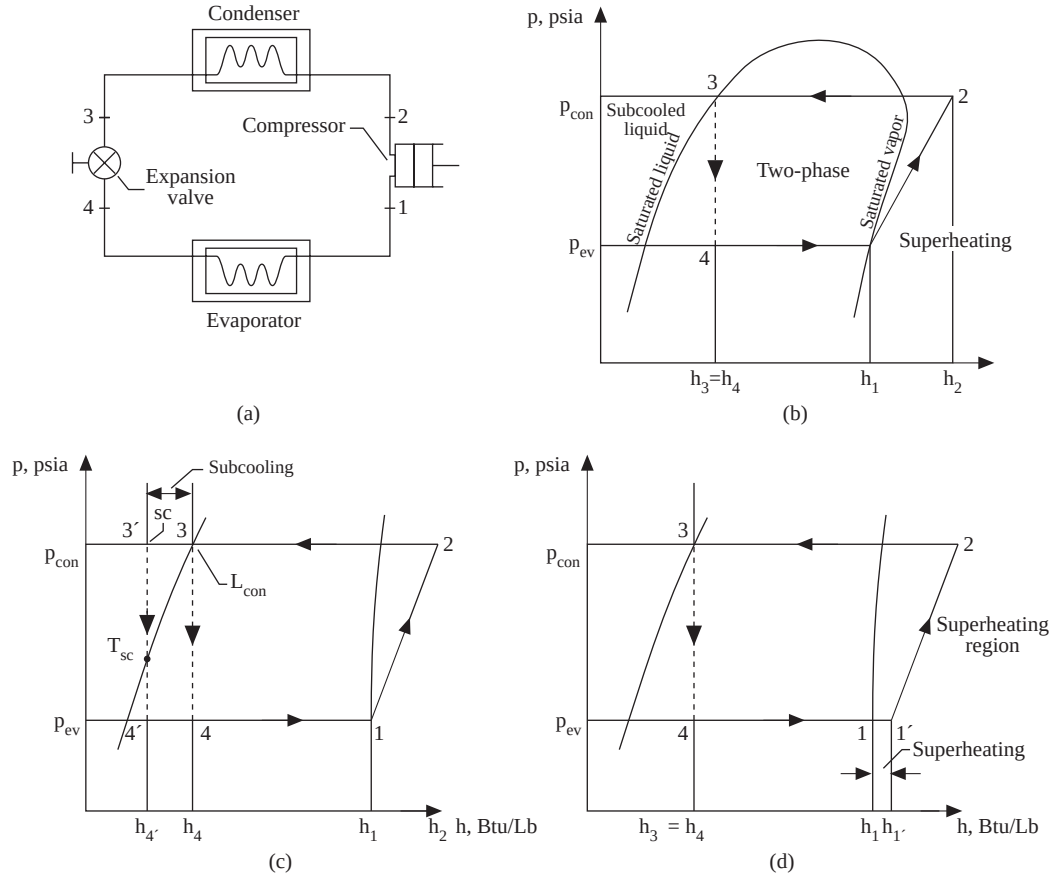

FIGURE 9.4.2 A single-stage ideal vapor compression refrigeration cycle: (a) schematic diagram, (b) *p-h* diagram, (c) subcooling, and (d) superheating.

3. Isothermal condensation process 2–3 — Hot gaseous refrigerant discharged from the compressor is condensed in the condenser into liquid, and the latent heat of condensation is rejected to the condenser water or ambient air. The heat rejection during condensation, q_{2-3}, in Btu/lb, is

$$-q_{2-3} = \left(h_2 - h_3\right) \tag{9.4.3}$$

where h_3 = enthalpy of refrigerant at state point 3, Btu/lb.

4. Throttling process 3–4 — Liquid refrigerant flows through a throttling device (e.g., an expansion valve, a capillary tube, or orifices) and its pressure is reduced to the evaporating pressure. A portion of the liquid flashes into vapor and enters the evaporator. This is the only irreversible process in the ideal cycle, usually represented by a dotted line. For a throttling process, assuming that the heat gain from the surroundings is negligible:

$$h_3 = h_4 \tag{9.4.4}$$

The mass flow rate of refrigerant $\dot{m}_r$, in lb/min, is

$$\dot{m}_r = q_{rc}/60q_{rf} \tag{9.4.5}$$

© 1999 by CRC Press LLC

where q_{rc} = refrigeration capacity of the system, Btu/hr.
The ideal single-stage vapor compression refrigeration cycle on a *p-h* diagram is divided into two pressure regions: high pressure (p_{con}) and low pressure (p_{ev}).

Coefficient of Performance of Refrigeration Cycle

The *coefficient of performance* (COP) is a dimensionless index used to indicate the performance of a thermodynamic cycle or thermal system. The magnitude of COP can be greater than 1.

- If a *refrigerator* is used to produce a refrigeration effect, COP_{ref} is

$$COP_{ref} = q_{rf} / W_{in} \tag{9.4.6}$$

- If a *heat pump* is used to produce a useful heating effect, its performance denoted by COP_{hp} is

$$COP_{hp} = q_{2-3} / W_{in} \tag{9.4.7}$$

- For a heat recovery system when both refrigeration and heating effects are produced, the COP_{hr} is denoted by the ratio of the sum of the absolute values of q_{rf} and $q_{2\text{-}3}$ to the work input, or

$$COP_{hr} = \left(\left|q_{rf}\right| + \left|q_{2-3}\right|\right) / W_{in} \tag{9.4.8}$$

Subcooling and Superheating

Condensed liquid is often subcooled to a temperature lower than the saturated temperature corresponding to the condensing pressure p_{con}, in psia or psig, as shown in Figure 9.4.2(c). *Subcooling* increases the refrigeration effect to $q_{rf.sc}$ as shown in Figure 9.4.2(c):

$$q_{rf.sc} = \left(h_{4'} - h_1\right) > \left(h_4 - h_1\right) \tag{9.4.9}$$

The enthalpy of subcooled liquid refrigerant h_{sc} approximately equals the enthalpy of the saturated liquid refrigerant at subcooled temperature $h_{s.sc}$, both in Btu/lb:

$$h_{sc} = h_{3'} = h_{4'} = h_{1.con} - c_{pr}\left(T_{con} - T_{sc}\right) \approx h_{s.sc} \tag{9.4.10}$$

where $h_{3'}$, $h_{4'}$ = enthalpy of liquid refrigerant at state points 3′ and 4′ respectively, Btu/lb
$h_{l.con}$ = enthalpy of saturated liquid at condensing temperature, Btu/lb
c_{pr} = specific heat of liquid refrigerant at constant pressure, Btu/lb °F
T_{con} = condensing temperature or saturated temperature of liquid refrigerant at condensing pressure, °F
T_{sc} = temperature of subcooled liquid refrigerant, °F

The purpose of *superheating* is to prevent liquid refrigerant flooding back into the compressor and causing slugging damage as shown in Figure 9.4.2(d). The degree of superheating depends mainly on the types of refrigerant feed, construction of the suction line, and type of compressor. The state point of vapor refrigerant after superheating of an ideal system must be at the evaporating pressure with a specific degree of superheat and can be plotted on a *p-h* diagram for various refrigerants.

Refrigeration Cycle of Two-Stage Compound Systems with a Flash Cooler

A *multistage system* employs more than one compression stage. Multistage vapor compression systems are classified as compound systems and cascade systems. A *compound system* consists of two or more

© 1999 by CRC Press LLC

compression stages connected in series. It may have one high-stage compressor (higher pressure) and one low-stage compressor (lower pressure), several compressors connected in series, or two or more impellers connected internally in series and driven by the same motor.

The *compression ratio* R_{com} is defined as the ratio of discharge pressure p_{dis} to the suction pressure at the compressor inlet p_{suc}:

$$R_{com} = p_{dis} / p_{suc} \tag{9.4.11}$$

Compared to a single-stage system, a multistage has a smaller compression ratio and higher compression efficiency for each stage of compression, greater refrigeration effect, lower discharge temperature at the high-stage compressor, and greater flexibility. At the same time, a multistage system has a higher initial cost and more complicated construction.

The pressure between the discharge pressure of the high-stage compressor and the suction pressure of the low-stage compressor of a multistage system is called *interstage pressure* p_i, in psia. Interstage pressure for a two-stage system is usually determined so that the compression ratios are nearly equal between two stages for a higher COP. Then the interstage pressure is

$$p_i = \sqrt{\left(p_{con} p_{ev}\right)} \tag{9.4.12}$$

where p_{con}, p_{ev} = condensing and evaporating pressures, psia.

For a multistage system of n stages, then, the compression ratio of each stage is

$$R_{com} = \left(p_{con} / p_{suc}\right)^{1/n} \tag{9.4.13}$$

Figure 9.4.3(a) shows a schematic diagram and Figure 9.4.3(b) the refrigeration cycle of a two-stage compound system with a flash cooler. A *flash cooler*, sometimes called an economizer, is used to subcool the liquid refrigerant to the saturated temperature corresponding to the interstage pressure by vaporizing a portion of the liquid refrigerant in the flash cooler.

Based on the principle of heat balance, the fraction of evaporated refrigerant, x, or quality of the mixture in the flash cooler is

$$x = \left(h_{5'} - h_8\right) / \left(h_7 - h_8\right) \tag{9.4.14}$$

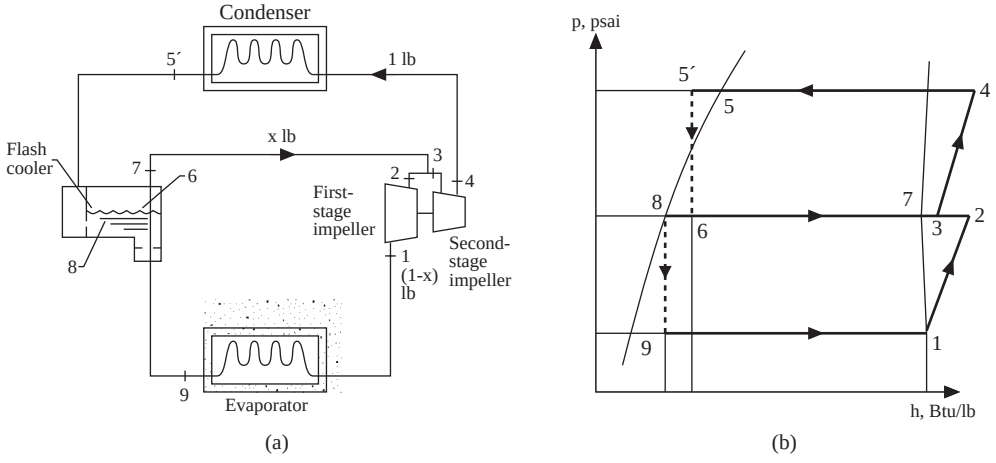

FIGURE 9.4.3 Two-stage compound system with a flash cooler: (a) schematic diagram and (b) refrigeration cycle.

© 1999 by CRC Press LLC

where $h_{5'}$, h_7, h_8 = enthalpy of the refrigerant at state points 5′, 7, and 8, respectively, Btu/lb. The coefficient of performance of the refrigeration cycle of a two-stage compound system with a flash cooler, COP_{ref}, is given as

$$COP_{ref} = q_{rf}/W_{in} = (1-x)(h_1 - h_9)/[(1-x)(h_2 - h_1) + (h_4 - h_3)] \quad (9.4.15)$$

where h_1, h_2, h_3, h_4, h_9 = enthalpy of refrigerant at state points 1, 2, 3, 4, and 9, respectively, Btu/lb. The mass flow rate of refrigerant flowing through the condenser, $\dot{m}_r$, in lb/min, can be calculated as

$$\dot{m}_r = q_{rc}/60q_{rf} \quad (9.4.16)$$

Because a portion of liquid refrigerant is flashed into vapor in the flash cooler and goes directly to the second-stage impeller inlet, less refrigerant is compressed in the first-stage impeller. In addition, the liquid refrigerant in the flash cooler is cooled to the saturated temperature corresponding to the interstage temperature before entering the evaporator, which significantly increases the refrigeration effect of this compound system. Two-stage compound systems with flash coolers are widely used in large central air-conditioning systems.

Cascade System Characteristics

A *cascade system* consists of two independently operated single-stage refrigeration systems: a lower system that maintains a lower evaporating temperature and produces a refrigeration effect and a higher system that operates at a higher evaporating temperature as shown in Figure 9.4.4(a) and (b). These two separate systems are connected by a *cascade condenser* in which the heat released by the condenser in the lower system is extracted by the evaporator in the higher system.

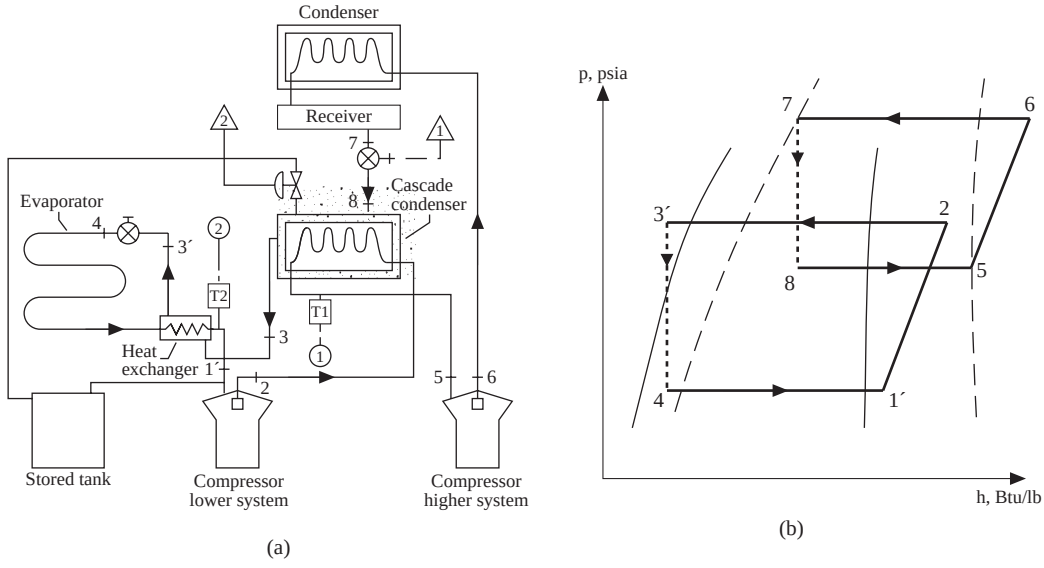

FIGURE 9.4.4 Cascade system: (a) schematic diagram and (b) refrigeration cycle.

© 1999 by CRC Press LLC

A heat exchanger is often used between the liquid refrigerant from the condenser and the vapor refrigerant leaving the evaporator of the lower system. When the system is shut down in summer, a relief valve connected to a stored tank should be used to relieve the higher pressure of refrigerant at the higher storage temperature.

The main advantages of a cascade system compared with a compound system are that different refrigerants, oils, and equipment can be used for the lower and higher systems. Disadvantages are the overlap of the condensing temperature of the lower system and the evaporating temperature of the higher system because of the heat transfer in the cascade condenser and a more complicated system.

The refrigeration effect q_{rf} of the cascade system is

$$q_{rf} = \left(h_1 - h_4\right) \tag{9.4.17}$$

where h_1, h_4 = enthalpy of the refrigerant leaving and entering the evaporator of the lower system, Btu/lb. The total work input to the compressors in both higher and lower systems W_{in}, in Btu/lb, can be calculated as

$$W_{in} = \left(h_2 - h_{1'}\right) + \mathring{m}_h\left(h_6 - h_5\right) \Big/ \mathring{m}_1 \tag{9.4.18}$$

where h_2 = enthalpy of refrigerant discharged from the compressor of the lower system
$h_{1'}$ = enthalpy of the vapor refrigerant leaving the heat exchanger
h_6, h_5 = enthalpy of the refrigerant leaving and entering the high-stage compressor
$\mathring{m}_h, \mathring{m}_1$ = mass flow rate of the refrigerant of the higher and lower systems, respectively

The coefficient of performance of a cascade system COP_{ref} is

$$COP_{ref} = q_{rf} / W_{in} = \mathring{m}_1\left(h_1 - h_4\right) \Big/ \left[\mathring{m}_1\left(h_2 - h_{1'}\right) + \mathring{m}_h\left(h_6 - h_5\right)\right] \tag{9.4.19}$$

9.5 Outdoor Design Conditions and Indoor Design Criteria

Outdoor Design Conditions

In principle, the capacity of air-conditioning equipment should be selected to offset or compensate for the space load so that indoor design criteria can be maintained if the outdoor weather does not exceed the design values. Outdoor and indoor design conditions are used to calculate the design space loads. In energy use calculations, hour-by-hour outdoor climate data of a design day should be adopted instead of summer and winter design values.

ASHRAE Handbook 1993 Fundamentals (Chapter 24 and 27) and *Wang's Handbook of Air Conditioning and Refrigeration* (Chapter 7) both list tables of climate conditions for the U.S. and Canada based on the data from the National Climate Data Center (NCDC), U.S. Air Force, U.S. Navy, and Canadian Atmospheric Environment Service. In these tables:

- *Summer design dry bulb temperature* in a specific location $T_{o.s}$, in °F, is the rounded higher integral number of the statistically determined summer outdoor design dry bulb temperature $T_{o.ss}$ so that the average number of hours of occurrence of outdoor dry bulb temperature T_o higher than $T_{o.ss}$ during June, July, August, and September is less than 1, 2.5, or 5% of the total number of hours in these summer months (2928 hr). The data are an average of 15 years. An occurrence of less than 2.5% of 2928 hr of summer months, that is, $0.025 \times 2928 = 73$ hr, is most widely used.
- *Summer outdoor mean coincident wet bulb temperature* $T'_{o.s}$, in °F, is the mean of all the wet bulb temperatures at the specific summer outdoor design dry bulb temperature $T_{o.s}$ during the summer months.
- *Summer outdoor 2.5% design wet bulb temperature* is the design wet bulb temperature that has an average annual occurrence of $T'_o > T'_{o.s}$ less than 73 hr. This design value is often used for evaporative cooling design.
- *Mean daily range*, in °F, is the difference between the average daily maximum and the average daily minimum temperature during the warmest month.
- In *ASHRAE Handbook 1993 Fundamentals, solar heat gain factors* (SHGFs), in Btu/h.ft^2, are the average solar heat gain per hour during cloudless days through double-strength sheet (DSA) glass. The *maximum SHGFs* are the maximum values of SHGFs on the 21st of each month for a specific latitude.
- *Winter outdoor design dry bulb temperature* $T_{o.w}$, in °F, is the rounded lower integral value of the statically determined winter outdoor design temperature $T_{o.ws}$, so that the annual average number of hours of occurrence of outdoor temperature $T_o > T_{o.ws}$ is equal to or exceeds 99%, or 97.5% of the total number of hours in December, January, and February (2160 hr).

A *degree day* is the difference between a base temperature and the mean daily outdoor air temperature $T_{o.m}$ for any one day, in °F. The total numbers of heating degree days HDD65 and cooling degree days CDD65 referring to a base temperature of 65°F per annum are

$$\text{HDD65} = \sum_{n=1} \left(65 - T_{o.m}\right)$$
$$\text{CDD65} = \sum_{m=1} \left(T_{o.m} - 65\right) \tag{9.5.1}$$

where n = number of days for which $T_{o.m} < 65$°F
m = number of days for which $T_{o.m} > 65$°F

© 1999 by CRC Press LLC

Indoor Design Criteria and Thermal Comfort

Indoor design criteria, such as space temperature, humidity, and air cleanliness, specify the requirements for the indoor environment as well as the quality of an air-conditioning or HVAC&R project.

The human body requires energy for physical and mental activity. This energy comes from the oxidation of food. The rate of heat release from the oxidation process is called the *metabolic rate*, expressed in met (1 met = 18.46 Btu/h.ft^2). The metabolic rate depends mainly on the intensity of the physical activity of the human body. Heat is released from the human body by two means: *sensible heat exchange* and *evaporative heat loss*. Experience and experiments all show that there is thermal comfort only under these conditions:

- Heat transfer from the human body to the surrounding environment causes a steady state of thermal equilibrium; that is, there is no heat storage in the body core and skin surface.
- Evaporative loss or regulatory sweating is maintained at a low level.

The physiological and environmental factors that affect the thermal comfort of the occupants in an air-conditioned space are mainly:

1. Metabolic rate M determines the amount of heat that must be released from the human body.
2. *Indoor air temperature* T_r and *mean radiant temperature* T_{rad}, both in °F. The *operating temperature* T_o is the weighted sum of T_r and T_{rad}. T_{rad} is defined as the temperature of a uniform black enclosure in which the surrounded occupant would have the same radiative heat exchange as in an actual indoor environment. T_r affects both the sensible heat exchange and evaporative losses, and T_{rad} affects only sensible heat exchange. In many indoor environments, $T_{rad} \approx T_r$.
3. Relative humidity of the indoor air φ_r, in %, which is the primary factor that influences evaporative heat loss.
4. Air velocity of the indoor air v_r, in fpm, which affects the heat transfer coefficients and therefore the sensible heat exchange and evaporative loss.
5. *Clothing insulation* R_{cl}, in clo (1 clo = 0.88 h.ft^2.°F/Btu), affects the sensible heat loss. Clothing insulation for occupants is typically 0.6 clo in summer and 0.8 to 1.2 clo in winter.

Indoor Temperature, Relative Humidity, and Air Velocity

For comfort air-conditioning systems, according to ANSI/ASHRAE Standard 55-1981 and ASHRAE/IES Standard 90.1-1989, the following indoor design temperatures and air velocities apply for conditioned spaces where the occupant's activity level is 1.2 met, indoor space relative humidity is 50% (in summer only), and $T_r = T_{rad}$:

	Clothing insulation (clo)	**Indoor temperature (°F)**	**Air velocity (fpm)**
Winter	0.8–0.9	69–74	<30
Summer	0.5–0.6	75–78	<50

If a suit jacket is the clothing during summer for occupants, the summer indoor design temperature should be dropped to 74 to 75°F.

Regarding the indoor humidity:

1. Many comfort air-conditioning systems are not equipped with humidifiers. Winter indoor relative humidity should not be specified in such circumstances.
2. When comfort air-conditioning systems are installed with humidifiers, ASHRAE/IES Standard 90.1-1989 requires that the humidity control prevent "the use of fossil fuel or electricity to produce humidity in excess of 30% ... or to reduce relative humidity below 60%."

© 1999 by CRC Press LLC

3. Indoor relative humidity should not exceed 75% to avoid increasing bacterial and viral populations.
4. For air-conditioning systems that use flow rate control in the water cooling coil, space indoor relative humidity may be substantially higher in part load than at full load.

Therefore, for comfort air-conditioning systems, the recommended indoor relative humidities, in %, are

	Tolerable range	**Preferred value**
Summer	30–65	40–50
Winter		
With humidifier		25–30
Without humidifier		Not specified

In surgical rooms or similar health care facilities, the indoor relative humidity is often maintained at 40 to 60% year round.

Indoor Air Quality and Outdoor Ventilation Air Requirements

According to the National Institute for Occcupational Safety and Health (NIOSH), 1989, the causes of indoor air quality complaints in buildings are inadequate outdoor ventilation air, 53%; indoor contaminants, 15%; outdoor contaminants, 10%; microbial contaminants, 5%; construction and furnishings, 4%; unknown and others, 13%. For space served by air-conditioning systems using low- and medium-efficiency air filters, according to the U.S. Environmental Protection Agency (EPA) and Consumer Product Safety Commission (CPSC) publication "A Guide to Indoor Air Quality" (1988) and the field investigations reported by Bayer and Black (1988), *indoor air contaminants* may include some of the following:

1. *Total particulate concentration.* This concentration comprises particles from building materials, combustion products, mineral fibers, and synthetic fibers. In February 1989, the EPA specified the allowable indoor concentration of particles of 10 μm and less in diameter (which penetrate deeply into lungs) as:

   50 $\mu g/m^3$ (0.000022 grain/ft^3), 1 year
   150 $\mu g/m^3$ (0.000066 grain/ft^3), 24 hr

   In these specifications, "1 year" means maximum allowable exposure per day over the course of a year.
2. *Formaldehyde and organic gases*. Formaldehyde is a colorless, pungent-smelling gas. It comes from pressed wood products, building materials, and combustion. Formaldehyde causes eye, nose, and throat irritation as well as coughing, fatigue, and allergic reactions. Formaldehyde may also cause cancer. Other organic gases come from building materials, carpeting, furnishings, cleaning materials, etc.
3. *Radon*. Radon, a colorless and odorless gas, is released by the decay of uranium from the soil and rock beneath buildings, well water, and building materials. Radon and its decay products travel through pores in soil and rock and infiltrate into buildings along the cracks and other openings in the basement slab and walls. Radon at high levels causes lung cancer. The EPA believes that levels in most homes can be reduced to 4 pCi/l (picocuries per liter) of air. The estimated national average is 1.5 pCi/l, and levels as high as 200 pCi/l have been found in houses.
4. *Biologicals*. These include bacteria, fungi, mold and mildew, viruses, and pollen. They may come from wet and moist walls, carpet furnishings, and poorly maintained dirty air-conditioning systems and may be transmitted by people. Some biological contaminants cause allergic reactions, and some transmit infectious diseases.

© 1999 by CRC Press LLC

5. *Combustion products*. These include environmental tobacco smoke, nitrogen dioxide, and carbon monoxide. *Environmental tobacco* smoke from cigarettes is a discomfort factor to other persons who do not smoke, especially children. Nicotine and other tobacco smoke components cause lung cancer, heart disease, and many other diseases. *Nitrogen dioxide* and *carbon monoxide* are both combustion products from unvented kerosene and gas space heaters, woodstoves, and fireplaces. Nitrogen dioxide (NO_2) causes eye, nose, and throat irritation; may impair lung function; and increases respiratory infections. Carbon monoxide (CO) causes fatigue at low concentrations; impaired vision, headache, and confusion at higher concentrations; and is fatal at very high concentrations. Houses without gas heaters and gas stoves may have CO levels varying from 0.5 to 5 parts per million (ppm).
6. *Human bioeffluents*. These include the emissions from breath including carbon dioxide exhaled from the lungs, body odors from sweating, and gases emitted as flatus.

There are three basic means of reducing the concentration of indoor air contaminants and improving indoor air quality: (1) eliminate or reduce the source of air pollution, (2) enhance the efficiency of air filtration, and (3) increase the ventilation (outdoor) air intake. Dilution of the concentrations of indoor contaminants by outdoor ventilation air is often the simple and cheapest way to improve indoor air quality. The amount of outdoor air required for metabolic oxidation is rather small.

Abridged outdoor air requirements listed in ANSI/ASHRAE Standard 62-1989 are as follows:

Applications	cfm/person
Hotels, conference rooms, offices	20
Retail stores	0.2–0.3 cfm/ft^2
Classrooms, theaters, auditoriums	15
Hospital patient rooms	25

These requirements are based on the analysis of dilution of CO_2 as the representative human bioeffluent to an allowable indoor concentration of 1000 ppm. Field measurements of daily maximum CO_2 levels in office buildings reported by Persily (1993) show that most of them were within the range 400 to 820 ppm. The quality of outdoor air must meet the EPA's National Primary and Secondary Ambient Air Quality Standards, some of which is listed below:

	Long-term concentration			**Short-term concentration**		
Pollutants	**μg/m^3**	**ppm**	**Exposure**	**μg/m^3**	**ppm**	**Exposure**
Particulate	75		1 year	260		24 hr
SO_2	80	0.03	1 year	365	0.14	24 hr
CO				40,000	35	1 hr
				10,000	9	8 hr
NO_2	100	0.055	1 year			
Lead	1.5		3 months			

Here exposure means average period of exposure.

If unusual contaminants or unusually strong sources of contaminants are introduced into the space, or recirculated air is to replace part of the outdoor air supply for occupants, then acceptable indoor air quality is achieved by controlling known and specific contaminants. This is called an indoor air quality procedure. Refer to ANSI/ASHRAE Standard 62-1989 for details.

Clean Rooms

Electronic, pharmaceutical, and aerospace industries and operating rooms in hospitals all need strict control of air cleanliness during manufacturing and operations. According to ASHRAE Handbook 1991 HVAC Applications, clean rooms can be classified as follows based on the particle count per ft^3:

© 1999 by CRC Press LLC

Class	Particle size	
	0.5 μm and larger	5 μm and larger
	Particle count per ft^3 not to exceed	
1	1	0
10	10	0
100	100	
1000	1000	
10,000	10,000	65
100,000	100,000	700

For clean rooms, space temperature is often maintained at 72 ± 2°F and space humidity at 45 ± 5%. Here, ±2°F and ±5% are allowable tolerances. Federal Standard 209B specifies that the ventilation (outdoor air) rate should be 5 to 20% of the supply air.

Space Pressure Differential

Most air-conditioning systems are designed to maintain a slightly higher pressure than the surroundings, a positive pressure, to prevent or reduce infiltration and untreated air entering the space directly. For laboratories, restrooms, or workshops where toxic, hazardous, or objectional gases or contaminants are produced, a slightly lower pressure than the surroundings, a negative pressure, should be maintained to prevent or reduce the diffusion of these contaminants' exfiltrate to the surrounding area.

For comfort air-conditioning systems, the recommended pressure differential between the indoor and outdoor air is 0.02 to 0.05 in in. WG. WG indicates the pressure at the bottom of a top-opened water column of specific inches of height; 1 in. WG = 0.03612 psig.

For clean rooms, Federal Standard No. 209B, Clean Rooms and Work Stations Requirements (1973), specifies that the minimum positive pressure between the clean room and any adjacent area with lower cleanliness requirements should be 0.05 in. WG with all entryways closed. When the entryways are open, an outward flow of air is to be maintained to prevent migration of contaminants into the clean room. In comfort systems, the space pressure differential is usually not specified in the design documents.

Sound Levels

Noise is any unwanted sound. In air-conditioning systems, noise should be attenuated or masked with another less objectionable sound.

Sound power is the capability to radiate power from a sound source exited by an energy input. The intensity of sound power is the output from a sound source expressed in watts (W). Due to the wide variation of sound output at a range of 10^{20} to 1, it is more convenient to use a logarithmic expression to define a *sound power level* L_w, in dB:

$$L_w = 10\log\left(w/10^{-12}\ \text{W}\right)\ \text{re 1 pW} \tag{9.5.2}$$

where w = sound source power output, W.

The human ear and microphones are sound pressure sensitive. Similarly to the sound power level, the *sound pressure level* L_p, in dB, is defined as:

$$L_p = 20\log\left(p/2\times10^{-5}\ \text{Pa}\right)\ \text{re 20 μPa} \tag{9.5.3}$$

where p = sound pressure, Pa.

The sound power level of any sound source is a fixed output. It cannot be measured directly; it can only be calculated from the measured sound pressure level. The sound pressure level at any one point is affected by the distance from the source and the characteristics of the surroundings.

© 1999 by CRC Press LLC

Human ears can hear frequencies from 20 Hz to 20 kHz. For convenience in analysis, sound frequencies are often subdivided into eight octave bands. An *octave* is a frequency band in which the frequency of the upper limit of the octave is double the frequency of the lower limit. An octave band is represented by its center frequency, such as 63, 125, 250, 500, 1000, 2000, 4000, and 8000 Hz. On 1000 Hz the octave band has a higher limit of 1400 Hz and a lower limit of 710 Hz. Human ears do not respond in the same way to low frequencies as to high frequencies.

The object of noise control in an air conditioned space is to provide background sound low enough that it does not interfere with the acoustical requirements of the occupants. The distribution of background sound should be balanced over a broad range of frequencies, that is, without whistle, hum, rumble, and beats.

The most widely used criteria for sound control are the noise criteria NC curves. The shape of NC curves is similar to the equal-loudness contour representing the response of the human ear. NC curves also intend to indicate the permissible sound pressure level of broad-band noise at various octave bands rated by a single NC curve. NC curves are practical and widely used.

Other criteria used are room criteria RC curves and A-weighted sound level, dBA. RC curves are similar to NC curves except that the shape of the RC curves is a close approximation to a balanced, bland-sounding spectrum. The A-weighted sound level is a single value and simulates the response of the human ear to sound at low sound pressure levels.

The following are abridged indoor design criteria, NC or RC range, listed in *ASHRAE Handbook 1987 Systems and Applications*:

Type of area	Recommended NC or RC range (dB)
Hotel guest rooms	30–35
Office	
Private	30–35
Conference	25–30
Open	30–35
Computer equipment	40–45
Hospital, private	25–30
Churches	25–30
Movie theaters	30–35

For industrial factories, if the machine noise in a period of 8 hr exceeds 90 dBA, Occupational Safety and Health Administration Standard Part 1910.95 requires the occupants to use personal protection equipment. If the period is shorter, the dBA level can be slightly higher. Refer to this standard for details.

9.6 Load Calculations

Space Loads

Space, Room, and Zone

Space indicates a volume or a site without partitions, or a partitioned room or a group of rooms. A *room* is an enclosed or partitioned space that is considered as a single load. An air-conditioned room does not always have an individual zone control system. A *zone* is a space of a single room or group of rooms having similar loads and operating characteristics. An air-conditioned zone is always installed with an individual control system. A typical floor in a building may be treated as a single zone space, or a *multizone space* of perimeter, interior, east, west, south, north, ... zones.

Space and equipment loads can be classified as:

1. *Space heat gain* q_e, in Btu/hr, is the rate of heat transfer entering a conditioned space from an external heat source or heat releases to the conditioned space from an internal source. The rate of sensible heat entering the space is called *sensible heat gain* q_{es}, whereas the rate of latent heat entering the space is called *latent heat gain* q_{el}. In most load calculations, the time interval is often 1 hr, and therefore q_e, q_{es}, and q_{el} are all expressed in Btu/hr.
2. *Space cooling load* or simply *cooling load* q_{rc}, also in Btu/hr, is the rate at which heat must be removed from a conditioned space to maintain a constant space temperature and an acceptable relative humidity. The sensible heat removed is called *sensible cooling load* q_{rs}, and the latent heat removed is called *latent cooling load* q_{rl}, both in Btu/hr.
3. *Space heat extraction rate* q_{ex}, in Btu/hr, is the rate at which heat is removed from the conditioned space. When the space air temperature is constant, $q_{ex} = q_{rc}$.
4. *Space heating load* q_{rh}, in Btu/hr, is the rate at which heat must be added to the conditioned space to maintain a constant temperature.
5. *Coil load* q_c, in Btu/hr, is the rate of heat transfer at the coil. The cooling *coil load* q_{cc} is the rate of heat removal from the conditioned air by the chilled water or refrigerant inside the coil. The *heating coil load* q_{ch} is the rate of heat energy addition to the conditioned air by the hot water, steam, or electric elements inside the coil.
6. *Refrigeration load* q_{rl}, in Btu/hr, is the rate at which heat is extracted by the evaporated refrigerant at the evaporator. For packaged systems using a DX coil, $q_{rl} = q_{cc}$. For central systems:

$$q_{rl} = q_{cc} + q_{pi} + q_{pu} + q_{s.t} \tag{9.6.1}$$

where q_{pi} = chilled water piping heat gain, Btu/hr
q_{pu} = pump power heat gain, Btu/hr
$q_{s.t}$ = storage tank heat gain, if any, Btu/hr

Heat gains q_{pi} and q_{pu} are usually about 5 to 10% of the cooling coil load q_{cc}.

Convective Heat and Radiative Heat

Heat enters a space and transfer to the space air from either an external source or an internal source is mainly in the form of *convective heat* and *radiative heat* transfer.

Consider radiative heat transfer, such as solar radiation striking the outer surface of a concrete slab as shown in Figure 9.6.1(a) and (b). Most of the radiative heat is absorbed by the slab. Only a small fraction is reflected. After the heat is absorbed, the outer surface temperature of the slab rises. If the slab and space air are in thermal equilibrium before the absorption of radiative heat, heat is convected from the outer surface of the slab to the space air as well as radiated to other surfaces. At the same time, heat is conducted from the outer surface to the inner part of the slab and stored there when the temperature of the inner part of the slab is lower than that of its outer surface. Heat convected from the outer surface of the concrete slab to the space air within a time interval forms the sensible cooling load.

© 1999 by CRC Press LLC

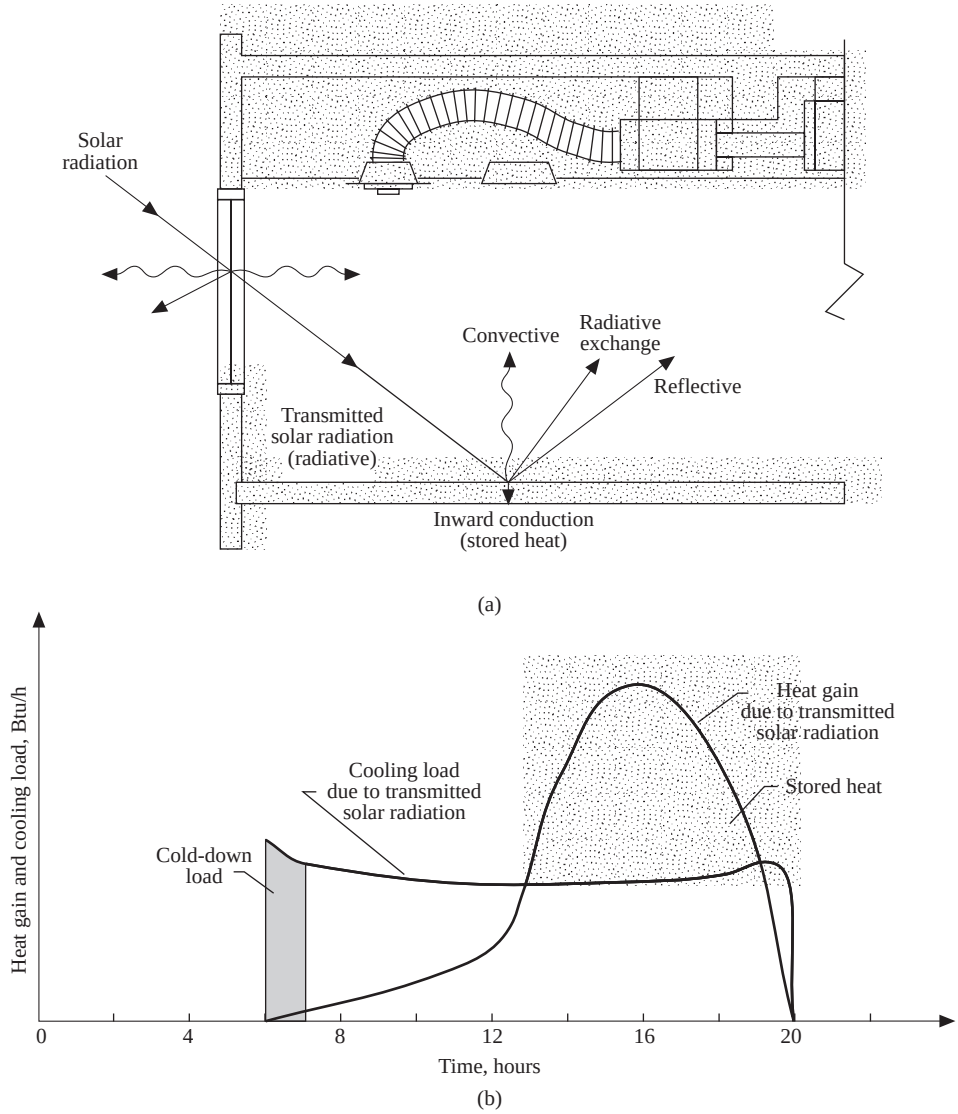

FIGURE 9.6.1 Solar heat gain from west window and its corresponding space cooling load for a night shutdown air system: (a) convective and radiative heat transfer and (b) heat gain and cooling load curves.

The sensible heat gain entering the conditioned space does not equal the sensible cooling load during the same time interval because of the stored heat in the building envelope. Only the convective heat becomes cooling load instantaneously. The sum of the convective heats from the outer surfaces, including the outer surfaces of the internal heat gains in a conditioned space, becomes cooling load. This phenomenon results in a smaller cooling load than heat gain, as shown in Figure 9.6.1(a) and (b). According to *ASHRAE Handbook 1993 Fundamentals*, the percentages of convective and radiative components of the sensible heat gains are as follows:

Sensible heat gains	Convective (%)	Radiative (%)
Solar radiation with internal shading	42	58
Fluorescent lights	50	50
Occupants	67	33
External wall, inner surface	40	60

© 1999 by CRC Press LLC

Load Profile, Peak Load, and Block Load

A *load profile* shows the variation of space, zone, floor, or building load in a certain time period, such as a 24-hr day-and-night cycle. In a load profile, load is always plotted against time. The load profile depends on the outdoor climate as well as the space operating characteristics.

Peak load is the maximum cooling load in a load profile. *Block load* is the sum of the zone loads and floor loads at a specific time. The sum of the zone peak loads in a typical floor does not equal the block load of that floor because the zone peak loads may all not appear at the same time.

Moisture Transfer in Building Envelope

Moisture transfer takes place along two paths:

1. Moisture migrates in the building envelope in both liquid and vapor form. It is mainly liquid if the relative humidity of the ambient air exceeds 50%. Liquid flow is induced by capillary flow and moisture content gradient. Vapor diffusion is induced by vapor pressure gradients. *Moisture content* is defined as the ratio of the mass of moisture contained in a solid to the mass of bone-dry solid. During the migration, the moisture content and the vapor pressure are in equilibrium at a specific temperature and location.
2. Air leakage and its associated water vapor infiltrate or exfiltrate through the cracks, holes, and gaps between joints because of poor construction of the building envelope. The driving potential of this air leakage and associated water vapor is the pressure differential across the building envelope. If the insulating material is of open-cell structure, air leakage and associated water vapor may penetrate the perforated insulating board through cracks and gaps. Condensation, even freezing, will occur inside the perforated insulation board if the temperature of the board is lower than the dew point of the leaked air or the freezing point of the water.

In most comfort air-conditioning systems, usually only the space temperature is controlled within limits. A slight variation of the space relative humidity during the operation of the air system is often acceptable. Therefore, the store effect of moisture is ignored except in conditioned spaces where both temperature and relative humidity need to be controlled or in a hot and humid area where the air system is operated at night shutdown mode. In most cases, latent heat gain is considered equal to latent cooling load instantaneously. For details refer to Wang's *Handbook of Air Conditioning and Refrigeration* (1993), Chapters 6 and 7.

Cooling Load Calculation Methodology

Basic considerations include the following:

- It is assumed that equations of heat transfer for cooling load calculation within a time interval are linear. It is also assumed that the superposition principle holds. When a number of changes occur simultaneously in the conditioned space, they will proceed as if independent of each other. The total change is the sum of the responses caused by the individual changes.
- Space load calculations are often performed by computer-aided design (CAD), with market-available software like DOE-2.1D, TRACE-600, and Carrier E20-II Loads.
- Peak load calculations evaluate the maximum load to size and select the equipment. The energy analysis program compares the total energy use in a certain period with various alternatives in order to determine the optimum one.
- The methodology of various cooling load calculations is mainly due to their differences in the conversion of space radiative heat gains into space cooling loads. Convective heat, latent heat, and sensible heat gains from infiltration are all equal to cooling loads instantaneously.
- Space cooling load is used to calculate the supply volume flow rate and to determine the size of the air system, ducts, terminals, and diffusers. The coil load is used to determine the size of the

© 1999 by CRC Press LLC

cooling coil and the refrigeration system. Space cooling load is a component of the cooling coil load.

The Rigorous Approach

The rigorous approach to the calculation of the space cooling load consists of (1) finding the inside surface temperatures of the building structures that enclose the conditioned space due to heat balance at time *t* and (2) calculating the sum of the convective heats transferred from these surfaces as well as from the occupants, lights, appliances, and equipment in the conditioned space at time *t*.

The inside surface temperature of each surface $T_{i,t}$, in °F, can be found from the following simultaneous heat balance equations:

$$q_{i,t} = \left[h_{ci}\left(T_{r,t} - T_{i,t}\right) + \sum_{j=1}^{m} g_{ij}\left(T_{j,t} - T_{i,t}\right) \right] A_i + S_{i,t} + L_{i,t} + P_{i,t} + E_{i,t} \qquad (9.6.2)$$

where h_{ci} = convective heat transfer coefficient, Btu/hr.ft^2.°F
g_{ij} = radiative heat transfer factor between inside surface *i* and inside surface *j*, Btu/hr.ft^2.°F
$T_{r,t}$ = space air temperature at time *t*, °F
$T_{i,t}$, $T_{j,t}$ = average temperature of inside surfaces *i* and *j* at time *t*, °F
A_i = area of inside surface *i*, ft^2
$S_{i,t}$, $L_{i,t}$, $P_{i,t}$, $E_{i,t}$ = solar radiation transmitted through windows and radiative heat from lights, occupants, and equipment absorbed by inside surface *i* at time *t*, Btu/hr

In Equation (9.6.2), $q_{i,t}$, in Btu/hr, is the conductive heat that comes to surface *i* at time *t* because of the temperature excitation on the outer opposite surface of *i*. This conductive heat can be found by solving the partial differential equations or by numerical solutions. The number of inside surfaces *i* is usually equal to 6, and surface *i* is different from *j* so that radiative exchange can proceed. $q_{i,t}$ could also be expressed in Btu/min or even Btu/sec.

The space sensible cooling load q_{rs}, in Btu/hr, is the sum of the convective heat from the inside surfaces, including the convective heat from the inner window glass due to the absorbed solar radiation and the infiltration:

$$q_{rs} = \left[\sum_{i=1}^{6} h_{ci}\left(T_{i,t} - T_{r,t}\right) \right] A_i + 60\dot{V}_{if}\rho_o c_{pa}\left(T_{o,t} - T_{r,t}\right) + S_{c,t} + L_{c,t} + P_{c,t} + E_{c,t} \qquad (9.6.3)$$

where $\dot{V}_{if}$ = volume flow rate of infiltrated air, cfm
ρ_o = air density of outdoor air, lb/ft^3
c_{pa} = specific heat of moist air, Btu/lb.°F
$T_{o,t}$ = temperature of outdoor air at time *t*, °F
$S_{c,t}$, $L_{c,t}$, $P_{c,t}$, $E_{c,t}$ = heat convected from the windows, lights, occupants, and equipment, Btu/hr

Equations (9.6.2) and (9.6.3), and partial differential equations to determine conductive heat $q_{i,t}$ must be solved simultaneously. Using a rigorous approach to find the space cooling load requires numerous computer calculations. It is laborious and time consuming. The rigorous approach is impractical and is suitable for research work only.

Transfer Function Method (TFM)

The *transfer function* of a system relates its output in Laplace transform *Y* to its input in Laplace transform *G* by a ratio *K*, that is,

© 1999 by CRC Press LLC

$$K = Y/G = \left(v_o + v_1 z^{-1} + v_2 z^{-2} + \ldots\right) \Big/ \left(1 + w_1 z^{-1} + w_2 z^{-2} + \ldots\right)$$
$$z = e^{s\Delta} \tag{9.6.4}$$

where Δ = time interval.

In Equation (9.6.4), K, Y, and G are all expressed in z-transforms of the time series function. Coefficients v_n and w_n are called *transfer function coefficients*, or weighting factors. *Weighting factors* are used to weight the importance of the effect of current and previous heat gains as well as the previous space sensible cooling load on the current space sensible cooling load $q_{rs,t}$. Then, the output $q_{rs,t}$ can be related to the input, the space sensible heat gain $q_{es,t}$, through $q_{rs,t} = Kq_{es,t}$.

Mitalas and Stevenson (1967) and others developed a method for determining the transfer function coefficients of a zone of given geometry and details of the calculated space heat gains and the previously known space sensible cooling load through rigorous computation or through tests and experiments. In DOE 2.1A (1981) software for custom weighting factors (tailor made according to a specific parametric zone) is also provided. Sowell (1988) and Spitler et al. (1993) expanded the application of TFM to zones with various parameters: zone geometry, different types of walls, roof, floor, ceilings, building material, and mass locations. Mass of construction is divided into light construction, 30 lb/ft^2 of floor area; medium construction, 70 lb/ft^2; and heavy construction, 130 lb/ft^2. Data are summarized into groups and listed in tabular form for user's convenience.

Cooling Load Temperature Difference/Solar Cooling Load Factor/Cooling Load Factor (CLTD/SCL/CLF) Method

The *CLTD/SCL/CLF method* is a one-step simplification of the transfer function method. The space cooling load is calculated directly by multiplying the heat gain q_e with CLTD, SCL, or CLF instead of first finding the space heat gains and then converting into space cooling loads through the room transfer function. In the CLTD/SCL/CLF method, the calculation of heat gains is the same as in the transfer function method.

The CLTD/SCL/CLF method was introduced by Rudoy and Duran (1975). McQuiston and Spitler (1992) recommended a new SCL factor. In 1993 they also developed the CLTD and CLF data for different zone geometries and constructions.

Finite Difference Method

Since the development of powerful personal computers, the finite difference or numerical solution method can be used to solve transient simultaneous heat and moisture transfer in space cooling load calculations. Wong and Wang (1990) emphasized the influence of moisture stored in the building structure on the cool-down load during the night shut-down operating mode in locations where the summer outdoor climate is hot and humid. The finite difference method is simple and clear in concept as well as more direct in computation than the transfer function method. Refer to Wang's *Handbook of Air Conditioning and Refrigeration* for details.

Total Equivalent Temperature Differential/Time Averaging (TETD/TA) Method

In this method, the heat gains transmitted through external walls and roofs are calculated from the Fourier series solution of one-dimensional transient heat conduction. The conversion of space heat gains to space cooling loads takes place by (1) averaging the radiative heat gains to the current and successive hours according to the mass of the building structure and experience and (2) adding the instantaneous convective fraction and the allocated radiative fraction in that time period. The TETD/TA method is simpler and more subjective than the TFM.

Conduction Heat Gains

Following are the principles and procedures for the calculation of space heat gains and their conversion to space cooling loads by the TFM. TFM is the method adopted by software DOE-2.1D and is also one

© 1999 by CRC Press LLC

of the computing programs adopted in TRACE 600. Refer to *ASHRAE Handbook 1993 Fundamentals*, Chapters 26 and 27, for detail data and tables.

Surface Heat Transfer Coefficients

ASHRAE Handbook 1993 Fundamentals adopts a constant *outdoor heat transfer coefficient* h_o = 3.0 Btu/hr.ft^2.°F and a constant *inside heat transfer coefficient* h_i = 1.46 Btu/hr.ft^2.°F during cooling load calculations. However, many software programs use the following empirical formula (TRACE 600 *Engineering Manual*):

$$h_{o.t} = 2.00 + 0.27v_{\text{wind}.t} \tag{9.6.5}$$

where $h_{o.t}$ = h_o at time t, Btu/hr.ft^2.°F
$v_{\text{wind}.t}$ = wind velocity at time t, ft/sec

Coefficient h_i may be around 2.1 Btu/hr.ft^2.°F when the space air system is operating, and h_i drops to only about 1.4 Btu/hr.ft^2.°F when the air system is shut down. The *R value*, expressed in hr.ft^2.°F/Btu, is defined as the reciprocal of the overall heat transfer coefficient U value, in Btu/hr.ft^2.°F. The R value is different from the thermal resistance R^*, since $R^* = 1/UA$, which is expressed in hr.°F/Btu.

Sol-air temperature T_{sol} is a fictitious outdoor air temperature that gives the rate of heat entering the outer surface of walls and roofs due to the combined effect of incident solar radiation, radiative heat exchange with the sky vault and surroundings, and convective heat exchange with the outdoor air. T_{sol}, in °F, is calculated as

$$T_{sol} = T_o + \alpha I_t / h_o - \varepsilon \Delta R / h_o \tag{9.6.6}$$

where T_o = outdoor air temperature, °F
α = absorptance of incident solar radiation on outer surface
ϵ = hemispherical emittance of outer surface, assumed equal to 1
I_t = total intensity of solar radiation including diffuse radiation, Btu/hr.ft^2

Tabulated sol-air temperatures that have been calculated and listed in *ASHRAE Handbook 1993 Fundamentals* are based on the following: if ϵ = 1 and h_o = 3 Btu/hr.ft^2.°F, $\Delta R/h_o$ is –7°F for horizontal surfaces and 0°F for vertical surfaces, assuming that the long-wave radiation from the surroundings compensates for the loss to the sky vault.

External Wall and Roof

The sensible heat gain through a wall or roof at time t, $q_{e,t}$, in Btu/hr, can be calculated by using the sol-air temperature at time t-$n\delta$, $T_{sol,t-n\delta}$, in °F, as the outdoor air temperature and a constant indoor space air temperature T_r, in °F, as

$$q_{e,t} = A\left[\sum_{n=0} b_n T_{sol,t-n\delta} - \sum_{n=1} d_n \left(q_{e,t-n\delta}/A\right)\right] - T_r \sum_{n=0} c_n \tag{9.6.7}$$

where A = surface area of wall or roof, ft^2
$q_{e,t-n\delta}$ = heat gain through wall or roof at time t-$n\delta$, Btu/hr
n = number of terms in summation

In Equation (9.6.7), b_n, c_n, and d_n are *conduction transfer function* coefficients.

© 1999 by CRC Press LLC

Ceiling, Floor, and Partition Wall

If the variation of the temperature of the adjacent space T_{aj}, in °F, is small compared with the differential $(T_{aj} - T_r)$, or even when T_{aj} is constant, the heat gain to the conditioned space through ceiling, floor, and partition wall $q_{aj,t}$, in Btu/hr, is

$$q_{aj,t} = UA\left(T_{aj} - T_r\right) \tag{9.6.8}$$

where U = overall heat transfer coefficient of the ceiling, floor, and partition (Btu/hr.ft².°F).

Heat Gain through Window Glass

Shading Devices. There are two types of shading devices: indoor shading devices and outdoor shading devices. *Indoor shading devices* increase the reflectance of incident radiation. *Venetian blinds* and draperies are the most widely used indoor shading devices. Most horizontal venetian blinds are made of plastic, aluminum, or rigid woven cloth slats spaced 1 to 2 in. apart. Vertical venetian blinds with wider slats are also used. *Draperies* are made of fabrics of cotton, rayon, or synthetic fibers. They are usually loosely hung, wider than the window, often pleated, and can be drawn open and closed as needed. Draperies also increase thermal resistance in winter.

External shading devices include overhangs, side fins, louvers, and pattern grilles. They reduce the sunlit area of the window glass effectively and therefore decrease the solar heat gain. External shading devices are less flexible and are difficult to maintain.

Shading Coefficient (SC). The shading coefficient is an index indicating the glazing characteristics and the associated indoor shading device to admit solar heat gain. SC of a specific window glass and shading device assembly at a summer design solar intensity and outdoor and indoor temperatures can be calculated as

$$\text{SC} = \frac{\text{solar heat gain of specific type of window glass assembly}}{\text{solar heat gain of reference (DSA) glass}} \tag{9.6.9}$$

Double-strength sheet glass (DSA) has been adopted as the reference glass with a transmittance of $\tau = 0.86$, reflectance $\rho = 0.08$, and absorptance $\alpha = 0.06$.

Solar Heat Gain Factors (SHGFs). SHGFs, in Btu/hr.ft², are the average solar heat gains during cloudless days through DSA glass. SHGF_{max} is the maximum value of SHGF on the 21st day of each month for a specific latitude as listed in *ASHRAE Handbook 1993 Fundamentals*. At high elevations and on very clear days, the actual SHGF may be 15% higher.

Heat Gain through Window Glass. There are two kinds of heat gain through window glass: heat gain due to the solar radiation transmitted and absorbed by the window glass, $q_{es,t}$, and conduction heat gain due to the outdoor and indoor temperature difference, $q_{ec,t}$, both in Btu/hr:

$$q_{es,t} = \left(A_s \times \text{SHGF} \times \text{SC}\right) + \left(A_{sh} \times \text{SHGF}_{sh} \times \text{SC}\right) \tag{9.6.10}$$

where A_s, A_{sh} = sunlit and shaded areas of the glass (ft²).

In Equation (9.6.10), SHGF_{sh} represents the SHGF of the shaded area of the glass having only diffuse radiation. Generally, the SHGF of solar radiation incident on glass facing north without direct radiation can be considered as SHGF_{sh}. Because the mass of window glass is small, its heat storage effect is often neglected; then the conduction heat gain at time t is

$$q_{ec,t} = U_g\left(A_s + A_{sh}\right)\left(T_{o,t} - T_r\right) \tag{9.6.11}$$

© 1999 by CRC Press LLC

where U_g = overall heat transfer coefficient of window glass, Btu/hr.ft^2.°F
$T_{o,t}$ = outdoor air temperature at time t, °F

The inward heat transfer due to the solar radiation absorbed by the glass and the conduction heat transfer due to the outdoor and indoor temperature difference is actually combined. It is simple and more convenient if they are calculated separately.

Internal Heat Gains

Internal heat gains are heat released from the internal sources.

People

The sensible heat gain and latent heat gain per person, $q_{es,t}$ and $q_{el,t}$, both in Btu/hr, are given as

$$q_{es,t} = N_t q_{os}$$
$$q_{el,t} = N_t q_{ol} \tag{9.6.12}$$

where N_t = number of occupants in the conditioned space at time t.

Heat gains q_{os} and q_{ol} depend on the occupant's metabolic level, whether the occupant is an adult or a child, male or female, and the space temperature. For a male adult seated and doing very light work, such as system design by computer in an office of space temperature 75°F, q_{os} and q_{ol} are both about 240 Btu/hr.

Lights

Heat gain in the conditioned space because of the electric lights, $q_{e.li}$, in Btu/hr, is calculated as

$$q_{e.li} = \sum_{n=1}\left[3.413 W_{li} N_{li} F_{ul} F_{al}\left(1 - F_{lp}\right)\right] = 3.413 W_{lA} A_{fl} \tag{9.6.13}$$

where W_{li} = watt input to each lamp, W
W_{lA} = lighting power density, W/ft^2
A_{fl} = floor area of conditioned space, ft^2
N_{li}, n = number of lamps (each type) and number of types of electric lamp
F_{al}, F_{ul} = use factor of electric lights and allowance factor for ballast loss, usually taken as 1.2
F_{lp} = heat gain carried away by the return air to plenum or by exhaust device; it varies from 0.2 to 0.5

Machines and Appliances

The sensible and latent heat gains in the conditioned space from machines and appliances, $q_{e.ap}$ and $q_{l.ap}$, both in Btu/hr, can be calculated as

$$q_{e.ap} = 3.413 W_{ap} F_{ua} F_{load} F_{ra} = q_{is} F_{ua} F_{ra}$$
$$q_{l.ap} = q_{il} F_{ua} \tag{9.6.14}$$

where W_{ap} = rated power input to the motor of the machines and appliances, W
F_{ua} = use factor of machine and appliance
F_{load} = ratio of actual load to the rated power
F_{ra} = radiation reduction factor because of the front shield of the appliance
q_{is}, q_{il} = sensible and latent heat input to the appliance, Btu/hr

© 1999 by CRC Press LLC

Infiltration

Infiltration is the uncontrolled inward flow of unconditioned outdoor air through cracks and openings on the building envelope because of the pressure difference across the envelope. The pressure difference is probably caused by wind pressure, stack effect due to outdoor–indoor temperature difference, and the operation of an air system(s).

Today new commercial buildings have their external windows well sealed. If a positive pressure is maintained in the conditioned space when the air system is operating, infiltration is normally considered as zero.

When the air system is shut down, or for hotels, motels, and high-rise residential buildings, ASHRAE/IES Standard 90.1-1989 specifies an infiltration of 0.038cfm/ft^2 of gross area of the external wall, 0.15 air change per hour (ach) for the perimeter zone.

When exterior windows are not well sealed, the outdoor wind velocity is high at winter design conditions, or there is a door exposed to the outdoors directly, an infiltration rate of 0.15 to 0.4 ach for perimeter zone should be considered.

When the volume flow rate of infiltration is determined, the sensible heat gain due to infiltration $q_{s.if}$ and latent heat gain due to infiltration $q_{l.if}$, in Btu/hr, are

$$q_{s.if} = 60\mathring{V}_{if}\rho_o c_{pa}\left(T_o - T_r\right)$$
$$q_{l.if} = 60\times 1060\mathring{V}_{if}\rho_o\left(w_o - w_r\right) \tag{9.6.15}$$

where $\mathring{V}_{if}$ = volume flow rate of infiltration, cfm
ρ_o = air density of outdoor air, lb/ft^3
c_{pa} = specific heat of moist air, 0.243 Btu/lb.°F
w_o,w_r = humidity ratio of outdoor and space air, lb/lb
$h_{fg.58}$ = latent heat of vaporization, 1060 Btu/lb

Infiltration enters the space directly and mixes with space air. It becomes space cooling load instantaneously. Ventilation air is often taken at the AHU or PU and becomes sensible and latent coil load components.

Conversion of Heat Gains into Cooling Load by TFM

The space sensible cooling load $q_{rs,t}$, in Btu/hr, is calculated as

$$q_{rs,t} = q_{s-e,t} + q_{s-c,t} \tag{9.6.16}$$

where $q_{s\text{-}e,t}$ = space sensible cooling load converted from heat gains having radiative and convective components, Btu/hr
$q_{s\text{-}c,t}$ = space sensible cooling load from convective heat gains, Btu/hr

Based on Equation (9.6.4), space sensible cooling load $q_{s\text{-}e,t}$ can be calculated as

$$q_{s-e,t} = \sum_{i=1}\left(v_o q_{e,t} + v_1 q_{e,t-\delta} + v_2 q_{e,t-2\delta} + \ldots\right) - \left(w_1 q_{r,t-\delta} + w_2 q_{r,t-2\delta} + \ldots\right) \tag{9.6.17}$$

where $q_{e,t}$, $q_{e,t\text{-}\delta}$, $q_{e,t\text{-}2\delta}$ = space sensible heat gains having both radiative and convective heats at time t, t-δ, and t-2δ, Btu/hr
$q_{r,t\text{-}\delta}$, $q_{r,t\text{-}2\delta}$ = space sensible cooling load at time t-δ, and t-2δ, Btu/hr

© 1999 by CRC Press LLC

In Equation (9.6.17), v_n and w_n are called *room transfer function coefficients* (RTFs). RTF is affected by parameters like zone geometry; wall, roof, and window construction; internal shades; zone location; types of building envelope; and air supply density. Refer to RTF tables in *ASHRAE Handbook 1993 Fundamentals*, Chapter 26, for details.

Space sensible cooling load from convective heat gains can be calculated as

$$q_{s-c,t} = \sum_{k=1} q_{ec,t} \tag{9.6.18}$$

where $q_{ec,t}$ = each of k space sensible heat gains that have convective heat gains only (Btu/hr). Space latent cooling load at time t, $q_{rl,t}$, in Btu/hr, can be calculated as

$$q_{rl,t} = \sum_{m=1} q_{el,t} \tag{9.6.19}$$

where $q_{el,t}$ = each of m space latent heat gains (Btu/hr).

Space Air Temperature and Heat Extraction Rate

At equilibrium, the space sensible heat extraction rate at time t, $q_{xs,t}$, is approximately equal to the space sensible cooling load, $q_{rs,t}$, when zero offset proportional plus integral or proportional-integral-derivative control mode is used. During the cool-down period, the sensible heat extraction rate of the cooling coil or DX coil at time t, $q_{xs,t}$, or the sensible cooling coil load, in Btu/hr, is greater than the space sensible cooling load at time t and the space temperature T_r, in °F then drops gradually. According to *ASHRAE Handbook 1993 Fundamentals*, the relationship between the space temperature T_r and the sensible heat extraction rate $q_{xs,t}$ can be expressed as

$$\sum_{i=0}^{1} p_i \left(q_{xs,t} - q_{rs,t-i\delta}\right) = \sum_{i=0}^{2} g_i \left(T_r - T_{r,t-i\delta}\right) \tag{9.6.20}$$

where $q_{rs,t\text{-}i\delta}$ = space sensible cooling load calculated on the basis of constant space air temperature T_r, Btu/hr
$T_{r,t\text{-}i\delta}$ = space temperature at time t-iδ

In Equation (9.6.20), p_i, g_i are called *space air transfer function coefficients*. Space air temperature T_r can be considered an average reference temperature within a time interval.

Cooling Coil Load

Cooling coil load q_{cc}, in Btu/hr, can be calculated from Equation (9.3.11). The sensible and latent cooling coil loads can then be calculated as

$$\begin{aligned} q_{cs} &= 60 \mathring{V}_s \rho_s c_{pa} \left(T_m - T_{cc}\right) \\ q_{cl} &= 60 \mathring{V}_s \rho_s \left(w_m - w_{cc}\right) \end{aligned} \tag{9.6.21}$$

where q_{cs}, q_{cl} = sensible and latent cooling coil load, Btu/hr
T_m, T_{cc} = air temperature of the mixture and leaving the cooling coil, °F
w_m, w_{cc} = humidity ratio of the air mixture and air leaving the cooling coil, lb/lb

© 1999 by CRC Press LLC

Heating Load

The *space heating load* or simply *heating load* is always the possible maximum heat energy that must be added to the conditioned space at winter design conditions to maintain the indoor design temperature. It is used to size and select the heating equipment. In heating load calculations, solar heat gain, internal heat gains, and the heat storage effect of the building envelope are usually neglected for reliability and simplicity.

Normally, space heating load q_{rh}, in Btu/hr, can be calculated as

$$\begin{aligned} q_{rl} &= q_{trans} + q_{if.s} + q_{ma} + q_{hu} \\ &= \left[\left(\sum_{n=1} AU \right) + 60 \mathring{V}_{if} \rho_o c_{pa} \mathring{m}_m c_m \right] \left(T_r - T_o \right) + \mathring{m}_w h_{fg.58} \end{aligned} \tag{9.6.22}$$

where A = area of the external walls, roofs, glasses, and floors, ft²
U = overall heat transfer coefficient of the walls, roofs, glasses, and floors, Btu/hr.ft².°F
c_m, $\mathring{m}_m$ = specific heat and mass flow rate of the cold product entering the space per hour, Btu/lb.°F and lb/hr
$\mathring{m}_w$ = mass flow rate of water evaporated for humidification, lb/hr
$h_{fg.58}$ = latent heat of vaporization at 58°F, 1060 Btu/lb

In Equation 9.88, q_{trans} indicates the *transmission loss* through walls, roofs, glasses, and floors, $q_{if.s}$ the *sensible infiltration heat loss*, q_{ma} the heat required to heat the cold product that enters the conditioned space, and q_{hu} the heat required to raise the space air temperature when water droplets from a space humidifier are evaporated in the conditioned space. For details, refer to *ASHRAE Handbook 1993 Fundamentals*.

9.7 Air Handling Units and Packaged Units

Terminals and Air Handling Units

A *terminal unit*, or *terminal*, is a device or equipment installed directly in or above the conditioned space to cool, heat, filter, and mix outdoor air with recirculating air. Fan-coil units, VAV boxes, fan-powered VAV boxes, etc. are all terminals.

An *air handling unit* (AHU) handles and conditions the air, controls it to a required state, and provides motive force to transport it. An AHU is the primary equipment of the air system in a central air-conditioning system. The basic components of an AHU include a supply fan with a fan motor, a water cooling coil, filters, a mixing box except in a makeup AHU unit, dampers, controls, and an outer casing. A return or relief fan, heating coil(s), and humidifier are optional depending on requirements. The supply volume flow rate of AHUs varies from 2000 to about 60,000 cfm.

AHUs are classified into the followings groups according to their structure and location.

Horizontal or Vertical Units

Horizontal AHUs have their fan, coils, and filters installed at the same level as shown in Figure 9.7.1(a). They need more space and are usually for large units. In *vertical units*, as shown in Figure 9.7.1(b), the supply fan is installed at a level higher than coils and filters. They are often comparatively smaller than horizontal units.

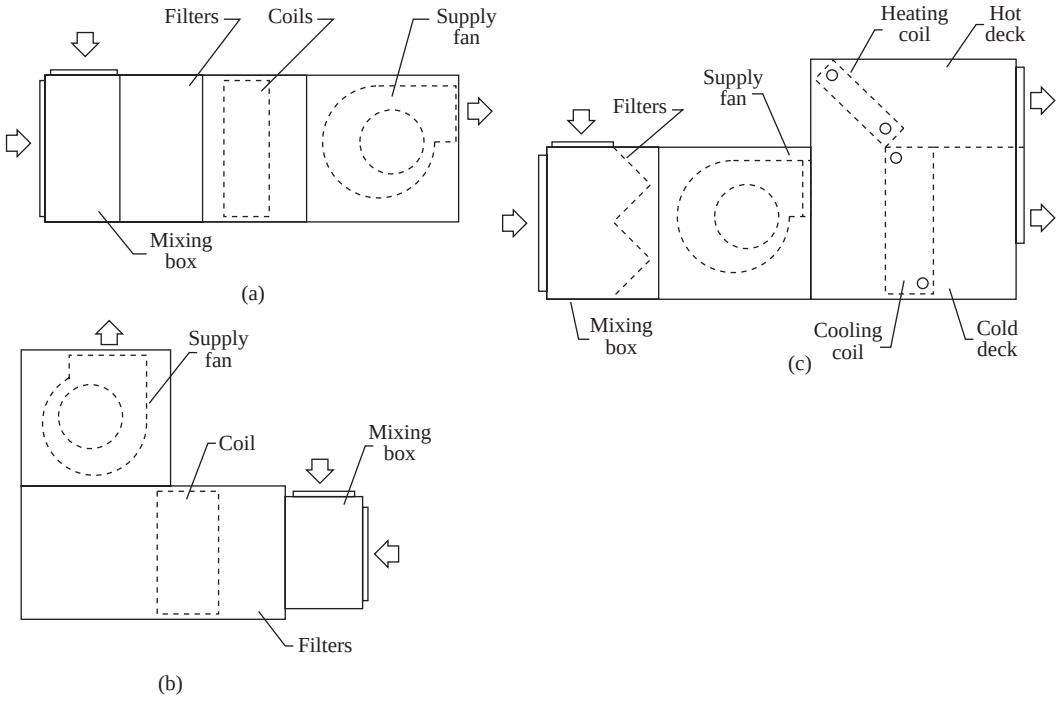

FIGURE 9.7.1 Type of air handling units: (a) horizontal draw-through unit, (b) vertical draw-through unit, and (c) multizone blow-through unit.

Draw-Through or Blow-Through Units

In a *draw-through unit*, as shown in Figure 9.7.1(a), the supply fan is located downstream of the coils. Air is evenly distributed over the coil section, and the fan discharge can easily be connected to a supply duct of nearly the same air velocity. In a *blow-through unit*, as shown in Figure 9.7.1(c), the supply fan

© 1999 by CRC Press LLC

is located upstream of the coils. It usually has hot and cold decks with discharge dampers connected to warm and cold ducts, respectively.

Factory-Fabricated and Field Built-Up Units

Factory-fabricated units are standard in construction and layout, low in cost, of higher quality, and fast in installation. *Field built-up units* or *custom-built units* are more flexible in construction, layout, and dimensions than factory-built standardized units.

Rooftop and Indoor Units

A *rooftop AHU*, sometimes called a penthouse unit, is installed on the roof and will be completely weatherproof. An *indoor AHU* is usually located in a fan room or ceiling and hung like small AHU units.

Make-Up Air and Recirculating Units

A *make-up AHU*, also called a primary-air unit, is used to condition outdoor air entirely. It is a once-through unit. There is no return air and mixing box. *Recirculating units* can have 100% outdoor air intake or mixing of outdoor air and recirculating air.

Packaged Units

A *packaged unit* (PU) is a self-contained air conditioner. It conditions the air and provides it with motive force and is equipped with its own heating and cooling sources. The packaged unit is the primary equipment in a packaged air-conditioning system and is always equipped with a DX coil for cooling, unlike an AHU. R-22, R-134a, and others are used as refrigerants in packaged units. The portion that handles air in a packaged unit is called an *air handler* to distinguish it from an AHU. Like an AHU, an indoor air handler has an indoor fan, a DX coil (indoor coil), filters, dampers, and controls. Packaged units can be classified according to their place of installation: rooftop, indoor, and split packaged units.

Rooftop Packaged Units

A *rooftop packaged unit* is mounted on the roof of the conditioned space as shown in Figure 9.7.2. From the types of heating/cooling sources provided, rooftop units can be subdivided into:

- Gas/electric rooftop packaged unit, in which heating is provided by gas furnace and cooling by electric power-driven compressors.
- Electric/electric rooftop packaged unit, in which electric heating and electric power-driven compressors provide heating and cooling.
- Rooftop packaged heat pump, in which both heating and cooling are provided by the same refrigeration system using a four-way reversing valve (heat pump) in which the refrigeration flow changes when cooling mode is changed to heating mode and vice versa. Auxiliary electric heating is provided if necessary.

Rooftop packaged units are single packaged units. Their cooling capacity may vary from 3 to 220 tons with a corresponding volume flow rate of 1200 to 80,000 cfm. Rooftop packaged units are the most widely used packaged units.

Indoor Packaged Units

An *indoor packaged unit* is also a single packaged and factory-fabricated unit. It is usually installed in a fan room or a machinery room. A small or medium-sized indoor packaged unit could be floor mounted directly inside the conditioned space with or without ductwork. The cooling capacity of an indoor packaged unit may vary from 3 to 100 tons and volume flow rate from 1200 to 40,000 cfm.

Indoor packaged units are also subdivided into:

- Indoor packaged cooling units

© 1999 by CRC Press LLC

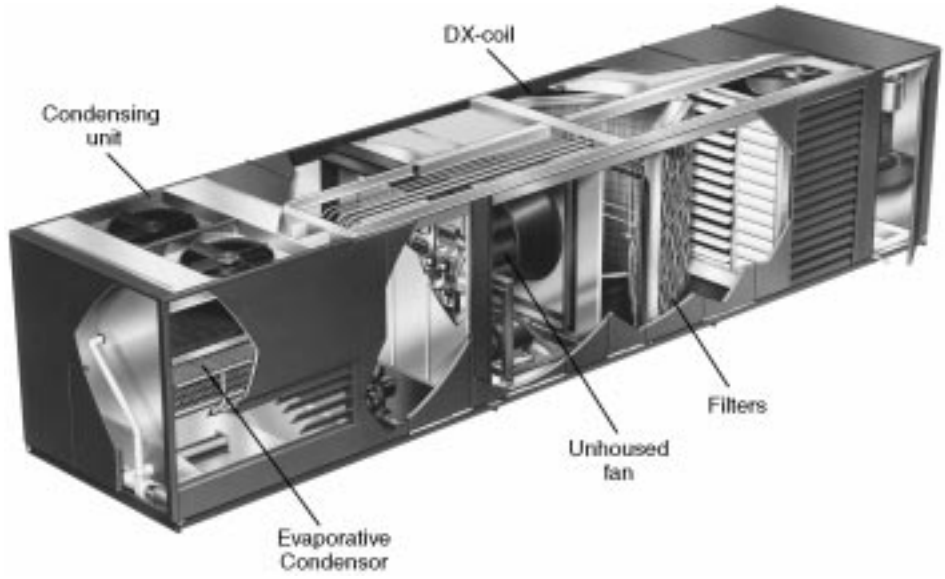

FIGURE 9.7.2 A cut view of a rooftop package unit. (Source: Mammoth, Inc. Reprinted by permission.)

- Indoor packaged cooling/heating units, in which heating may be provided from a hot water heating coil, a steam heating coil, and electric heating
- Indoor packaged heat pumps

Indoor packaged units have either an air-cooled condenser on the rooftop or a shell-and-tube or double-tube water-cooled condenser inside the unit.

Split Packaged Units

A *split packaged unit* consists of two separate pieces of equipment: an indoor air handler and an outdoor condensing unit. The indoor air handler is often installed in the fan room. Small air handlers can be ceiling hung. The condensing unit is usually located outdoors, on a rooftop or podium or on the ground.

A split packaged unit has its compressors and condenser in its outdoor condensing unit, whereas an indoor packaged unit usually has its compressors indoors. The cooling capacity of split packaged units varies from 3 to 75 tons and the volume flow rate from 1200 to 30,000 cfm.

Rating Conditions and Minimum Performance

Air Conditioning and Refrigeration Institute (ARI) Standards and ASHRAE/IES Standard 90.1-1989 specified the following rating indices:

- Energy efficiency ratio (EER) is the ratio of equipment cooling capacity, in Btu/hr, to the electric input, in W, under rating conditions.
- SEER is the seasonal EER, or EER during the normal annual usage period.
- IPLV is the integrated part-load value. It is the summarized single index of part-load efficiency of PUs based on weighted operations at several load conditions.
- HSPF is the heating seasonal performance factor. It is the total heating output of a heat pump during its annual usage period for heating, in Btu, divided by the total electric energy input to the heat pump during the same period, in watt-hours.

According to ARI standards, the minimum performance for air-cooled, electrically operated single packaged units is

© 1999 by CRC Press LLC

	q_{rc} (Btu/hr)	T_o (°F)	EER	T_o (°F)	IPLV
Air-cooled	<65,000	95	9.5		
	65,000 ≤ q_{rc} < 135,000	95	8.9	80	8.3
	135,000 ≤ q_{rc} < 760,000		8.5		7.5

For water- and evaporatively cooled packaged units including heat pumps, refer to ASHRAE/IES Standard 90.1-1989 and also ARI Standards.

Coils

Coils, Fins, and Water Circuits

Coils are indirect contact heat exchangers. Heat transfer or heat and mass transfer takes place between conditioned air flowing over the coil and water, refrigerant, steam, or brine inside the coil for cooling, heating, dehumidifying, or cooling/dehumidifying. Chilled water, brine, and refrigerants that are used to cool and dehumidify the air are called *coolants*. Coils consist of tubes and external fins arranged in rows along the air flow to increase the contact surface area. Tubes are usually made of copper; in steam coils they are sometimes made of steel or even stainless steel. Copper tubes are staggered in 2, 3, 4, 6, 8, or up to 10 rows.

Fins are extended surfaces often called *secondary surfaces* to distinguish them from the *primary surfaces*, which are the outer surfaces of the tubes. Fins are often made from aluminum, with a thickness F_t = 0.005 to 0.008 in., typically 0.006 in. Copper, steel, or sometimes stainless steel fins are also used. Fins are often in the form of continuous plate fins, corrugated plate fins to increase heat transfer, crimped spiral or smooth spiral fins that may be extruded from the aluminum tubes, and spine pipes, which are shaved from the parent aluminum tubes. Corrugated plate fins are most widely used.

Fin spacing S_f is the distance between two fins. *Fin density* is often expressed in fins per inch and usually varies from 8 to 18 fins/in.

In a water cooling coil, *water circuits* or *tube feeds* determine the number of water flow passages. The greater the finned width, the higher the number of water circuits and water flow passages.

Direct Expansion (DX) Coil

In a *direct expansion coil*, the refrigerant, R-22, R-134a, or others, is evaporated and expanded directly inside the tubes to cool and dehumidify the air as shown in Figure 9.7.3(a). Refrigerant is fed to a distributor and is then evenly distributed to various copper tube circuits typically 0.375 in. in diameter. Fin density is usually 12 to 18 fins/in. and a four-row DX coil is often used. On the inner surface of the copper tubes, microfins, typically at 60 fins/in. and a height of 0.008 in., are widely used to enhance the boiling heat transfer.

Air and refrigerant flow is often arranged in a combination of counterflow and cross flow and the discharge header is often located on the air-entering side. Refrigerant distribution and loading in various circuits are critical to the coil's performance. Vaporized vapor refrigerant is superheated 10 to 20°F in order to prevent any liquid refrigerant from flooding back to the reciprocating compressors and damaging them. Finally, the vapor refrigerant is discharged to the suction line through the header.

For comfort air-conditioning systems, the evaporating temperature of refrigerant T_{ev} inside the tubes of a DX coil is usually between 37 and 50°F. At such a temperature, the surface temperature of the coil is often lower than the dew point of the entering air. Condensation occurs at the coil's outside surface, and the coil becomes a wet coil. A condensate *drain pan* is necessary for each vertically banked DX coil, and a trap should be installed to overcome the negative pressure difference between the air in the coil section and the ambient air.

Face velocity of the DX coil v_a, in fpm, is closely related to the blow-off of the water droplets of the condensate, the heat transfer coefficients, the air-side pressure drop, and the size of the air system. For corrugated fins, the upper limit is 600 fpm, with an air-side pressure drop of 0.20 to 0.30 in. WG/row.

© 1999 by CRC Press LLC

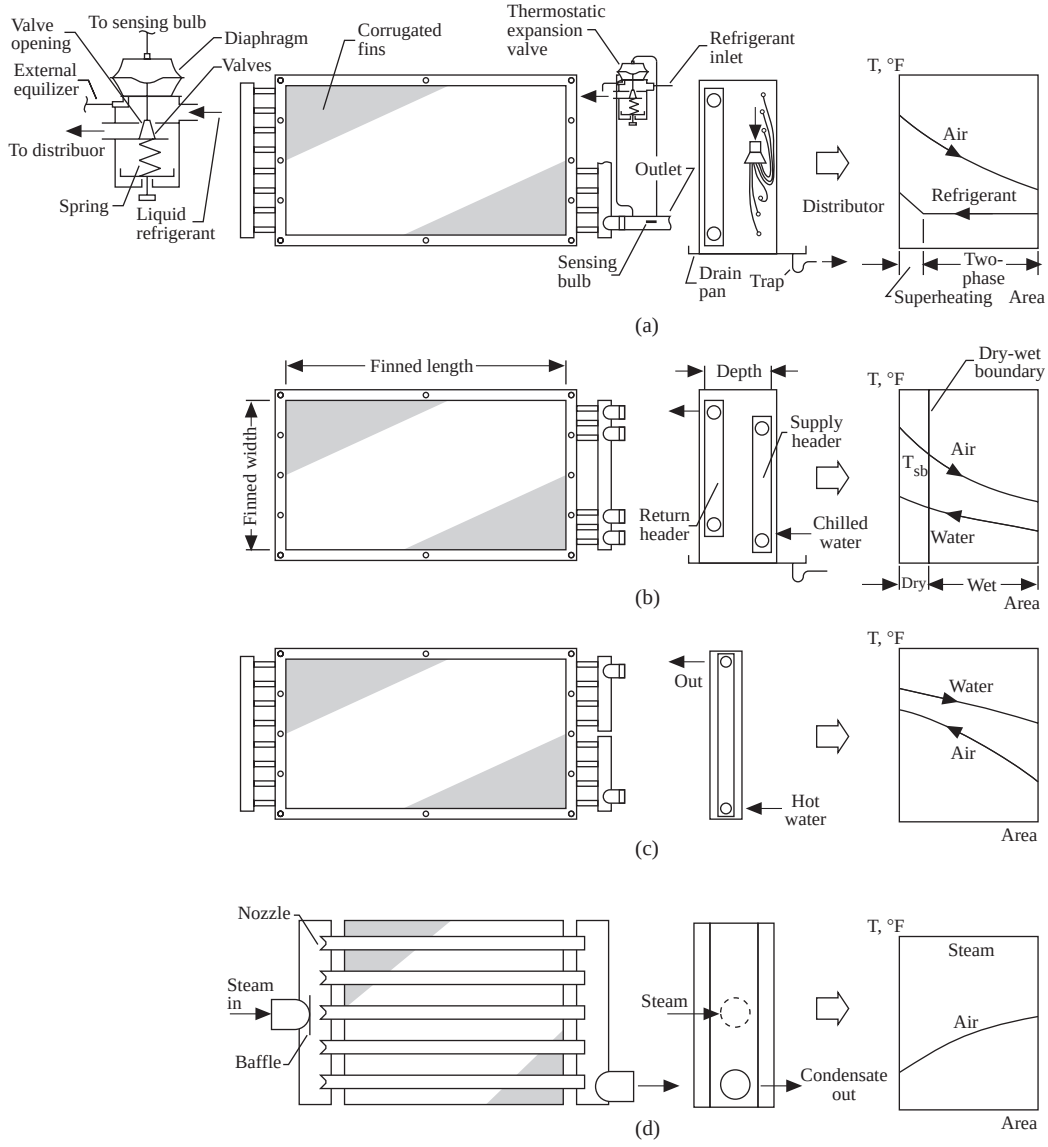

FIGURE 9.7.3 Types of coils: (a) direct expansion coil, (b) water cooling coil, (c) water heating coil, and (d) steam heating coil.

A large DX coil is often divided into two refrigerant sections, each with its own expansion valve, distributor, and discharge header.

For a packaged unit of a specific model, size, face velocity and condition of entering air and outdoor air, the DX coil's cooling capacities in nominal tons, number of rows, and fin density are all fixed values.

Water Cooling Coils — Dry–Wet Coils

In a water cooling coil, chilled water at a temperature of 40 to 50°F, brine, or glycol-water at a temperature of 34 to 40°F during cold air distribution enters the coil. The temperature of chilled water, brine, or glycol-water is usually raised 12 to 24°F before it leaves the water cooling coil.

The water tubes are usually copper tubes of 1/2 to 5/8 in. diameter with a tube wall thickness of 0.01 to 0.02 in. They are spaced at a center-to-center distance of 0.75 to 1.25 in. longitudinally and 1 to 1.5

© 1999 by CRC Press LLC

in. transversely. These tubes may be staggered in 2, 3, 4, 6, 8, or 10 rows. Chilled water coils are often operated at a pressure of 175 to 300 psig.

As in a DX coil, the air flow and water flow are in a combination of counterflow and cross flow. The outer surface of a chilled water cooling coil at the air entering side T_{se} is often greater than the dew point of the entering air T''_{ae}, or $T_{se} > T''_{ae}$. The outer surface temperature of coil at the air leaving side T_{sl} may be smaller than T''_{ae}, or $T_{sl} < T''_{ae}$. Then the water cooling coil becomes a dry–wet coil with part of the dry surface on the air entering side and part of the wet surface on the air leaving side. A *dry–wet boundary* divides the dry and wet surfaces. At the boundary, the tube outer surface temperature $T_{sb} = T''_{ae}$ as shown in Figure 9.7.3(b). A condensate drain pan is necessary for a dry–wet coil.

A water cooling coil is selected from the manufacturer's selection program or from its catalog at (1) a dry and wet bulb of entering air, such as 80°F dry bulb and 67°F wet bulb; (2) an entering water temperature, such as 44 or 45°F; (3) a water temperature rise between 10 and 24°F; and (4) a coil face velocity between 400 and 600 fpm. The number of rows and fins per inch is varied to meet the required sensible and cooling coil load, in Btu/hr.

Water Cooling Coil–Dry Coil

When the temperature of chilled water entering the water cooling coil $T_{we} \geq T''_{ae}$, condensation will not occur on the outer surface of the coil. This coil becomes a sensible cooling–dry coil, and the humidity ratio of the conditioned air w_a remains constant during the sensible cooling process.

The construction of a sensible cooling–dry coil, such as material, tube diameter, number of rows, fin density, and fin thickness, is similar to that of a dry–wet coil except that a dry coil always has a poorer surface heat transfer coefficient than a wet coil, and therefore a greater coil surface area is needed; the maximum face velocity of a dry coil can be raised to $v_a \leq 800$ fpm; and the coil's outer surface is less polluted. The effectiveness of a dry coil $\in_{dry}$ is usually 0.55 to 0.7.

Water Heating Coil

The construction of a water heating coil is similar to that of a water cooling coil except that in water heating coils hot water is supplied instead of chilled water and there are usually fewer rows, only 2, 3, and 4 rows, than in water cooling coils. Hot water pressure in water heating coils is often rated at 175 to 300 psig at a temperature up to 250°F. Figure 9.7.3(c) shows a water heating coil.

Steam Heating Coil

In a steam heating coil, latent heat of condensation is released when steam is condensed into liquid to heat the air flowing over the coil, as shown in Figure 9.7.3(d). Steam enters at one end of the coil, and the condensate comes out from the opposite end. For more even distribution, a baffle plate is often installed after the steam inlet. Steam heating coils are usually made of copper, steel, or sometimes stainless steel.

For a steam coil, the coil core inside the casing should expand or contract freely. The coil core is also pitched toward the outlet to facilitate condensate drainage. Steam heating coils are generally rated at 100 to 200 psig at 400°F.

Coil Accessories and Servicing

Coil accessories include air vents, drain valves, isolation valves, pressure relief valves, flow metering valves, balancing valves, thermometers, pressure gauge taps, condensate drain taps, and even distribution baffles. They are employed depending on the size of the system and operating and serving requirements.

Coil cleanliness is important for proper operation. If a medium-efficiency air filter is installed upstream of the coil, dirt accumulation is often not a problem. If a low-efficiency filter is employed, dirt accumulation may block the air passage and significantly increase the pressure drop across the coil. Coils should normally be inspected and cleaned every 3 months in urban areas when low-efficiency filters are used. Drain pans should be cleaned every month to prevent buildup of bacteria and microorganisms.

© 1999 by CRC Press LLC

Coil Freeze-Up Protection

Improper mixing of outdoor air and recirculating air in the mixing box of an AHU or PU may cause coil freeze-up when the outdoor air temperature is below 32°F. Outdoor air should be guided by a baffle plate and flow in an opposite direction to the recirculating air stream so that they can be thoroughly mixed without stratification.

Run the chilled water pump for the idle coil with a water velocity of 2.5 ft/sec, so that the cooling coil will not freeze when the air temperature drops to 32°F. A better method is to drain the water completely. For a hot water coil, it is better to reset the hot water temperature at part-load operation instead of running the system intermittently. A steam heating coil with inner distributor tubes and outer finned heating tubes provides better protection against freeze-up.

Air Filters

Air Cleaning and Filtration

Air cleaning is the process of removing airborne particles from the air. Air cleaning can be classified into air filtration and industrial air cleaning. Industrial air cleaning involves the removal of dust and gaseous contaminants from manufacturing processes as well as from the space air, exhaust air, and flue gas for air pollution control. In this section, only air filtration is covered.

Air filtration involves the removal of airborne particles presented in the conditioned air. Most of the airborne particles removed by air filtration are smaller than 1 μm, and the concentration of these particles in the airstream seldom exceeds 2 mg/m^3. The purpose of air filtration is to benefit the health and comfort of the occupants as well as meet the cleanliness requirements of the working area in industrial buildings.

An *air filter* is a kind of air cleaner that is installed in AHUs, PUs, and other equipment to filter the conditioned air by inertial impaction or interception and to diffuse and settle fine dust particles on the fibrous medium. The filter medium is the fabricated material that performs air filtration.

Operating performance of air filters is indicated by their:

- *Efficiency* or effectiveness of dust removal
- *Dust holding capacity* m_{dust}, which is the amount of dust held in the air filter, in grains/ft^2
- *Initial pressure drop* when the filter is clean Δp_{fi} and *final pressure drop* Δp_{ff} when the filter's m_{dust} is maximum, both in in. WG
- *Service life*, which is the operating period between Δp_{fi} and Δp_{ff}

Air filters in AHUs and PUs can be classified into low-, medium-, and high-efficiency filters and carbon activated filters.

Test Methods

The performance of air filters is usually tested in a test unit that consists of a fan, a test duct, the tested filter, two samplers, a vacuum pump, and other instruments. Three test methods with their own test dusts and procedures are used for the testing of low-, medium-, and high-efficiency air filters.

The *weight arrestance test* is used for low-efficiency air filters to assess their ability to remove coarse dusts. Standard synthetic dusts that are considerably coarser than atmospheric dust are fed to the test unit. By measuring the weight of dust fed and the weight gain due to the dust collected on the membrane of the sampler after the tested filter, the arrestance can be calculated.

The *atmospheric dust spot efficiency test* is used for medium-efficiency air filters to assess their ability to remove atmospheric dusts. *Atmospheric dusts* are dusts contained in the outdoor air, the outdoor atmosphere. Approximately 99% of atmospheric dusts are dust particles <0.3 μm that make up 10% of the total weight; 0.1% of atmospheric dusts is particles >1 μm that make up 70% of the total weight.

Untreated atmospheric dusts are fed to the test unit. Air samples taken before and after the tested filter are drawn through from identical fiber filter-paper targets. By measuring the light transmission of these discolored white filter papers, the efficiency of the filter can be calculated. Similar atmospheric

© 1999 by CRC Press LLC

dust spot test procedures have been specified by American Filter Institute (AFI), ASHRAE Standard 52.1, and former National Bureau of Standards (NBS).

The *DOP penetration and efficiency test* or simply *DOP test* is used to assess high-efficiency filters removing dusts particles of 0.18 μm. According to U.S. Military Standard MIL-STD-282 (1956), a smoke cloud of uniform dioctyl phthalate (DOP) droplets 0.18 μm in diameter, generated from the condensation of the DOP vapor, is fed to the test unit. By measuring the concentration of these particles in the air stream upstream and downstream of the tested filter using an electronic particle counter or laser spectrometer, the penetration and efficiency of the air filter can be calculated.

Low-Efficiency Air Filters

ASHRAE weight arrestance for low-efficiency filters is between 60 and 95%, and ASHRAE dust spot efficiency for low-efficiency filters is less than 20%. These filters are usually in panels as shown in Figure 9.7.4(a). Their framework is typically 20 × 20 in. or 24 × 24 in. Their thickness varies from 1 to 4 in.

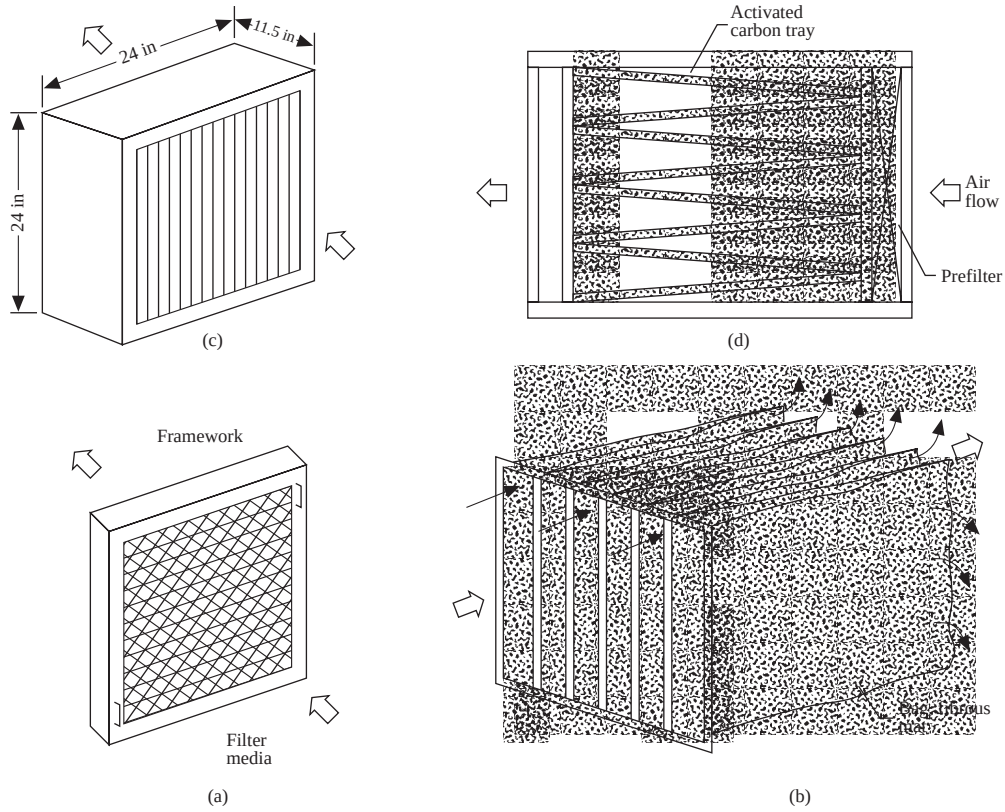

FIGURE 9.7.4 Various types of air filters: (a) low efficiency, (b) medium efficiency, (c) HEPA and ULPA filters, and (d) activated carbon filter.

For low-efficiency filters, the filter media are often made of materials such as

- Corrugated wire mesh and screen strips coated with oil, which act as adhesives to enhance dust removal. Detergents may be used to wash off dusts so that the filter media can be cleaned and reused — they are therefore called *viscous and reusable*.
- Synthetic fibers (nylon, terylene) and polyurethane foam can be washed, cleaned, and reused if required — *dry and reusable*.

© 1999 by CRC Press LLC

- Glass fiber mats with fiber diameter greater than 10 μm. The filter medium is discarded when its final pressure drop is reached — *dry and disposable*. The face velocity of the panel filter is usually between 300 and 600 fpm. The initial pressure drop varies from 0.05 to 0.25 in. WG and the final pressure drop from 0.2 to 0.5 in. WG.

Medium-Efficiency Air Filters

These air filters have an ASHRAE dust spot efficiency usually between 20 and 95%. Filter media of medium-efficiency filters are usually made of glass fiber mat with a fiber diameter of 10 to 1 μm using nylon fibers to join them together. They are usually dry and disposable. In addition:

- As the dust spot efficiency increases, the diameter of glass fibers is reduced, and they are placed closer together.
- Extended surfaces, such as pleated mats or bags, are used to increase the surface area of the medium as shown in Figure 9.7.4(b). Air velocity through the medium is 6 to 90 fpm. Face velocity of the air filter is about 500 fpm to match the face velocity of the coil in AHUs and PUs.
- Initial pressure drop varies from 0.20 to 0.60 in. WG and final pressure drop from 0.50 to 1.20 in. WG.

High-Efficiency Particulate Air (HEPA) Filters and Ultra-Low-Penetration Air (ULPA) Filters

HEPA filters have a DOP test efficiency of 99.97% for dust particles ≥0.3 μm in diameter. *ULPA filters* have a DOP test efficiency of 99.999% for dust particles ≥0.12 μm in diameter.

A typical HEPA filter, shown in Figure 9.7.4(d), has dimensions of 24 × 24 × 11.5 in. Its filter media are made of glass fibers of submicrometer diameter in the form of pleated paper mats. The medium is dry and disposable. The surface area of the HEPA filter may be 50 times its face area, and its rated face velocity varies from 190 to 390 fpm, normally at a pressure drop of 0.50 to 1.35 in. WG for clean filters. The final pressure drop is 0.8 to 2 in. WG. Sealing of the filter pack within its frame and sealing between the frame and the gaskets are critical factors that affect the penetration and efficiency of the HEPA filter.

An ULPA filter is similar to a HEPA filter in construction and filter media. Both its sealing and filter media are more efficient than those of a HEPA filter.

To extend the service life of HEPA filters and ULPA filters, both should be protected by a medium-efficiency filter, or a low-efficiency and a medium-efficiency filter in the sequence low–medium just before the HEPA or ULPA filters. HEPA and ULPA filters are widely used in clean rooms and clean spaces.

Activated Carbon Filters

These filters are widely used to remove objectional odors and irritating gaseous airborne particulates, typically 0.003 to 0.006 μm in size, from the air stream by adsorption. *Adsorption* is physical condensation of gas or vapor on the surface of an activated substance like activated carbon. Activated substances are extremely porous. One pound of activated carbon contains 5,000,000 ft^2 of internal surface.

Activated carbon in the form of granules or pellets is made of coal, coconut shells, or petroleum residues and is placed in trays to form activated carbon beds as shown in Figure 9.7.4(d). A typical carbon tray is 23 × 23 × 5/8 in. thick. Low-efficiency prefilters are used for protection. When air flows through the carbon beds at a face velocity of 375 to 500 fpm, the corresponding pressure drop is 0.2 to 0.3 in. WG.

Humidifiers

A *humidifier* adds moisture to the air. Air is humidified by: (1) heating the liquid to evaporate it; (2) atomizing the liquid water into minute droplets by mechanical means, compressed air, or ultrasonic vibration to create a larger area for evaporation; (3) forcing air to flow through a wetted element in

© 1999 by CRC Press LLC

which water evaporates; and (4) injecting steam into air directly before it is supplied to the conditioned space.

For comfort air-conditioning systems, a steam humidifier with a separator as shown in Figure 9.7.5(a) is widely used. Steam is supplied to a jacketed distribution manifold. It enters a separating chamber with its condensate. Steam then flows through a control valve, throttles to a pressure slightly above atmospheric, and enters a dry chamber. Due to the high temperature in the surrounding separating chamber, the steam is superheated. Dry steam is then discharged into the ambient air stream through the orifices on the inner steam discharge tubes.

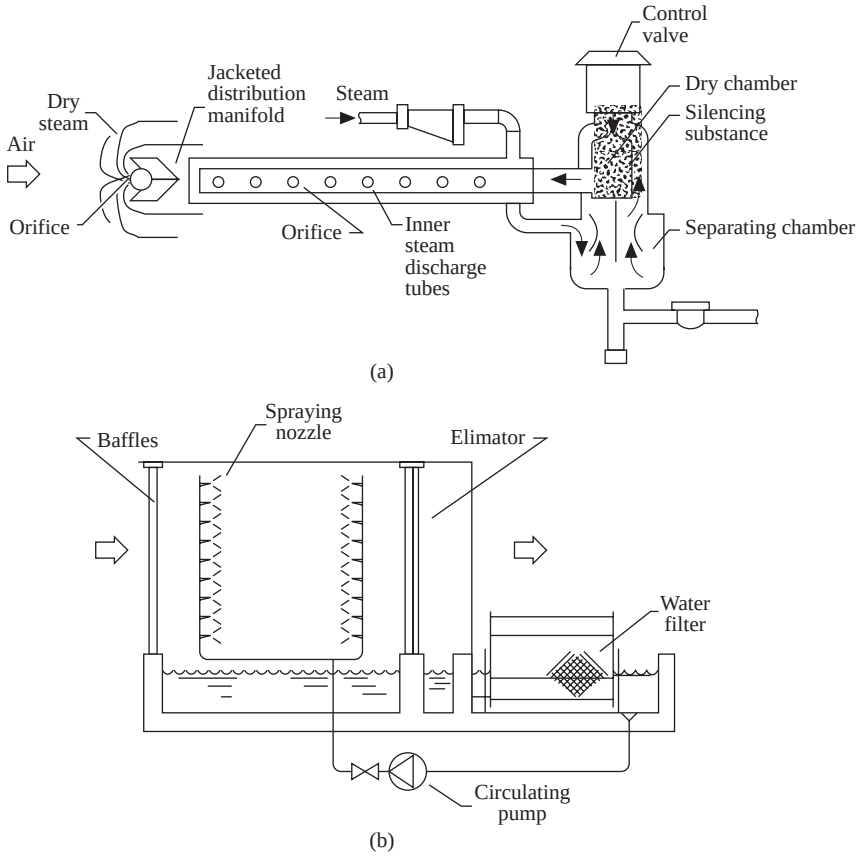

FIGURE 9.7.5 Steam grid humidifier (a) and air washer (b).

For an air system of cold air supply with humidity control during winter mode operation, an air washer is economical for large-capacity humidification in many industrial applications.

An air washer is a humidifier, a cooler, a dehumidifier, and an air cleaner. An air washer usually has an outer casing, two banks of spraying nozzles, one bank of guide baffles at the entrance, one bank of eliminators at the exit, a water tank, a circulating pump, a water filter, and other accessories as shown in Figure 9.7.5(b). Outer casing, baffles, and eliminators are often made of plastics or sometimes stainless steel. Spraying nozzles are usually made of brass or nylon, with an orifice diameter of 1/16 to 3/16 in., a smaller orifice for humidification, and a larger orifice for cooling and dehumidification. An eccentric inlet connected to the discharge chamber of the spraying nozzle gives centrifugal force to the water stream and atomizes the spraying water. Water is supplied to the spraying nozzle at a pressure of 15 to 30 psig. The distance between two spraying banks is 3 to 4.5 ft, and the total length of the air water from 4 to 7 ft. The air velocity inside an air washer is usually 500 to 800 fpm.

© 1999 by CRC Press LLC

Selection of AHUs and PUs

- The size of an AHU is usually selected so that the face velocity of its coil is 600 fpm or less in order to prevent entrained condensate droplets. The cooling and heating capacities of an AHU can be varied by using coils of different numbers of rows and fin densities. The size of a PU is determined by its cooling capacity. Normally, the volume flow rate per ton of cooling capacity in PUs is 350 to 400 cfm. In most packaged units whose supply fans have belt drives, the fan speed can be selected so that the volume flow rate is varied and external pressure is met.
- ASHRAE/IES Standard 90.1-1989 specifies that the selected equipment capacity may exceed the design load only when it is the smallest size needed to meet the load. Selected equipment in a size larger always means a waste of energy and investment.
- To improve the indoor air quality, save energy, and prevent smudging and discoloring building interiors, a medium-efficiency filter of dust spot efficiency ≥50% and an air economizer are preferable for large AHUs and PUs.

9.8 Refrigeration Components and Evaporative Coolers

Refrigeration Compressors

A refrigeration compressor is the heart of a vapor compression system. It raises the pressure of refrigerant so that it can be condensed into liquid, throttled, and evaporated into vapor to produce the refrigeration effect. It also provides the motive force to circulate the refrigerant through condenser, expansion valve, and evaporator.

According to the compression process, refrigeration compressors can be divided into *positive displacement* and *nonpositive displacement* compressors. A positive displacement compressor increases the pressure of the refrigerant by reducing the internal volume of the compression chamber. Reciprocating, scroll, rotary, and screw compressors are all positive displacement compressors. The centrifugal compressor is the only type of nonpositive displacement refrigeration compressor widely used in refrigeration systems today.

Based on the sealing of the refrigerant, refrigeration compressors can be classified as

- *Hermetic compressors*, in which the motor and the compressor are sealed or welded in the same housing to minimize leakage of refrigerant and to cool the motor windings by using suction vapor
- *Semihermetic compressors*, in which motor and compressor are enclosed in the same housing but are accessible from the cylinder head for repair and maintenance
- *Open compressors*, in which compressor and motor are enclosed in two separate housings

Refrigeration compressors are often driven by motor directly or by gear train.

Performance Indices

Volumetric efficiency η_v of a refrigeration compressor is defined as

$$\eta_v = \mathring{V}_{a.v} \Big/ \mathring{V}_p \tag{9.8.1}$$

where $\mathring{V}_{a.v}$ = actual induced volume of the suction vapor at suction pressure, cfm
V_p = calculated displacement of the compressor, cfm

Isentropic efficiency η_{isen}, *compression efficiency* η_{cp}, compressor efficiency η_{com}, and *mechanical efficiency* η_{mec} are defined as

$$\begin{aligned} \eta_{isen} &= \left(h_2 - h_1\right) \Big/ \left(h_2' - h_1\right) = \eta_{cp}\eta_{mec} = \eta_{com} \\ \eta_{cp} &= W_{sen} / W_v \\ \eta_{mec} &= W_v / W_{com} \end{aligned} \tag{9.8.2}$$

where h_1, h_2, h_2' = enthalpy of the suction vapor, ideal discharged hot gas, and actual discharged hot gas, respectively, Btu/lb
W_{isen}, W_v, W_{com} = isentropic work = $(h_2 - h_1)$, work delivered to the vapor refrigerant, and work delivered to the compressor shaft, Btu/lb

The actual power input to the compressor P_{com}, in hp, can be calculated as

$$\begin{aligned} P_{com} &= \mathring{m}_r \left(h_2 - h_1\right) \Big/ \left(42.41\eta_{isen}\eta_{mo}\right) \\ \mathring{m}_r &= \mathring{V}_p \, \eta_v \rho_{suc} \\ \eta_{mo} &= P_{com} / P_{mo} \end{aligned} \tag{9.8.3}$$

© 1999 by CRC Press LLC

where $\dot{m}_r$ = mass flow rate of refrigerant, lb/min
ρ_{suc} = density of suction vapor, lb/ft^3
P_{mo} = power input to the compressor motor, hp

Power consumption, kW/ton refrigeration, is an energy index used in the HVAC&R industry in addition to EER and COP.

Currently used refrigeration compressors are reciprocating, scroll, screw, rotary, and centrifugal compressors.

Reciprocating Compressors

In a reciprocating compressor, as shown in Figure 9.8.1(a), a crankshaft connected to the motor shaft drives 2, 3, 4, or 6 single-acting pistons moving reciprocally in the cylinders via a connecting rod.

The refrigeration capacity of a reciprocating compressor is a fraction of a ton to about 200 tons. Refrigerants R-22 and R-134a are widely used in comfort and processing systems and sometimes R-717 in industrial applications. The maximum compression ratio R_{com} for a single-stage reciprocating compressor is about 7. Volumetric efficiency η_v drops from 0.92 to 0.65 when R_{com} is raised from 1 to 6. Capacity control of reciprocating compressor including: on-off and cylinder unloader in which discharge gas is in short cut and return to the suction chamber.

Although reciprocating compressors are still widely used today in small and medium-sized refrigeration systems, they have little room for significant improvement and will be gradually replaced by scroll and screw compressors.

Scroll Compressors

A scroll compressor consists of two identical spiral scrolls assembled opposite to each other, as shown in Figure 9.8.1(b). One of the scrolls is fixed, and the other moves in an orbit around the motor shaft whose amplitude equals the radius of the orbit. The two scrolls are in contact at several points and therefore form a series of pockets.

Vapor refrigerant enters the space between two scrolls through lateral openings. The lateral openings are then sealed and the formation of the two trapped vapor pockets indicates the end of the suction process. The vapor is compressed and the discharge process begins when the trapped gaseous pockets open to the discharge port. Compressed hot gas is then discharged through this opening to the discharge line. In a scroll compressor, the scrolls touch each other with sufficient force to form a seal but not enough to cause wear.

The upper limit of the refrigeration capacity of currently manufactured scroll compressors is 60 tons. A scroll compressor has $\eta_v > 95\%$ at $R_{com} = 4$ and $\eta_{isen} = 80\%$. A scroll compressor also has only about half as many parts as a reciprocating compressor at the same refrigeration capacity. Few components result in higher reliability and efficiency. Power input to the scroll compressor is about 5 to 10% less than to the reciprocating compressor. A scroll compressor also operates more smoothly and is quieter.

Rotary Compressors

Small rotary compressors for room air conditioners and refrigerators have a capacity up to 4 tons. There are two types of rotary compressors: rolling piston and rotating vane. A typical rolling piston rotary compressor is shown in Figure 9.8.1(c). A rolling piston mounted on an eccentric shaft is kept in contact with a fixed vane that slides in a slot. Vapor refrigerant enters the compression chamber and is compressed by the eccentric motion of the roller. When the rolling piston contacts the top housing, hot gas is squeezed out from the discharge valve.

Screw Compressors

These are also called *helical rotary compressors*. Screw compressors can be classified into single-screw compressors, in which there is a single helical rotor and two star wheels, and twin-screw compressors. Twin-screw compressors are widely used.

© 1999 by CRC Press LLC

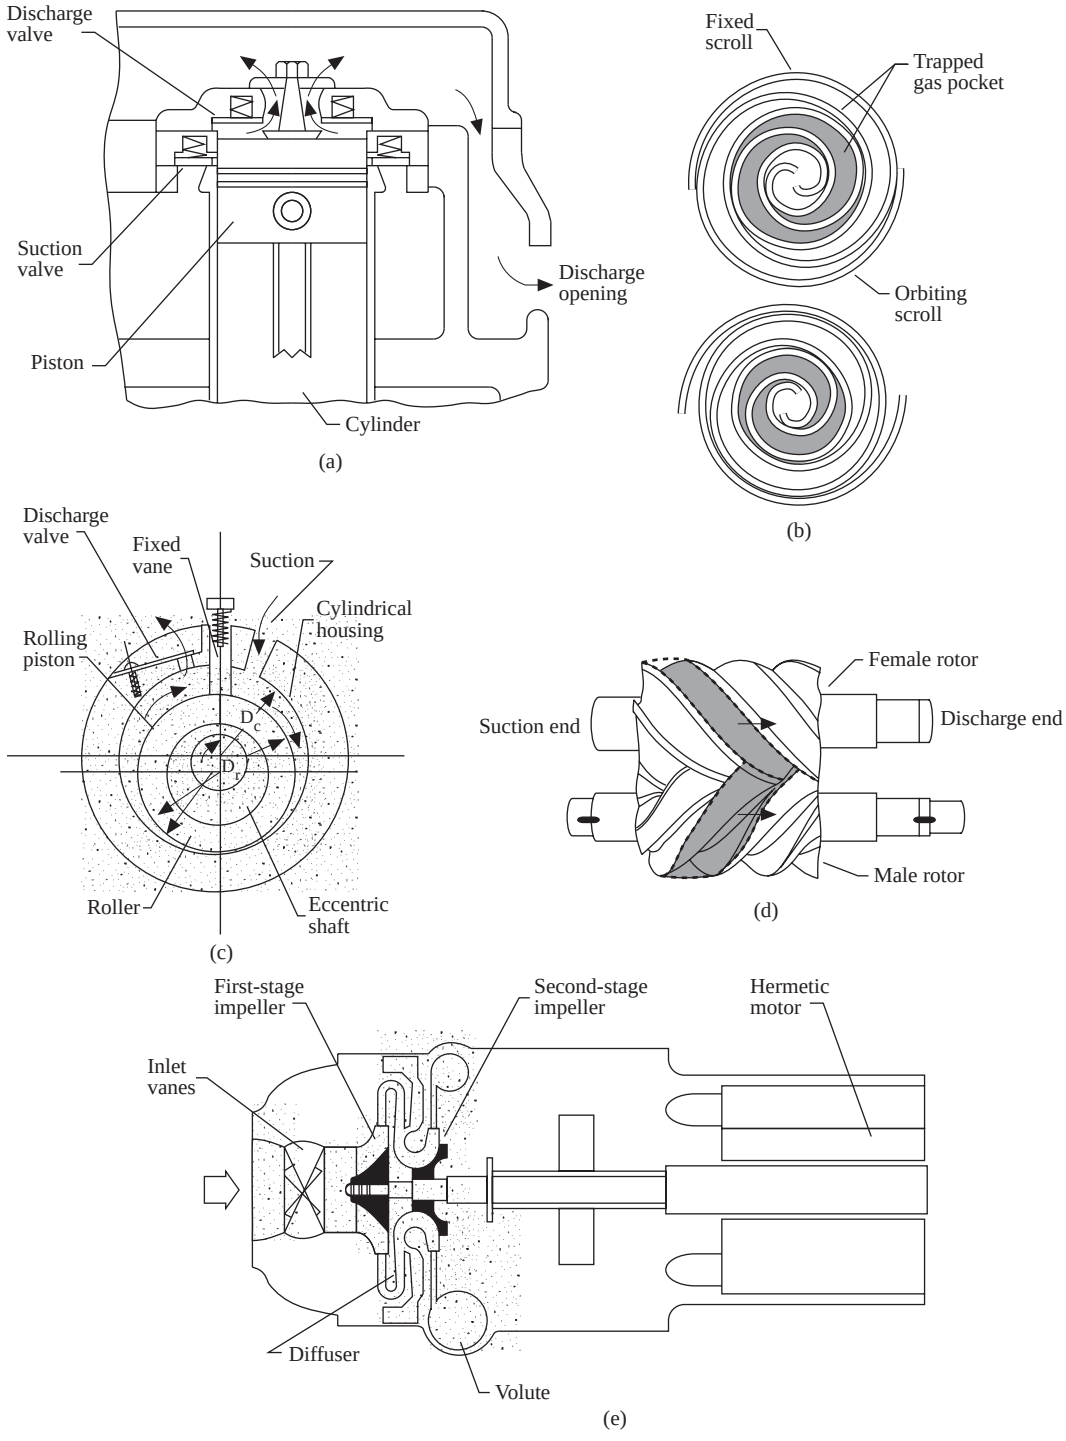

FIGURE 9.8.1 Various types of refrigeration compressors: (a) reciprocating, (b) scroll, (c) rotary, (d) twin-screw, and (e) centrifugal.

A typical twin-screw compressor, as shown in Figure 9.8.1(d) consists of a four-lobe male rotor and a six-lobe female rotor, a housing with suction and discharge ports, and a sliding valve to adjust the

© 1999 by CRC Press LLC

capacity during part load. Normally, the male rotor is the driver. Twin-screw compressors are often direct driven and of hermetic type.

Vapor refrigerant is extracted into the interlobe space when the lobes are separated at the suction port. During the successive rotations of the rotor, the volume of the trapped vapor is compressed. When the interlobe space is in contact with the discharge port, the compressed hot gas discharges through the outlet. Oil injection effectively cools the rotors and results in a lower discharge temperature. Oil also provides a sealing effect and lubrication. A small clearance of 0.0005 in. as well as the oil sealing minimizes leakage of the refrigerant.

The refrigeration capacity of twin-screw compressors is 50 to 1500 tons. The compression ratio of a twin-screw compressor can be up to 20:1. R-22 and R-134a are the most widely used refrigerants in comfort systems. In a typical twin-screw compressor, η_v decreases from 0.92 to 0.87 and η_{isen} drops from 0.82 to 0.67 when R_{com} increases from 2 to 10. Continuous and stepless capacity control is provided by moving a sliding valve toward the discharge port, which opens a shortcut recirculating passage to the suction port.

Twin-screw compressors are more efficient than reciprocating compressors. The low noise and vibration of the twin-screw compressor together with its positive displacement compression results in more applications today.

Centrifugal Compressors

A *centrifugal compressor* is a turbomachine and is similar to a centrifugal fan. A hermetic centrifugal compressor has an outer casing with one, two, or even three impellers internally connected in series and is driven by a motor directly or by a gear train. At the entrance to the first-stage impeller are inlet guide vanes positioned at a specific opening to adjust refrigerant flow and therefore the capacity of the centrifugal compressor.

Figure 9.8.1(e) shows a two-stage hermetic centrifugal compressor. The total pressure rise in a centrifugal compressor, often called head lift, in psi, is due to the conversion of the velocity pressure into static pressure. Although the compression ratio R_{com} of a single-stage centrifugal compressor using R-123 and R-22 seldom exceeds 4, two or three impellers connected in series satisfy most of the requirements in comfort systems.

Because of the high head lift to raise the evaporating pressure to condensing pressure, the discharge velocity at the exit of the second-stage impeller approaches the acoustic velocity of saturated vapor v_{ac} of R-123, 420 ft/sec at atmospheric pressure and a temperature of 80°F. Centrifugal compressors need high peripheral velocity and rotating speeds (up to 50,000 rpm) to produce such a discharge velocity. It is not economical to manufacture small centrifugal compressors. The available refrigeration capacity for centrifugal compressors ranges from 100 to 10,000 tons. Centrifugal compressors have higher volume flow per unit refrigeration capacity output than positive displacement compressors. Centrifugal compressors are efficient and reliable. Their volumetric efficiency almost equals 1. At design conditions, their η_{isen} may reach 0.83, and it drops to 0.6 during part-load operation. They are the most widely used refrigeration compressors in large air-conditioning systems.

Refrigeration Condensers

A *refrigeration condenser* or simply a *condenser* is a heat exchanger in which hot gaseous refrigerant is condensed into liquid and the latent heat of condensation is rejected to the atmospheric air, surface water, or well water. In a condenser, hot gas is first desuperheated, then condensed into liquid, and finally subcooled.

The capacity of a condenser is rated by its *total heat rejection* Q_{rej}, in Btu/hr, which is defined as the total heat removed from the condenser during desuperheating, condensation, and subcooling. For a refrigeration system using a hermetic compressor, Q_{rej} can be calculated as

© 1999 by CRC Press LLC

$$Q_{rej} = U_{con} A_{con} \Delta T_m = 60 \mathring{m}_r \left(h_2 - h_3'\right) = q_{rl} + \left(2545 P_{com}\right) / \eta_{mo} \tag{9.8.4}$$

where U_{con} = overall heat transfer coefficient across the tube wall in the condenser, Btu/hr.ft^2.°F
A_{con} = condensing area in the condenser, ft^2
ΔT_m = logarithmic temperature difference, °F
$\mathring{m}_r$ = mass flow rate of refrigerant, lb/min
h_2, h_3' = enthalpy of suction vapor refrigerant and hot gas, Btu/lb
q_{rl} = refrigeration load at the evaporator, Btu/hr

A factor that relates Q_{rej} and q_{rl} is the *heat rejection factor* F_{rej}, which is defined as the ratio of total heat rejection to the refrigeration load, or

$$F_{rej} = Q_{rej} / q_{rl} = 1 + \left(2545 P_{com}\right) / \left(q_{rl} \eta_{mo}\right) \tag{9.8.5}$$

Fouling factor R_f, in hr.ft^2.°F/Btu, is defined as the additional resistance caused by a dirty film of scale, rust, or other deposits on the surface of the tube. ARI Standard 550-88 specifies the following for evaporators and condensers:

Field fouling allowance	0.00025 hr.ft^2.°F/Btu
New evaporators and condensers	0

According to the cooling process used during condensation, refrigeration condensers can be classified as air-cooled, water-cooled, and evaporative-cooled condensers.

Air-Cooled Condensers

In an *air-cooled condenser*, air is used to absorb the latent heat of condensation released during desuperheating, condensation, and subcooling.

An air-cooled condenser consists of a condenser coil, a subcooling coil, condenser fans, dampers, and controls as shown in Figure 9.8.2(a). There are refrigeration circuits in the condensing coil. Condensing coils are usually made of copper tubes and aluminum fins. The diameter of the tubes is 1/4 to 3/4 in., typically 3/8 in., and the fin density is 8 to 20 fins/in. On the inner surface of the copper tubes, microfins, typically 60 fins/in. with a height of 0.008 in., are used. A condensing coil usually has only two to three rows due to the low pressure drop of the propeller-type condenser fans. A subcooling coil is located at a lower level and is connected to the condensing coil.

Hot gas from the compressor enters the condensing coil from the top. When the condensate increases, part of the condensing area can be used as a subcooling area. A receiver is necessary only when the liquid refrigerant cannot all be stored in the condensing and subcooling coils during the shut-down period in winter.

Cooling air is drawn through the coils by a condenser fan(s) for even distribution. Condenser fans are often propeller fans for their low pressure and large volume flow rate. A damper(s) may be installed to adjust the volume flow of cooling air.

In air-cooled condensers, the volume flow of cooling air per unit of total heat rejection $\mathring{V}_{ca} / Q_{u.rej}$ is 600 to 1200 cfm/ton of refrigeration capacity at the evaporator, and the optimum value is about 900 cfm/ton. The corresponding cooling air temperature difference — cooling air leaving temperature minus outdoor temperature ($T_{ca.l} - T_o$) — is around 13°F.

The condenser temperature difference (CTD) for an air-cooled condenser is defined as the difference between the saturated condensing temperature corresponding to the pressure at the inlet and the air intake temperature, or ($T_{con.i} - T_o$). Air-cooled condensers are rated at a specific CTD, depending on the evaporating temperature of the refrigeration system T_{ev} in which the air-cooled condenser is installed. For a refrigeration system having a lower T_{ev}, it is more economical to equip a larger condenser with a smaller CTD. For a comfort air-conditioning system having a T_{ev} of 45°F, CTD = 20 to 30°F.

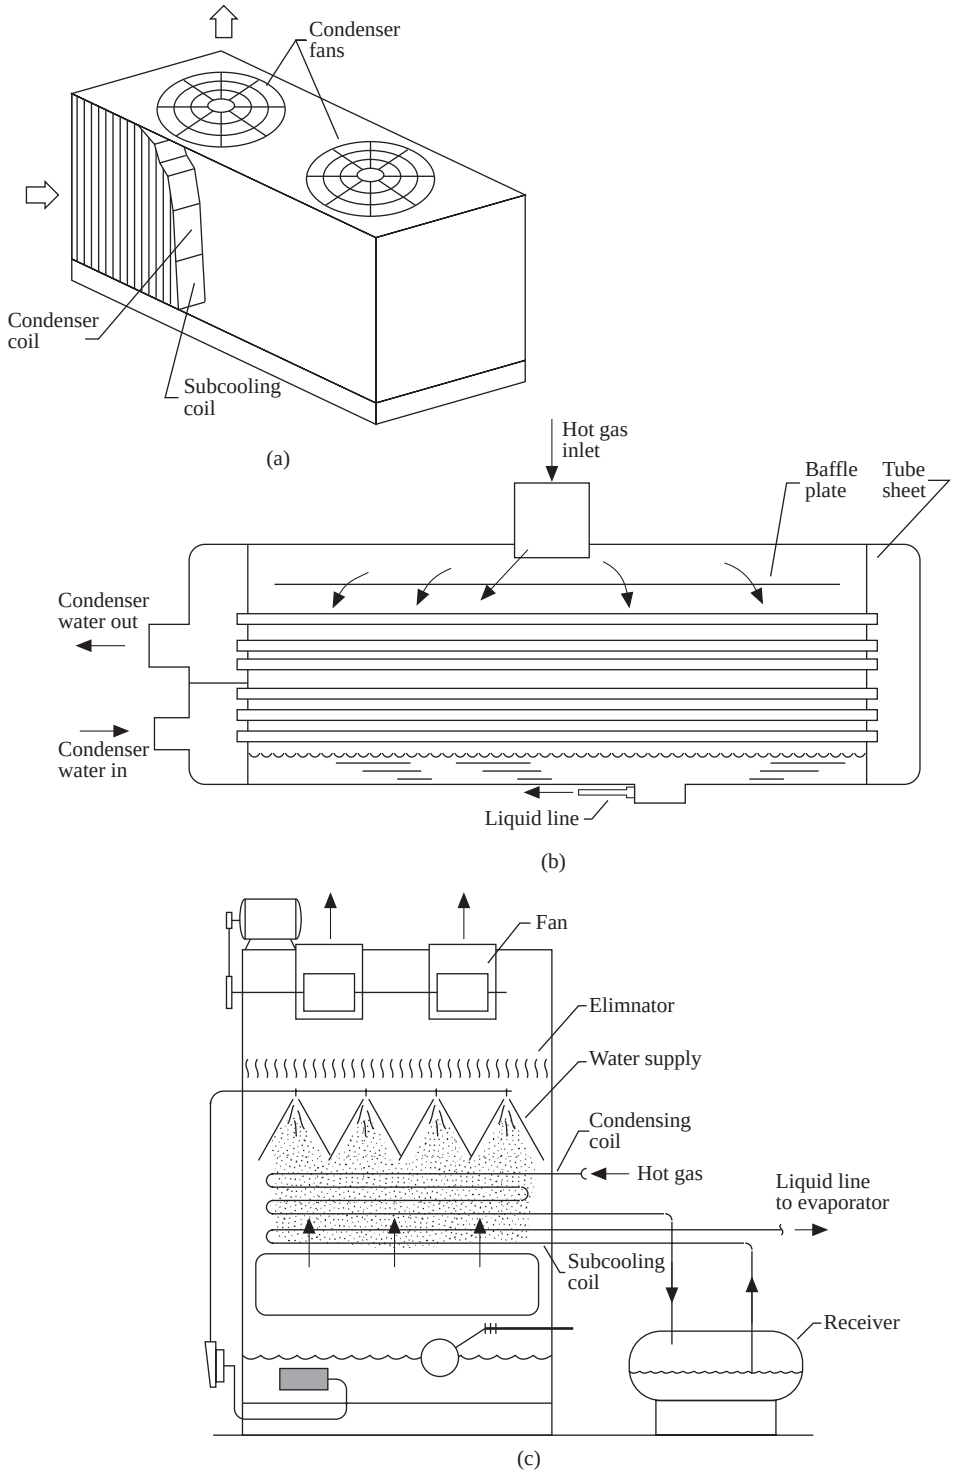

FIGURE 9.8.2 Various types of refrigeration condensers: (a) air-cooled, (b) shell-and-tube water-cooled, and (c) evaporative cooled.

© 1999 by CRC Press LLC

A higher condensing temperature T_{con}, a higher condensing pressure p_{con}, and a higher compressor power input may be due to an undersized air-cooled condenser, lack of cooling air or low $\mathring{V}_{ca}/Q_{u.rej}$ value, a high entering cooling air temperature at the roof, a dirty condensing coil, warm air circulation because of insufficient clearance between the condenser and the wall, or a combination of these. The clearance should not be less than the width of the condensing coil.

If p_{con} drops below a certain value because of a lower outdoor temperature, the expansion valve in a reciprocating vapor compression system may not operate properly. At a low ambient temperature T_o, the following controls are often used:

- Duty cycling, turning the condenser fans on and off until all of them are shut down, to reduce cooling air volume flow
- Modulating the air dampers to reduce the volume flow
- Reducing the fan speed

Some manufacturers' catalogs start low ambient control at T_o = 65°F and some specify a minimum operating temperature at T_o = 0°F.

Water-Cooled Condensers

In a *water-cooled condenser*, latent heat of condensation released from the refrigerant during condensation is extracted by water. This cooling water, often called condenser water, is taken directly from river, lake, sea, underground well water or a cooling tower.

Two types of water-cooled condensers are widely used for air-conditioning and refrigeration: double-tube condensers and horizontal shell-and-tube condensers.

A *double-tube condenser* consists of two tubes, one inside the other. Condenser water is pumped through the inner tube and refrigerant flows within the space between the inner and outer tubes in a counterflow arrangement. Because of its limited condensing area, the double-tube condenser is used only in small refrigeration systems.

A horizontal *shell-and-tube water-cooled condenser* using halocarbon refrigerant usually has an outer shell in which copper tubes typically 5/8 to 3/4 in. in diameter are fixed in position by tube sheets as shown in Figure 9.8.2(b). Integral external fins of 19 to 35 fins/in. and a height of 0.006 in. and spiral internal grooves are used for copper tubes to increase both the external and the inner surface area and their heat transfer coefficients.

Hot gas from the compressor enters the top inlet and is distributed along the baffle to fill the shell. Hot gas is then desuperheated, condensed, subcooled into liquid, and discharged into the liquid line at the bottom outlet. Usually one sixth of the volume is filled with subcooled liquid refrigerant. Subcooling depends on the entering temperature of condenser water T_{ce}, in °F, and usually varies between 2 and 8°F.

Condenser water enters the condenser from the bottom for effective subcooling. After extracting heat from the gaseous refrigerant, condenser water is discharged at a higher level. Two-pass or three-pass water flow arrangements are usually used in shell-and-tube water-cooled condensers. The two-pass arrangement means that water flows from one end to the opposite end and returns to the original end. Two-pass is the standard setup. In a shell-and-tube water-cooled condenser, the condensing temperature T_{con} depends mainly on the entering temperature of condenser water T_{ce}, the condenser area, the fouling factor, and the configuration of the copper tube.

Evaporative Condenser

An *evaporative condenser* uses the evaporation of water spray on the outer surface of the condensing tubes to remove the latent heat of condensation of refrigerant during condensation.

An evaporative condenser consists of a condensing coil, a subcooling coil, a water spray, an induced draft or sometimes forced draft fan, a circulating water pump, a water eliminator, a water basin, an outer casing, and controls as shown in Figure 9.8.2(c). The condensing coil is usually made of bare copper, steel, or sometimes stainless steel tubing.

© 1999 by CRC Press LLC

Water is sprayed over the outside surface of the tubing. The evaporation of a fraction of condenser water from the saturated air film removes the sensible and latent heat rejected by the refrigerant. The wetted outer surface heat transfer coefficient h_{wet} is about four or five times greater than the dry surface heat transfer coefficient h_o, in Btu/hr.ft^2.°F. The rest of the spray falls and is collected by the basin. Air enters from the inlet just above the basin. It flows through the condensing coil at a face velocity of 400 to 700 fpm, the water spray bank, and the eliminator. After air absorbs the evaporated water vapor, it is extracted by the fan and discharged at the top outlet. The water circulation rate is about 1.6 to 2 gpm/ton, which is far less than that of the cooling tower.

An evaporative condenser is actually a combination of a water-cooled condenser and a cooling tower. It is usually located on the rooftop and should be as near the compressor as possible. Clean tube surface and good maintenance are critical factors for evaporative condensers. An evaporative condenser also needs low ambient control similar as in an air-cooled condenser.

Comparison of Air-Cooled, Water-Cooled, and Evaporative Condensers

An air-cooled condenser has the highest condensing temperature T_{con} and therefore the highest compressor power input. For an outdoor dry bulb temperature of 90°F and a wet bulb temperature of 78°F, a typical air-cooled condenser has T_{con} = 110°F. An evaporative condenser has the lowest T_{con} and is most energy efficient. At the same outdoor dry and wet bulb temperatures, its T_{con} may be equal to 95°F, even lower than that of a water-cooled condenser incorporating with a cooling tower, whose T_{con} may be equal to 100°F. An evaporative condenser also consumes less water and pump power. The drawback of evaporative condensers is that the rejected heat from the interior zone is difficult to recover and use as winter heating for perimeter zones and more maintenance is required.

Evaporators and Refrigerant Flow Control Devices

An *evaporator* is a heat exchanger in which the liquid refrigerant is vaporized and extracts heat from the surrounding air, chilled water, brine, or other substance to produce a refrigeration effect.

Evaporators used in air-conditioning can be classified according to the combination of the medium to be cooled and the type of refrigerant feed, as the following.

Direct expansion DX coils are air coolers, and the refrigerant is fed according to its degree of superheat after vaporization. DX coils were covered earlier.

Direct expansion ice makers or *liquid overfeed ice makers* are such that liquid refrigerant is forced through the copper tubes or the hollow inner part of a plate heat exchanger and vaporized. The refrigeration effect freezes the water in the glycol-water that flows over the outside surface of the tubes or the plate heat exchanger. In direct expansion ice makers, liquid refrigerant completely vaporizes inside the copper tubes, and the superheated vapor is extracted by the compressor. In liquid overfeed ice makers, liquid refrigerant floods and wets the inner surface of the copper tubes or the hollow plate heat exchanger. Only part of the liquid refrigerant is vaporized. The rest is returned to a receiver and pumped to the copper tubes or plate heat exchanger again at a circulation rate two to several times greater than the evaporation rate.

Flooded shell-and-tube liquid coolers, or simply *flooded liquid coolers*, are such that refrigerant floods and wets all the boiling surfaces and results in high heat transfer coefficients. A flooded shell-and-tube liquid cooler is similar in construction to a shell-and-tube water-cooled condenser, except that its liquid refrigeration inlet is at the bottom and the vapor outlet is at the top. Water velocity inside the copper tubes is usually between 4 and 12 ft/sec and the water-side pressure normally drops below 10 psi. Flooded liquid coolers can provide larger evaporating surface area and need minimal space. They are widely used in large central air-conditioning systems.

Currently used refrigerant flow control devices include thermostatic expansion valves, float valves, multiple orifices, and capillary tubes.

A *thermostatic expansion valve* throttles the refrigerant pressure from condensing to evaporating pressure and at the same time regulates the rate of refrigerant feed according to the degree of superheat

© 1999 by CRC Press LLC

of the vapor at the evaporator's exit. A thermostatic expansion valve is usually installed just prior to the refrigerant distributor in DX coils and direct-expansion ice makers.

A thermostatic expansion valve consists of a valve body, a valve pin, a spring, a diaphragm, and a sensing bulb near the outlet of the DX coil, as shown in Figure 9.7.3(a). The sensing bulb is connected to the upper part of the diaphragm by a connecting tube.

When the liquid refrigerant passes through the opening of the thermostatic expansion valve, its pressure is reduced to the evaporating pressure. Liquid and a small fraction of vaporized refrigerant then flow through the distributor and enter various refrigerant circuits. If the refrigeration load of the DX coil increases, more liquid refrigerant evaporizes. This increases the degree of superheat of the leaving vapor at the outlet and the temperature of the sensing bulb. A higher bulb temperature exerts a higher saturated pressure on the top of the diaphragm. The valve pin then moves downward and widens the opening. More liquid refrigerant is allowed to enter the DX coil to match the increase of refrigeration load. If the refrigeration load drops, the degree of superheat at the outlet and the temperature of the sensing bulb both drop, and the valve opening is narrower. The refrigeration feed decreases accordingly. The degree of superheat is usually 10 to 20°F. Its value can also be adjusted manually by varying the spring tension.

A *float valve* is a valve in which a float is used to regulate the valve opening to maintain a specific liquid refrigerant level. A lower liquid level causes a lower valve pin and therefore a wider opening and vice versa.

In a centrifugal refrigeration system, two or more orifice plates, *multiple orifices*, are sometimes installed in the liquid line between the condenser and the flash cooler and between the flash cooler and the flooded liquid cooler to throttle their pressure as well as to regulate the refrigerant feed.

A *capillary tube*, sometimes called a *restrictor tube*, is a fixed length of small-diameter tubing installed between the condenser and the evaporator to throttle the refrigerant pressure from p_{con} to p_{ev} and to meter the refrigerant flow to the evaporator. Capillary tubes are usually made of copper. The inside diameter D_{cap} is 0.05 to 0.06 in. and the length L_{cap} from an inch to several feet. There is a trend to use short capillary tubes of L_{cap}/D_{cap} between 3 and 20. Capillary tubes are especially suitable for a heat pump system in which the refrigerant flow may be reversed.

Evaporative Coolers

An evaporative cooling system is an air-conditioning system in which air is cooled evaporatively. It consists of evaporative coolers, fan(s), filters, dampers, controls, and others. A mixing box is optional. An evaporative cooler could be a stand-alone cooler or installed in an air system as a component. There are three types of evaporative coolers: (1) direct evaporative coolers, (2) indirect evaporative coolers, and (3) indirect–direct evaporative coolers.

Direct Evaporative Cooler

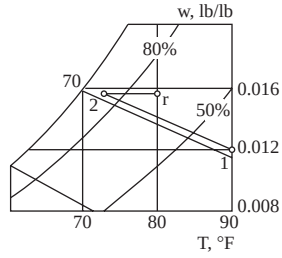
In a *direct evaporative cooler*, the air stream to be cooled directly contacts the water spray or wetted medium as shown in Figure 9.8.3(a). Evaporative pads made of wooden fibers with necessary treatment at a thickness of 2 in., rigid and corrugated plastics, impregnated cellulose, or fiber glass all dripping with water are wetted mediums.

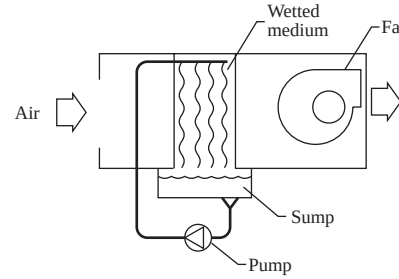
The direct evaporation process 12 takes place along the thermodynamic wet bulb line on the psychrometric chart. Saturation effectiveness ε_{sat} is an index that assesses the performance of a direct evaporative cooler:

$$\varepsilon_{sat} = \left(T_{ae} - T_{al}\right) \Big/ \left(T_{ae} - T_{ae}^{*}\right) \tag{9.8.6}$$

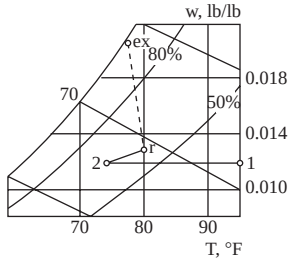
where T, T^* = temperature and thermodynamic wet bulb temperature of air stream, °F. Subscript ae indicates the entering air and al the leaving air. ε_{sat} usually varies between 0.75 and 0.95 at a water–air ratio of 0.1 to 0.4.

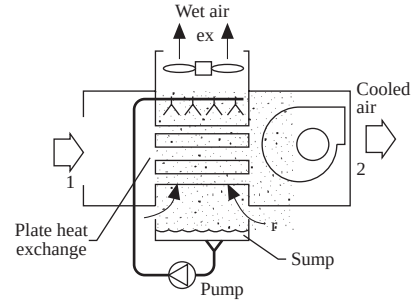
© 1999 by CRC Press LLC



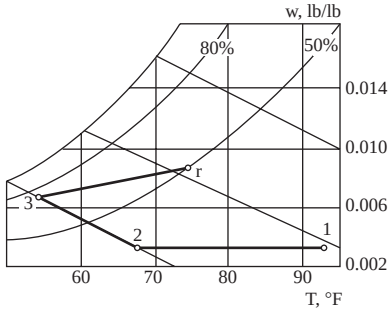


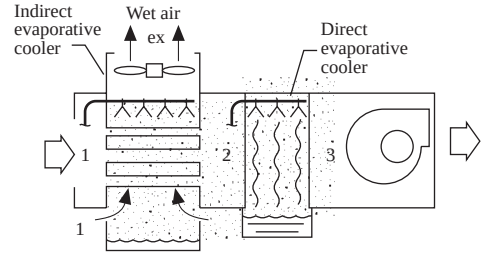
(a)





(b)





(c)

FIGURE 9.8.3 Types of evaporative coolers: (a) direct, (b) indirect, and (c) indirect–direct.

Indirect Evaporative Coolers

In an *indirect evaporative cooler*, the cooled-air stream to be cooled is separated from a wetted surface by a flat plate or tube wall as shown in Figure 9.8.3(b). A wet-air stream flows over the wetted surface so that liquid water is evaporated and extracts heat from the cooled-air stream through the flat plate or tube wall. The cooled-air stream is in contact with the wetted surface indirectly.

The core part of an indirect evaporative cooler is a plate heat exchanger. It is made of thin polyvinyl chloride plates 0.01 in. thick and spaced from 0.08 to 0.12 in. apart to form horizontal passages for cooled air and vertical passages for wet air and water. As in a direct evaporative cooler, there are also fan(s), water sprays, circulating pump, air intake, dampers, controls, etc.

An indirect evaporative cooling process is represented by a horizontal line on a psychrometric chart, which shows that humidity ratio remains constant. If the space air is extracted and used as the wet air intake, the wet air will be exhausted at point x at nearly saturated state.

The performance of an indirect evaporative cooler can be assessed by its performance factor e_{in}, which is calculated as:

© 1999 by CRC Press LLC

$$e_{in} = \left(T_{ca.e} - T_{ca.l}\right) / \left(T_{ca.e} - T_{s.a}\right) \tag{9.8.7}$$

where $T_{ca.e}$, $T_{ca.l}$ = temperature of cooled air entering and leaving the indirect evaporative cooler, °F, and $T_{s.a}$ = temperature of the saturated air film on the wet air side and is about 3°F higher than the wet bulb temperature of the entering air, °F.

An indirect evaporative cooler could be so energy efficient as to provide evaporative cooling with an EER up to 50 instead of 9 to 12 for a reciprocating compression refrigeration system.

Direct–Indirect Evaporative Cooler. A direct–indirect evaporative cooler is a two-stage evaporating cooler, as shown in Figure 9.8.3(c), in which the first-stage indirect evaporative cooler is connected in series with a second-stage direct evaporative cooler for the purpose of increasing the evaporating effect.

Operating Characteristics. The saturation effectiveness ε_{sat} and performance factor e_{in} are both closely related to the air velocity flowing through the air passages. For a direct evaporative cooler, face velocity is usually less than 600 fpm to reduce drift carryover. For an indirect evaporative cooler, face velocity v_s is usually between 400 to 1000 fpm. A higher v_s results at a greater air-side pressure drop.

Scofield et al. (1984) reported the performance of an indirect–direct evaporative cooler in Denver, Colorado. Outdoor air enters the indirect cooler at a dry bulb of 93°F and a wet bulb of 67.5° and was evaporatively cooled to 67.5°F dry bulb and 49.8°F wet bulb with an e_{in} = 0.76 as shown in Figure 9.8.3(c). In the direct cooler, conditioned air was further cooled to a dry bulb of 53.5°F and the wet bulb remained at 49.8°F at a saturation effectiveness ε_{sat} = 0.8.

In locations where outdoor wet bulb $T_o' \leq 60$°F, a direct evaporative can often provide an indoor environment of 78°F and a relative humidity of 60%. In locations $T_o' \leq 68$°F, an indirect–direct evaporative cooler can maintain a comfortable indoor environment. In locations $T_o' \geq 72$°F, an evaporative cooler with a supplementary vapor compression refrigeration may be cost effective. Because the installation cost of an indirect–direct cooler is higher than that of refrigeration, cost analysis is required to select the right choice. Evaporative coolers are not suitable for dehumidification except in locations where $T_o' \leq 60$°F.

9.9 Water Systems

Types of Water Systems

In central and space conditioning air-conditioning systems, water that links the central plant and the air handling units or terminals, that extracts condensing heat, or that provides evaporative cooling may be classified as

- *Chilled water system*, in which chilled water is first cooled in the centrifugal, screw, and reciprocating chillers in a central plant. Chilled water is then used as a cooling medium to cool the air in the cooling coils in AHUs and terminals.
- *Evaporative-cooled water system*, used to cool air directly or indirectly in evaporative coolers.
- *Hot water system*, in which hot water is heated in the boiler and then used to heat the air through heating coils in AHUs, terminals, or space finned-tube heaters.
- *Dual-temperature water system*, in which chilled water and hot water are supplied to and returned from the coils in AHUs and terminals through separate or common main and branch pipes. Using common main and branch pipes requires a lengthy changeover from chilled water to hot water or vice versa for a period of several hours.
- *Condenser water system*, which is a kind of cooling water system used to extract the latent heat of condensation from the condensing refrigerant in a water-cooled condenser and heat of absorption from the absorber.

Water systems can also be classified according to their operating characteristics.

Closed System

In a closed system, water forms a closed loop for water conservation and energy saving when it flows through the coils, chillers, boilers, heaters, or other heat exchangers and water is not exposed to the atmosphere.

Open System

In an open system, water is exposed to the atmosphere.

Once-Through System

In a once-through system, water flows through a heat exchanger(s) only once without recirculation.

Basics

Volume Flow and Temperature Difference

The rate of heat transfer between water and air or water and refrigerant when water flows through a heat exchanger q_w, in Btu/hr, can be calculated as

$$q_w = 500\,\mathring{V}_{gal}\left(T_{wl} - T_{we}\right) = 500\,\mathring{V}_{gal}\,\Delta T_w \tag{9.9.1}$$

where $\mathring{V}_{gal}$ = volume flow rate of water, gpm
T_{wl}, T_{we} = temperature of water leaving and entering the heat exchanger, °F
ΔT_w = temperature rise or drop of water when it flows through a heat exchanger, °F

The temperature of chilled water leaving the water chiller T_{el} should not be lower than 38°F in order to prevent freezing in the evaporator. Otherwise, brine or glycol-water should be used. The T_{el} of chilled water entering the coil T_{we} and the temperature difference of chilled water leaving and entering the coil ΔT_w directly affect the temperature of air leaving the cooling coil T_{cc}. The lower T_{we}, the higher will be the compressor power input. The smaller ΔT_w, the greater will be the water volume flow rate, the pipe

© 1999 by CRC Press LLC

size, and the pump power. For chilled water in conventional comfort systems, T_{we} is usually 40 to 45°F and ΔT_w 12 to 24°F. Only in cold air distribution, T_{we} may drop to 34°F. For a cooling capacity of 1 ton refrigeration, a ΔT_w of 12°F requires a $\mathring{V}_{gal} = 2$ gpm.

For hot water heating systems in buildings, hot water often leaves the boiler and enters the heating coil or heaters at a temperature T_{we} of 190 to 200°F. It returns at 150 to 180°F. For dual-temperature systems, hot water is usually supplied at 100 to 150°F and returns at a ΔT_w of 20 to 40°F.

Pressure Drop

Usually the pressure drop of water in pipes due to friction for HVAC&R systems, H_f, is in the range 0.75 ft/100 ft length of pipe to 4 ft/100 ft. A pressure loss of 2.5 ft/100 ft is most often used. ASHRAE/IES Standard 90.1-1989 specifies that water piping systems should be designed at a pressure loss of no more than 4.0 ft/100 ft. Figure 9.9.1(a), (b), and (c) shows the friction charts for steel, copper, and plastic pipes for closed water systems.

Water Piping

The piping materials of various water systems for HVAC&R are as follows:

Chilled water	Black and galvanized steel
Hot water	Black steel, hard copper
Condenser water	Black steel, galvanized ductile iron, polyvinyl chloride (PVC)

The pipe thickness varies from Schedule 10, a light wall pipe, to Schedule 160, a very heavy wall pipe. Schedule 40 is the standard thickness for a pipe of up to 10 in. diameter. For copper tubing, type K is the heaviest, and type L is generally used as the standard for pressure copper tubes.

Steel pipes of small diameter are often joined by threaded cast-iron fittings. Steel pipes of diameter 2 in. and over, welded joints, and bolted flanges are often used.

In a water system, the maximum allowable working pressure for steel and copper pipes at 250°F varies from 125 to 400 psig, depending on the pipe wall thickness. Not only pipes, but also their joints and fittings should be considered.

During temperature changes, pipes expand and contract. Both operating and shut-down periods should be taken into consideration. Bends like U-, Z-, and L-bends, loops, and sometimes packed expansion joints, bellows, or flexible metal hose mechanical joints are used.

ASHRAE/IES Standard 90.1-1989 specifies that for chilled water between 40 to 55°F, the minimum thickness of the external pipe insulation varies from 0.5 to 1 in. depending on the pipe diameter. For chilled water temperature below 40°F, the minimum thickness varies from 1 to 1.5 in. For hot water temperatures not exceeding 200°F, the minimum thickness varies from 0.5 to 1.5 in. depending on the pipe diameter and the hot water temperature.

Corrosion, Impurities, and Water Treatments

Corrosion is a destructive process caused by a chemical or electrochemical reaction on metal or alloy. In water systems, dissolved *impurities* cause corrosion and scale and the growth of microbiologicals like algae, bacteria, and fungi. *Scale* is the deposit formed on a metal surface by precipitation of the insoluble constituents. In addition to the dissolved solids, unpurified water may contain suspended solids.

Currently used chemicals include crystal modifiers to change the crystal formation of scale and sequestering chemicals. Growth of bacteria, algae, and fungi is usually treated by biocides to prevent the formation of an insulating layer resulting in lower heat transfer as well as restricted water flow. Chlorine and its compounds are effective and widely used. Blow-down is an effective process in water treatment and should be considered as important as chemical treatments.

Piping Arrangements

Main and Branch Pipes. In a piping circuit as shown in Figure 9.9.2(a), chilled water from a chiller or hot water from a boiler is often supplied to a *main pipe* and then distributed to *branch pipes* that

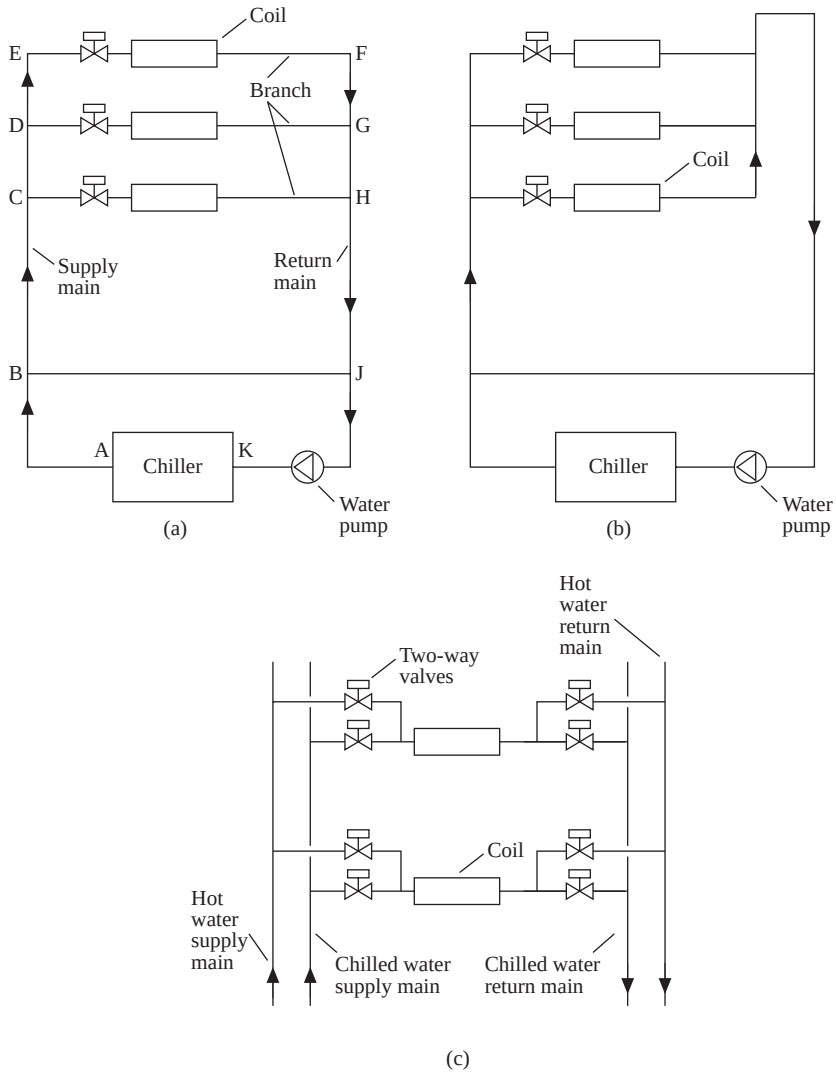

FIGURE 9.9.2 Piping arrangements: (a) two-pipe direct return system, (b) two-pipe reverse system, and (c) four-pipe system.

connect to coils and heat exchangers. Chilled or hot water from the coils and heat exchangers is accumulated by the return main pipe through return branch pipes and then returned to the chiller or boiler.

Constant Flow and Variable Flow. In a constant-flow water system, the volume flow rate at any cross-sectional plane of the supply and return mains remains constant during the entire operating period. In a variable-flow water system, the volume flow rate varies when the system load changes during the operating period.

Direct Return and Reverse Return. In a *direct return* system, the water supplies to and returns from various coils through various piping circuits. ABCHJKA, ... ABCDEFGHJKA are not equal in length, as shown in Figure 9.9.2(a). Water flow must be adjusted and balanced by using balance valves to provide required design flow rates at design conditions. In a *reverse-return* system, as shown in Figure 9.9.2(b), the piping lengths for various piping circuits including the branch and coil are almost equal. Water flow rates to various coils are easier to balance.

© 1999 by CRC Press LLC

Two-Pipe or Four-Pipe. In a dual-temperature water system, the piping from the chiller or boiler to the coils can be either a *two-pipe* system with a supply main and return main as shown in Figure 9.9.2(a) or (b) or a *four-pipe* system with a chilled water supply main, a hot water supply main, a chilled water return main, and a hot water return main as shown in Figure 9.9.2(c). The two-pipe system needs a changeover from chilled to hot water and vice versa. A four-pipe system is more expensive to install.

Plant-Building Loop

System Description

The chillers/boilers in a central plant are often located in the basement, machinery room, or on the rooftop of the building. Generally, a fairly constant-volume water flow is required in the evaporator to protect it from freezing at part load. ASHRAE/IES Standard 90.1-1989 specifies that water systems using control valves to modulate the coil load must be designed for variable flow for energy savings.

Current chilled water systems or dual-temperature water systems often adopt a *plant-building loop* that consists of two piping loops as shown in Figure 9.9.3(a) for reliable and energy-efficient operation:

Plant Loop. A plant loop ABJKA is comprised of chiller(s)/boiler(s); plant chilled/hot water pump(s) usually of split-case, double suction, or end suction type; a diaphragm expansion tank to allow water expansion and contraction during water temperature changes; an air separator to purge dissolved air from water; corresponding piping and fittings; and control systems. The plant loop is operated at constant flow.

Building Loop. A building loop BCDEFGHJB contains coils; building circulating water pumps, often variable-speed pumps, one being a standby pump; corresponding pipes and fittings; and control systems. A differential pressure transmitter is often installed at the farthest end from the building pump between the supply and return mains. The building loop is operated at variable flow.

A short common pipe connects these two loops and combines them into a plant-building loop combination. It is also called a *primary-secondary loop*, with the plant loop the primary loop and the building loop the secondary loop. The location of the pump in a water system should be arranged so that the pressure at any point in the system is greater than atmospheric pressure to prevent air leaking into the system.

Operating Characteristics

In a dual-temperature water system, when the coil load q_{cc}, in Btu/hr, drops, two-way valves close to a smaller opening. The pressure drop across the coils then increases. As soon as the increase of the pressure differential is sensed by the transmitter, a DDC controller reduces the flow rate of the variable-speed pump to match the reduction of the coil load during part load. The pressure differential transmitter functions similarly to a duct static pressure sensor in a VAV system.

Since the plant loop is at constant flow, excess chilled water bypasses the building loop and flows back to the chiller(s) through the common pipe. When the reduction of coil loads in the building loop is equal to or greater than the refrigeration capacity of a single chiller, the DDC controller will shut down a chiller and its associated chilled water pump. The operating characteristics of the hot water in a dual-temperature water system are similar to those in a chilled water system.

Due to the coil's heat transfer characteristics, the reduction of a certain fraction of the design sensible cooling coil load $q_{cs.d}$ does not equal the reduction of the same fraction of design water volume flow $\mathring{V}_{w.d}$ (Figure 9.9.3[c]). Roughly, a 0.7 $q_{cs.d}$ needs only a 0.45 $\mathring{V}_{w.d}$, and the temperature difference $\Delta T_w = (T_{wl} - T_{we})$ will be about 150% of that at the design condition. When an equal-percentage contour two-way control valve is used, the valve stem displacement of the cooling coil's two-way valve is approximately linearly proportional to the sensible cooling coil's load change.

Comparison of a Single-Loop and a Plant-Building Loop

Compared with a single-loop water system as shown in Figure 9.9.3(b) that has only a single-stage water pump(s), the plant-building loop:

- Provides variable flow at the building loop and thus saves pump power at reduced flow during part load.
- Separates plant and building loops and makes design, operation, maintenance, and control simpler and more stable as stated in Carlson (1968). The pressure drop across the two-way control valve is considerably reduced as the control valve is only a component of the building loop.

Plant-Distribution-Building Loop

In universities, medical centers, and airports, buildings are often scattered from the central plant. A campus-type chilled water system using a plant-distribution-building loop is often reliable in operation, requires less maintenance, has minimal environmental impact, and sometimes provides energy cost savings.

In a plant-distribution-building loop, plant loop water is combined with many building loops through a distribution loop as shown in Figure 9.9.4(a). The water flow in the plant loop is constant, whereas in both distribution and building loops it is variable. Chilled water often leaves the chiller at a temperature of 40 to 42°F. It is extracted by the distribution pumps and forced into the distribution supply main. At the entrance of each building, chilled water is again extracted by the building pumps and supplied to the cooling coils in AHUs and fan-coil units. From the coils, chilled water is returned through the building return main and the distribution return main and enters the chillers at a temperature around 60°F at design volume flow. System performances of the plant and building loops in a plant-distribution-building loop are similar to those in a plant-building loop.

A campus-type central plant may transport several thousand gallons of chilled water to many buildings, and the farthest building may be several thousand feet away from the central plant. A smaller pressure gradient and end pressure differential between distribution supply and return mains, $\Delta H_{s.d}$, save energy. Meanwhile, a larger diameter of pipes is needed. For a distribution loop, a pressure drop of 0.5 to 1 ft head loss per 100 ft of piping length may be used. A low pressure differential may be offset at the control valves without affecting the normal operation of the coils. Usually, direct return is used for distribution loops.

Using a two-way distribution from the central plant with two separate supply and return loops often reduces the main pipe length and diameter.

A differential pressure transmitter may be located at the farthest end of the distribution mains. As the pressure loss in the building loop is taken care of by the variable-speed building pump(s), a set point of 5 ft WG pressure differential across the supply and return mains seems appropriate.

Chilled water and hot water distribution pipes are often mounted in underground accessible tunnels or trenches. They are well insulated except when chilled water return temperature $T_{ret} > 55$°F. Under such circumstances, the return main may not be insulated, depending on local conditions and cost analysis.

Many retrofits of campus-type chilled water systems required an existing refrigeration plant(s) and a new developed plant(s) connected to the same plant-distribution-building loop. A stand-alone DDC panel is often used to optimize the turning on and off of the chillers in the existing and developed plants according to the system loads and available sources (chillers).

9.10 Heating Systems

Types of Heating Systems

According to EIA Commercial Buildings Characteristics 1992, for the 57.8 billion ft^2 of heated commercial buildings in the United States in 1992, the following types of heating systems were used:

Warm air heating systems using warm air furnace	27%
Hot water heating systems using boilers	33%
Heat pumps	13%
District heating	8%
Individual space heaters and others heaters	19%

Modera (1989) reported that nearly 50% of U.S. residential houses are using warm air heating systems with direct-fired warm air furnaces.

Warm Air Furnaces

A *warm air furnace* is a device in which gaseous or liquid fuel is directly fired or electric resistance heaters are used to heat the warm supply air. Natural gas, liquefied petroleum gas (LPG), oil, electric energy, or occasionally wood may be used as the fuel or energy input. Among these, natural gas is most widely used. In a warm air furnace, the warm air flow could be *upflow*, in which the warm air is discharged at the top, as shown in Figure 9.10.1(a) and (b); downflow, with the warm air discharged at the bottom; or *horizontal flow*, with the warm air discharged horizontally.

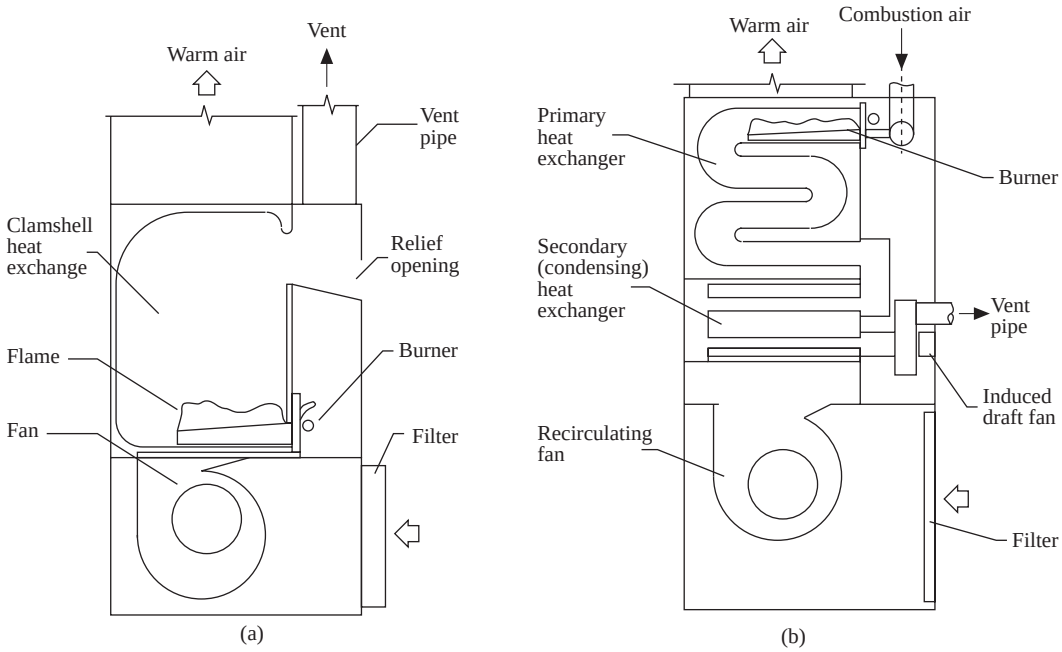

FIGURE 9.10.1 Upflow warm air gas furnace: (a) a natural-vent gas furnace and (b) a power-vent high-efficiency gas furnace.

Natural Vent Combustion Systems. There are two types of combustion systems in a natural gas-fired warm air furnace: natural vent or power vent combustion systems. In a *natural vent* or *atmospheric vent* combustion system, the buoyancy of the combustion products carries the flue gas flowing through the heat exchanger and draft hood, discharging from the chimney or vent pipe. The gas burner is an

© 1999 by CRC Press LLC

atmospheric burner. In an atmospheric burner, air is exracted for combustion by the suction effect of the high-velocity discharged gas and the buoyance effect of the combustion air. An atmospheric burner can be either an in-shot or an up-shot burner or multiple ports. Atmospheric burners are simple, require only a minimal draft of air, and need sufficient gas pressure for normal functioning.

Two types of ignition have been used in burners: standing pilot and spark ignition. In *standing pilot ignition*, the small pilot flame is monitored by a sensor and the gas supply is shut off if the flame is extinguished. *Spark ignition* fires intermittently only when ignition is required. It saves gas fuel if the furnace is not operating.

In a natural vent combustion system, the heat exchanger is often made from cold-rolled steel or aluminized steel in the shape of a clamshell or S. A fan or blower is always used to force the recirculating air flowing over the heat exchanger and distribute the heated air to the conditioned space. A low-efficiency disposable air filter is often located upstream of the fan to remove dust from the recirculating air. A draft hood is also installed to connect the flue gas exit at the top of the heat exchanger to a vent pipe or chimney. A relief air opening is employed to guarantee that the pressure at the flue gas exit is atmospheric and operates safely even if the chimney is blocked. The outer casing of the furnace is generally made of heavy-gauge steel with access panels.

Power Vent Combustion Systems. In a *power vent* combustion system, either a forced draft fan is used to supply the combustion air or an induced draft fan is used to induce the flue gas to the vent pipe or chimney. A power vent is often used for a large gas furnace or a high-efficiency gas furnace with condensing heat exchangers.

Gas burners in a power vent system are called *power burners*. The gas supply to the power burner is controlled by a pressure regulator and a gas valve to control the firing rate. Intermittent spark ignition and *hot surface ignition* that ignites the main burners directly are often used.

Usually, there are two heat exchangers in a power vent combustion system: a primary heat exchanger and a secondary or condensing heat exchanger. The primary heat exchanger constitutes the heating surface of the combustion chamber. When the water vapor in the flue gas is condensed by indirect contact with the recirculating air, part of the latent heat of condensation released is absorbed by the air. Thus the furnace efficiency is increased in the *secondary* or *condensing heat exchanger.* Both primary and secondary heat exchangers are made from corrosion-resistant steel. A fan is also used to force the recirculating air to flow over the heat exchangers and to distribute the heated air to the conditioned space.

Most natural gas furnaces can use LPG. LPG needs a pressure of 10 in. WG at the manifold, compared with 3 to 4 in. for natural gas. It also needs more primary air for gas burners. Oil furnaces are usually of forced draft and installed with pressure-atomizing burners. The oil pressure and the orifice size of the injection nozzle control the firing rate.

Furnace Performance Indices. The performance of a gas-fired furnace is usually assessed by the following indices:

- Thermal efficiency E_t, in percent, is the ratio of the energy output of heated air or water to the fuel energy input during specific test periods using the same units:

$$E_t = 100(\text{fuel energy output})/(\text{fuel energy input}) \tag{9.10.1}$$

- Annual fuel utilization efficiency (AFUE), in percent, is the ratio of the annual output energy from heated air or water to the annual input energy using the same units:

$$\text{AFUE} = (100 \text{ annual output energy})/(\text{annual input energy}) \tag{9.10.2}$$

- Steady-state efficiency (SSE) is the efficiency of a given furnace according to an ANSI test procedure, in percent:

© 1999 by CRC Press LLC

$$\text{SSE} = 100(\text{fuel input} - \text{fuel loss})/(\text{fuel input}) \tag{9.10.3}$$

Jakob et al. (1986) and Locklin et al. (1987), in a report on ASHRAE Special Project SP43, gave the following performance indices based on a nighttime setback period of 8 hr with a setback temperature of 10°F:

Description	AFUE (%)	SSE (%)
Natural vent		
Pilot ignition	64.5	77
Intermittent ignition	69	77
Intermittent ignition plus vent damper	78	77
Power vent		
Noncondensing	81.5	82.5
Condensing	92.5	93

ASHRAE/IES Standard 90.1-1989 specifies a minimum AFUE of 78% for both gas-fired and oil-fired furnaces of heating capacity <225,000 Btu/hr. For a gas-fired warm air furnace ≥225,000 Btu/hr at maximum rating capacity (steady state) the minimum E_t is 80%, and at minimum rating capacity, E_t is 78%.

Operation and Control. Gas is usually brought from the main to the pressure regulator, where its pressure is reduced to 3.5 in. WG. Gas then flows through a valve and mixes with the necessary amount of outside primary air. The mixture mixes again with the ambient secondary air and is burned. The combustion products flow through the heat exchanger(s) due either to natural draft or power vent by a fan. The flue gas is then vented to the outside atmosphere through a vent pipe or chimney.

Recirculating air is pulled from the conditioned space through the return duct and is mixed with the outdoor air. The mixture is forced through the heat exchanger(s) by a fan and is then heated and distributed to the conditioned space. The fan is often started 1 min after the burner is fired in order to prevent a cold air supply.

At part-load operation, the reduction of the heating capacity of the warm air furnace is usually controlled by the gas valve and the ignition device. For small furnaces, the gas valve is often operated at on–off control. For large furnaces, a two-stage gas valve operates the furnace at 100, 50, and 0% heating capacity as required.

Low NO_x Emissions. NO_x means nitrogen oxides NO and NO_2. They are combustion products in the flue gas and become air pollutants with other emissions like SO_2 and CO when they are discharged to the atmosphere. NO_x cause ozone depletion as well as smog.

Southern California regulations required that NO_x emissions should be 30 ppm or less for gas-fired warm air furnaces and boilers. Many gas burner manufactures use induced flue gas recirculation to cool the burner's flame, a cyclonic-type burner to create a swirling high-velocity flame, and other technologies to reduce NO_x and other emissions while retaining high furnace and boiler efficiencies.

Hot Water Boilers

Types of Hot Water Boilers. A *hot water boiler* is an enclosed pressure vessel used as a heat source for space heating in which water is heated to a required temperature and pressure without evaporation. Hot water boilers are fabricated according to American Society of Mechanical Engineers (ASME) codes for boilers and pressure vessels. Boilers are generally rated on the basis of their gross output delivered at the boiler's outlet. Hot water boilers are available in standard sizes from 50 to 50,000 MBtu/hr (1 MBtu/hr = 1000 Btu/hr).

According to EIA Characteristics of Commercial Buildings (1991), the percentages of floor area served by different kinds of fuel used in hot water and steam boilers in 1989 in the United States are gas-fired, 69%; oil-fired, 19%; electric, 7%; others, 5%.

© 1999 by CRC Press LLC

Hot water boilers can be classified as *low-pressure boilers*, whose working pressure does not exceed 160 psig and working temperature is 250°F or less, and *medium-* and *high-pressure boilers*, whose working pressure is above 160 psig and working temperature above 250°F. Most of the hot water boilers are low-pressure boilers except those in campus-type or district water heating systems.

Based on their construction and material, hot water boilers can be classified as fire tube boilers, water tube boilers, cast iron sectional boilers, and electric boilers. Water tube boilers are used mainly to generate steam. Cast iron sectional boilers consist of many vertical inverted U-shaped cast iron hollow sections. They are lower in efficiency and used mainly for residential and small commercial buildings. Electric boilers are limited in applications because of their higher energy cost in many locations in the United States.

Scotch Marine Boiler. In a *fire tube* hot water boiler, the combustion chamber and flue gas passages are in tubes. These tubes are enclosed by an outer shell filled with water. A recently developed fire tube model is the modified Scotch Marine packaged boiler, which is a compact, efficient, and popular hot water boiler used today.

A *Scotch Marine* boiler, as shown in Figure 9.10.2, consists of a gas, oil, or gas/oil burner, a mechanical forced-draft fan, a combustion chamber, fire tubes, flue gas vent, outer shell, and corresponding control system. A packaged boiler is a one-piece factory-assembled boiler.

This figure is not available.

FIGURE 9.10.2 A Scotch Marine packaged boiler.

© 1999 by CRC Press LLC

Gas or oil and air are measured, mixed, and injected into the combustion chamber in which they are initially ignited by an ignition device. The mixture burns and the combustion process is sustained when there is a high enough temperature in the combustion chamber. Because the number of fire tubes decreases continuously in the second, third, and fourth passes due to the volume contraction at lower flue gas temperatures, the gas velocity and heat transfer coefficients are maintained at reasonably high values.

Return water enters the side of the boiler. It sinks to the bottom, rises again after heating, and then discharges at the top outlet.

The dew point of the flue gas is often 130°F. If the temperature of the return water in a *condensing boiler* is below 125°F, it can be used as a condensing cooling medium to condense the water vapor contained in the flue gas. Latent heat of condensation of water vapor can then be recovered. Corrosion in the condensing heat exchanger and the flue gas passage should be avoided.

The *chimney,* or *stack*, is the vertical pipe or structure used to discharge flue gas, which usually has a temperature rise of 300 to 400°F above the ambient temperature. The chimney or stack should be extended to a certain height above adjacent buildings according to local codes.

Operation and Safety Controls. During part-load operation, reduction of heating capacity is achieved by sensing the temperature of return water and controlling the firing rate of the gas burners in on–off, high–low–off, or modulating modes.

For gas burners, two pressure sensors are often provided to maintain the gas pressure within a narrow range. For modulating controls, the ratio of maximum to minimum input is called the *turn-down* ratio. The minimum input is usually 5 to 25% of the maximum input, that is, a turn-down ratio of 20:1 to 4:1. The boiler should be shut off if the input is less than the minimum.

Pressure and temperature relief valves should be installed in each boiler. An additional high limit control is often equipped to shut down the boiler in case the sensed water pressure or temperature exceeds the predetermined limits. A flame detector is often used to monitor the flame and an airflow sensor to verify the combustion airflow. As soon as the flame is extinguished or the combustion airflow is not sensed, the fuel valve closes and the boiler is shut down. ASHRAE/IES Standard 90.1-1989 specifies that gas-fired boilers should have a minimum AFUE of 80%.

Low-Pressure Warm Air Heating Systems

A *low-pressure warm air heating system* is often equipped with an upflow gas-fired furnace having a furnace heat capacity Q_f to air flow $\dot{V}_a$ ratio, $Q_f / \dot{V}_a$, of 50 to 70 Btu/hr.cfm and a temperature rise immediately after the furnace of 50 to 70°F. The external pressure loss of the supply and return duct system is usually not higher than 0.5 in. WG. The supply temperature differential ($T_s - T_r$) is often 20 to 35°F. The heating system is often integrated with a cooling system, forming a heating/cooling system.

Low-pressure warm air heating systems usually have a heating capacity not exceeding 100,000 Btu/hr. They are often used in residences and sometimes in small commercial buildings.

System Characteristics. A low-pressure warm air heating system is equipped with either supply and return ducts or a supply duct and a return plenum. Recirculating air is then returned from living, dining, bed, and study rooms to the return plenum through door undercuts in case the doors are closed.

The location of the furnace has a significant effect on the efficiency of the heating system. According to Locklin et al. (1987), if the gas furnace of a low-pressure warm air heating system is installed in a closet and its supply duct is mounted inside the conditioned space, its system efficiency may be 20% higher than that of installations whose furnace and supply duct are in the attic or basement.

When a low-pressure warm air heating system is operating, the supply duct leakage in the attic or basement raises its pressure to a positive value and promotes exfiltration. Return duct leakage extracts the ambient air, lowers the attic or basement pressure to a negative value, and induces infiltration. Gammage et al. (1986) reported that both types of leakage increase the whole house infiltration to 0.78 ach when the low-pressure warm air heating system is operating. The infiltration rate is only 0.44 ach when the low-pressure warm air heating system is shut off.

© 1999 by CRC Press LLC

If the supply temperature differential $\Delta T_s = (T_s - T_r)$ exceeds 30°F, or if there is a high ceiling, thermal stratification may form in the conditioned space. Greater supply volume flow rates and suitable locations of the supply and return outlets may reduce thermal stratification and vertical temperature difference.

Part-Load Operation and Control. For a low-pressure warm air heating system, a space thermostat is often used to control the gas valve of the furnace operated in on–off or high–low–off mode. The proportion of on and off times in an operating cycle can be varied to meet the change of space heating load. The time period of an on–off operating cycle is usually 5 to 15 min.

A warm-air heating system that has an external pressure higher than 0.5 in. WG is often integrated with a cooling system and becomes a part of an air-conditioning system.

Low-Temperature Hot Water Heating System Using Fin-Tube Heaters

In a *low-temperature hot water heating system*, the operating temperature is 250°F or less with a maximum working pressure not exceeding 150 psig, usually less than 30 psig. Low-temperature hot water heating systems are widely used for space heating in residences and commercial buildings.

Fin-Tube Heaters. A *fin-tube heater* is a device installed directly inside the conditioned space to add heat to the space through radiant and convective heat transfer. A fin-tube heater consists of a finned-tube element and an outer casing as shown in Figure 9.10.3(a). The tubes are often made of copper and steel. Copper tubes are generally 0.75, 1, and 1.25 in. in diameter and steel tubes 1.25 and 2 in. in diameter. The fins are usually made of aluminum for copper tubes and of steel for steel tubes. Fin density may vary from 24 to 60 fins per foot. A fin heater may have a maximum length of 12 ft. The outer casing of a finned-tube heater always has a bottom inlet and top outlet for better convection.

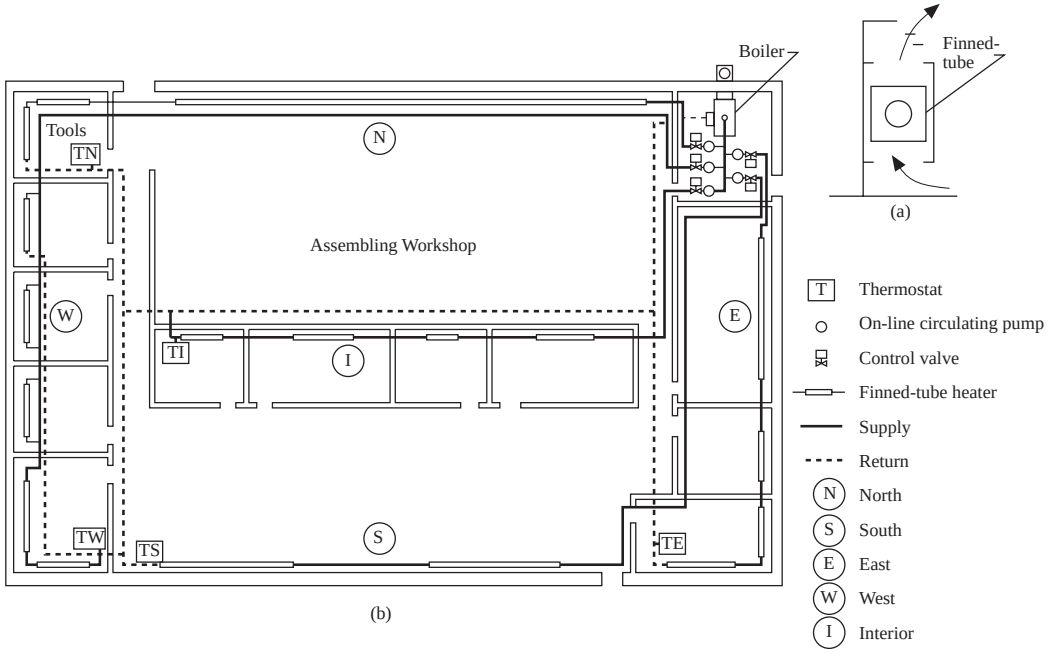

FIGURE 9.10.3 A two-pipe individual-loop low-temperature hot water heating system: (a) finned-tube heater and (b) piping layout.

The most widely used finned-tube heater is the *baseboard heater*, which is often mounted on cold walls at a level 7 to 10 in. from the floor. It is usually 3 in. deep and has one fin-tube row. A wall finned-tube heater has a greater height. A convector has a cabinet-type enclosure and is often installed under the windowsill.

© 1999 by CRC Press LLC

Two-Pipe Individual-Loop Systems. Current low-temperature hot water heating systems using finned-tube heaters are often equipped with zone controls. Zone controls can avoid overheating rooms facing south and underheating rooms facing north because of the effects of solar radiation.

Figure 9.10.3(b) shows the piping layout of a *two-pipe individual-loop system* that is widely used in low-temperature hot water heating systems. Two-pipe means that there are a supply main and a return main pipe instead of one common main for both supply and return. Individual-loop means that there is an individual loop for each control zone. Several finned-tube heaters in a large room can be connected in series, while finned-tube heaters in several small rooms can be connected in reverse return arrangement.

The sizing of low-temperature hot water pipes is usually based on a pressure drop of 1 to 3 ft per 100 ft of pipe length. For a small low-temperature hot water heating system, an open-type expansion tank is often used. A diaphragm tank is often used for a large system. On-line circulating pumps with low head are often used.

Part Load and Control. Usually a hot water sensor located at the exit of the hot water boiler is used to control the firing rate of the boiler at part-load operation. Its set point is usually reset according to the outdoor temperature. Zone control is provided by sensing the return hot water temperature from each individual loop or zone and then varying the water volume flow rate supplied to that zone by modulating the speed of each corresponding on-line circulating pump or its control valve. For hot water heating systems using multiple boilers, on and off for each specific boiler depend not only on the heating demand, but also on minimizing the energy cost.

Infrared Heating

Infrared heating is a process that uses radiant heat transfer from a gas-fired or electrically heated high-temperature device to provide space heating on a localized area for the health and comfort of the occupants or to maintain a suitable indoor environment for a manufacturing process.

An *infrared heater* is a device used to provide infrared heating. Heat radiates from an infrared heater in the form of electromagnetic waves and scatters in all directions. Most infrared heaters have reflectors to focus the radiant beam onto a localized area. Therefore, they are often called *beam radiant heaters.* Infrared heaters are widely used in high-ceiling supermarkets, factories, warehouses, gymnasiums, skating rinks, and outdoor loading docks.

Gas Infrared Heaters. Infrared heaters can be divided into two categories: gas and electric infrared heaters. *Gas infrared heaters* are again divided into porous matrix gas infrared heaters and indirect gas infrared heaters. In a *porous matrix gas infrared heater,* a gas and air mixture is supplied and distributed evenly through a porous ceramic, a stainless steel panel, or a metallic screen, which is exposed to the ambient air and backed by a reflector. Combustion takes place at the exposed surface with a maximum temperature of about 1600°F. An indirect infrared heater consists of a burner, a radiating tube, and a reflector. Combustion takes place inside the radiating tube at a temperature not exceeding 1200°F.

Gas infrared heaters are usually vented and have a small conversion efficiency. Only 10 to 20% of the input energy of an open combustion gas infrared heater is radiated in the form of infrared radiant energy. Usually 4 cfm of combustion air is required for 1000 Btu/hr gas input. A thermostat often controls a gas valve in on–off mode. For standing pilot ignition, a sensor and a controller are used to cut off the gas supply if the flame is extinguished.

Electric Infrared Heaters. An *electric infrared heater* is usually made of nickel–chromium wire or tungsten filaments mounted inside an electrically insulated metal tube or quartz tube with or without inert gas. The heater also contains a reflector that directs the radiant beam to the localized area requiring heating. Nickel–chromium wires often operate at a temperature of 1200 to 1800°F. A thermostat is also used to switch on or cut off the electric current. An electric infrared heater has a far higher conversion efficiency and is cleaner and more easily managed.

Design Considerations. An acceptable radiative temperature increase ($T_{rad} - T_r$) of 20 to 25°F is often adopted for normal clothed occupants using infrared heating. The corresponding required watt density

© 1999 by CRC Press LLC

for infrared heaters is 30 to 37 W/ft^2. At a mounting height of 11 ft, two heaters having a spacing of 6.5 ft can provide a watt density of 33 W/ft^2 and cover an area of 12 × 13 ft. The mounting height of the infrared heaters should not be lower than 10 ft. Otherwise the occupants may feel discomfort from the overhead radiant beam. Refer to Grimm and Rosaler (1990), *Handbook of HVAC Design*, for details.

Gas and electric infrared heaters should not be used in places where there is danger of ignitable gas or materials that may decompose into toxic gases.

9.11 Refrigeration Systems

Classifications of Refrigeration Systems

Most of the refrigeration systems used for air-conditioning are vapor compression systems. Because of the increase in the energy cost of natural gas in the 1980s, the application of absorption refrigeration systems has dropped sharply. According to Commercial Buildings Characteristics 1992, absorption refrigeration system have a weight of less than 3% of the total amount of refrigeration used in commercial buildings in the United States. Air expansion refrigeration systems are used mainly in aircraft and cryogenics.

Refrigeration systems used for air-conditioning can be classified mainly in the following categories:

- Direct expansion (DX) systems and heat pumps
- Centrifugal chillers
- Screw chillers
- Absorption systems

Each can be either a single-stage or a multistage system.

Direct Expansion Refrigeration Systems

A *direct expansion refrigeration (DX) system*, or simply *DX system*, is part of the packaged air-conditioning system. The DX coil in the packaged unit is used to cool and dehumidify the air directly as shown in Figure 9.11.1(a). According to EIA Commercial Buildings Characteristics 1992, about 74% of the floor space of commercial buildings in the United States was cooled by DX refrigeration systems.

Refrigerants R-22 and R-134a are widely used. Azeotropics and near azeotropics are the refrigerants often used for low-evaporating-temperature systems like those in supermarkets. Because of the limitation of the size of the air system, the refrigeration capacity of DX systems is usually 3 to 100 tons.

Components and Accessories. In addition to the DX coil, a DX refrigeration system has the following components and accessories:

- *Compressor(s)* — Both reciprocating and scroll compressors are widely used in DX systems. Scroll compressors are gradually replacing reciprocating compressors because they have fewer parts and comparatively higher efficiency. For large DX systems, multiple compressors are adopted.
- *Condensers* — Most DX systems in rooftop packaged units are air cooled. Water-cooled condensers are adopted mainly for DX systems in indoor packaged units due to their compact volume. Evaporative-cooled condensers are also available.
- *Refrigeration feed* — Thermostatic expansion valves are widely used as the throttling and refrigerant flow control devices in medium and large DX systems, whereas capillary tubes are used in small and medium-sized systems.
- *Oil lubrication* — R-22 is partly miscible with mineral oil. Since R-134a is not miscible with mineral oil, synthetic polyolester oil should be used. For medium and large reciprocating compressors, an oil pump of vane, gear, or centrifugal type is used to force the lubricating oil to the bearings and moving surfaces via grooves. For small reciprocating compressors, splash lubrication using the rotation of the crankshaft and the connecting rod to splash oil onto the bearing surface and the cylinder walls is used.

A scroll compressor is often equipped with a centrifugal oil pump to force the oil to lubricate the orbiting scroll journal bearing and motor bearing. For the scroll contact surfaces, lubrication is provided by the small amount of oil entrained in the suction vapor.

© 1999 by CRC Press LLC

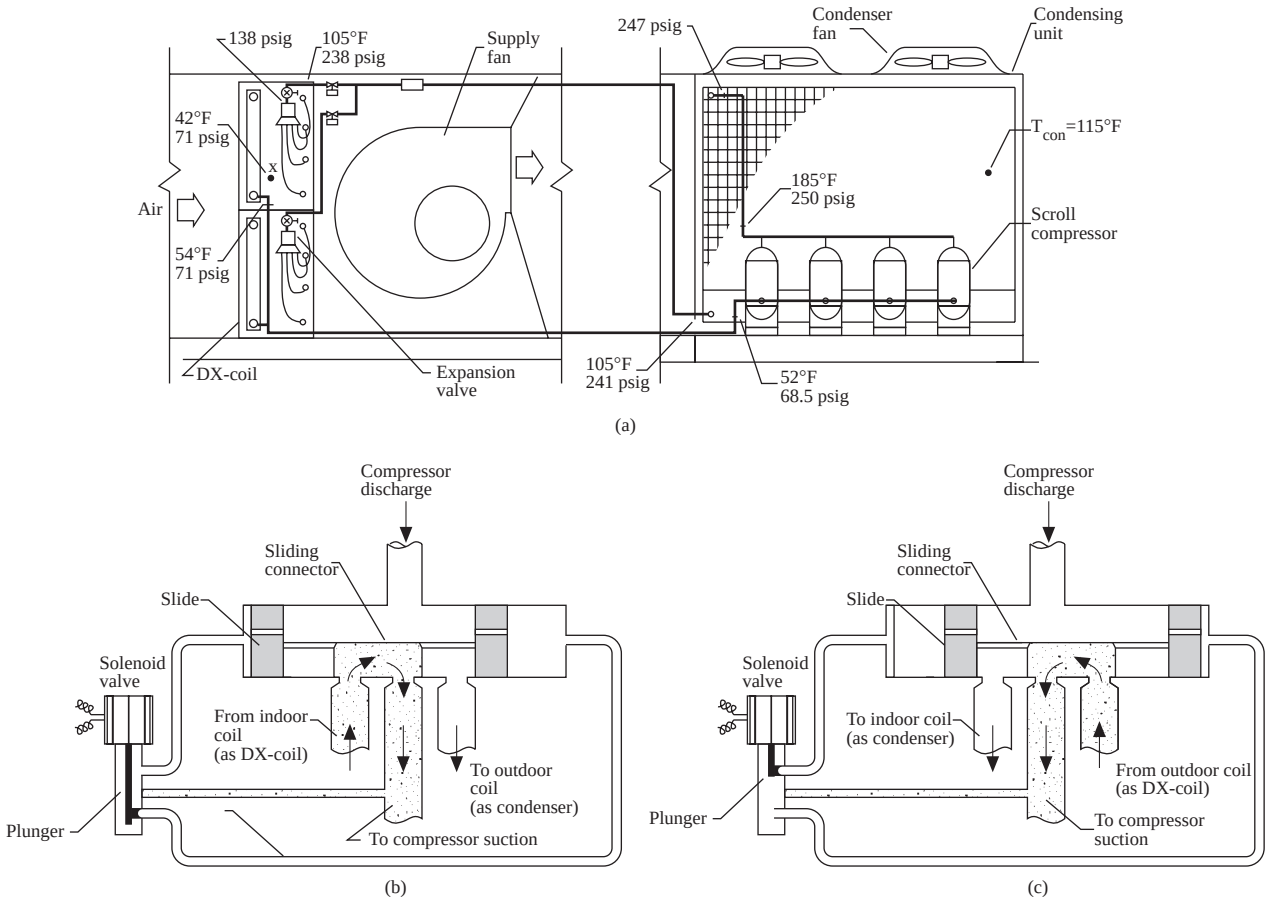

FIGURE 9.11.1 A DX refrigeration system: (a) schematic diagram: (b) four-way reversing valve, cooling mode; and (c) four-way reversing valve, heating mode.

© 1999 by CRC Press LLC

- *Refrigerant piping* — Refrigerant piping transports refrigerant through the compressor, condenser, expansion valve, and DX coil to provide the required refrigeration effect. As shown in Figure 9.11.1(a), from the exit of the DX coil to the inlet of the compressor(s) is the *suction line*. From the outlet of the compressor to the inlet of the air-cooled condenser is the *discharge line*. From the exit of the condenser to the inlet of the expansion valve is the *liquid line*.

Halocarbon refrigerant pipes are mainly made of copper tubes of L type. In a packaged unit, refrigerant pipes are usually sized and connected in the factory. However, the refrigerant pipes in field-built and split DX systems for R-22 are sized on the basis of a pressure drop of 2.91 psi corresponding to a change of saturated temperature ΔT_{suc} of 2°F at 40°F for the suction line and a pressure drop of 3.05 psi corresponding to 1°F at 105°F for the discharge and liquid line. The pressure drop includes pressure losses of pipe and fittings. Refrigerant pipes should also be sized to bring back the entrained oil from the DX coil and condenser through the discharge and suction lines.

Accessories include a filter dryer to remove moisture from the refrigerant, strainer to remove foreign matter, and sight glass to observe the condition of refrigerant flow (whether bubbles are seen because of the presence of flash gas in the liquid line).

Capacity Controls. In DX systems, control of the mass flow rate of refrigerant through the compressor(s) is often used as the primary refrigeration capacity control. Row or intertwined face control at the DX coil is also used in conjunction with the capacity control of the compressor(s).

Three methods of capacity controls are widely used for reciprocating and scroll compressors in DX systems:

- *On–off control* — Starting or stopping the compressor is a kind of step control of the refrigerant flow to the compressor. It is simple and inexpensive, but there is a 100% variation in capacity for DX systems installed with only a single compressor. On–off control is widely used for small systems or DX systems with multiple compressors.
- *Cylinder unloader* — For a reciprocating compressor having multiple cylinders, a cylinder unloader mechanism bypasses the compressed gas from one, two, or three cylinders to the suction chamber to reduce the refrigeration capacity and compressing energy.
- *Speed modulation* — A two-speed motor is often used to drive scroll or reciprocating compressors so that the capacity can be reduced 50% at lower speed.

Safety Controls. In *low- and high-pressure control*, the compressor is stopped when suction pressure drops below a preset value, the cut-in pressure, or the discharge pressure of the hot gas approaches a dangerous level, the cut-out pressure.

In *low-temperature control*, a sensor is mounted on the outer pipe surface of the DX coil. When the surface temperature drops below 32°F, the controller stops the compressor to prevent frosting.

If the pressure of the oil discharged from the pump does not reach a predetermined level within a certain period, a mechanism in *oil pressure failure control* opens the circuit contact and stops the compressor.

In *motor overload control*, a sensor is used to measure the temperature of the electric winding or the electric current to protect the motor from overheating and overloading.

Pump-down control is an effective means of preventing the migration of the refrigerant from the DX coil (evaporator) to the crankcase of the reciprocating compressor. This prevents mixing of refrigerant and oil to form slugs, which may damage the compressor.

When a rise of suction pressure is sensed by a sensor, a DDC controller opens a solenoid valve and the liquid refrigerant enters the DX coil. As the buildup of vapor pressure exceeds the cut-in pressure, the compressor starts. When the DX system needs to shut down, the solenoid valve is closed first; the compressor still pumps the gaseous refrigerant to the condenser. As the suction pressure drops below the cut-in pressure, the compressor stops.

© 1999 by CRC Press LLC

Full- and Part-Load Operations. Consider a DX system in a rooftop packaged unit using four scroll compressors, each with a refrigeration capacity of 10 tons at full load. Performance curves of the condensing unit and the DX coil of this DX system are shown in Figure 9.11.2(a). A DDC controller actuates on–off for these scroll compressors based on the signal from a discharge air temperature T_{dis} sensor.

On a hot summer day, when the rooftop packaged unit starts with a DX coil load or refrigeration capacity, $q_{rc} \approx 40$ tons, all four scroll compressors are operating. The operating point is at A′ with a suction temperature T_{suc} of about 42°F, and the discharge air temperature T_{dis} is maintained around 53°F. As the space cooling load q_{rc} as well as T_{dis} decreases, the required DX coil load q_{rl} drops to 35 tons. Less evaporation in the DX coil causes a decrease of T_{suc} to about 40°F, and the operating point may move downward to point A with a DX coil refrigeration capacity of 39 tons. Since $q_{rc} > q_{rl}$, T_{dis} drops continually until it reaches 50°F, point A in Figure 9.11.2(b), and the DDC controller shuts down one of the scroll compressors. The operating point immediately shifts to B′ on the three-compressor curve.

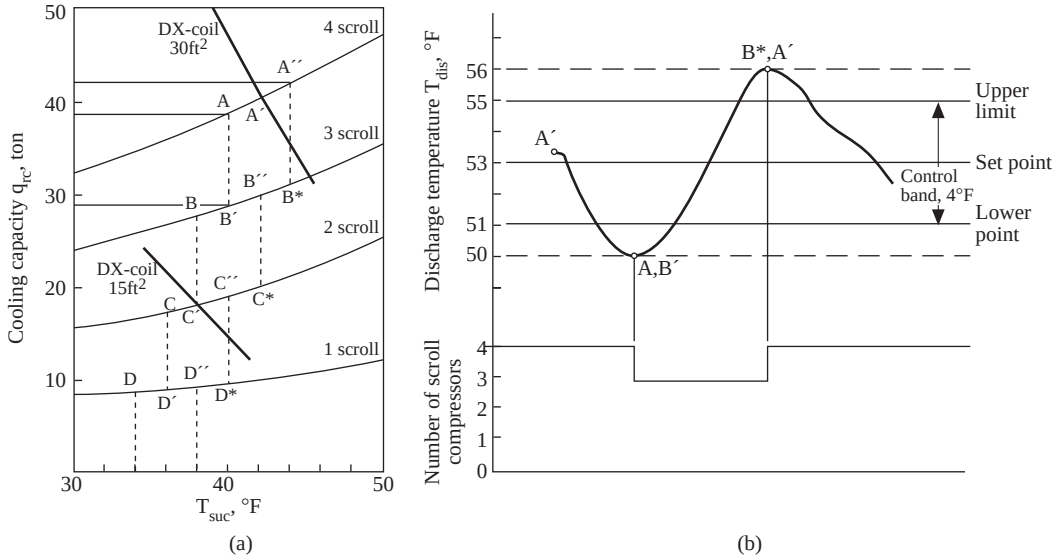

FIGURE 9.11.2 Capacity control of a DX refrigeration system: (a) performance curves and operating points and (b) locus of control point.

Because the refrigeration capacity at point B′ q_{rc} is 29 tons, which is less than the required q_{rl} = 35 tons, both T_{dis} and T_{suc} rise. When the operating point moves up to B* and T_{dis} reaches 56°F, the DDC controller starts all four scroll compressors at operating point A″ with a refrigeration capacity of 42 tons. Since $q_{rc} > q_{rl}$, the operating point again moves downward along the four-compressor curve and forms an operating cycle A″AB′ and B*. The timing of the operating period on four- or three-compressor performance curves balances any required q_{rl} between 29 and 42 tons. Less evaporation at part load in the DX coil results in a greater superheating region and therefore less refrigeration capacity to balance the reduction of refrigeration capacity of the compressor(s) as well as the condensing unit. The condition will be similar when $q_{rl} < 30$ tons, only three- or two-compressor, or two- or one-compressor, or even on–off of one compressor forms an operating cycle.

Main Problems in DX Systems

- *Liquid slugging* is formed by a mixture of liquid refrigerant and oil. It is formed because of the flooding back of liquid refrigerant from the DX coil to the crankcase of the reciprocating compressor due to insufficient superheating. It also may be caused by migration of liquid refrig-

© 1999 by CRC Press LLC

erant from the warmer indoor DX coil to the colder outdoor compressor during the shut-down period in a split packaged unit. Liquid slugging dilutes the lubricating oil and causes serious loss of oil in the crankcase of the reciprocating compressor. Liquid slugging is incompressible. When it enters the compression chamber of a reciprocating compressor, it may damage the valve, piston, and other components. Pump-down control and installation of a crankcase heater are effective means of preventing liquid refrigerant migration and flooding back.

- *Compressor short cycling* — For on–off control, too short a cycle, such as less than 3 min, may pump oil away from the compressor or damage system components. It is due mainly to a too close low-pressure control differential or to reduced air flow.
- *Defrosting* — If the surface of a DX coil is 32°F or lower, frost accumulates on it. Frost blocks the air passage and reduces the rate of heat transfer. It should be removed periodically. The process of removing frost is called defrosting.

  Air at a temperature above 36°F, hot gas inside the refrigerant tubes and an installed electric heating element can be used for defrosting. The defrosting cycle is often controlled by sensing the temperature or pressure difference of air entering the DX coil during a fixed time interval.
- *Refrigerant charge* — Insufficient refrigerant charge causes lower refrigeration capacity, lower suction temperature, and short on–off cycles. Overcharging refrigerant may cause a higher condensing pressure because part of the condensing surface becomes flooded with liquid refrigerant.

Heat Pumps

A *heat pump* in the form of a packaged unit is also a *heat pump system*. A heat pump can either extract heat from a heat source and reject heat to air and water at a higher temperature for heating, or provide refrigeration at a lower temperature and reject condensing heat at a higher temperature for cooling. During summer, the heat extraction, or refrigeration effect, is the useful effect for cooling in a heat pump. In winter, the rejected heat and the heat from a supplementary heater provide heating in a heat pump.

There are three types of heat pumps: air-source, water-source, and ground-coupled heat pumps. Ground-coupled heat pumps have limited applications. Water-source heat pump systems are covered in detail in a later section.

Air-Source Heat Pump. An *air-source heat pump*, or *air-to-air heat pump*, is a DX system with an additional four-way reversing valve to change the refrigerant flow from cooling mode in summer to heating mode in winter and vice versa. The variation in connections between four means of refrigerant flow — compressor suction, compressor discharge, DX coil exit, and condenser inlet — causes the function of the indoor and outdoor coils to reverse. In an air-source heat pump, the coil used to cool or to heat the recirculating/outdoor air is called the *indoor coil*. The coil used to reject heat to or absorb heat from the outside atmosphere is called the *outdoor coil*. A short capillary or restrict tube is often used instead of a thermostatic expansion valve. Both reciprocating and scroll compressors are used in air-source heat pumps. R-22 is the refrigerant widely used. Currently available air-source heat pumps usually have a cooling capacity of $1^1/_2$ to 40 tons.

Cooling and Heating Mode Operation. In *cooling mode operation*, as shown in Figure 9.11.1(b), the solenoid valve is deenergized and drops downward. The high-pressure hot gas pushes the sliding connector to the left end. The compressor discharge connects to the outdoor coil, and the indoor coil connects to the compressor inlet.

In *heating mode operation*, as shown in Figure 9.11.1(c), the solenoid plunger moves upward and pushes the slide connector to the right-hand side. The compressor discharge connects to the indoor coil, and the outdoor coil exit connects to the compressor suction.

System Performance. The performance of an air-source heat pump depends on the outdoor air temperature T_o, in °F as well as the required space heating load q_{rh}. During cooling mode operation, both the refrigeration capacity q_{rc}, in Btu/hr, and EER for the heat pump EER_{hp}, in Btu/hr.W, increase as T_o drops.

© 1999 by CRC Press LLC

During heating mode operation, the heating capacity q_{hp}, in Btu/hr, and COP_{hp} decrease, and q_{rh} increases as the T_o drops. When $q_{rh} > q_{hp}$, supplementary heating is required. If COP_{hp} drops below 1, electric heating may be more economical than a heat pump.

If on–off is used for compressor capacity control for an air-source heat pump in a split packaged unit, refrigerant tends to migrate from the warmer outdoor coil to the cooler indoor coil in summer and from the warmer indoor coil to the cooler outdoor coil in winter during the off period. When the compressor starts again, 2 to 5 min of reduced capacity is experienced before the heat pump can be operated at full capacity. Such a loss is called a *cycling loss*.

In winter, most air-source heat pumps switch from the heating mode to cooling mode operation and force the hot gas to the outdoor coil to melt frost. After the frost is melted, the heat pump is switched back to heating mode operation. During defrosting, supplementary electric heating is often necessary to prevent a cold air supply from the air-source heat pump.

Minimum Performance. ASHRAE/IES Standard 90.1-1989 specifies a minimum performance for air-cooled DX systems in packaged units as covered in Section 9.7. For air-cooled, electrically operated rooftop heat pumps (air-source heat pumps), minimum performance characteristics are:

Cooling EER	8.9
Heating, COP (at T_oF = 47°F)	3.0
Heating, COP (at T_oF = 17°F)	2.0

Centrifugal Chillers

A chiller is a refrigeration machine using a liquid cooler as an evaporator to produce chilled water as the cooling medium in a central air-conditioning system. A *centrifugal chiller*, as shown in Figure 9.11.3(a), is a refrigeration machine using a centrifugal compressor to produce chilled water. It is often a factory-assembled unit with an integrated DDC control system and sometimes may separate into pieces for transportation. A centrifugal chiller is also a *centrifugal vapor compression refrigeration system.*

Refrigerants. According to Hummel et al. (1991), in 1988 there were about 73,000 centrifugal chillers in the United States. Of these, 80% use R-11, 10% use R-12, and the remaining 10% use R-22 and others. As mentioned in Section 9.4, production of CFCs, including R-11 and R-12, ceased at the end of 1995 with limited exception for service. R-123 (HCFC) will replace R-11. The chiller's efficiency may drop 2 to 4%, and a capacity reduction of 5% is possible. R-123 has low toxicity. Its allowable exposure limit was raised to 50 ppm in 1997 from 30 ppm in 1993 by its manufacturers. A monitor and alarm device to detect R-123 in air should be installed in plant rooms and places where there may be refrigerant leaks.

R-134a (HFC) will replace R-12. According to Lowe and Ares (1995), as a result of the changeout from R-12 to R-134a for a 5000-hp centrifugal chiller in Sears Tower, Chicago, its speed increased from 4878 to 5300 rpm, its cooling capacity is 12 to 24% less, and its efficiency is 12 to 16% worse.

System Components. A centrifugal chiller consists of a centrifugal compressor, an evaporator or liquid cooler, a condenser, a flash cooler, throttling devices, piping connections, and controls. A purge unit is optional.

- Centrifugal compressor — According to the number of internally connected impellers, the centrifugal compressor could have a single, two, or more than two stages. A two-stage impeller with a flash cooler is most widely used because of its higher system performance and comparatively simple construction. Centrifugal compressors having a refrigeration capacity less than 1200 tons are often hermetic. Very large centrifugal compressors are of open type. A gear train is often required to raise the speed of the impeller except for very large impellers using direct drive.
- Evaporator — Usually a liquid cooler of flooded shell-and-tube type evaporator is adopted because of its compact size and high rate of heat transfer.
- Condenser — Water-cooled, horizontal shell-and-tube condensers are widely used.

© 1999 by CRC Press LLC

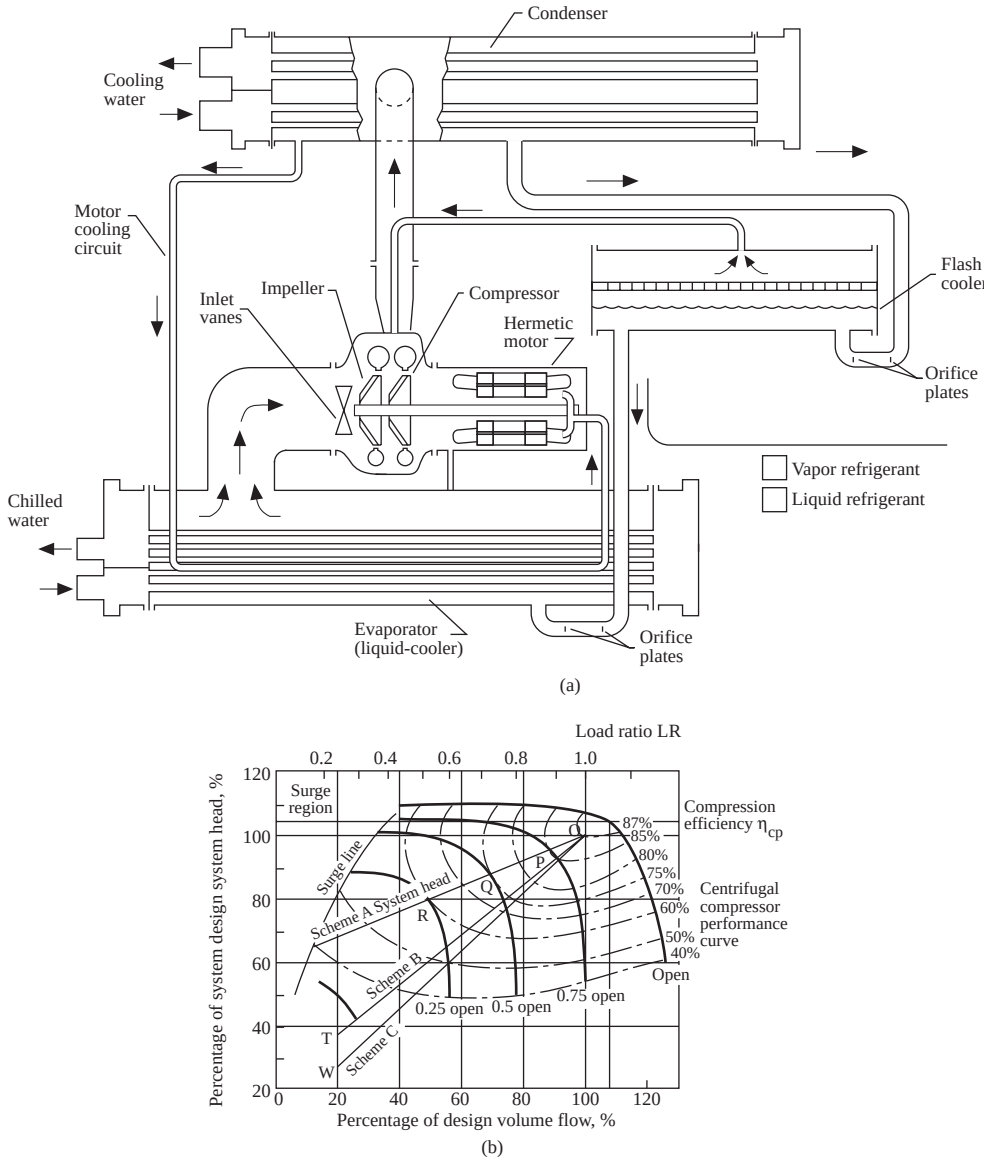

FIGURE 9.11.3 A two-stage water-cooled centrifugal chiller: (a) schematic diagram and (b) centrifugal compressor performance map at constant speed.

- Flash cooler — For a two-stage centrifugal compressor, a single-stage flash cooler is used. For a three-stage compressor, a two-stage flash cooler is used.
- Orifice plates and float valves — Both multiple-orifice plates such as that shown in Figure 9.11.3(a) and float valves are used as throttling devices in centrifugal chillers.
- Purge unit — R-123 has an evaporating pressure p_{ev} = 5.8 psia at 40°F, which is lower than atmospheric pressure. Air and other noncondensable gases may leak into the evaporator through cracks and gaps and usually accumulate in the upper part of the condenser. These noncondensable gases raise the condensing pressure, reduce the refrigerant flow, and lower the rate of heat transfer. A purge unit uses a cooling coil to separate the refrigerant and water from the noncondensable gases and purge the gases by using a vacuum pump.

Performance Ratings. The refrigeration cycle of a typical water-cooled, two-stage centrifugal chiller with a flash cooler was covered in Section 9.4. Centrifugal chillers have the same refrigeration capacity as centrifugal compressors, 100 to 10,000 tons. According to ARI Standard 550-88, the refrigeration capacity of a centrifugal chiller is rated as follows:

Chilled water temperature leaving evaporator T_{el}:	100% load 44°F
	0% load 44°F
Chilled water flow rate:	2.4 gpm/ton
Condenser water temperature entering condenser T_{ce}:	100% load 85°F
	0% load 60°F
Condenser water flow rate:	3.0 gpm/ton
Fouling factor in evaporator and condenser:	0.00025 hr.ft^2.°F/Btu

The integrated part-load value (IPLV) of a centrifugal chiller or other chillers at standard rating conditions can be calculated as:

$$\text{IPLV} = 0.1(A+B)/2 + 0.5(B+C)/2 + 0.3(C+D)/2 + 0.1D \tag{9.11.1}$$

where A, B, C, and D = kW/ton or COP at 100, 75, 50, and 25% load, respectively. If the operating conditions are different from the standard rating conditions, when T_{el} is 40 to 50°F, for each °F increase or decrease of T_{el}, there is roughly a 1.5% difference in refrigeration capacity and energy use; when T_{ce} is between 80 to 90°F, for each °F of increase or decrease of T_{ce}, there is roughly a 1% increase or decrease in refrigeration capacity and 0.6% in energy use.

ASHRAE/IES Standard 90.1-1989 and ARI Standard 550-88 specify the minimum performance for water-cooled water chillers from January 1, 1992:

	COP	**IPLV**
≥300 tons	5.2	5.3
≥150 tons < 300 tons	4.2	4.5
<150 tons	3.8	3.9

COP = 5.0 is equivalent to about 0.70 kW/ton. New, installed centrifugal chillers often have an energy consumption of 0.50 kW/ton.

Air-cooled centrifugal chillers have COPs from 2.5 to 2.8. Their energy performance is far poorer than that of water-cooled chillers. Their application is limited to locations where city water is not allowed to be used as makeup water for cooling towers.

Capacity Control. The refrigeration capacity of a centrifugal chiller is controlled by modulating the refrigerant flow at the centrifugal compressor. There are mainly two types of capacity controls: varying the opening and angle of the inlet vanes, and using an adjustable-frequency AC inverter to vary the rotating speed of the centrifugal compressor.

When the opening of the inlet vanes has been reduced, the refrigerant flow is throttled and imparted with a rotation. The result is a new performance curve at lower head and flow. If the rotating speed of a centrifugal compressor is reduced, it also has a new performance curve at lower volume flow and head. Inlet vanes are inexpensive, whereas the AC inverter speed modulation is more energy efficient at part-load operation.

Centrifugal Compressor Performance Map. Figure 9.11.3(b) shows a single-stage, water-cooled *centrifugal compressor performance map* for constant speed using inlet vanes for capacity modulation. A performance map consists of the compressor's performance curves at various operating conditions. The *performance curve* of a centrifugal compressor shows the relationship of volume flow of refrigerant $\dot{V}_r$

© 1999 by CRC Press LLC

and its head lift Δp or compression efficiency η_{cp} at that volume flow. It is assumed that η_{cp} for a two-stage compressor is equal to the average of the two single-stage impellers having a head of their sum.

On the map, the required *system head curve* indicates the required system head lift at that volume flow of refrigerant. The intersection of the performance curve and the required system head curve is called the *operating point* O, P, Q, R, … as shown in Figure 9.11.3(b). One of the important operating characteristics of a centrifugal chiller (a centrifugal vapor compression refrigeration system as well) is that the required system head lift is mainly determined according to the difference in condensing and evaporating pressure $\Delta p_{c\text{-}e} = (p_{con} - p_{ev})$. The pressure losses due to the refrigerant piping, fittings, and components are minor.

In Figure 9.11.3(b), the abscissa is the percentage of design volume flow of refrigerant, % $\mathring{V}_r$, or load ratio; the ordinate is the percentage of design system head $\Delta H_{s.d}$, or percentage of design temperature lift $(T_{con} - T_{ev})$. Here load ratio LR is defined as the ratio of the refrigeration load to the design refrigeration load $q_{rl}/q_{rl.d}$. There are three schemes of required system head curves:

- Scheme A — T_{ce} = constant and T_{el} = constant
- Scheme B — T_{el} = constant and a drop of 2.5°F of T_{ce} for each 0.1 reduction of load ratio
- Scheme C — A reset of T_{el} of 1°F increase and a drop of 2.5°F of T_{ce} for each 0.1 reduction of load ratio

At design $\mathring{V}_r$ and system head $H_{s.d}$, $\eta_{cp} = 0.87$. As $\mathring{V}_r$, load ratio, and required system head Δp decrease, η_{cp} drops accordingly.

Surge is a unstable operation of a centrifugal compressor or fan resulting in vibration and noise. In a centrifugal chiller, surge occurs when the centrifugal compressor is unable to develop a discharge pressure that satisfies the requirement at the condenser. A centrifugal compressor should never be operated in the surge region.

Part-Load Operation. During part-load operation, if T_{el} and T_{ce} remain constant, the evaporating temperature T_{ev} tends to increase from the design load value because there is a greater evaporating surface and a smaller temperature difference $(T_{el} - T_{ev})$. Similarly, T_{con} tends to decrease.

The ratio of actual compressor power input at part load to the power input at design load may be slightly higher or lower than the load ratios, depending on whether the outdoor wet bulb is constant or varying at part load or whether there is a T_{el} reset; it also depends on the degree of drop of η_{cp} at part load.

Specific Controls. In addition to generic controls, specific controls for a centrifugal chiller include:

- Chilled water leaving temperature T_{el} and reset
- Condenser water temperature T_{ce} control
- On and off of multiple chillers based on actual measured coil load
- Air purge control
- Safety controls like oil pressure, low-temperature freezing protection, high condensing pressure control, motor overheating, and time delaying

Centrifugal Chillers Incorporating Heat Recovery. A *HVAC&R heat recovery system* converts waste heat or waste cooling from any HVAC&R process into useful heat and cooling. A heat recovery system is often subordinate to a parent system, such as a heat recovery system to a centrifugal chiller.

A centrifugal chiller incorporating a heat recovery system often uses a double-bundle condenser in which water tubes are classified as tower bundles and heating bundles. Heat rejected in the condenser may be either discharged to the atmosphere through the tower bundle and cooling tower or used for heating through the heating bundle. A temperature sensor is installed to sense the temperature of return hot water from the heating coils in the perimeter zone. A DDC controller is used to modulate a bypass three-way valve which determines the amount of condenser water supplied to the heating bundle. The tower and heating bundles may be enclosed in the same shell, but baffle sheets are required to guide the water flows.

© 1999 by CRC Press LLC

A centrifugal chiller incorporating a heat recovery system provides cooling for the interior zone and heating for the perimeter zone simultaneously in winter with a higher COP_{hr}. However, it needs a higher condenser water-leaving temperature T_{cl} of 105 to 110°F, compared with 95°F or even lower in a cooling-only centrifugal chiller. An increase of 10 to 12°F of the difference ($T_{con} - T_{ev}$) requires an additional 10 to 15% power input to the compressor. For a refrigeration plant equipped with multiple chillers, it is more energy efficient and lower in first cost to have only part of them equipped with double-bundle condensers.

Screw Chillers

A *screw chiller* or a *helical rotary chiller* is a refrigeration machine using a screw compressor to produce chilled water. A factory-fabricated and assembled screw chiller itself is also a screw vapor compression refrigeration system.

Twin-screw chillers are more widely used than single-screw chillers. A twin-screw chiller consists of mainly a twin-screw compressor, a flooded shell-and-tube liquid cooler as evaporator, a water-cooled condenser, throttling devices, an oil separator, an oil cooler, piping, and controls as shown in Figure 9.11.4(a). The construction of twin-screw compressors has already been covered. For evaporator, condenser, and throttling devices, they are similar to those in centrifugal chillers. Most twin-screw chillers have a refrigeration capacity of 100 to 1000 tons.

Following are the systems characteristics of screw chillers.

Variable Volume Ratio. The ratio of vapor refrigerant trapped within the interlobe space during the intake process V_{in} to the volume of trapped hot gas discharged V_{dis} is called the *built-in volume ratio* of the twin-screw compressor $V_i = V_{in}/V_{dis}$, or simply *volume ratio*, all in ft^3.

There are two types of twin-screw chiller: fixed and variable volume ratio. For a twin-screw chiller of *fixed volume ratio*, the isentropic efficiency η_{isen} becomes maximum when the system required compression ratio $R_{s.com} \approx V_i$. Here $R_{s.com} = p_{con}/p_{ev}$. If $p_{dis} > p_{con}$, overcompression occurs, as shown in Figure 9.11.4(b). The discharged hot gas reexpands to match the condensing pressure. If $p_{dis} < p_{con}$, undercompression occurs (Figure 9.11.4[c]). A volume of gas at condensing pressure reenters the trapped volume at the beginning of the discharge process. Both over- and undercompression cause a reduction of η_{isen}.

For a twin-screw chiller of *variable volume ratio*, there are two slides: a sliding valve is used for capacity control and a second slide. By moving the second slide back and forth, the radial discharge port can be relocated. This allows variation of suction and discharge pressure levels and still maintains maximum efficiency.

Economizer. The hermetic motor shell is connected to an intermediate point of the compression process and maintains an intermediate pressure p_i between p_{con} and p_{ev}. Liquid refrigerant at condensing pressure p_{con} is throttled to p_i, and a portion of the liquid is flashed into vapor. This causes a drop in the temperature of the remaining liquid refrigerant down to the saturated temperature corresponding to p_i. Although the compression in a twin-screw compressor is in continuous progression, the mixing of flashed gas with the compressed gas at the intermediate point actually divides the compression process into two stages. The resulting economizing effect is similar to that of a two-stage compound refrigeration system with a flash cooler: an increase of the refrigeration effect and a saving of the compression power from ($p_{con} - p_{ev}$) to ($p_{con} - p_i$).

Oil Separation, Oil Cooling, and Oil Injection. Oil entrained in the discharged hot gas enters an oil separator. In the separator, oil impinges on an internal perforated surface and is collected because of its inertia. Oil drops to an oil sump through perforation. It is then cooled by condenser water in a heat exchanger. A heater is often used to vaporize the liquid refrigerant in the oil sump to prevent dilution of the oil. Since the oil sump is on the high-pressure side of the refrigeration system, oil is forced to the rotor bearings and injected to the rotors for lubrication.

© 1999 by CRC Press LLC

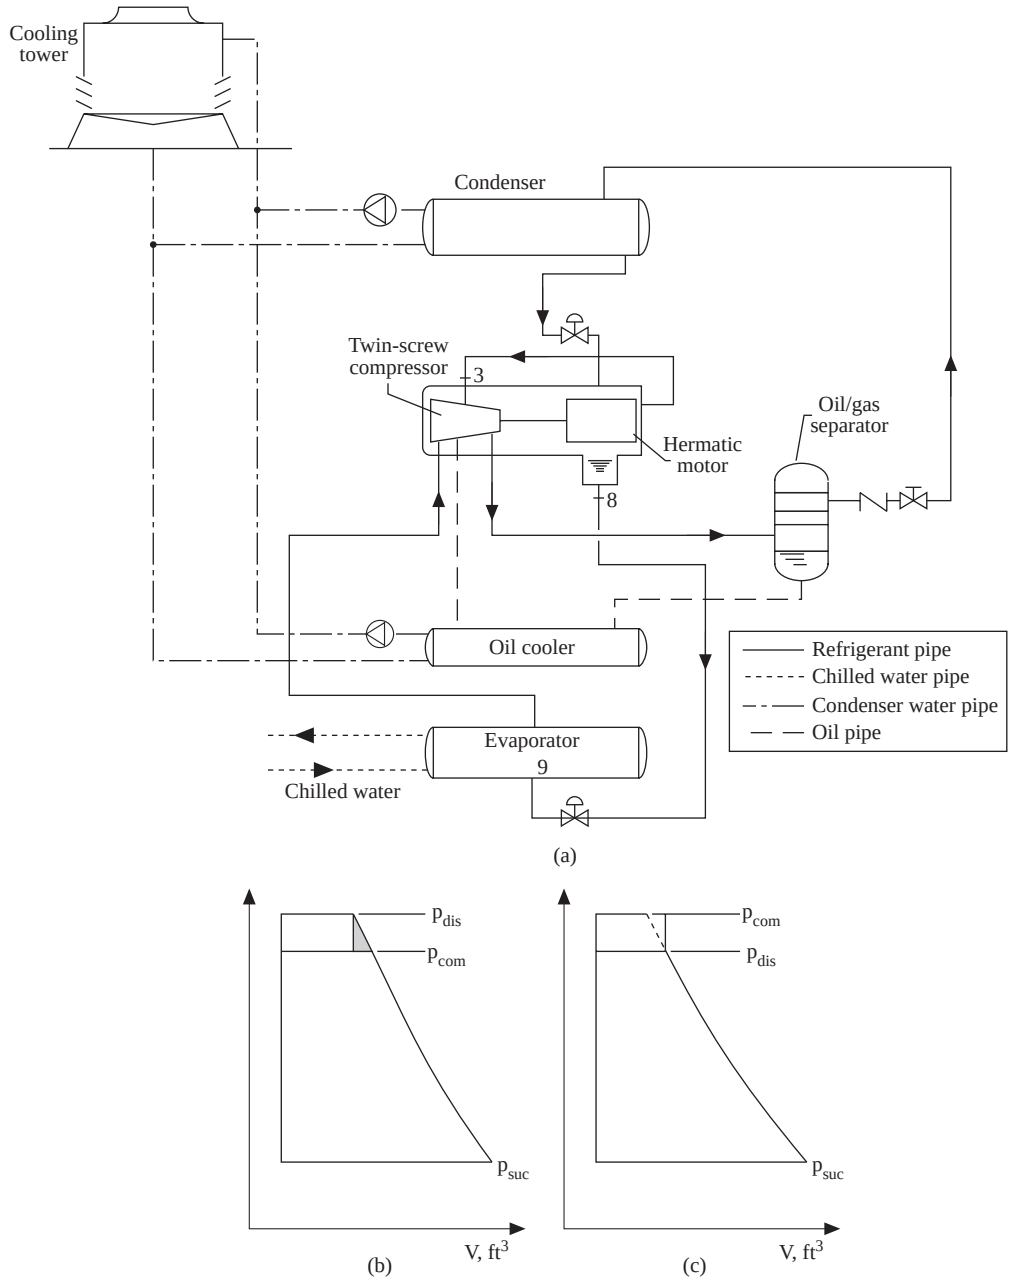

FIGURE 9.11.4 A typical twin-screw chiller: (a) schematic diagram, (b) over-compression, and (c) under-compression.

Oil slugging is not a problem for twin-screw compressors. When suction vapor contains a small amount of liquid refrigerant that carries over from the oil separator, often called *wet suction*, it often has the benefit of scavenging the oil from the evaporator.

Twin-screw compressors are positive displacement compressors. They are critical in oil lubrication, sealing, and cooling. They are also more energy efficient than reciprocating compressors. Twin-screw chillers are gaining more applications, especially for ice-storage systems with cold air distribution.

9.12 Thermal Storage Systems

Thermal Storage Systems and Off-Peak Air-Conditioning Systems

Many electric utilities in the United States have their *on-peak hours* between noon and 8 p.m. during summer weekdays, which include the peak-load hours of air-conditioning. Because the capital cost of a new power plant is so high, from $1200 to $4000 per kW, electric utilities tend to increase their power output by using customers' thermal energy storage (TES) systems, or simply thermal storage systems, which are much less expensive.

A *thermal storage system* as shown in Figure 9.12.1(a) may have the same refrigeration equipment, like chillers, additional storage tank(s), additional piping, pumps, and controls. The electric-driven compressors are operated during off-peak, partial-peak, and on-peak hours. *Off-peak hours* are often nighttime hours. *Partial-peak hours* are hours between on-peak and off-peak hours in a weekday's 24-hr day-and-night cycle. Chilled water or ice is stored in tanks to provide cooling for buildings during on-peak hours when higher electric demand and electric rates are effective. Although thermal storage systems operate during nighttime when outdoor dry and wet bulbs are lower, they are not necessarily energy saving due to lower evaporating temperature, additional pump power, and energy losses. Thermal storage systems significantly reduce the electric energy cost.

Utilities in the United States often use higher electric demand and rates as well as incentive bonus to encourage the shift of electric load from on-peak to off-peak hours by using thermal storage systems and others. Such a shift not only saves expensive capital cost, but also increases the use of base-load high-efficiency coal and nuclear plants instead of inefficient diesel and gas turbine plants.

The air-conditioning systems that operate during off-peak and partial-peak hours for thermal storage, or those that use mainly natural gas to provide cooling to avoid higher electric demand and rates during on-peak hours, are called *off-peak air-conditioning systems*. These systems include ice-storage and chilled-water storage systems, desiccant cooling systems, absorption systems, and gas engine chillers.

Absorption chillers and desiccant cooling systems are covered in other sections. Gas engine-driven reciprocating chillers are often a cogeneration plant with heat recovery from engine jacket and exhaust gas, and will not be covered here.

Full Storage and Partial Storage

Ice and chilled-water storage systems are the two most common thermal energy storage systems today. Knebel (1995) estimated that more than 4000 cool storage systems are operated in various commercial buildings.

The unit of stored thermal energy for cooling is ton-hour, or ton.hr. One *ton.hr* is the refrigeration capacity of one refrigeration ton during a 1-hr period, or 12,000 Btu.

In order to achieve minimum life-cycle cost, thermal storage systems could be either full storage or partial storage. For a *full-storage*, or *load shift*, thermal storage system, all refrigeration compressors cease to operate during on-peak hours. Building refrigeration loads are entirely offset by the chilled water or brine from the thermal storage system within an on-peak period. In a *partial storage*, or *load-leveling*, thermal storage system as shown in Figure 9.12.1(b) all or some refrigeration compressor(s) are operated during on-peak hours.

Direct cooling is the process in which refrigeration compressors produce refrigeration to cool the building directly. During a specific time interval, if the cost of direct cooling is lower than the stored energy, the operation of a thermal storage system is said to be in *chiller priority.* On the contrary, if the cost of direct cooling is higher than the cost of stored energy, the operation is said to be at *storage priority.*

The optimum size of a thermal storage system is mainly determined according to the utility's electric rate structure, especially a time-of-day structure whose electric rates are different between on-peak, partial-peak, and off-peak hours. Not only the design day's instantaneous building peak cooling load is important, but also an hour-by-hour cooling load profile of the design day is required for thermal storage design. A simple payback or a life-cycle cost analysis is usually necessary.

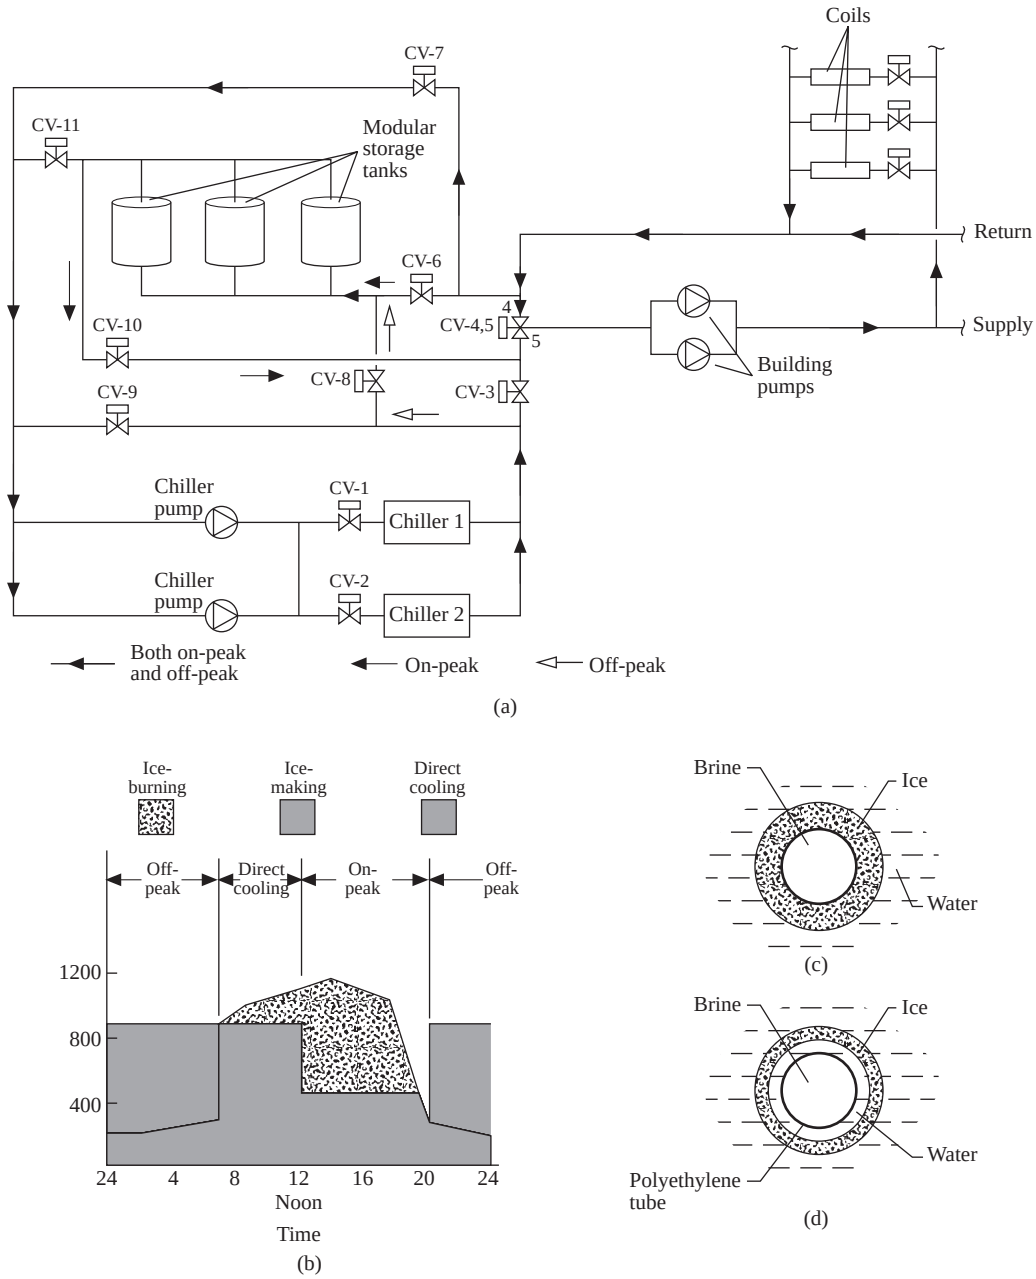

FIGURE 9.12.1 A brine-coil ice-storage system: (a) schematic diagram, (b) partial-storage time schedule, (c) ice making, and (d) ice burning.

Ice-Storage Systems

System Characteristics

In an *ice-thermal-storage* system, or simply an *ice-storage* system, ice is stored in a tank or other containers to provide cooling for buildings in on-peak hours or on- and partial-peak hours. One pound of ice can store [(1 × 144) + (55 – 35)] = 164 Btu instead of (60 – 44) = 16 Btu for chilled water storage. For the same cooling capacity, the storage volume of ice is only about 12% of chilled water. In addition,

© 1999 by CRC Press LLC

an air-conditioning system using ice storage often adopts cold air distribution to supply conditioned air at a temperature typically at 44°F. Cold air distribution reduces the size of air-side equipment, ducts, and investment as well as fan energy use. It also improves the indoor air quality of the conditioned space. Since the late 1980s, ice storage has gained more applications than chilled water storage.

Brine is a coolant without freezing and flashing during normal operation. The freezing point of brine, which has a mass fraction of ethylene glycol of 25%, drops to 10°F, and a mass fraction of propylene glycol of 25% drops to 15°F. Glycol-water, when glycol is dissolved in water, is another coolant widely used in ice-storage systems. Ice crystals are formed in glycol-water when its temperature drops below its freezing point during normal operation.

In an ice-storage system, *ice making* or *charging* is a process in which compressors are operated to produce ice. *Ice burning*, or *discharging*, is a process in which ice is melted to cool the brine or glycol-water to offset refrigeration load.

Brine-Coil Ice-Storage Systems. Currently used ice-storage systems include brine-coil, ice-harvester, and ice-on-coil systems. According to Knebel (1995), the brine-coil ice-storage system is most widely used today because of its simplicity, flexibility, and reliability as well as using modular ice-storage tanks.

In a typical brine-coil ice-storage system, ice is charged in multiple modular factory-fabricated storage tanks as shown in Figure 9.12.1(a). In each storage tank, closely spaced polyethylene or plastic tubes are surrounded by water. Brine, a mixture of 25 to 30% of ethylene glycol by mass and 70 to 75% water, circulates inside the tubes at an entering temperature of 24°F during the ice-making process. The water surrounding the tubes freezes into ice up to a thickness of about 1/2 in. as shown in Figure 9.12.1(c). Brine leaves the storage tank at about 30°F. Water usually at atmospheric pressure is separated from brine by a plastic tube wall. Plastic tubes occupy about one tenth of the tank volume, and another one tenth remains empty for the expansion of ice. Multiple modular storage tanks are always connected in parallel.

During the ice-melting or -burning process, brine returns from the cooling coils in the air-handling units (AHUs) at a temperature of 46°F or higher. It melts the ice on the outer surface of the tubes and is thus cooled to a temperature of 34 to 36°F, as shown in Figure 9.12.1(d). Brine is then pumped to the AHUs to cool and dehumidify the air again.

Case Study of a Brine-Coil Ice-Storage System. In Tackett (1989), a brine-coil ice-storage system cools a 550,000-ft^2 office building near Dallas, TX, as shown in Figure 9.12.1(a). Ethylene glycol water is used as the brine. There are two centrifugal chillers, each of them having a refrigeration capacity of 568 tons when 34°F brine is produced with a power consumption of 0.77 kW/ton for direct cooling. The refrigeration capacity drops to 425 tons if 24°F brine leaves the chiller with a power consumption of 0.85 kW/ton. A demand-limited partial storage is used, as shown in Figure 9.12.1(b). During on-peak hours, ice is melted; at the same time one chiller is also operating. The system uses 90 brine-coil modular storage tanks with a full-charged ice-storaged capacity of 7500 ton.hr.

For summer cooling, the weekdays' 24-hr day-and-night cycle is divided into three periods:

- Off peak lasts from 8 p.m. to AHU's start the next morning. Ice is charged at a maximum capacity of 650 tons. The chillers also provide 200 tons of direct cooling for refrigeration loads that operate 24 hr continuously.
- Direct cooling lasts from AHU's start until noon on weekdays. Chillers are operated for direct cooling. If required refrigeration load exceeds the chillers' capacity, some ice storage will be melted to supplement the direct cooling.
- On peak lasts from noon to 8 p.m. Ice is burning with one chiller in operation. During ice burning, water separates the tube and ice. Water has a much lower thermal conductivity (0.35 Btu/hr.ft.°F) than ice (1.3 Btu/hr.ft.°F). Therefore, the capacity of a brine-coil ice-storage system is dominated by the ice burning.

Ice-Harvester Ice-Storage Systems. In an *ice-harvester* system, glycol-water flows on the outside surface of the evaporator and forms ice sheets with a thickness of 0.25 to 0.40 in. within 20 to 30 min. Ice is harvested in the form of flakes when hot gas is flowing inside the tubes of the evaporator during a time interval of 20 to 30 sec. Ice flakes fall to the glycol-water in the storage tank below. The glycol-water at a temperature of 34°F is then supplied to the cooling coils in AHUs for conditioning. After cooling and dehumidifying the air, glycol-water returns to the storage tank at a temperature of 50 to 60°F and is again cooled to 34°F again.

Ice harvesting is an intermittent process. It has a cycle loss due to harvesting of about 15%. In addition, because of its operating complexity and maintenance, its applications are more suitable for large ice-storage systems.

Ice-on-Coil Ice-Storage Systems. In an ice-on-coil system, refrigerant is evaporated in the coils submerged in water in a storage tank. Ice of a thickness not exceeding 0.25 in. builds up on the outer surface of the coils. The remaining water in the storage tank is used for cooling in AHUs. Ice-on-coil systems need large amounts of refrigerant charge and are less flexible in operation. They are usually used in industrial applications.

Ice-in-Containers Ice-Storage Systems. Ice-in-containers ice-storage systems store ice in enclosed containers. Brine circulating over the containers produces the ice inside containers. Complexity in control of the ice inventory inside the containers limits the application of the ice-in-containers systems.

Chilled-Water Storage Systems

Basics

Chilled-water storage uses the same water chiller and a similar coolant distribution system, except for additional water storage tanks and corresponding piping, additional storage pumps, and controls. The larger the chilled-water storage system, the lower the installation cost per ton.hr storage capacity.

Various types of storage tanks had been used in chilled-water storage systems during the 1970s. A diaphragm tank uses a rubber diaphragm to separate the colder and warmer water. Baffles divide the tank into cells and compartments. Today, stratified tanks have become the most widely used chilled-water storage systems because of their simplicity, low cost, and negligible difference in loss of cooling capacity between stratified tanks and other types of storage tanks.

During the storage of chilled water, the loss in cooling capacity includes direct mixing, heat transfer between warmer return chilled water and colder stored chilled water, and also heat transfer between warmer ambient air and colder water inside the tank. An enthalpy-based easily measured index called *figure of merit* (*FOM*) is often used to indicate the loss in cooling capacity during chilled-water storage. FOM is defined as:

$$\text{FOM} = q_{\text{dis}} / q_{\text{ch}} \tag{9.12.1}$$

where q_{dis} = cooling capacity available in the discharge process, Btu/hr
q_{ch} = theoretical cooling capacity available during charging process, Btu/hr

Charging is the process of filling the storage tank with colder chilled water from the chiller. At the same time, warmer return chilled water is extracted from the storage tank and pumped to the chiller for cooling.

Discharging is the process of discharging the colder stored chilled water from the storage tank to AHUs and terminals. Meanwhile, the warmer return chilled water from the AHUs and terminals fills the tank.

Stratified Tanks. *Stratified tanks* utilize the buoyancy of warmer return chilled water to separate it from the colder stored chilled water during charging and discharging, as shown in Figure 9.12.2(a). Colder stored chilled water is always charged and discharged from bottom diffusers, and the warmer return chilled water is introduced to and withdrawn from the top diffusers.

© 1999 by CRC Press LLC

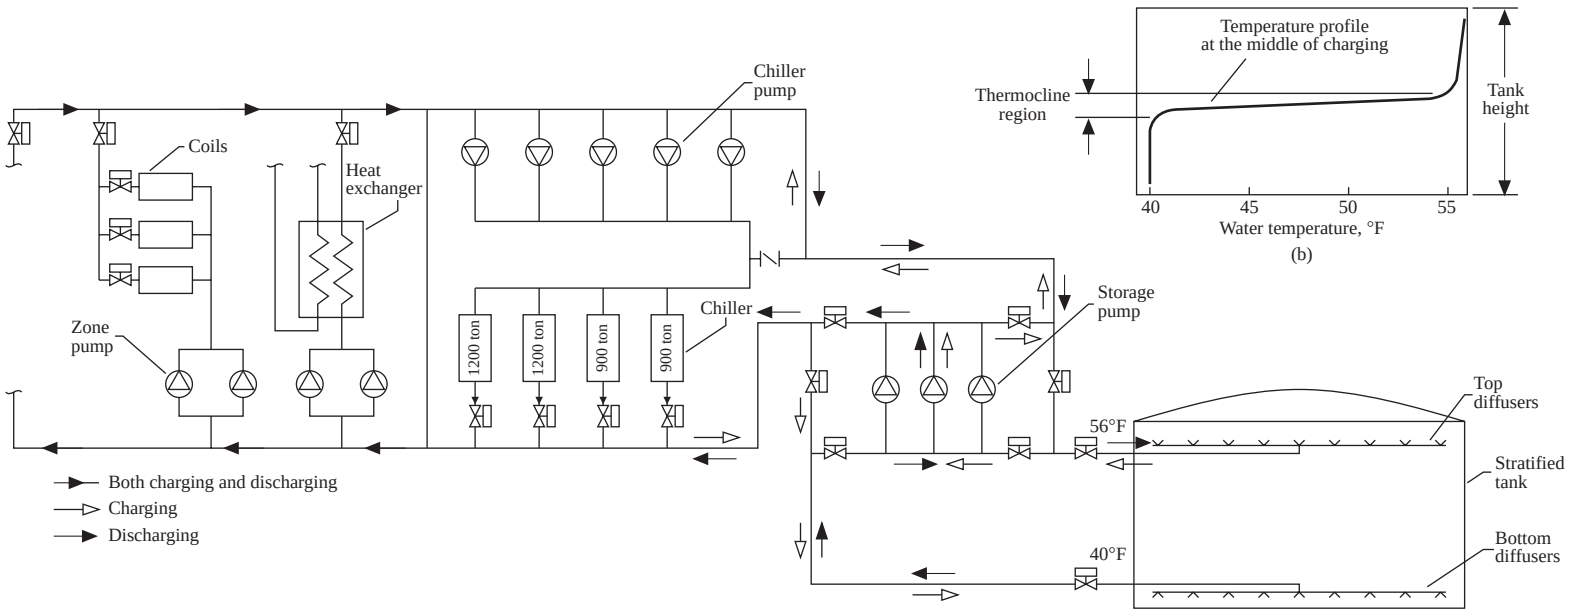

FIGURE 9.12.2 A chilled-water storage system using stratified tanks: (a) schematic diagram of a chilled-water storage system and (b) thermocline at the middle of charging process.

© 1999 by CRC Press LLC

Chilled-water storage tanks are usually vertical cylinders and often have a height-to-diameter ratio of 0.25:0.35. Steel is the most commonly used material for above-grade tanks, with a 2-in.-thick spray-on polyurethane foam, a vapor barrier, and a highly reflective coating. Concrete, sometimes precast, prestressed tanks are widely used for underground tanks.

A key factor to reduce loss in cooling capacity during chilled water storage is to reduce mixing of colder and warmer water streams at the inlet. If the velocity pressure of the inlet stream is less than the buoyancy pressure, the entering colder stored chilled water at the bottom of tank will stratify. Refer to Wang's handbook (1993) and Knebel (1995) for details.

A *thermocline* is a stratified region in a chilled-water storage tank of which there is a steep temperature gradient as shown in Figure 9.12.2(b). Water temperature often varies from 42°F to about 60°F. Thermocline separates the bottom colder stored chilled water from the top warmer return chilled water. The thinner the thermocline, the lower the mixing loss.

Diffusers and symmetrical connected piping are used to evenly distribute the incoming water streams with sufficient low velocity, usually lower than 0.9 ft/sec. Inlet stream from bottom diffusers should be downward and from the top diffusers should be upward or horizontal.

Field measurements indicate that stratified tanks have a FOM between 0.85 to 0.9.

9.13 Air System Basics

Fan-Duct Systems

Flow Resistance

Flow resistance is a property of fluid flow which measures the characteristics of a flow passage resisting the fluid flow with a corresponding total pressure loss Δp, in in. WG, at a specific volume flow rate $\mathring{V}$, in cfm:

$$\Delta p = R\mathring{V}^2 \tag{9.13.1}$$

where R = flow resistance (in. WG/(cfm)^2).

For a duct system that consists of several duct sections connected in series, its flow resistance R_s, in in. WG/(cfm)^2, can be calculated as

$$R_s = R_1 + R_2 + \ldots + R_n \tag{9.13.2}$$

where R_1, R_2, … R_n = flow resistance of duct section 1, 2, … n in the duct system (in. WG/(cfm)^2).

For a duct system that consists of several duct sections connected in parallel, its flow resistance R_p, in in. WG/(cfm)^2, is:

$$1/\sqrt{R_p} = 1/\sqrt{R_1} + 1/\sqrt{R_2} + \ldots + 1/\sqrt{R_n} \tag{9.13.3}$$

Fan-Duct System

In a *fan-duct system*, a fan or several fans are connected to ductwork or ductwork and equipment. The volume flow and pressure loss characteristics of a duct system can be described by its performance curve, called *system curve*, and is described by $\Delta p = R\,\mathring{V}^2$.

An *air system* or an air handling system is a kind of fan-duct system. In addition, an outdoor ventilation air system to supply outdoor ventilation air, an exhaust system to exhaust contaminated air, and a smoke control system to provide fire protection are all air systems, that is, fan-duct systems.

Primary, Secondary, and Transfer Air

Primary air is the conditioned air or makeup air. Secondary air is often the induced space air, plenum air, or recirculating air. Transfer air is the indoor air that moves to a conditioned space from an adjacent area.

System-Operating Point

A *system-operating point* indicates the operating condition of an air system or fan-duct system. Since the operating point of a fan must lie on the fan performance curve, and the operating point of a duct system on the system curve, the system operating point of an air system must be the intersection point P_s of the fan performance curve and system curve as shown in Figure 9.13.1(a).

Fan-Laws

For the same air system operated at speeds n_1 and n_2, both in rpm, their relationship of $\mathring{V}$ volume flow rate, in cfm, system total pressure loss, in in. WG, and fan power input, in hp, can be expressed as

$$\begin{aligned} \mathring{V}_2/\mathring{V}_1 &= n_2/n_1 \\ \Delta p_{t2}/\Delta p_{t1} &= (n_2/n_1)^2(\rho_2/\rho_1) \\ P_2/P_1 &= (n_2/n_1)^3(\rho_2/\rho_1) \end{aligned} \tag{9.13.4}$$

© 1999 by CRC Press LLC

where ρ = air density (lb/ft^3). Subscripts 1 and 2 indicate the original and the changed operating conditions. For air systems that are geometrically and dynamically similar:

$$\begin{aligned} \mathring{V}_2/\mathring{V}_1 &= \left(D_2/D_1\right)^3\left(n_2/n_1\right) \\ \Delta p_{t2}/\Delta p_{t1} &= \left(D_2/D_1\right)^2\left(n_2/n_1\right)^2\left(\rho_2/\rho_1\right) \\ P_2/P_1 &= \left(D_2/D_1\right)^5\left(n_2/n_1\right)^3\left(\rho_2/\rho_1\right) \end{aligned} \tag{9.13.5}$$

where D = diameter of the impeller (ft).

Geometrically similar means that two systems are similar in shape and construction. For two systems that are dynamically similar, they must be geometrically similar, and in addition, their velocity distribution or profile of fluid flow should also be similar. When fluid flows in the air systems are at high Reynolds number, such as Re > 10,000, their velocity profiles can be considered similar to each other.

System Effect

The system effect Δp_{se}, in in. WG, of an air system is its additional total pressure loss caused by uneven or nonuniform velocity profile at the fan inlet, or at duct fittings after fan outlet, due to the actual inlet and outlet connections as compared with the total pressure loss of the fan test unit during laboratory ratings. The selected fan total pressure which includes the system effect Δp_{ts}, in in. WG, as shown in Figure 9.13.1(a), can be calculated as

$$\begin{aligned} \Delta p_{ts} &= \Delta p_{sy} + \Delta p_{se} = \Delta p_{sy} + \Delta p_{s.i} + \Delta p_{s.o} \\ &= \Delta p_{sy} + C_{s.i}\left(v_{fi}/4005\right)^2 + C_{s.o}\left(v_{fo}/4005\right)^2 \end{aligned} \tag{9.13.6}$$

where Δp_{sy} = calculated total pressure loss of the air system, in WG
$\Delta p_{s.i}$, $\Delta p_{s.o}$ = fan inlet and outlet system effect loss, in WG
$C_{s.i}$, $C_{s.o}$ = local loss coefficient of inlet and outlet system effect, in WG
v_{fi}, v_{fo} = velocity at fan inlet (fan collar) and fan outlet, fpm

Both $C_{s.i}$ and $C_{s.o}$ are mainly affected by the length of connected duct between the duct fitting and fan inlet or outlet, by the configuration of the duct fitting, and by the air velocity at the inlet or outlet. Because v_{fi} and v_{fo} are often the maximum velocity of the air system, system effect should not be overlooked. According to AMCA Fan and Systems (1973), a square elbow (height to turning radius ratio R/H = 0.75) connected to a fan inlet with a connected duct length of 2 D_e (equivalent diameter) and v_{fi} = 3000 fpm may have a 0.67 in. WG $\Delta p_{i.o}$ loss. Refer to AMCA Fan and Systems (1973) or Wang's handbook (1993) for details.

Modulation of Air Systems

Air systems can be classified into two categories according to their operating volume flow: constant volume and variable-air-volume systems. The volume flow rate of a *constant volume system* remains constant during all the operating time. Its supply temperature is raised during part load. For a *variable-air-volume* (*VAV*) *system*, its volume flow rate is reduced to match the reduction of space load at part-load operation. The system pressure loss of a VAV system can be divided into two parts: variable part Δp_{var} and fixed part Δp_{fix}, which is the set point of the duct static pressure control as shown in Figure 9.13.1(b) and (c). The *modulation curve* of a VAV air system its its operating curve, or the locus of system operating points when its volume flow rate is modulated at full- and part-load operation.

© 1999 by CRC Press LLC

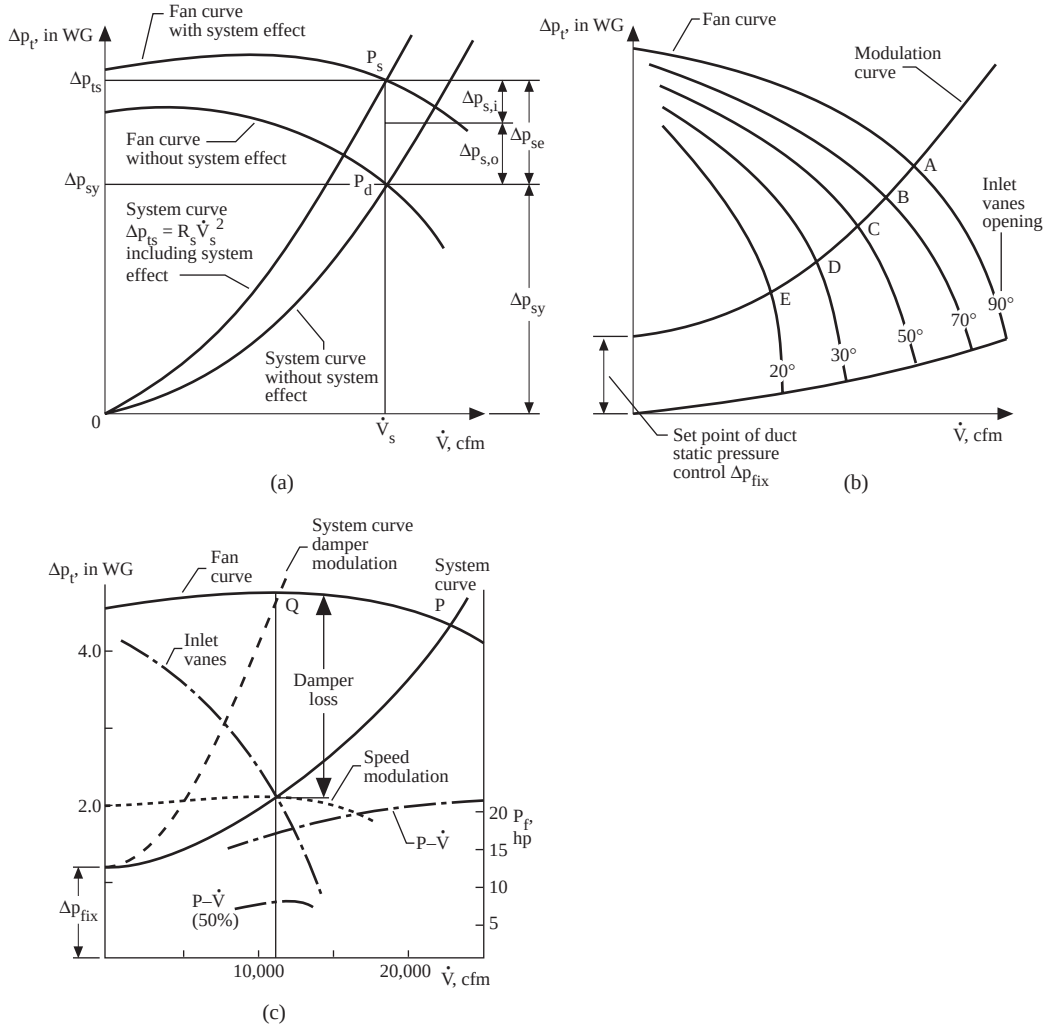

FIGURE 9.13.1 Air system $\dot{V}$-Δp_t performance: (a) system operating point and system effect, (b) modulation curve, and (c) damper, inlet vanes, and fan speed modulation.

The volume flow and system pressure loss of an air system can be modulated either by changing its fan characteristics or by varying its flow resistance of the duct system. Currently used types of modulation of volume flow rate of VAV air systems are

1. *Damper modulation* uses an air damper to vary the opening of the air flow passage and therefore its flow resistance.
2. *Inlet vanes modulation* varies the opening and the angle of inlet vanes at the centrifugal fan inlet and then gives different fan performance curves.
3. *Inlet cone modulation* varies the peripheral area of the fan impeller and therefore its performance curve.
4. *Blade pitch modulation* varies the blade angle of the axial fan and its performance curve.
5. *Fan speed modulation* using *adjustable frequency AC drives* varies the fan speed by supplying a variable-frequency and variable-voltage power source. There are three types of AC drives: adjustable voltage, adjustable current, and pulse width modulation (PWM). The PWM is universally applicable.

© 1999 by CRC Press LLC

Damper modulation wastes energy. Inlet vanes are low in cost and are not so energy efficient compared with AC drives and inlet cones. Inlet cone is not expensive and is suitable for backward curved centrifugal fans. Blade pitch modulation is energy efficient and is mainly used for vane and tubular axial fans. AC drive is the most energy-efficient type of modulation; however, it is expensive and often considered cost effective for air systems using large centrifugal fans.

Example 9.13.1

A multizone VAV system equipped with a centrifugal fan has the following characteristics:

$\mathring{V}$ (cfm)	5,000	10,000	15,000	20,000	25,000
Δp_t, in. WG	4.75	4.85	4.83	4.60	4.20
P, hp		17.0	18.6	20.5	21.2

At design condition, it has a volume flow rate of 22,500 cfm and a fan total pressure of 4.45 in. WG. The set point of duct static pressure control is 1.20 in. WG.

When this VAV system is modulated by inlet vanes to 50% of design flow, its fan performance curves show the following characteristics:

$\mathring{V}$ (cfm)	5,000	10,000	11,250
Δp_t, in. WG	3.6	2.5	2.1
P, hp		7.5	7.8

Determine the fan power input when damper, inlet vanes, or AC drive fan speed modulation is used. Assume that the fan total efficiency remains the same at design condition when the fan speed is reduced.

Solutions

1. At 50% design flow, the volume flow of this VAV system is $0.5 \times 22{,}500 = 11{,}250$ cfm. The flow resistance of the variable part of this VAV system is

$$R_{var} = \Delta p_{va} = R\mathring{V}^2 = (4.45 - 1.20)/(22{,}500)^2 = 6.42 \times 10^{-9} \text{ in. WG}/(\text{cfm})^2$$

   When damper modulation is used, the system operating point Q must be the intersection of the fan curve and the system curve that has a higher flow resistance and a $\mathring{V}$ = 11,250 cfm. From Figure 9.13.1(c), at point Q, the fan power input is 17.0 hp.
2. From the given information, when inlet vane modulation is used, the fan power input is 7.8 hp.
3. The total pressure loss of the variable part of the VAV system at 50% volume flow is

$$\Delta p_{var} = R_{var}\mathring{V}^2 = 6.42 \times 10^{-9}(11{,}250)^2 = 0.81 \text{ in. WG}$$

   From Figure 9.13.1(c), since the fan power input at design condition is 21.2 hp, then its fan total efficiency is:

$$\eta_f = \mathring{V}\Delta p_{tf}/(6356P_f) = 22{,}500 \times 4.45/(6356 \times 21.2) = 74.3\%$$

   The fan power input at 50% design volume flow is:

$$P = \mathring{V}\Delta p_{tf}/(6356\eta_f) = 11{,}250(0.81 + 1.20)/(6356 \times 0.743) = 4.8 \text{ hp}$$

   Damper modulation has a energy waste of (17 – 4.8) = 12.2 hp

Fan Combinations in Air-Handling Units and Packaged Units

Currently used fan combinations in air-handling units (AHUs) and packaged units (PUs) (except dual-duct VAV systems) are shown in Figure 9.13.2(a), (b), and (c):

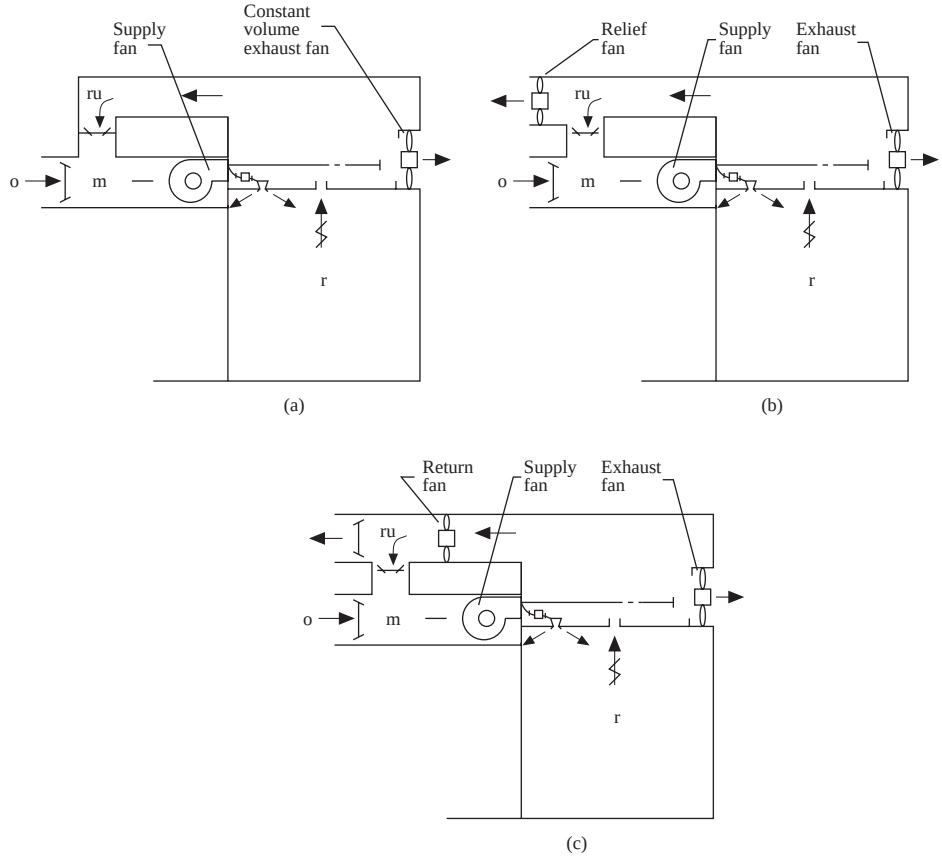

FIGURE 9.13.2 Fan combinations: (a) supply and exhaust fan, (b) supply and relief fan, and (c) supply and return fan.

Supply and Exhaust Fan/Barometric Damper Combination

An air system equipped with a single supply fan and a constant-volume exhaust fan, or a supply fan and a barometric damper combination as shown in Figure 9.13.2(a), is often used in buildings where there is no return duct or the pressure loss of the return duct is low. An all-outdoor air economizer cycle is usually not adopted due to the extremely high space pressure. A barometric relief damper is often installed in or connected to the conditioned space to prevent excessively high space pressure. When the space-positive pressure exerted on the barometric damper is greater than the weight of its damper and/or a spring, the damper is opened and the excessive space pressure is relieved.

Consider a VAV rooftop packaged system using a supply fan and a constant-volume exhaust system to serve a typical floor in an office building. This air system has the following design parameters:

During minimum outdoor ventilation air *recirculating mode* at summer design volume flow and at 50% of design volume flow, the outdoor damper is at its minimum opening. The recirculating damper is fully opened. The outdoor air intake at the PU must be approximately equal to the exfiltration at the conditioned space due to the positive space pressure p_r, in in. WG. By using the iteration method, the calculated pressure characteristics and the corresponding volume flow rates are shown below:

© 1999 by CRC Press LLC

Supply volume flow rate:		20,000 cfm
Total pressure loss:	Across the recirculating damper	0.1 in. WG
	Filter and coils	2.5 in. WG
	Supply main duct	0.85 in. WG
	Return system between point r and ru	0.2 in. WG
Effective leakage area on the building shell		3.35 ft^2
Minimum outdoor ventilation air		3000 cfm
Space pressure at design flow		+0.05 in. WG

Point	**o**	**m**	**r**	**ru**
Design flow:				
p_o, in. WG	0	–0.20	+0.05	–0.15
$\dot{V}$, cfm	3,000	20,000	20,000	17,000
50% design:				
p_o, in. WG	0	–0.092	+0.0225	–0.052
$\dot{V}$, cfm	2,025	10,000	10,000	7,975

Here, o represents outdoor, m the mixing box, r the space, and ru the recirculating air inlet to the PU.

When the supply volume flow is reduced from the design volume flow to 50% of design flow during the recirculating mode, the total pressure in the mixing box increases from –0.20 to –0.092 in. WG and the outdoor air intake reduces from 3000 to 2025 cfm. Refer to Wang's (1993) *Handbook of Air Conditioning and Refrigeration* for details.

Supply and Relief Fan Combination

Figure 9.13.2(b) shows the schematic diagrams of an air system of supply fan and relief fan combination. A relief fan is used to relieve undesirable high positive space pressure by extracting space air and relieving it to the outside atmosphere. A relief fan is always installed in the relief flow passage after the junction of return flow, relief flow, and recirculating flow passage, point ru. It is usually energized only when the air system is operated in air economizer mode. A relief fan is often an axial fan. Since the relief fan is not energized during recirculating mode operation, the volume flow and pressure characteristics of a supply fan and relief fan combination are the same as that in a single supply fan and barometric damper combination when they have the same design parameters.

During air economizer mode, the outdoor air damper(s) are fully opened and the recirculating damper closed. The space pressure p_r = +0.05 in. WG is maintained by modulating the relief fan speed or relief damper opening. The pressure and volume flow characteristics of a supply and relief fan combination at design volume flow and 50% of design flow are as follows:

Point	**o**	**m**	**r**	**ru**
Design flow:				
p_o, in. WG	0	–0.20	+0.05	–0.15
$\dot{V}$, cfm	20,000	20,000	20,000	17,000

Point	**o**	**m**	**r**	**ru**
50% design:				
p_o, in. WG	0	–0.057	+0.05	+0.007
$\dot{V}$, cfm	10,000	10,000	10,000	7,000

Supply Fan and Return Fan Combination

A *return fan* is always installed at the upstream of the junction of return, recirculating, and exhaust flow passage, point ru as shown in Figure 9.13.2(c). A supply and return fan combination has similar pressure and volume flow characteristics as that of a supply and relief fan combination, except a higher total

© 1999 by CRC Press LLC

pressure at point ru. If the return fan is improperly selected and has an excessive fan total pressure, total pressure at point m may be positive. There will be no outdoor intake at the PU or AHU, and at the same time there will also be a negative space pressure and an infiltration to the space.

Comparison of These Three Fan Combination Systems

A supply fan and barometric damper combination is simpler and less expensive. It is suitable for an air system which does not operate at air economizer mode and has a low pressure drop in the return system.

For those air systems whose pressure drop of return system is not exceeding 0.3 in. WG, or there is a considerable pressure drop in relief or exhaust flow passage, a supply and relief fan combination is recommended. For air systems whose return system has a pressure drop exceeding 0.6 in. WG, or those requiring a negative space pressure, a supply and return fan combination seems more appropriate.

Year-Round Operation and Economizers

Consider a typical single-duct VAV reheat system to serve a typical floor whose indoor temperature is 75°F with a relative humidity of 50%, as shown in Figure 9.13.3(a). During summer, the off-coil temperature is 55°F. The year-round operation of this air system can be divided into four regions on the psychrometric chart, as shown in Figure 9.13.3(b):

- *Region I — Refrigeration/evaporative cooling.* In this region, the enthalpy of the outdoor air h_o is higher than the enthalpy of the recirculating air h_{ru}, $h_o > h_{ru}$. It is more energy efficient to condition the mixture of recirculating air and minimum outdoor air.
- *Region II — Free cooling and refrigeration.* In this region, $h_o \le h_{ru}$. It is more energy efficient and also provides better indoor air quality to extract 100% outdoor air.
- *Region III — Free cooling evaporative cooling, and refrigeration.* In this region, extract 100% outdoor air for free cooling because $h_o \le h_{ru}$. Use evaporative cooling and refrigeration to cool and humidify if necessary.
- *Region IV — Winter heating.* Maintain a 55°F supply temperature by mixing the recirculating air with the outdoor air until the outdoor air is reduced to a minimum value. Provide heating if necessary.

An economizer is a device consisting of dampers and control that uses the free cooling capacity of either outdoor air or evaporatively cooled water from the cooling tower instead of mechanical refrigeration. An air economizer uses outdoor air for free cooling. There are two kinds of air economizers: enthalpy-based, in which the enthalpy of outdoor and recirculating air is compared, and temperature-based, in which temperature is compared. A water economizer uses evaporatively cooled water.

Fan Energy Use

For an air system, fan energy use for each cfm of conditioned air supplied from the AHUs and PUs to the conditioned space within a certain time period, in W/cfm, can be calculated as

$$\text{W/cfm} = 0.1175\Delta p_{sy} / (\eta_f \eta_m) \tag{9.13.7}$$

where Δp_{sy} = mean system total pressure loss during a certain time period, in. WG
η_f = fan total efficiency
η_m = combined motor and drive (direct drive or belt drive) efficiency

For an air system using a separate outdoor ventilation system, its fan energy use, in W/cfm, is then calculated as

$$\text{W/cfm} = (1 + R_{o.s})\left[0.1175\Delta p_{sy} / (\eta_f \eta_m)\right] \tag{9.13.8}$$

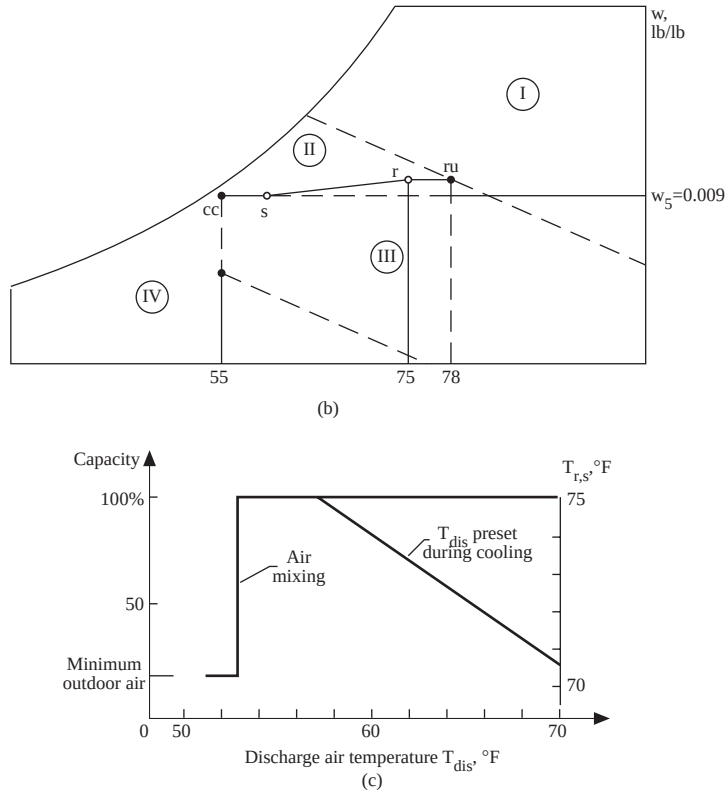

FIGURE 9.13.3bc

where $R_{o.s}$ = ratio of outdoor air volume flow rate to supply volume flow rate.

Outdoor Ventilation Air Supply

Basics

- An adequate amount of outdoor ventilation air supply is the key factor to provide acceptable indoor air quality (IAQ) for a conditioned space. Although an inadequate amount of outdoor ventilation air supply causes poor IAQ, an oversupply of outdoor ventilation air other than in an air economizer cycle is often a waste of energy.
- According to local codes and ANSI/ASHRAE Standard 62-1989, the minimum outdoor ventilation rate for each person must be provided at the outdoor air intake of AHU or PU, or by an outdoor air ventilation system. If the minimum outdoor ventilation air rate is reduced by using higher efficiency filters to remove air contaminants in the recirculating air, then indoor air contaminant concentration must be lower than the specified level in ANSI/ASHRAE Standard 62-1989.
- For a multizone air system, although the ratio of outdoor ventilation air rate to supply air volume flow rate required may be varied from zone to zone, the excessive outdoor air supply to a specified zone will increase the content of unused outdoor air in the recirculating air in AHU or PU. This helps to solve the problem in any zone that needs more outdoor air.
- Since the occupancy in many buildings is often variable and intermittent, a demand-based variable amount of outdoor ventilation air control should be used instead of time-based constant volume outdoor ventilation air control, except during the air economizer cycle.

© 1999 by CRC Press LLC

- Carbon dioxide (CO_2) is a gaseous body effluent. CO_2 is an indicator of representative odor and an indicator of adequate outdoor ventilation rate at specific outdoor and indoor air concentration in a control zone at steady state. For most of the comfort air-conditioning systems, it is suitable to use CO_2 as a key parameter to control the intake volume flow rate of outdoor ventilation air to maintain an indoor CO_2 concentration not exceeding 800 to 1000 ppm in a critical or representative zone. As mentioned in Section 9.5, Persily (1993) showed that the actual measured indoor daily maximum CO_2 concentration levels in five buildings were all within 400 to 820 ppm.

If a field survey finds that a specific indoor air contaminant exceeds a specified indoor concentration, then a gas sensor for this specific contaminant or a mixed gas sensor should be used to control this specific indoor concentration level.

Types of Minimum Outdoor Ventilation Air Control. There are four types of minimum outdoor ventilation air control that are currently used:

- Type I uses a CO_2 sensor or a mixed gas sensor and a DDC controller to control the volume flow rate of outdoor ventilation air for a separate outdoor ventilation air system on the demand-based principle.
- Type II uses a CO_2 or mixed gas sensor and a DDC controller to control the ratio of the openings between outdoor and recirculating dampers and, therefore, the volume flow rates of outdoor air and recirculating air in AHUs or PUs on the demand-based principle.
- Type III uses a flow sensor or a pressure sensor and a DDC controller to control the openings of outdoor and recirculating dampers to provide a nearly constant volume outdoor air intake in VAV AHUs or VAV PUs.
- Type IV adjusts the opening of the outdoor damper manually to provide a constant volume of outdoor air in constant-volume AHUs and PUs. If the outdoor intake is mounted on the external wall without a windshield, the volume flow of outdoor ventilation air intake will be affected by wind force and direction.

Type I is the best minimum outdoor ventilation air control for the air system. For a VAV system, it is expensive. Type II is a better choice. Type III is more complicated and may cause energy waste. Type IV has the same result as Type III and is mainly used in constant-volume systems.

Outdoor intake must be located in a position away from the influence of exhaust outlets. Fans, control dampers, and filters should be properly operated and maintained in order to provide a proper amount of outdoor ventilation air as well as an acceptable IAQ.

9.14 Absorption System

Absorption systems use heat energy to produce refrigeration as well as heating if it is required. Water is the refrigerant and aqueous lithium bromide (LiBr) is widely used as the carrier to absorb the refrigerant and provide a higher coefficient of performance.

The mixture of water and anhydrous LiBr is called *solution*. The composition of a solution is usually expressed by its mass fraction, or percentage of LiBr, often called *concentration*. When the water vapor has boiled off from the solution, it is called *concentration solution*. If the solution has absorbed the water vapor, it is called *diluted solution*.

Absorption systems can be divided into the following categories:

- *Absorption chillers* use heat energy to produce refrigeration.
- *Absorption chiller/heaters* use direct-fired heat input to provide cooling or heating separately.
- *Absorption heat pumps* extract heat energy from the evaporator, add to the heat input, and release them both to the hot water for heating.
- *Absorption heat transformers* raise the temperature of the waste heat source to a required level.

Most recently installed absorption chillers use direct-fired natural gas as the heat source in many locations in the United States where there are high electric demand and electric rate at on-peak hours. Absorption chillers also are free from CFC and HCFC. An energy cost analysis should be done to determine whether an electric chiller or a gas-fired absorption chiller is the suitable choice.

Absorption heat pumps have only limited applications in district heating. Most absorption heat transformers need industrial waste heat. Both of them will not be covered here.

Double-Effect Direct-Fired Absorption Chillers

Figure 9.14.1(a) shows a double-effect direct-fired absorption chiller. *Double effect* means that there are two generators. *Direct fired* means that gas is directly fired at the generator instead of using steam or hot water. A single-effect absorption chiller using steam as the heat input to its single generator has a COP only from 0.7 to 0.8, whereas a double-effect direct-fired absorption chiller has a COP approximately equal to 1 and therefore is the mot widely used absorption chiller in the United States for new and retrofit projects today. The refrigeration capacity of double-effect direct-fired absorption chillers varies from 100 to 1500 tons.

A double-effect direct-fired absorption chiller mainly consists of the following components and controls:

- Evaporator — An *evaporator* is comprised of a tube bundle, spray nozzles, a water trough, a refrigerant pump, and an outer shell. Chilled water flows inside the tubes. A refrigerant pump sprays the liquid refrigerant over the outer surface of the tube bundle for a higher rate of evaporation. A water trough is located at the bottom to maintain a water level for recirculation.
- Absorber — In an *absorber*, there are tube bundles in which cooling water flows inside the tubes. Solution is sprayed over the outer surface of the tube bundle to absorb the water vapor. A solution pump is used to pump the diluted solution to the heat exchanger and low-temperature generator.
- Heat exchangers — There are two heat exchangers: *low-temperature heat exchanger* in which the temperature of hot concentrated solution is lower, and *high-temperature heat exchanger* in which the temperature of hot concentrated solution is higher. In both heat exchangers, heat is transferred from the hot concentrated solution to the cold diluted solution. Shell-and-tube or plate-and-frame heat exchangers are most widely used for their higher effectiveness.
- Generators — *Generators* are also called *desorbers*. In the *direct-fired generator*, there are the fire tube, flue tube, vapor/liquid separator, and flue-gas economizer. Heat is supplied from the gas burner or other waste heat source. The *low-temperature generator* is often of the shell-and-tube type. The water vapor vaporized in the direct-fired generator is condensed inside the tubes. The

latent heat of condensation thus released is used to vaporize the dilute solution in the low-temperature generator.

© 1999 by CRC Press LLC

- Condenser — A condenser is usually also of the shell-and-tube type. Cooling water from the absorber flows inside the tubes.
- Throttling devices — Orifices and valves are often used as throttling devices to reduce the pressure of refrigerant and solution to the required values.
- Air purge unit — Since the pressure inside the absorption chiller is below atmospheric pressure, air and other noncondensable gases will leak into it from the ambient air. An *air purge unit* is used to remove these noncondensable gases from the chiller. A typical air purge unit is comprised of a pickup tube, a purge chamber, a solution spray, cooling water tubes, a vacuum pump, a solenoid valve, and a manual shut-off valve.

When noncondensable gases leak into the system, they tend to migrate to the absorber where pressure is lowest. Noncondensable gases and water vapor are picked from the absorber through the pickup tube. Water vapor is absorbed by the solution spray and returned to the absorber through a liquid trap at the bottom of the purge chamber. Heat of absorption is removed by the cooling water inside the tubes. Noncondensable gases are then evacuated from the chamber periodically by a vacuum pump to the outdoor atmosphere.

Palladium cells are used to continuously remove a small amount of hydrogen that is produced due to corrosion. Corrosion inhibitors like lithium chromate are needed to protect the machine parts from the corrosive effect of the absorbent when air is present.

Absorption Cycles, Parallel-, Series-, and Reverse-Parallel Flow

An *absorption* cycle shows the properties of the solution and its variation in concentrations, temperature, and pressure during absorbing, heat exchanging, and concentration processes on an equilibrium chart as shown in Figure 9.14.1(b). The ordinate of the equilibrium chart is the saturated temperature and pressure of water vapor, in °F and mm Hg abs. The abscissa is the temperature of the solution, in °F. Concentration lines are incline lines. At the bottom of the concentration lines, there is a *crystallization line* or *saturation line*. If the mass of fraction of LiBr in a solution which remains at constant temperature is higher than the saturated condition, that part of LiBr exceeding the saturation condition tends to form solid crystals.

Because there are two generators, the flow of solution from the absorber to generators can be in series flow, parallel flow, or reverse-parallel flow. In a series-flow system, the diluted solution from the absorber is first pumped to the direct-fired generator and then to the low-temperature generator. In a parallel-flow system, diluted solution is pumped to both direct-fired and low-temperature generators in parallel. In a reverse-parallel-flow system as shown in Figure 9.14.1(a), diluted solution is first pumped to the low-temperature generator. After that, the partly concentrated solution is then sent to the direct-fired generator as well as to the intermediate point 4 between high- and low-temperature heat exchangers in parallel. At point 4, partly concentrated solution mixes with concentrated solution from a direct-fired generator. A reverse-parallel-flow system is more energy efficient.

Solution and Refrigerant Flow

In a typical double-effect direct-fired reverse-parallel-flow absorption chiller operated at design full load, water is usually evaporated at a temperature of 42°F and a saturated pressure of 6.8 mm Hg abs in the evaporator. Chilled water returns from the AHUs or fan coils at a temperature typically 54°F, cools, and leaves the evaporator at 44°F. A refrigeration effect is produced due to the vaporization of water vapor and the removal of latent heat of vaporization from the chilled water.

Water vapor in the evaporator is then extracted to the absorber due to its lower vapor pressure. It is absorbed by the concentrated LiBr solution at a pressure of about 5 mm Hg abs. After absorption, the solution is diluted to a concentration of 58.6% and its temperature increases to 95°F (point 1). Most of the heat of absorption and the sensible heat of the solution is removed by the cooling water inside the

© 1999 by CRC Press LLC

tube bundle. Diluted solution is then pumped by a solution pump to the low-temperature generator through a low-temperature heat exchanger.

In the low-temperature generator, the dilute solution is partly concentrated to 60.3% at a solution temperature of 180°F (point 3). It then divides into two streams: one of them is pumped to the direct-fired generator through a high-temperature heat exchanger, and the other stream having a slightly greater mass flow rate is sent to the intermediate point 4. In the direct-fired generator, the concentrated solution leaves at a concentration of 66% and a solution temperature of 306°F (point 7).

The mixture of concentrated and partly concentrated solution at point 4 has a concentration of 63% and a temperature of 192°F. It enters the low-temperature heat exchanger. Its temperature drops to 121°F before entering the absorber (point 5).

In the direct-fired generator, water is boiled off at a pressure of about 390 mm Hg abs. The boiled-off water vapor flows through the submerged tube in the low-temperature generator. The release of latent heat of condensation causes the evaporation of water from the dilution solution at a vapor pressure of about 50 mm Hg abs. The boiled-off water vapor in the low-temperature generator flows to the condenser through the top passage and is condensed into liquid water at a temperature of about 99°F and a vapor pressure of 47.7 mm Hg abs. This condensed liquid water is combined with the condensed water from the submerged tube at the trough. Both of them return to the evaporator after its pressure is throttled by an orifice plate.

Part-Load Operation and Capacity Control

During part-load operation, a double-effect direct-fired reverse-parallel-flow absorption chiller adjusts its capacity by reducing the heat input to the direct-fired generator through the burner. Lower heat input results at less water vapor boiled off from the solution in the generators. This causes the drop in solution concentration, the amount of water vapor extracted, the rate of evaporation, and the refrigeration capacity. Due to less water vapor being extracted, both evaporating pressure and temperature will rise. Since the amount of water vapor to be condensed is greater than that boiled off from the generators, both the condensing pressure and condensing temperature decrease.

Coefficient of Performance (COP)

The COP of an absorption chiller can be calculated as

$$\text{COP} = 12{,}000/q_{lg} \tag{9.14.1}$$

where q_{lg} = heat input to the direct-fired generator per ton of refrigeration output (Btu/hr.ton).

Safety Controls

Safety controls in an absorption chiller include the following:

- Crystallization controls are devices available to prevent crystallization and dissolve crystals. Absorption chillers are now designed to operate in a region away from the crystallization line. It is no longer a serious problem in newly developed absorption systems. One such device uses a bypass valve to permit refrigerant to flow to the concentration solution line when crystallization is detected. Condenser water temperature is controlled by using a three-way bypass valve to mix the recirculating water with the evaporated cooled water from the tower to avoid the sudden drop of the temperature of concentrated solution in the absorber.
- Low-temperature cut-out control shuts down the absorption chiller if the temperature of the refrigerant in the evaporator falls below a preset limit to protect the evaporator from freezing.
- Chilled and cooling water flow switches stop the absorption chiller when the mass flow rate of chilled water or the supply of cooling water falls below a preset value.
- A high-pressure relief valve is often installed on the shell of the direct-fired generator to prevent its pressure from exceeding a predetermined value.

© 1999 by CRC Press LLC

- Monitoring of low and high pressure of gas supply and flame ignition are required for direct-fired burner(s).
- Interlocked controls between absorption chiller and chilled water pumps, cooling water pumps, and cooling tower fans are used to guarantee that they are in normal operation before the absorption chiller starts.

Absorption Chiller/Heater

A double-effect direct-fired reverse-parallel-flow absorption chiller/heater has approximately the same system components, construction, and flow process as the absorption chiller. The cooling mode operation is the same as in an absorption chiller. During the heating mode of an absorption chiller/heater, its evaporator becomes the condenser and is used to condense the water vapor that has been boiled off from the direct-fired generator. At design condition, hot water is supplied at a temperature of 130 to 140°F. The condenser and the low-temperature generator are not in operation. (See Figure 9.14.1.)

In order to increase the coefficient of performance of the absorption chiller, a triple-effect cycle with three condensers and three desorbers has been proposed and is under development. A triple-effect absorption chiller is predicted to have a coefficient of performance of around 1.5. Its initial cost is also considerably increased due to a greater number of condensers and desorbers.

9.15 Air-Conditioning Systems and Selection

Basics in Classification

The purpose of classifing air-conditioning or HVAC&R systems is to distinguish one type from another so that an optimum air-conditioning system can be selected according to the requirements. Proper classification of air-conditioning systems also will provide a background for using knowledge-based expert systems to help the designer to select an air-conditioning system and its subsystems.

Since air system characteristics directly affect the space indoor environmental parameters and the indoor air quality, the characteristics of an air system should be clearly designated in the classification.

The system and equipment should be compatible with each other. Each system has its own characteristics which are significantly different from others.

Individual Systems

As described in Section 9.1, air conditoning or HVAC&R systems can be classified as individual, space, packaged, and central systems.

Individual systems usually have no duct and are installed only in rooms that have external walls and external windows. Individual systems can again be subdivided into the following.

Room Air-Conditioner Systems

A room air conditioner is the sole factory-fabricated self-contained equipment used in the room air-conditioning system. It is often mounted on or under the window sill or on a window frame as shown in Figure 9.1.1. A room air-conditioner consists mainly of an indoor coil, a small forward-curved centrifugal fan for indoor coil, a capillary tube, a low-efficiency dry and reusable filter, grilles, a thermostat or other controls located in the indoor compartment, and a rotary, scroll, or reciprocating compressor, an outdoor coil, and a propeller fan for the outdoor coil located in the outdoor compartment. There is an outdoor ventilation air intake opening and a manually operated damper on the casing that divides the indoor and outdoor compartments. Room air-conditioners have a cooling capacity between 1/2 to 2 tons.

The following are system characteristics of a room air-conditioner system:

Room heat pump system is a room air-conditioner plus a four-way reversing valve which provides both the summer cooling and winter heating.
Air system: single supply fan
Fan, motor, and drive combined efficiency: 25%
Fan energy use: 0.3 to 0.4 W/cfm
Fan speed: HI-LO 2-speed or HI-MED-LO 3-speed
Outdoor ventilation air system: type IV
Cooling system: DX system, air-cooled condenser
EER 7.5 to 9.5 Btu/hr.W
Evaporating temperature T_{ev} at design load: typically 45°F
Heating system: electric heating (if any)
Part-load: on–off of refrigeration compressor
Sound level: indoor NC 45 to 50
Maintenance: More maintenance work is required.

Summer and winter mode air-conditioning cycles of a room air-conditioning system are similar to that shown in Figure 9.3.4.

All fan, motor, and drive combined efficiencies for various air-conditioning systems are from data in ASHRAE Standard 90.1-1989.

© 1999 by CRC Press LLC

Packaged Terminal Air-Conditioner (PTAC) Systems

A packaged terminal air-conditioner is the primary equipment in a PTAC system. A PTAC system is similar to a room air-conditioner system. Their main differences are

- A PTAC uses a wall sleeve and is intended to be mounted through the wall.
- Heating is available from hot water, steam, heat pump, electric heater, and sometimes even direct-fired gas heaters.

PTACs are available in cooling capacity between 1/2 to 1 1/2 tons and a heating capacity of 2500 to 35,000 Btu/hr.

Space (Space-Conditioning) Systems

Most space conditioning air-conditioning systems cool, heat, and filtrate their recirculating space air above or in the conditioned space. Space conditioning systems often incorporate heat recovery by transferring the heat rejected from the interior zone to the perimeter zone through the condenser(s). Space systems often have a separate outdoor ventilation air system to supply the required outdoor ventilation air.

Space systems can be subdivided into four-pipe fan-coil systems and water-source heat pump systems.

Four-Pipe Fan-Coil Systems

In a four-pipe fan-coil unit system, space recirculating air is cooled and heated at a fan coil by using four pipes: one chilled water supply, one hot water supply, one chilled water return, and one hot water return. Outdoor ventilation air is conditioned at a make-up AHU or primary AHU. It is then supplied to the fan coil where it mixes with the recirculating air, as shown in Figure 9.15.1(a), or is supplied to the conditioned space directly.

A *fan-coil unit* or a *fan coil* is a *terminal* as shown in Figure 9.15.1(b). Fan-coil units are available in standard sizes 02, 03, 04, 06, 08, 10, and 12 which correspond to 200 cfm, 400 cfm, and so on in volume flow.

The following are system characteristics of a four-pipe fan-coil system:

A *two-pipe fan-coil system* has a supply and a return pipe only. Because of the problems of changeover from chilled water to hot water and vice versa, its applications are limited.

A *water-cooling electric heating fan-coil system* uses chilled water for cooling and an electric heater for heating as shown in Figure 9.1.2. This system is often used in a location that has a mild winter.

Air system:

Fan-coil, space air recirculating
Fan, motor, and drive combined efficiency: 25%
Fan speed: HI-LO 2-speed and HI-MED-LO 3-speed
External pressure for fan coil: 0.06 to 0.2 in. WG
System fan(s) energy use: 0.45 to 0.5 W/cfm
No return air and return air duct
Outdoor ventilation air system: type I
An exhaust system to exhaust part of the outdoor ventilation air

Cooling system: chilled water from centrifugal or screw chiller

Water-cooled chiller energy use: 0.4 to 0.65 kW/ton

Heating system: hot water from boiler, electric heater

Part load: control the flow rate of chilled and hot water supplied to the coil. Since air leaving coil temperature T_{cc} rises during summer mode part load, space relative humidity will be higher.

Sound level: indoor NC 40 to 45

Maintenance: higher maintenance cost

System fan(s) energy use: 0.45 to 0.55 W/cfm (includes all fans in the four-pipe fan-coil system)

FIGURE 9.15.1 A four-pipe fan-coil system: (a) schematic diagram, (b) fan-coil unit, and (c) air-conditioning cycle.

An air-conditioning cycle for a four-pipe fan-coil system with outdoor ventilation air delivered to the suction side of the fan coil is shown in Figure 9.15.1(c). A part of the space cooling and dehumidifying load is usually taken care by the conditioned outdoor ventilation air from the make-up AHU. A double-bundle condenser is often adopted in a centrifugal chiller to incorporate heat recovery for providing winter heating.

Water-Source Heat Pump Systems

Water-source heat pumps (WSHPs) are the primary equipment in a water-source heat pump system as shown in Figure 9.15.2(a). A *water-source heat pump* usually consists of an air coil to cool and heat the air; a water coil to reject and extract heat from the condenser water; a forward-curved centrifugal fan; reciprocating, rotary, or scroll compressor(s); a short capillary tube; a reversing valve; controls; and an outer casing. WSHPs could be either a horizontal or vertical unit. WSHPs usually have cooling

© 1999 by CRC Press LLC

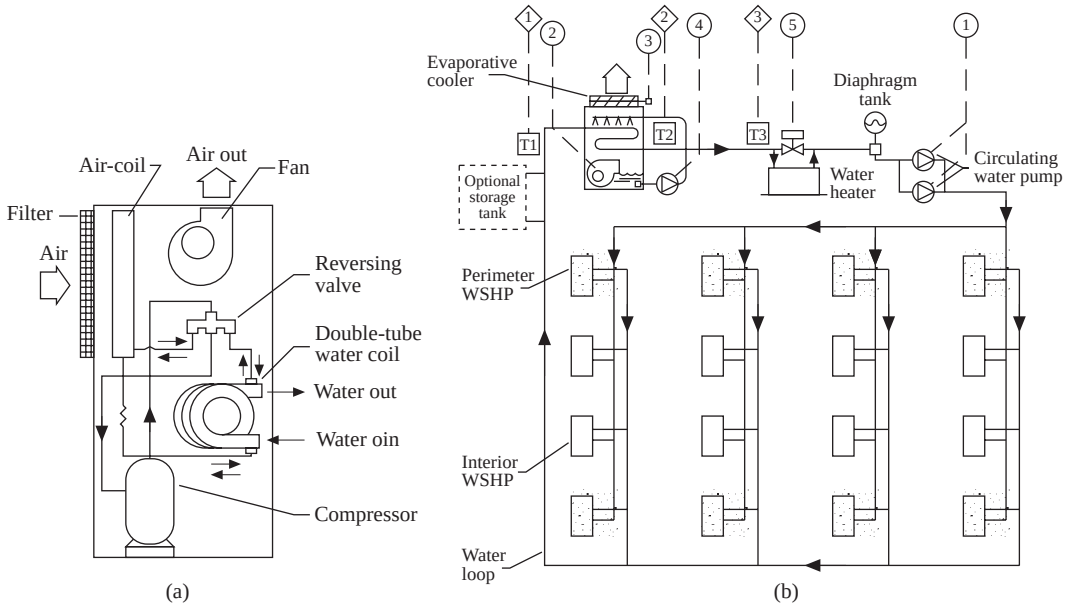

FIGURE 9.15.2 A water-source heat pump system: (a) vertical system and (b) system schematic diagram..

capacities between 1/2 to 26 tons. Small-capacity WSHPs of 3 tons or less without ducts are used in perimeter zones, whereas large-capacity WSHPs with ductwork are used only in interior zones.

In addition to the WSHPs, a WSHP system usually is also comprised of an evaporative cooler or cooling tower to cool the condenser water; a boiler to provide the supplementary heat for the condenser water if necessary; two circulating pumps, one of them being standby; and controls, as shown in Figure 9.15.2(b). A separate outdoor ventilation air system is required to supply outdoor air to the WSHP or directly to the space.

During hot weather, such as outdoor wet bulb at 78°F, all the WSHPs are operated in cooling mode. Condenser water leaves the evaporative cooler at a temperature typically 92°F and absorbs condensing heat rejected from the condensers — the water coils in WSHPs. Condenser water is then raised to 104°F and enters the evaporative cooler. In an evaporative cooler, condenser water is evaporatively cooled indirectly by atmospheric air, so that it would not foul the inner surface of water coils in WSHPs.

During moderate weather, the WSHPs serving the shady side of a building may be in heating mode, and while serving the sunny side of the building and the interior space in cooling mode. During cold weather, most of the WSHPs serving perimeter zones are in heating mode, while serving interior spaces are in cooling mode except morning warm-up. Cooling WSHPs reject heat to the condenser water loop; meanwhile heating WSHPs absorb heat from the condenser water loop. The condenser water is usually maintained at 60 to 90°F. If its temperature rises above 90°F, the evaporative cooler is energized. If it drops below 60°F, the boiler or electric heater is energized. A WSHP system itself is a combination of WSHP and a heat recovery system to transfer the heat from the interior space and sunny side of the building to the perimeter zone and shady side of building for heating in winter, spring, and fall.

System characteristics of air, cooling, and heating in a WSHP system are similar to a room conditioner heat pump system. In addition:

Outdoor ventilating air system: type I and IV
Water system: two-pipe, close circuit
Centrifugal water circulating pump
Water storage tank is optional

© 1999 by CRC Press LLC

To prevent freezing in locations where outdoor temperature may drop below 32°F, isolate the outdoor portion of the water loop, outdoor evaporative cooler, and the pipe work from the indoor portion by using a plate-and-frame heat exchanger. Add ethylene or propylene glycol to the outdoor water loop for freezing protection.

There is another space system called a panel heating and cooling system. Because of its higher installation cost and dehumidification must be performed in the separate ventilation systems, its applications are very limited.

A space conditioning system has the benefit of a separate demand-based outdoor ventilation air system. A WSHP system incorporates heat recovery automatically. However, its indoor sound level is higher; only a low-efficiency air filter is used for recirculating air, and more space maintenance is required than central and packaged systems. Because of the increase of the minimum outdoor ventilation air rate to 15 cfm/person recently, it may gain more applications in the future.

Packaged Systems

In packaged systems, air is cooled directly by a DX coil and heated by direct-fired gas furnace or electric heater in a packaged unit (PU) instead of chilled and hot water from a central plant in a central system. Packaged systems are different from space conditioning systems since variable-air-volume supply and air economizer could be features in a packaged system. Packaged systems are often used to serve two or more rooms with supply and return ducts instead of serving individual rooms only in an individual system.

As mentioned in Section 9.7, packaged units are divided according to their locations into rooftop, split, or indoor units. Based on their operating characteristics, packaged systems can be subdivided into the following systems:

Single-Zone Constant-Volume (CV) Packaged Systems

Although a single-zone CV packaged system may have duct supplies to and returns from two or more rooms, there is only a single zone sensor located in the representative room or space. A CV system has a constant supply volume flow rate during operation except the undesirable reduction of volume flow due to the increase of pressure drop across the filter.

A single-zone CV packaged system consists mainly of a centrifugal fan, a DX coil, a direct-fired gas furnace or an electric heater, a low or medium efficiency filter, mixing box, dampers, DDC controls, and an outer casing. A relief or a return fan is equipped for larger systems.

A single-zone CV packaged system serving a church is shown in Figure 9.1.3. This system operates on basic air-conditioning cycles as shown in Figure 9.3.4 during cooling and heating modes.

The system characteristics of a single-zone CV packaged system are

Air system: single supply fan, a relief or return fan for a large system
- Fan, motor, and drive combined efficiency: 40 to 45%
- Fan total pressure: 1.5 to 3 in. WG
- Fan(s) energy use: 0.45 to 0.8 W/cfm
- Outdoor ventilation air system: type IV and II
- Enthalpy or temperature air economizer

Cooling systems: DX system, air cooled
- Compressor: reciprocating or scroll
- EER: 8.9 to 10.0 Btu/hr.W

Heating system: direct-fired gas furnace, air-source heat pump, or electric heating

Part load: on–off or step control of the compressor capacity, DX-coil effective area, and the gas flow to the burner

Sound level: indoor NC 35 to 45

Maintenance: higher maintenance cost than central systems

© 1999 by CRC Press LLC

Single-zone, CV packaged systems are widely used in residences, small retail stores, and other commercial buildings.

Constant-Volume Zone-Reheat Packaged Systems

System construction and system characteristics of a CV zone-reheat system are similar to the single-zone CV packaged systems except:

1. It serves multizones and has a sensor and a DDC controller for each zone.
2. There is a reheating coil or electric heater in the branch duct for each zone.

A CV zone-reheat packaged system cools and heats simultaneously and therefore wastes energy. It is usually used for the manufacturing process and space needs control of temperature and humidity simultaneously.

Variable-Air-Volume Packaged Systems

A variable-air-volume (VAV) system varies its volume flow rate to match the reduction of space load at part load. A VAV packaged system, also called a *VAV cooling packaged system*, is a multizone system and uses a VAV box in each zone to control the zone temperature at part load during summer cooling mode operation, as shown in Figure 9.15.3(a).

A *VAV box* is a terminal in which the supply volume flow rate of the conditioned supply air is modulated by varying the opening of the air passage by means of a single blade damper, as shown in Figure 9.15.3(b), or a moving disc against a cone-shaped casing.

The following are the system characteristics of a VAV packaged system:

Single-zone VAV packaged system which serves a single zone without VAV boxes. A DDC controller modulates the position of the inlet vanes or the fan speed according to the signal of the space temperature sensor.

Air system: a supply/relief fan or supply/return fan combination. Space pressurization control by a relief/return fan
Fan, motor, and drive combined efficiency: 45%
Supply fan total pressure: 3.75 to 4.5 in. WG
Fan(s) energy use at design condition: 1 to 1.25 W/cfm
VAV box minimum setting: 30% of peak supply volume flow
Outdoor ventilation air system: type II and III
Economizer: enthalpy air economizer or water economizer
Cooling system: DX coil, air-, water-, or evaporative-cooled condenser
Compressor: reciprocating, scroll, and screw
EER: 8.9 to 12 Btu/hr.W
Capacity: 20 to 100 tons
Part load: zone volume flow modulation by VAV box; step control of compressor capacity; modulation of gas flow to burner; and discharge air temperature reset
Smoke control: exhausts smoke on the fire floor, and supplies air and pressurizes the floors immediately above or below the fire floor
Diagnostics: a diagnostic module displays the status and readings of various switches, dampers, sensors, etc. and the operative problems by means of expert system
Maintenance: higher than central system
Sound level: indoor NC 30 to 45

Heating system characteristics as well as the air-conditioning cycles are similar as that in a single-zone CV packaged system.

VAV Reheat Packaged Systems

A VAV reheat packaged system has its system construction and characteristics similar to that in a VAV packaged system except in each VAV box there is an additional reheating coil. Such a VAV box is called

© 1999 by CRC Press LLC

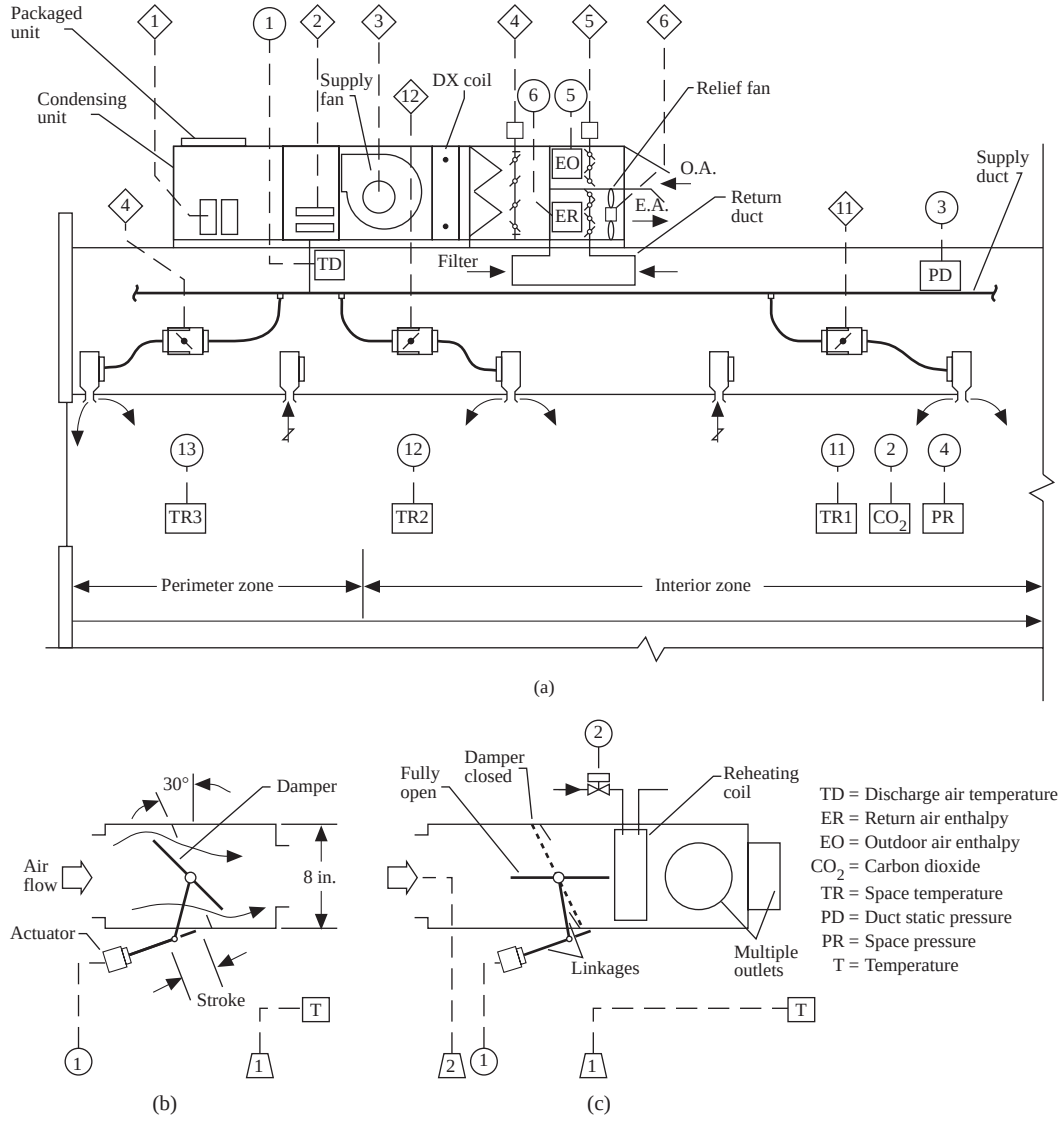

FIGURE 9.15.3 A variable-air-volume (VAV) package system: (a) schematic diagram, (b) VAV box, (c) reheating box, (d) parallel-flow fan-powered VAV box.

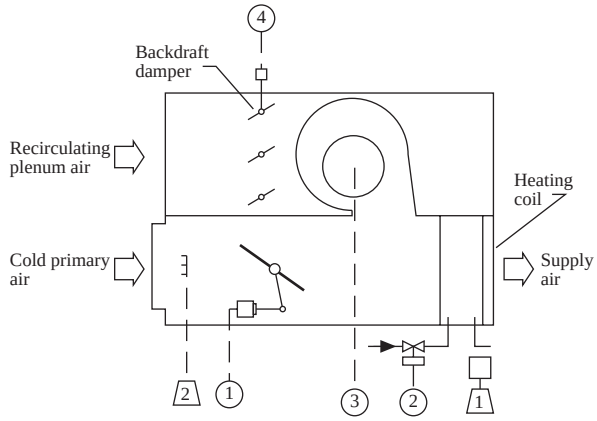
a *reheating VAV box*, as shown in Figure 9.15.2(a) and 9.15.3(c). VAV reheat packaged systems are used to serve perimeter zones where winter heating is required.

Fan-Powered VAV Packaged Systems

A fan-powered VAV packaged system is similar to that of a VAV packaged system except *fan-powered VAV boxes* as shown in Figure 9.15.3(d) are used instead of VAV boxes.

There are two types of fan-powered VAV boxes: parallel-flow and series-flow boxes. In a *parallel-flow* fan-powered box, the plenum air flow induced by the fan is parallel with the cold primary air flow through the VAV box. These two air streams are then combined and mixed together. In a *series-flow* box, cold primarily from the VAV box is mixed with the induced plenum air and then flows through the small fan. The parallel-flow fan-powered VAV box is more widely used.

© 1999 by CRC Press LLC



(d)

FIGURE 9.15.3d

In a fan-powered VAV box, volume flow dropping to minimum setting, extracting of ceiling plenum air, and energizing of reheating coil will actuate in sequence to maintain the space temperature during part-load/heating mode operation. A fan-powered VAV box can also mix the cold primary air from cold air distribution with the ceiling plenum air and provides greater space air movements during minimum space load.

Packaged systems are lower in installation cost and occupy less space than central systems. During the past two decades, DDC-controlled packaged systems have evolved into sophisticated equipment and provide many features that only a built-up central system could provide before.

Central Systems

Central systems use chilled and hot water that comes from the central plant to cool and heat the air in the air-handling units (AHUs). Central systems are built-up systems. The most clean, most quiet thermal-storage systems, and the systems which offer the most sophisticated features, are always central systems. Central systems can be subdivided into the following.

Single-Zone Constant-Volume Central Systems

A single-zone CV central system uses a single controller to control the flow of chilled water, hot water, or the opening of dampers to maintain a predetermined indoor temperature, relative humidity, or air contaminants. They are often used in manufacturing factories. The system characteristics of a single-zone CV central system are

Single-zone CV air washer central system uses air washer to control both space relative humidity and temperature. This system is widely used in textile mills. The reason to use constant volume is to dilute the fiber dusts produced during manufacturing. A rotary filter is often used for high dust-collecting capacity.

Air system: supply and return fan combination
    Fan, motor, and drive combined efficiency: 45 to 50%
    Outdoor ventilation air system: type II and IV
Economizer: air or water economizer
Smoke control: exhaust smoke on the fire floor, and pressurize adjacent floor(s) or area
Cooling system: centrifugal or screw chiller, water-cooled condenser
    Cooling energy use: 0.4 to 0.65 kW/ton
Heating system: hot water from boiler or from heat recovery system

© 1999 by CRC Press LLC

Part load: modulate the water mass flow to cooling and heating coils in AHUs, and discharge air temperature reset
Sound level: indoor NC 30 to 45. Silencers are used both in supply and return air systems if they are required
Maintenance: in central plant and fan rooms, lower maintenance cost

Single-Zone CV Clean Room Systems

This is the central system which controls the air cleanliness, temperature, and relative humidity in Class 1, 10, 100, 1000, and 10,000 clean rooms for electronic, pharmaceutical, and precision manufacturing and other industries. Figure 9.15.4(a) shows a schematic diagram of this system. The recirculating air unit (RAU) uses prefilter, HEPA filters, and a water cooling coil to control the space air cleanliness and required space temperature, whereas a make-up air unit (MAU) supplies conditioned outdoor air, always within narrow dew point limits to the RAU at any outside climate, as shown in Figure 9.15.4(b). A unidirectional air flow of 90 fpm is maintained at the working area. For details, refer to *ASHRAE Handbook 1991 HVAC Applications* and Wang's *Handbook of Air Conditioning and Refrigeration.*

CV Zone-Reheat Central Systems

These systems have their system construction and characteristics similar to that for a single-zone CV central system, except they serve multizone spaces and there is a reheating coil, hot water, or electric heating in each zone. CV zone-reheat central systems are often used for health care facilities and in industrial applications.

VAV Central Systems

A VAV central system is used to serve multizone space and is also called *VAV cooling central system.* Its schematic diagram is similar to that of a VAV packaged system (Figure 9.15.3) except air will be cooled or heated by water cooling or heating coils in the AHUs. The same VAV box shown in Figure 9.15.3(b) will be used in a VAV central system. The system characteristics of VAV central systems are as follows:

Single-zone VAV central system differs from a VAV central system only because it serves a single zone, and therefore there is no VAV box in the branch ducts. Supply volume flow is modulated by inlet vanes and AC inverter.

Air system: supply and relief/return fan combination
Fan, motor, and drive combined efficiency for airfoil centrifugal fan with AC inverter fan speed modulation: 55%
Fan(s) energy use: 0.9 to 1.2 W/cfm
VAV box: minimum setting 30% of peak supply volume flow
Outdoor ventilation air system: type I, II, and III
Cooling system: centrifugal, screw, and reciprocating chillers, water-cooled condenser, with energy use 0.4 to 0.65 kW/ton; or sometimes absorption chiller
Heating system: hot water from boiler or electric heating at the terminals
Economizer: air and water economizer
Part load: zone volume flow modulation, discharge air temperature reset, and chilled water temperature reset
Smoke control: exhausts smoke from the fire floor and pressurizes the immediate floors above and below
Sound level: indoor NC 20 to 40. Silencers are often used both in supply and return systems.
Maintenance: less space maintenance

VAV central systems are widely used for interior zone in buildings.

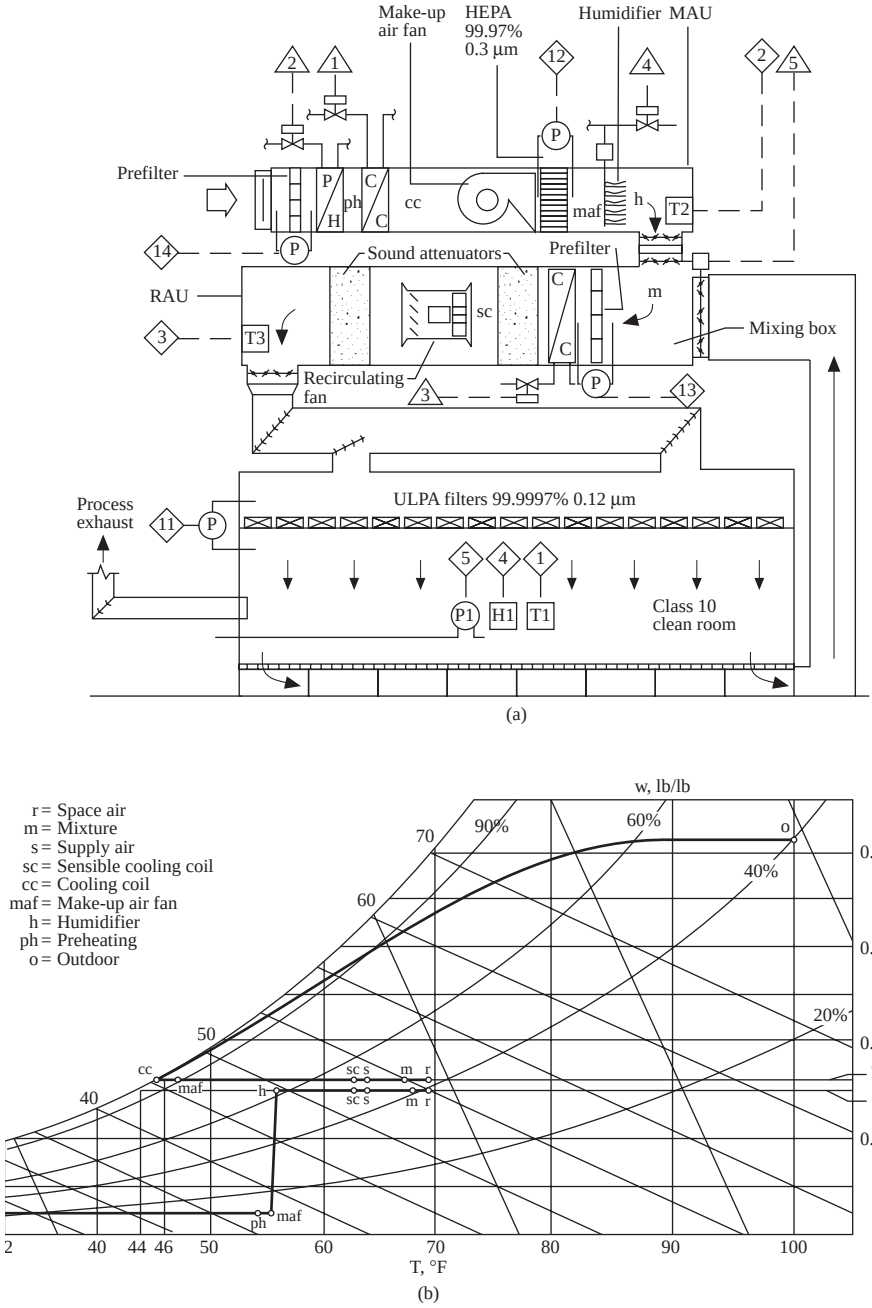

FIGURE 9.15.4 A single-zone CV clean room system: (a) schematic diagram and (b) air-conditioning cycle.

VAV Reheat Central Systems

A VAV reheat system is similar in system construction and characteristics to that in a VAV central system except that reheating boxes are used instead of VAV boxes in a VAV central system.

© 1999 by CRC Press LLC

Fan-Powered VAV Central Systems

A fan-powered VAV central system is similar in system construction and characteristics to that in a VAV central system except that fan-powered VAV boxes are used instead of VAV boxes.

Dual-Duct VAV Central Systems

A dual-duct VAV system uses a warm air duct and a cold air duct to supply both warm and cold air to each zone in a multizone space, as shown in Figure 9.15.5(a). Warm and cold air are first mixed in a mixing VAV box, and are then supplied to the conditioned space. Warm air duct is only used for perimeter zones.

A *mixing VAV box* consists of two equal air passages, one for warm air and one for cold air, arranged in parallel. Each of them has a single blade damper and its volume flow rate is modulated. Warm and cold air are then combined, mixed, and supplied to the space.

A dual-duct VAV system is usually either a single supply fan and a relief/return fan combination, or a warm air supply fan, a cold air supply fan, and a relief/return fan. A separate warm air fan and cold air supply fan are beneficial in discharge air temperature reset and fan energy use.

During summer cooling mode operation, the mixture of recirculating air and outdoor air is used as the warm air supply. The heating coil is not energized. During winter heating mode operation, mixture of outdoor and recirculating air or 100% outdoor air is used as the cold air supply; the cooling coil is not energized.

Because there is often air leakage at the dampers in the mixing VAV box, more cold air supply is needed to compensate for the leaked warm air or leaked cold air.

Other system characteristics of a dual-duct VAV central system are similar to a VAV central system.

Dual-Duct CV Central System

This is another version of a dual-duct VAV central system and is similar in construction to a dual-duct VAV system, except that a mixing box is used instead of a mixing VAV box. The supply volume flow rate from a mixing box is nearly constant. Dual-duct CV central systems have only limited applications, like health care facilities, etc.

An ice- or chilled-water storage system is always a central system plus a thermal storage system. The thermal storage system does not influence the system characteristics of the air distribution, and air cooling and heating — except for a greater head lift for a refrigeration compressor — is needed for ice-storage systems. Therefore, the following central systems should be added:

- VAV ice-storage or chilled-water systems
- VAV reheat ice-storage or chilled-water storage systems
- Fan-powered VAV ice-storage systems

Some of the air-conditioning systems are not listed because they are not effective or are a waste of energy, and therefore rarely used in new and retrofit projects such as:

- High-velocity induction space conditioning systems which need a higher pressure drop primary air to induce recirculating air in the induction unit and use more energy than fan-coil systems
- Multizone central systems which mix warm and cool air at the fan room and use a supply duct from fan room to each control zone
- Air skin central systems which use a warm air heating system to offset transmission loss in the perimeter zone and overlook the effect of the solar radiation from variation building orientations

In the future, there will be newly developed systems added to this classification list.

Air-Conditioning System Selection

As described in Section 9.1, the goal of an air-conditioning or HVAC&R system is to provide a healthy, comfortable, manufacturable indoor environment at acceptable indoor air quality, keeping the system

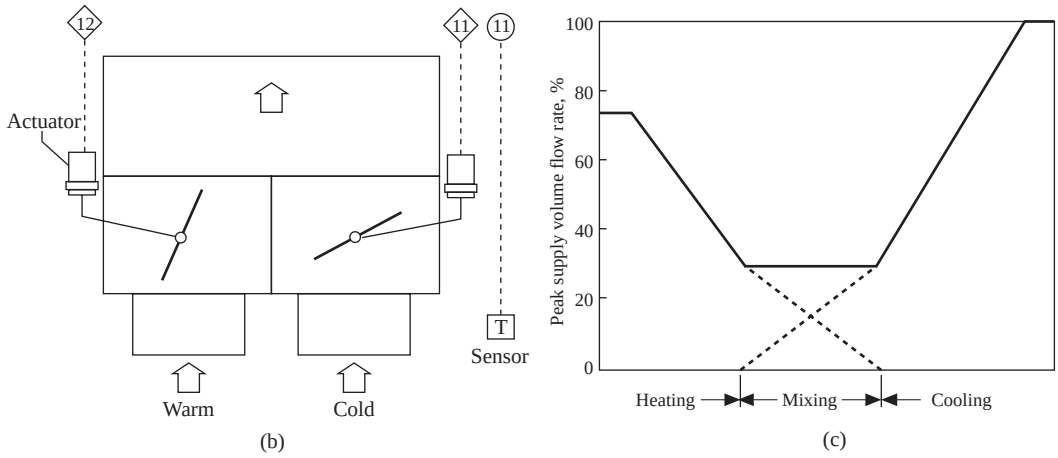

FIGURE 9.15.5 A dual-duct VAV central system: (b) mixing VAV box and (c) volume flow-operating mode diagram.

energy efficient. Various occupancies have their own requirements for their indoor environment. The basic considerations to select an air-conditioning system include:

1. The selection of an air-conditioning system must satisfy the required space temperature, relative humidity, air cleanliness, sound level, and pressurization. For a Class 100 clean room, a single-zone CV clean room system is always selected. A four-pipe fan-coil space conditioning system is usually considered suitable for guest rooms in hotels for operative convenience, better privacy, and a guaranteed outdoor ventilation air system. A concert hall needs a very quiet single-zone VAV central system for its main hall and balcony.
2. The size of the project has a considerable influence on the selection. For a small-size residential air-conditioning system, a single-zone constant-volume packaged system is often the first choice.
3. Energy-efficient measures are specified by local codes. Comparison of alternatives by annual energy-use computer programs for medium and large projects is often necessary. Selection of energy source includes electricity or gas, and also using electrical energy at off-peak hours, like thermal storage systems is important to achieve minimum energy cost.

   For a building whose sound level requirement is not critical and conditioned space is comprised of both perimeter and interior zones, a WSHP system incorporating heat recovery is especially suitable for energy saving.
4. First cost or investment is another critical factor that often determines the selection.
5. Selection of an air-conditioning system is the result of synthetical assessment. It is difficult to combine the effect of comfort, reliability, safety, and cost. Experience and detailed computer program comparisons are both important.

The selection procedure usually begins whether an individual, space conditioning, packaged, central system, or CV, VAV, VAV reheat, fan-powered VAV, dual-duct VAV, or thermal storage system is selected. Then the air, refrigeration, heating, and control subsystems will be determined. After that, choose the option, the feature, the construction, etc. in each subsystem.

Comparison of Various Systems

The sequential order of system performance — excellent, very good, good, satisfactory — regarding temperature and relative humidity control (T&HC), outdoor ventilation air (OA), sound level, energy use, first cost, and maintenance for individual, space conditioning (SC), packaged, and central systems is as follows:

© 1999 by CRC Press LLC

	Excellent (low or less)	Very good	Good	Satisfactory
T&HC	Central	Packaged	Space	Individual
IAQ	Space	Central	Packaged	Individual
Sound	Central	Packaged	Space	Individual
Energy use	Individual	Space	Packaged	Central
First cost	Individual	Packaged	Space	Central
Maintenance	Central	Packaged	Space	Individual

Among the packaged and central systems, VAV cooling systems are used only for interior zones. VAV reheat, fan-powered VAV, and dual-duct VAV central systems are all for perimeter zones. VAV reheat systems are simple and effective, but have a certain degree of simultaneous cooling and heating when their volume flow has been reduced to minimum setting. Fan-powered VAV systems have the function of mixing cold primary air with ceiling plenum air. They are widely used in ice-storage systems with cold air distribution. Fan-powered VAV is also helpful to create a greater air movement at minimum cold primary air flow. Dual-duct VAV systems are effective and more flexible in operation. They are also more complicated and expensive.

Subsystems

Air Systems

The economical size of an air system is often 10,000 to 25,000 cfm. A very large air system always has higher duct pressure loss and is more difficult to balance. For highrise buildings of four stories and higher, floor-by-floor AHU(s) or PU(s) (one or more AHU or PU per floor) are often adopted. Such an arrangement is beneficial for the balance of supply and return volume flow in VAV systems and also for fire protection. A fan-powered VAV system using a riser to supply less cold primary to the fan-powered VAV box at various floors may have a larger air system. Its risers can be used as supply and exhaust ducts for a smoke-control system during a building fire.

In air systems, constant-volume systems are widely used in small systems or to dilute air contaminants in health care facilities and manufacturing applications. VAV systems save fan energy and have better operating characteristics. They are widely used in commercial buildings and in many factories.

Refrigeration Systems

For comfort air-conditioning systems, the amounts of required cooling capacity and energy saving are dominant factors in the selection of the refrigeration system. For packaged systems having cooling capacity less than 100 tons, reciprocating and scroll vapor compression systems with air-cooled condensers are most widely used. Evaporative-cooled condensers are available in many packaged units manufactured for their lower energy use. Scroll compressors are gradually replacing the reciprocating compressors for their simple construction and energy saving. For chillers of cooling capacity of 100 tons and greater, centrifugal chillers are still most widely used for effective operation, reliability, and energy efficiency. Screw chillers have become more popular in many applications, especially for ice-storage systems.

Heating Systems

For locations where there is a cold and long winter, a perimeter baseboard hot water heating system or dual-duct VAV systems are often a suitable choice. For perimeter zones in locations where winter is mild, winter heating is often provided by using warm air supply from AHU or PU from terminals with electric or hot water heaters. Direct-fired furnace warm air supply may be used for morning warm-up. For interior or conditioned zones, a cold air supply during occupied periods in winter and a warm air supply from the PUs or AHUs during morning warm-up period is often used.

© 1999 by CRC Press LLC

Control Systems

Today, DDC microprocessor-based control with open data communication protocol is often the choice for medium- and large-size HVAC&R projects. For each of the air, cooling, and heating systems, carefully select the required generic and specific control systems. If a simple control system and a more complicated control system can provide the same required results, the simple one is always the choice.

Energy Conservation Recommendations

1. Turn off electric lights, personal computers, and office appliances when they are not needed. Shut down AHUs, PUs, fan coils, VAV boxes, compressors, fans, and pumps when the space or zone they serve is not occupied or working.
2. Provide optimum start and stop for the AHUs and PUs and terminals daily.
3. Temperature set point should be at its optimum value. For comfort systems, provide a dead band between summer and winter mode operation. Temperature of discharged air from the AHU or PU and chilled water leaving the chiller should be reset according to space or outdoor temperature or the system load.
4. Reduce air leakages from ducts and dampers. Reduce the number of duct fittings and pipe fittings and their pressure loss along the design path if this does not affect the effectiveness of the duct system. The maximum design velocity in ducts for comfort systems should not exceed 3000 fpm, except that a still higher velocity is extremely necessary.
5. Adopt first the energy-efficient cooling methods: air and water economizer, evaporative cooler, or ground water instead of refrigeration.
6. Use cost-effective high-efficiency compressors, fans, pumps, and motors as well as evaporative-cooled condensers in PUs. Use adjustable-frequency fan speed modulation for large centrifugal fans. Equipment should be properly sized. Over-sized equipment will not be energy efficient.
7. Use heat recovery systems and waste heat for winter heating or reheating. Use a heat-pump system whenever its COP_{hp} is greater than 1.
8. For medium- and large-size air-conditioning systems, use VAV systems instead of CV systems except for health care or applications where dilution of air contaminant is needed. Use variable flow for building-loop and distribution-loop water systems.
9. Use double- and triple-pane windows with low emissive coatings. Construct low U-value roofs and external walls.

9.16 Desiccant Dehumidification and Air-Conditioning

Zalman Lavan

Introduction

Desiccant air-conditioning is a promising emerging technology to supplement electrically driven vapor compression systems that rely almost exclusively on R22 refrigerant that causes depletion of the ozone layer. To date, this technology has only a limited market, e.g., in supermarkets where the latent heat loads are very high, in specialized manufacturing facilities that require very dry air, and in hospitals where maximum clean air is required. However, recent emphasis on increased air change requirements (see ASHRAE standards, ANSI 62-1989), improved indoor air quality, and restriction on use of CFC refrigerants (see The Montreal Protocol Agreement, as amended in Copenhagen in 1992, United Nations Environmental Programme, 1992) may stimulate wider penetration of desiccant-based air-conditioning which can be used as stand-alone systems or in combination with conventional systems. (See Table 9.4.1 for properties of some refrigerants.)

Sorbents and Desiccants

Sorbents are materials which attract and hold certain vapor or liquid substances. The process is referred to **absorption** if a chemical change takes place and as **adsorption** if no chemical change occurs. **Desiccants**, in both liquid and solid forms, are a subset of sorbents that have a high affinity to water molecules. Liquid desiccants *absorb* water molecules, while solid desiccants *adsorb* water molecules and hold them on their vast surfaces (specific surface areas are typically hundreds of square meters per gram).

While desiccants can sorb water in both liquid and vapor forms, the present discussion is limited to **sorption** of water vapor from adjacent air streams. The sorption driving force for both liquid and solid desiccants is a vapor pressure gradient. Adsorption (in solid desiccants) and absorption (in liquid desiccants) occur when the water vapor partial pressure of the surrounding air is larger than that at the desiccant surface. When an air stream is brought in contact with a desiccant, water vapor from the air is attracted by the desiccant, the air is **dehumidified**, and the water content of the desiccant rises. As the water sorbed by the desiccant increases, the sorption rate decreases and finally stops when *sorption equilibrium* is reached. For dehumidification to be resumed, water must be removed from the desiccant by heating. This process is referred to as **desorption**, **reactivation**, or **regeneration**. The heat of sorption (or desorption) is generally higher than the latent heat of vaporization of water; it approaches the latter as sorption equilibrium is reached.

Some typical *liquid desiccants* are water solutions of calcium chloride (CaCl), lithium chloride (LiCl), lithium bromide (LiBr), and triethylene glycol. The equilibrium water vapor pressure at the solution surface as a function of temperature and water content is shown in Figure 9.16.1 for water-lithium chloride solution. The surface vapor pressure (and dew point) increases with increasing solution temperature and decreases with increasing moisture content.

Common *solid desiccants* are silica gel, molecular sieves (zeolites), activated alumina, and activated carbon. The equilibrium sorption capacity (or moisture content) at a constant temperature, referred to as an **isotherm**, is usually presented as percent water (mass of water divided by mass of dry desiccant) vs. percent relative humidity (vapor pressure divided by saturation vapor pressure). Sorption capacity decreases with increasing temperature, but the spread of isotherms is relatively small (especially for concave down isotherms). Figure 9.16.2 shows normalized loading (sorption capacity divided by sorption capacity at 100% relative humidity) vs. relative humidity for silica gel, molecular sieve, and a generic desiccant, type 1 (modified) or simply 1-M (Collier et al., 1986).

Dehumidification

Dehumidification by vapor compression systems is accomplished by cooling the air below the dew point and then reheating it. The performance is greatly hindered when the desired outlet dew point is below 40°F due to frost formation on the cooling coils (*ASHRAE, Systems and Equipment Handbook*, 1992).

Desiccant dehumidification is accomplished by direct exchange of water vapor between an air stream and a desiccant material due to water vapor pressure difference. Figure 9.16.3 shows the cyclic operation of a desiccant dehumidification system.

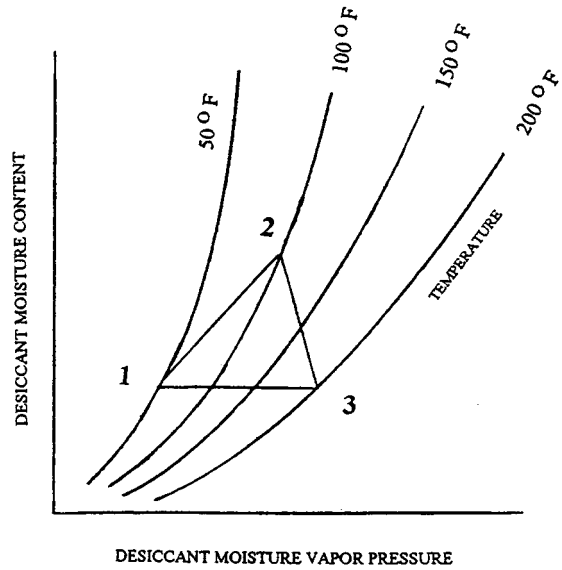

FIGURE 9.16.3 Cyclic dehumidification processes.

In *sorption (1–2)*, dry and cold desiccant (point 1) sorbs moisture since the vapor pressure at the surface is lower than that of the air stream. During this process the moisture content (loading or uptake) increases, the surface vapor pressure increases, and the liberated heat of sorption raises the desiccant temperature. During *desorption (2–3)*, the desiccant is subjected to a hot air stream, and moisture is removed and transferred to the surrounding air. The surface vapor pressure is increased and the desiccant temperature rises due to the added heat. The cycle is closed by *cooling (3–1)*. The desiccant is cooled while its moisture content is constant and the surface vapor pressure is lowered. The above cycle of sorption, desorption, and cooling can be modified by combining the sorption process with cooling to approach isothermal rather than adiabatic sorption.

Desirable Characteristics for High-Performance Liquid and Solid Desiccant Dehumidifiers

High equilibrium moisture sorption capacity
High heat and mass transfer rates
Low heat input for regeneration
Low pressure drop
Large contact transfer surface area per unit volume
Compatible desiccant/contact materials
Inexpensive materials and manufacturing techniques
Minimum deterioration and maintenance

Additional Requirements for Liquid Desiccant Dehumidifiers

Small liquid side resistance to moisture diffusion

© 1999 by CRC Press LLC

Minimum crystallization

Additional Requirements for Solid Desiccant Dehumidifiers

The desiccant should not deliquesce even at 100% relative humidity.
The airflow channels should be uniform.
The desiccant should be bonded well to the matrix.
The material should not be carciogenic or combustible.

Liquid Spray Tower

Figure 9.16.4 is a schematic of a liquid spray tower. A desiccant solution from the sump is continuously sprayed downward in the absorber, while air, the process stream, moves upward. The air is dehumidified and the desiccant solution absorbs moisture and is weakened. In order to maintain the desired solution concentration, a fraction of the solution from the sump is passed through the regenerator, where it is heated by the heating coil and gives up moisture to the desorbing air stream. The strong, concentrated solution is then returned to the sump. The heat liberated in the absorber during dehumidification is removed by the cooling coil to facilitate continuous absorption (see Figures 9.16.1 and 9.16.3). The process air stream exits at a relatively low temperature. If sufficiently low water temperature is available (an underground well, for example), the process stream could provide both sensible and latent cooling.

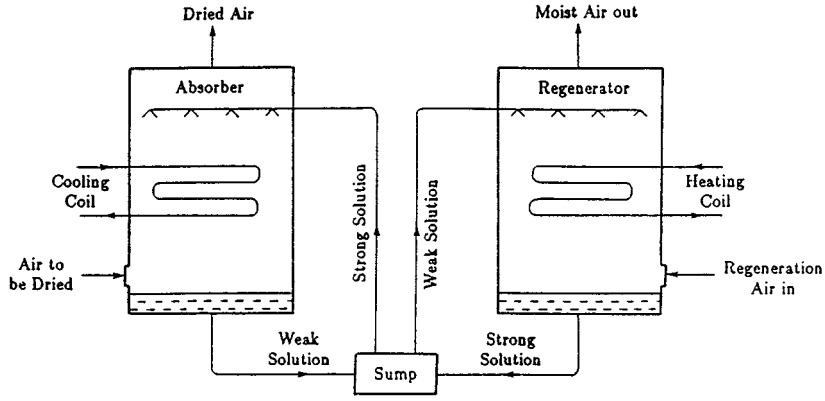

FIGURE 9.16.4 Liquid desiccant dehumidifier with heating and cooling coils.

The heating and cooling coils, shown in Figure 9.16.4, are often eliminated and the liquid solutions are passed through heating and cooling heat exchangers before entering the spray towers.

Advantages

The system is controlled to deliver the desired level of dry air by adjusting the solution concentration.

Uniform exit process stream conditions can be maintained.
A concentrated solution can be economically stored for subsequent drying use.
The system can serve as a humidifier when required by simply weakening the solution.
When used in conjunction with conventional A/C systems, humidity control is improved and energy is conserved.

Disadvantages

Some desiccants are corrosive.
Response time is relatively large.
Maintenance can be extensive.
Crystallization may be a problem.

© 1999 by CRC Press LLC

Solid Packed Tower

The dehumidification system, shown in Figure 9.16.5, consists of two side-by-side cylindrical containers filled with solid desiccant and a heat exchanger acting as a desiccant cooler. The air stream to be processed is passed through dry desiccant in one of the containers, while a heated air stream is passed over the moist desiccant in the other. Adsorption (1–2) takes place in the first container, desorption (2–3) in the other container, and cooling (3–1) occurs in the desiccant cooler. The function of the two containers is periodically switched by redirecting the two air streams.

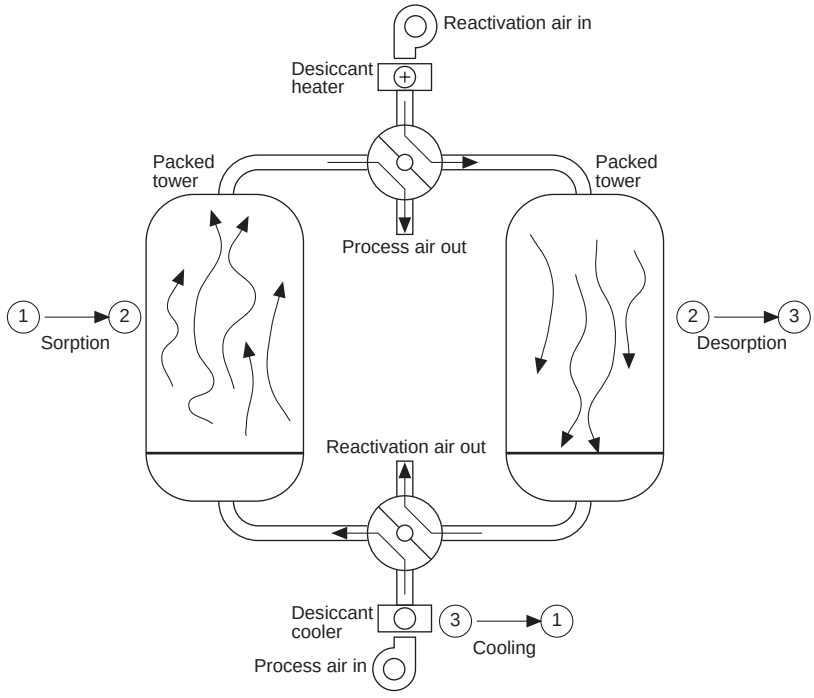

FIGURE 9.16.5 Solid packed tower dehumidification.

Advantages

No corrosion or crystallization
Low maintenance
Very low dew point can be achieved

Disadvantages

The air flow velocity must be low in order to maintain uniform velocity through the containers and to avoid dusting.
Uniform exit process stream dew point cannot be maintained due to changing moisture content in the adsorbing desiccant.

Rotary Desiccant Dehumidifiers

A typical rotary solid desiccant dehumidifier is shown in Figure 9.16.6. Unlike the intermittent operation of packed towers, rotary desiccant dehumidifiers use a wheel (or drum) that rotates continuously and delivers air at constant humidity levels.

© 1999 by CRC Press LLC

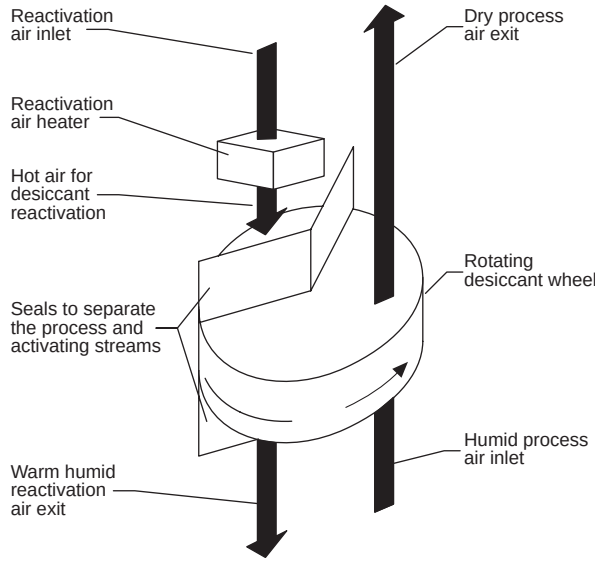

FIGURE 9.16.6 Rotary desiccant dehumidification wheel.

Desiccant wheels typically consist of very fine desiccant particles dispersed and impregnated with a fibrous or ceramic medium shaped like a honeycomb or fluted corrugated paper. The wheel is divided into two segments. The process stream flows through the channels in one segment, while the regenerating (or reactivating) stream flows through the other segment.

Desiccant Material

The desired desiccant properties for optimum dehumidification performance are a suitable isotherm shape and a large moisture sorption capacity. The isotherms of silica gel are almost linear. The moisture sorption capacity is high; the desiccant is reactivated at relatively low temperatures and is suitable for moderate dehumidification. Molecular sieves have very steep isotherms at low relative humidity. The desiccant is reactivated at relatively high temperatures and is used for deep dehumidification. The isotherm of the type 1-M yields optimum dehumidification performance (Collier et al., 1986), especially when used in conjunction with high regeneration temperatures.

The Desiccant Wheel

Some considerations for selection of desiccant wheels are:

Appropriate desiccant materials
Large desiccant content
Wheel depth and flute size (for large contact surface area and low pressure drop)
Size and cost

The actual performance depends on several additional factors that must be addressed. These include:

Inlet process air temperature and humidity
Desired exit process air humidity
Inlet reactivating air temperature and humidity
Face velocity of the two air streams
Size of reactivation segment

© 1999 by CRC Press LLC

It should be noted that:

Higher inlet process air humidity results in higher exit humidity and temperature (more heat of sorption is released).
Lower face velocity of the process stream results in lower exit humidity and higher temperature.
Higher regeneration temperatures result in deeper drying, hence lower exit process air humidity and higher temperature.
When lower exit air temperature is required, the exit process air should be cooled by a heat exchanger.
Final cooling of the exit process air can be achieved by partial humidification (this counteracts in part previous dehumidification).

The following is a range of typical parameters for rotary desiccant wheels:

Rotation speed: 4 to 10 rpm
Desiccant fraction: 70 to 80%
Flute size: 1 to 2 mm
Reactivation segment: 25 to 30% of wheel
Face velocity: 300 to 700 fpm
Reactivating temperature: 100 to 300°F

Hybrid Cycles

A limited number of hybrid systems consisting of desiccant dehumidifiers and electrically driven vapor compression air-conditioners are presently in use in supermarkets. This application is uniquely suited for this purpose since the latent heat loads are high due to the large number of people and frequent traffic through doors. Also, low relative humidity air is advantageous for open-case displays.

Vapor compression systems are inefficient below a dew point of 45 to 50°F. When used in supermarkets, they require high airflow rates, the air must be reheated for comfort, and the evaporator coils must be defrosted frequently. Hybrid systems offer improved performance and lower energy cost in these cases.

Figure 9.16.7 shows a typical hybrid air-conditioning system for supermarkets. A mixture of outdoor and recirculated air is first passed through the desiccant and sensible heat exchanger wheels, where it is dehumidified and precooled. It then enters the conventional chiller before it is introduced to the interior of the supermarket. The sensible heat exchanger wheel is cooled by outdoor air and the desiccant wheel is regenerated by air heated with natural gas. Energy cost can be further reduced by preheating the reactivating air stream with waste heat rejected from the condenser of the refrigeration and/or air-conditioning systems.

The advantages of these hybrid systems are

Air-conditioning requirement is reduced by up to 20%.
The vapor compression system operates at a higher coefficient of performance (COP) since the evaporator coils are at a higher temperature.
Airflow requirements are reduced; electric fan energy is saved and duct sizes are reduced.
The refrigeration cases run more efficiently since the frequency of defrost cycles is greatly reduced.

Solid Desiccant Air-Conditioning

Several stand-alone desiccant air-conditioning systems were suggested and extensively studied. These systems consist of a desiccant wheel, a sensible heat exchanger wheel, and evaporating pads. Sorption can be adiabatic or cooled (if cooling is combined with sorption). When room air is dehumidified and recirculated, the system is said to operate in the **recirculating** mode. When 100% outside air is used as the process stream, the system operates in the **ventilating mode**.

© 1999 by CRC Press LLC

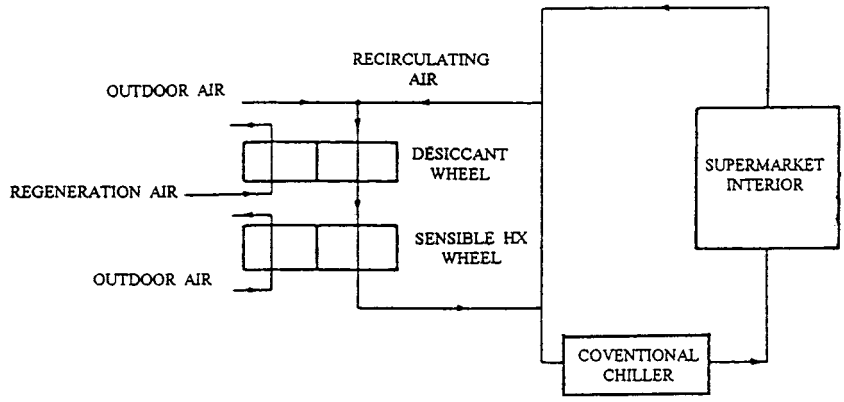

FIGURE 9.16.7 Hybrid air-conditioning system for supermarkets.

Ventilation Mode

In the *adsorption path* the process air stream drawn from the outdoors is passed through the dry section of the desiccant wheel where it is dehumidified and heated by the liberated heat of sorption. It then passes through the sensible heat exchanger wheel and exits as dry but slightly warm air. The hot and dry air leaving the dehumidifier enters the heat exchanger, where it is sensibly cooled down to near room temperature. It is then passed through the evaporative cooler, where it is further cooled and slightly humidified as it enters the conditioned space.

In the *desorption path*, air is drawn from the conditioned space; it is humidified (and thus cooled) in the evaporative cooler. The air stream enters the sensible heat exchanger, where it is preheated, and it is then heated to the desired regeneration temperature by a suitable heat source (natural gas, waste heat, or solar energy), passed through the desiccant wheel (regenerating the desiccant material), and discharged out of doors.

Performance. In order to achieve high performance, the maximum moisture content of the desiccant should be high and the isotherm should have the optimum shape (1 M). In addition, Zheng et al. (1993) showed that the optimum performance is very sensitive to the rotational speed of the desiccant wheel. Glav (1966) introduced stage regeneration. He showed that performance is improved when the reactivation segment of the wheel is at a temperature which increases in the direction of rotation. Collier (Collier et al., 1986) showed that well-designed open-cycle desiccant cooling systems can have a thermal COP of 1.3. This, however, would require the use of high-effectiveness sensible heat exchangers, which would be large and expensive. Smaller and more affordable heat exchangers should yield system COPs in the order of unity. An extensive review of the state-of-the-art assessment of desiccant cooling is given by Pesaran et al. (1992).

Conclusions

Desiccant-based air-conditioning offers significant advantages over conventional systems. Desiccant systems are already successfully used in some supermarkets. It is expected that these systems will gradually attain wider market penetration due to environmental requirements and potential energy savings.

The advantages of desiccant air-conditioning are summarized below:

No CFC refrigerants are used.
Indoor air quality is improved.
Large latent heat loads and dry air requirements are conveniently handled.
Individual control of temperature and humidity is possible.

© 1999 by CRC Press LLC

The energy source may be natural gas and/or waste heat.
Less circulated air is required.
Summer electric peak is reduced.

Defining Terms

Absorb, absorption: When a chemical change takes place during sorption.
Adsorb, adsorption: When no chemical change occurs during sorption.
Dehumidification: Process of removing water vapor from air.
Desiccant: A subset of sorbents that has a particular affinity to water.
Desorb, desorption: Process of removing the sorbed material from the sorbent.
Isotherm: Sorbed material vs. relative humidity at a constant temperature.
Reactivation: Process of removing the sorbed material from the sorbent.
Recirculation: Indoor air only is continuously processed.
Regeneration: Process of removing the sorbed material from the sorbent.
Sorbent: A material that attracts and holds other gases or liquids.
Sorption: Binding of one substance to another.
Staged regeneration: When the temperature of the regeneration segment of the desiccant wheel is not uniform.
Ventilation mode: 100% of outdoor air is processed.

Electronic packaging is the art and science of connecting circuitry to reliably perform some desired function in some application environment. Packaging also provides ease of handling and protection for assembly operations. This chapter defines chip, or die-level, and assembly-level packaging, with an emphasis on recent technologies. The relative advantages of each technology will be discussed in relation to performance, cost, reliability, and manufacturability. Extensive details on electronic packaging can be found in the references.[1–6]

10A.1.1 Packaging the Die

A semiconductor device, also known as a *die* or *chip*, is fragile and must be packaged for protection and for interfacing with the outside world. The chip package provides an electrical interconnection to the assembly, module, or display and protects the chip in the manufacturing and application environments. A number of different materials can be used in the die package, including ceramics, plastics, and metals. Single-chip, three-dimensional, and multichip module (MCM) packages are some of the packaging formats. Interconnection is the process and technique of making electrical connections between the bond pads of the chip and a leadframe, substrate, or even another chip.

Plastic Die Package

Plastic packages are very popular in commercial applications because of their low cost and small size compared to ceramic packages. The cost of plastic packages is typically one half to one tenth the cost of comparable ceramic or metal packages. More than 98% of all integrated circuits were packaged in plastic in 1992. In a plastic package, the chip is encapsulated by a polymer, usually referred to as the *encapsulant*. An encapsulant is generally an electrically insulating material formulation that protects an electronic device and die-leadframe assembly from the adverse effects of handling, storage, and operation.

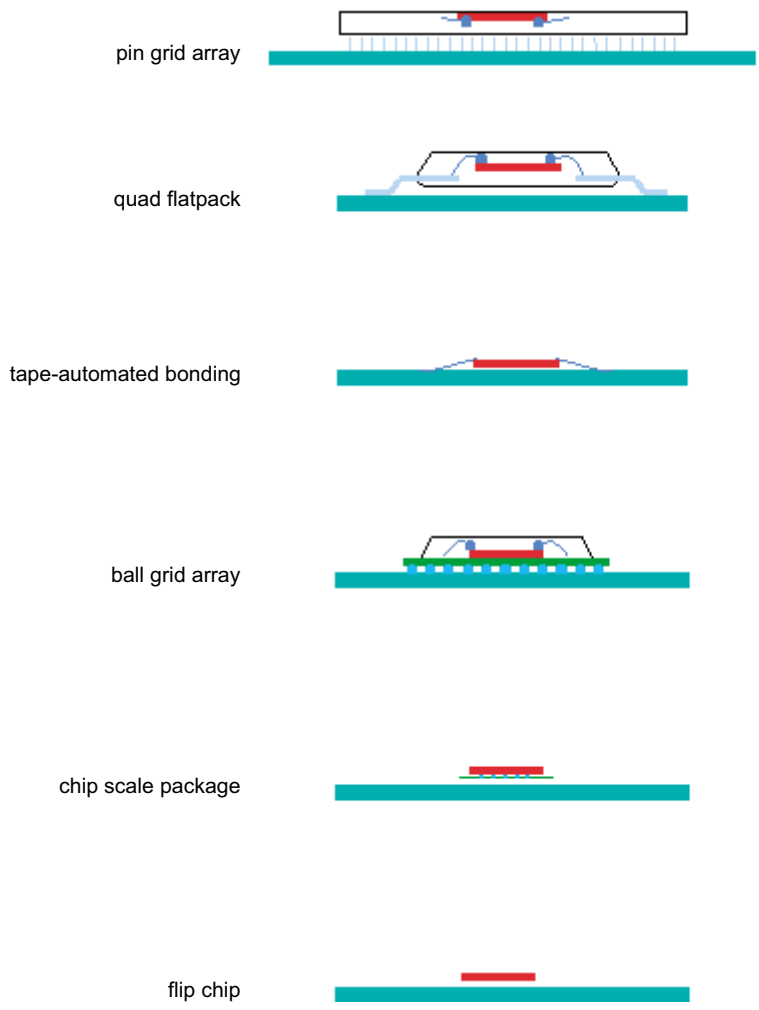

FIGURE 10A.1.1 Shrinking size of packaging.

Figure 10A.1.1 depicts the evolution of packaging shrinkage through the last three decades. Packaging size is being pressed by the shrinking feature size (approximately 15% per year) of CMOS integrated circuits. Package lead styles have changed dramatically from the 1970s when the dual in-line package (DIP) and pin grid array dominated the semiconductor industry. Even today, the DIP retains a sizable share of the market in which low-cost, rugged packaging meets the application need. Generally, there are at least three major lead types, with numerous variations of each: the through-hole, the surface-mount (J- or gull-lead), and the solder ball. The through-hole and leaded surface-mount packages usually have a leadframe to which the die is mounted. The plastic solder ball packages typically employ organic substrates that redistribute the die inputs-outputs (I/O) to an array or perimeter pattern of solder balls. (Substrate technologies are addressed in Section 10A.1.2.)

In the late 1980s, 1.27-mm pitch, surface-mount technology became prominent. As device complexity increased, the I/O count also increased. To keep electrical performance and package sizes reasonable, the lead pitch decreased, and fine-pitch leaded devices (lead pitch of less than or equal to 0.65 mm) were introduced.

Array packaging was first introduced in the mid-1970s with ceramic pin grid array packages. Surface-mount array packages evolved to plastic ball grid array (PBGA) and chip-scale packages (CSP). Solder

spheres — usually composed of 63% tin and 37% lead, 62/36/2 (% silver), or high-temperature 10/90 — form the connection between the package and the board.

The chip-scale package is typically defined as being not more than 20% larger than the die. The CSP interposer buffers the final assembly from die-shrink redesign. The interposer can be organic substrate, tape-automated bonded (TAB), or ceramic substrate. The interposer can also act as a stress buffer between the low thermal expansion of the semiconductor die and the higher expansion of the substrate. Tessera (San Jose, CA) adds a patented elastomer between the die and the interposer to further buffer the solder balls. While the majority of CSP used today have solder-ball interconnects, there are non-solder-ball variations that meet the CSP definition, such as the small-outline, no-lead (SON) and bottom-leaded plastic packages (BLP).

The coplanarity of surface-mount parts is an important mechanical parameter in assembly. Non-planar parts can lead to poor assembly yields (voids, electrical opens) and unreliable connections (misregistration). Table 10A.1.1 outlines typical coplanarity requirements.

Encapsulation techniques include molding, potting, glob-topping, and conformal coating, but the majority of encapsulated packages use the molding process. The molding compound is a proprietary multicomponent mixture of an encapsulating resin with various types of additives. The principal active and passive (inert) components in a molding compound include curing agents or hardeners, accelerators, inert fillers, coupling agents, flame retardants, stress-relief additives, coloring agents, and mold-release agents. Molding compounds have moved steadily toward all-epoxy systems.

Thermosetting encapsulation compounds are based on epoxy resins. In electrical and electronic applications, three types of epoxy resins are commonly used: the diglycidyl ethers of bisphenol A (DGEBA) or bisphenol F (DGEBF), the phenolic and cresol novolacs, and the cycloaliphatic epoxides. Novolac-based epoxies are supplied as molding bricks (preforms) that are ready for use in transfer-molding machines to produce single-in-line packages, dual-in-line packages, plastic leaded chip carriers, quad flatpacks, various types of small-outline integrated circuits (SOIC), and ball grid array packages.

Pin grid array carriers, some ball grid array packages, and carriers with metal cans frequently use multicomponent liquid epoxies or preforms. Flip chips mounted on organic substrates also use liquid epoxy underfills to protect the die surface environmentally as well as to provide stress relief to the solder balls. Polyurethanes, polyamides, and polyesters are used to encase modules and hybrids intended for use under low-temperature and high-humidity conditions. Modified polyimide encapsulants have the advantages of thermal and moisture stability, low coefficient of thermal expansion, and high material purity. Thermoplastics are rarely used because they generally require processing conditions of unacceptably high temperature and pressure, are low-purity materials, and can induce high moisture-induced stresses.

Several molding techniques (Table 10A.1.2) are available for the manufacture of plastic cases. The most widely used manufacturing process is the transfer molding process, used for molding thermosetting polymers. These polymers are plastic or fluid at low temperatures but, when heated, react irreversibly to

Reaction-injection molding	Energy efficiency Low mold pressure Good wetting of chip surface Adaptability to TAB	Few resin systems available for electronic packaging Requires good mixing

form a cross-linked network no longer capable of being melted. Other processes include the injection molding process and the reaction-injection molding process.

Hermetic (Metal and Ceramic) Packages

Hermetic packages have been used predominantly for military and government applications because of their perceived reliability advantage over plastic packages. They have also been employed in some high-power applications when heat must be dissipated from the device. Metal packages are typically used for small integrated circuits with a low lead count and in applications that require electromagnetic shielding.

Both metal and ceramic packages can be made nearly impervious to moisture when hermetically sealed. A package is classified as hermetic if it has a minimal leak rate (the rate at which gases can diffuse into or out of the package). Typical acceptable helium leak rates depend on the package size and helium pressure in the package. Some metal packages (e.g., Olin Metal quad flatpacks) are sealed using epoxies and, therefore, are not hermetic.

Several major semiconductor companies (Intel, Motorola, and AMD) have announced their exit from military markets, and the availability of these packages is shrinking dramatically. Plastic components are finding their way into many applications that had once been dominated by hermetic packages.

Interconnection Technologies at the First Level of Packaging

The major interconnection technologies at the first level of packaging are wirebonding, flip chip, and TAB. Wirebonding, the mainstay of the microelectronics industry, still accounts for more than 98% of all semiconductor interconnections. Invented more than 30 years ago, flip chip was once available only to large, vertically integrated companies. Now, contract sources of wafer bumping are available, making flip chip one of the fastest growing interconnect methods. Tape-automated bonding (TAB) techniques are mature, although they are utilized only in limited, specialized applications because of high tooling costs. Chip stacking or three-dimensional (3-D) interconnection is typically used in systems where size, weight, and speed are critical. Comparisons of these technologies are provided in Tables 10A.1.3 and 10A.1.4.

Wirebond Interconnects

Wirebond interconnects are formed by metallurgically bonding a small-diameter wire from the semiconductor device to the leadframe, substrate, or other semiconductor. The wirebond forms a low-resistance path for signal propagation. Typical wire materials include aluminum, gold, and copper. Gold is usually bonded by thermocompression, while aluminum is usually bonded ultrasonically.

Common materials for pads on bondable surfaces include aluminum, gold, silver, nickel, and copper. Aluminum and gold are the most frequently used bondpad materials. Silver has been used as a bondable plating material on leadframes and as a bondable thick-film metallization in alloy form with platinum

TABLE A10.1.4 Relative Advantages of Interconnect Technologies

	Advantages	Disadvantages
Wirebond	Low resistance interconnects Low capital investment Mature technology Highly stable manufacturing process	Potential for cross-talk High lead inductance Use of costly, precious metal wire Low interconnect density Limited chip size
Flip chip	Self-alignment during die joining Automatic die placement and testing Low lead inductance Less need for precious metals Simultaneous bonding	Potential for solder fatigue Thermal dissipation concerns
TAB	Lightweight packaging Small size/high I/O-count Simultaneous bonding	High capital investment
HDI	Power and signal distribution High frequency performance High clock-rate performance High wiring densities High device-to-substrate area ratio	Process not fully mature High cost of deposited HDI
3-D	Increased package density Better board utilization Increased electrical performance Shorter interchip connections Lower system power	Potential for cross-talk Thermal dissipation concerns Poor yields Process not fully mature

or palladium.[8] Nickel has been widely used as a substitute for gold in power devices. In addition, nickel or chromium serve as barrier layers to avoid unwanted intermetallic compounds and to facilitate adhesion.

Thermocompression and thermosonic bonds are typically used to produce a ball bond on the first bond and a wedge bond on the second. Thermocompression is used on gold and in plastic packages to prevent wire sweep. Thermocompression bonds occur when two metal surfaces are brought into intimate contact through a controlled time, temperature, and pressure cycle. Typical bonding temperatures during thermocompression bonding range from 300 to 400°C. Heat is generated during the manufacturing process, either by a heated pedestal on which the assembly is placed for bonding or by a heated capillary feeding the wire. Typically, bonding time is in the neighborhood of 40 ms, which translates to a machine speed of approximately two wires per second.

Thermosonic bonding combines ultrasonic energy with the ball-bonding capillary technique of thermocompression bonding. The processes are similar, but in thermosonic bonding the capillary is not heated and substrate temperatures are maintained between 100 and 150°C. Ultrasonic bursts of energy make the bond. Typically, at the second bond, the capillary leaves a characteristic circular pattern called a *crescent bond*. The bonding time is usually about 20 ms, or a machine speed of ten wires per second, for ball bonding and three wires per second for wedge bonding.

Ultrasonic bonding is a low-temperature process in which the source of energy for the metal welding is a transducer vibrating the bonding tool parallel to the bonding pad in a frequency range from 20 to 60 kHz. Ultrasonic bonding uses aluminum wire in ceramic/metal packages. Ultrasonic processes are used for wedge-wedge bonds, for which a common centerline and careful alignment during manufacture are critical to avoid large stresses and irregular deformation. Normally, the first bond is made to the die and the second to the substrate. Referred to as *forward bonding*, this is the preferred bonding procedure because it is less susceptible to edge shorts between the die and the wire. Typical bonding time for

© 2001 by CRC Press LLC

ultrasonic bonding is about 20 ms, which translates to a machine speed of four wires per second. A disadvantage of wedge bonding over ball bonding is the necessity of maintaining the directional first-to-second alignment by rotating and aligning the die and substrate with the direction of the wire. Rotation is difficult in large MCMs (>7 cm on the side), as most equipment was designed for much smaller integrated circuit (IC) bonding. Thus, while ultrasonic bonding has the advantage of small bond pitch, the overall speed of the process is less than that for thermosonic bonds, due to machine rotational movements.

Some quality/infant-mortality failure mechanisms associated with wirebonding include cratering of the die or chip-out due to excessive bond stress on the die. It is important to maintain adequate bonding load and temperature to allow dispersion of contaminants. Cleanliness, proper atmosphere during bonding, and surface finish are also important assembly factors. Long-term failure mechanisms include differential thermal fatigue, electrical leakage, and Kirkendall voids — voids formed by different interdiffusion rates of gold and aluminum. Purple plague is a brittle, gold-aluminum intermetallic formed at high temperatures.

Flip Chip Bonding

Flip chip bonding is an interconnection technique in which the die is connected facedown onto the substrate. Solder bumps on area-array metallized terminals are reflowed to matching footprints of pads on a substrate. Flip chip bonding grew at a rate of about 18% compound annual growth (CAG) between 1991 and 1997. With wafer bumping services readily available, growth from now to the year 2002 is projected at nearly 50% CAG. One of the first products with extensive use of flip chip packaging was a Sony camcorder that contained sixteen flip chip die on chip-scale interposers.[9]

The three major steps involved in manufacturing flip chip bonds are (1) die or wafer bumping, (2) alignment of the die and substrate, and (3) assembly. Flip chip technology has several advantages over wirebonding:

- Self-alignment during die joining, which allows for automatic die placement and testing
- Low lead inductances, due to shorter interconnection lengths than wirebonding
- Reduced need for precious attach metals
- Increased productivity, due to the ability to make large numbers of bonds simultaneously

Evaporating and plating are the major methods of bump formation. Evaporated bumps (125 μm diameter and 100 μm high) can be smaller and more uniform than plated bumps (125–175 μm diameter and 25–100 μm high).

The flip chip assembly of a microelectronic component package is a composite of multiple, thin layers of metals. On the die bond pads, the pad structure is called *ball-limiting metallurgy* (BLM), *pad-limiting metallurgy* (PLM), or *under-bump metallurgy* (UBM). On the substrate bond pads, the connection structure is called *top-surface metallurgy* (TSM). Figure 10A1.2 shows a typical flip chip bond structure.

The BLM structure and solder bump manufacturing, called the *bumping process*, can be implemented using a variety of methods, including metal masking, photolithography, electroplating and ultrasonic soldering, maskless bumping, and copper bumping. Critical properties of the BLM adhesive layer include good electrical contact with the metallization pad on the die, strong adhesion to the pad and to the passivation layer surrounding it, and selective etchability of the metal layer, enabling the use of photolithography techniques during fabrication. The BLM barrier layer must also have good solderability and the capability to prevent interdiffusion between the solder and the pad metallization. Finally, the BLM bonding layer must provide an inert surface during bonding and protect the barrier layer from oxidation during storage.

The barrier layer of the TSM structure is made of a metal that increases wettability and has a surface suitable for solder reflow. The bonding layer uses metals that have the ability to retain wetting properties and provide adequate shelf life prior to die attachment. The melting point is the most important material property when selecting solder materials. High-melting-point solders are selected for die-level

© 2001 by CRC Press LLC

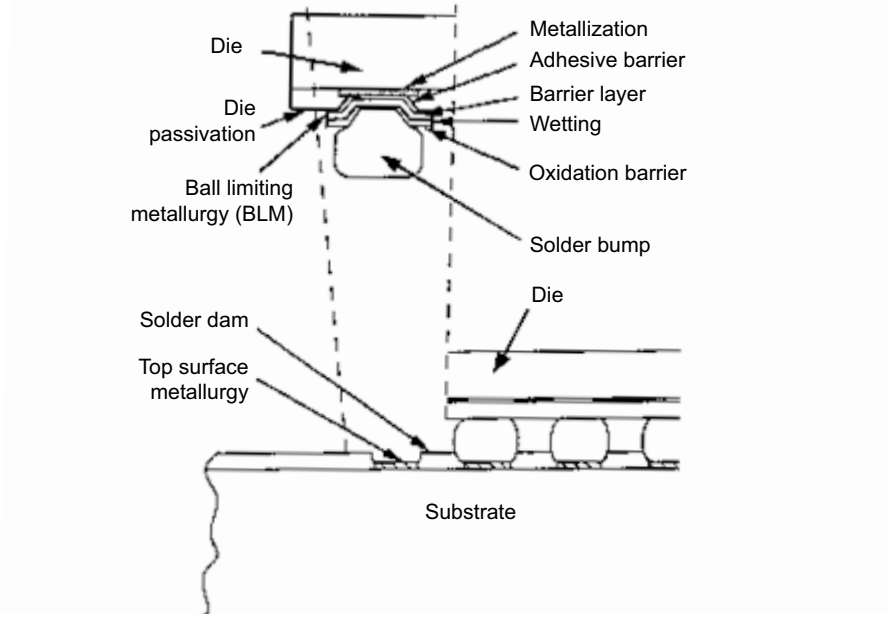

FIGURE 10A.1.2 Flip chip bond structure. (From Pecht, M. et al., *Quality Conformance and Qualification of Microelectronic Packages and Interconnects,* John Wiley & Sons, New York. With permission.)

interconnections to enable lower melting-point solders to be used for the board-level packaging. For example, 95Pb/5Sn solder (melting point around 315°C) is used with alumina ceramic substrates for die connections, while eutectic tin lead solder (melting point around 183°C) is used to attach dies to such organic substrates as Kapton film and glass/epoxy printed wiring boards.

Also important in solder selection is the cyclic strain hardening behavior of the solder, which describes the strain induced in the solder by a given stress condition. This material property strongly influences the thermal fatigue life of the solder. A slow interdiffusion rate that reduces intermetallic formation with the metal layers on the die and the substrate pads is required to enhance the thermal fatigue life of the solder. Intermetallics, though necessary to form a good bond, may reduce the thermal fatigue life if present in excessive quantities because of their brittle nature.

High corrosion resistance is required for solders used in non-hermetic packages to prevent corrosion-related failures. High oxidation resistance is also desirable, as the operational environment in non-hermetic packages accelerates solder oxidation, first on the surface and then in the bulk solder, which can eventually result in solder-die separation. High thermal conductivity is a benefit of metallic solders that allows the heat generated by the die to be dissipated to the substrate via solder bumps.

Tape-Automated Bonding (TAB)

Tape-automated bonding is particularly well suited for volume applications requiring small, lightweight, and high-I/O-count electronic packages. Furthermore, with hybrids and multichip modules, TAB has been used as a means to test and package very large-scale integration dies for a variety of products. (For TAB design guidelines and comparisons with other interconnect technologies, the interested reader is referred to Reference 2.)

The TAB assembly includes bumps, interface metallurgy, leads, lead plating, adhesive, polymeric tape, and encapsulant. In one-layer tape (all metal), the tape is made of metal foil with an etched lead pattern. In multiple-layer tape, the tape assembly consists of metal foil with an etched lead pattern and polymeric tape, with or without adhesive. A TAB assembly can be mounted onto the substrate face-up (conventional), facedown (flip-TAB), or in recessed pockets. Because of the geometry configuration, flip-TAB mounting offers options for either straight or formed leads.

TABLE 10A1.5 Dimensions of Tape-Automated Bonds[11–13]

Element of TAB	Dimensions
Bump	
Square	50–120 μm wide and 10–30 μm high
Truncated sphere	80- to 100-μm diameter and 25 μm high
Interface metallurgy	
Adhesion and barrier layers	0.08–1 μm
Bonding layer	0.1–0.3 μm
Lead	
Thickness	18–70 μm
Inner lead pitch	30–100 μm
Outer lead pitch	50–635 μm
Plating thickness	0.25–2 μm
Polymeric tape	
Width	8–70 mm
Thickness	25–127 μm
Polymeric adhesive thickness	12.7–25.4 μm
Die passivation thickness	1–1.5 μm

Common TAB dimensions are summarized in Table 10A.1.5. The bump configurations in TAB can be classified as bumped die, bumped leads (BTAB), transferred bumps (TTAB), or bumpless. The bumped-die approach requires bumping the die before bonding. One-layer tape typically consists of about 70-μm-thick etched copper foil. Two-layer tape consists of a polymeric film, approximately 50 μm thick, and a patterned metal layer of 20 to 40 μm. Three-layer tape consists of patterned metal, usually as sheets of electro-deposited or rolled copper (typically 35 μm thick), laminated with an adhesive to prepunched polymeric film (typically 125 μm thick). Two-metal-layer tapes with signal and ground planes and three-metal-layer tapes that provide signal, ground, and power planes are being used in some multichip modules.[10]

Ultrasonic bonding is typically used to create the inner-lead bond. The outer-lead bond can be ultrasonically bonded, adhesive bonded, or soldered to the board or substrate. The BTAB approach bonds an unbumped die to bumps on the tips of the inner leads. The TTAB approach bonds an unbumped die to bumps on a separate substrate, which are transferred to the inner leads. The bumpless TAB approach bonds the TAB inner leads directly to an unbumped die.

Tape-automated bonding is capable of accommodating dies with peripheral and area-array I/Os. In an area-array TAB (ATAB), a multilayer metal tape is usually used to provide interconnections between the die bumps and the substrate bonding pads. Area-array TAB increases the number of potential I/Os and improves integrated circuit design flexibility. The common inner lead pitch is 100 μm, with 50 μm wide lines and spacing.

The typical outer-lead pitch ranges from 200 to 625 μm. Tape widths can range from 8 to 70 mm to accommodate various die sizes and I/O counts. Multiple-conductor (multimetal) tapes have been developed to control impedance and reduce cross-talk.[10] An advantage of TAB is the ability to test the components at extremely fine pitches, prior to excision of the part from the tape. This practice prevents lead damage. TAB pitches of less than 50 μm are in production and perform electrically and thermally better than wirebonding.

Some disadvantages of TAB are tooling and nonrecurring costs. Each die design requires a new tape design. This reduces the flexibility to accommodate die shrinks.

Three-Dimensional Die Packaging

Three-dimensional (3-D) packaging and interconnection provide increased electrical performance and packaging density compared to traditional two-dimensional (2-D) approaches. Three-dimensional

© 2001 by CRC Press LLC

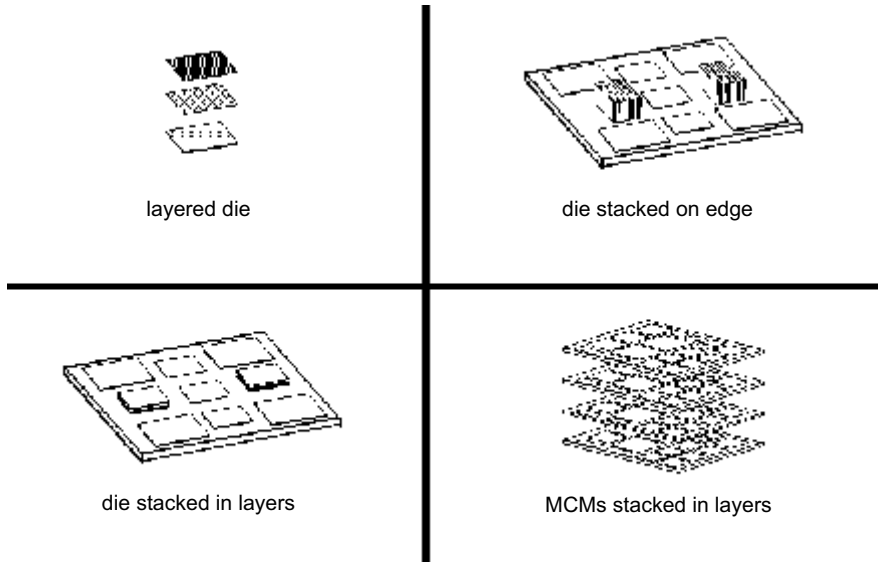

FIGURE 10A.1.3 Types of 3-D packaging. (From Pecht, M. et al., *Quality Conformance and Qualification of Microelectronic Packages and Interconnects,* John Wiley & Sons, New York. With permission.)

packaging and interconnection can increase density by a factor of more than 50 by stacking integrated circuits (ICs). Schematically illustrated in Figure 10A1.3 are four generic types of 3-D packaging: layered dies, dies stacked on edge, dies stacked in layers, and vertically stacked multichip modules.[3]

Cost-effective multiple IC packages have been in high volume production for several years. A polyimide tape interposer is used to mount mirrored memory die. One example of this is a Sharp (Osaka, Japan) device that integrates a static RAM with a flash memory. The result not only enhances access time but also reduces the area to about half of the size of conventional packaging.[14]

Three-dimensional packaging provides increased system performance over shorter interchip connections. Also, potentially lower system power is necessary for physically smaller and fewer drivers. To reduce the package thickness and bond length, the integrated circuits are often thinned. Three-dimensional techniques incorporate many of the manufacturing processes currently used in 2-D production, adapting standard semiconductor processing equipment. Most processing is accomplished simultaneously on multiple die.

The materials used in 3-D and their critical properties are the same as those used in advanced 2-D packaging and interconnection. Common materials found in both 2-D and 3-D structures include polyimides for dielectrics, copper or aluminum for conductors, solders for bonding, and a variety of substrates using alumina, silicon, and aluminum nitride. Common properties of these materials are discussed in the literature.[1,5] Much of the success of 3-D packaging will depend on adhesive technology. Thermosetting adhesives used to bond the dies together in a stack, including polyimides and epoxies, are selected for strength and stability. Thermoplastic adhesives used to bond stacked substrates are selected for compliance and reworkability. In some cases, a hierarchy of adhesives, based on melting or softening temperature, is needed to allow disassembly of the structure; this is unique to 3-D technology.

The manufacturing process for 3-D microelectronic devices depends on the format chosen for the final product. The package elements of layered die include the die themselves, the dielectric between the die, and interconnects. The elements of dies stacked on edge, layered dies, and vertically stacked modules include dies, attachments between dies or modules, wires and wirebonds, and interconnects between dies or modules. The package-to-substrate interconnects are usually solder bumps or pad arrays.

Table 10A1.6 compares the process attributes and interconnection techniques of some of the major 3-D package manufacturers. The manufacturing yield of 3-D packages depends on the number of directly

connected dies built into the device. For example, if the yield of a particular type of die is 90% and the completed 3-D module comprises three layers, the final yield of the module can be as low as 73%. In some format types, screening can be conducted prior to module assembly to remove defective dies from the 3-D structure or to "turn off" the defective die. In some cases, the fabrication process incorporates redundancy to minimize the number of costly screens.

In 3-D packaging, both single-level, horizontal cross-talk and cross-talk between different layers can be potential problems for very high-speed applications. Furthermore, the approach may require the use of heat spreaders when using multiple high-power devices in order to meet thermal operating specifications as well as thermal and thermomechanical stress design limits.

10A.1.2 Printed Wiring Board Technology

The printed wiring board is a substrate on which electronic components are mounted for electrical interconnection and mechanical support. The interconnection is provided by patterned metal tracks either on the surface or on the inner layers of the printed wiring board. Based on the raw materials used for manufacture, printed wiring boards can be either organic or ceramic boards. The most common organic board material consists of a woven glass fabric bound by a resin. Ceramic board materials typically include alumina, aluminum nitride, and beryllia. Often, in ceramic boards, materials and structures are added to create embedded capacitors and resistors, freeing precious top-layer real estate. While not widely in production, similar techniques can be used in the inner layers of organic boards.

Conventional Printed Circuit Board Technology

Conventional printed wiring board (PWB) technology can be categorized as single layer, double layer, or multilayer. Single-layer boards have conductors etched on one side of the board, usually without hole plating. Double-layer boards have conductors on both sides of the board, but no inner layers. Multilayer organic boards typically consist of stacks of partially or fully cured fabric-reinforced epoxy sheets and copper foil conductors.

While there are many ways to fabricate a multilayer printed wiring board, a typical flow chart of the fabrication process is shown in Figure 10A.1.4.[1] In conventional printed circuit board technology, the

© 2001 by CRC Press LLC

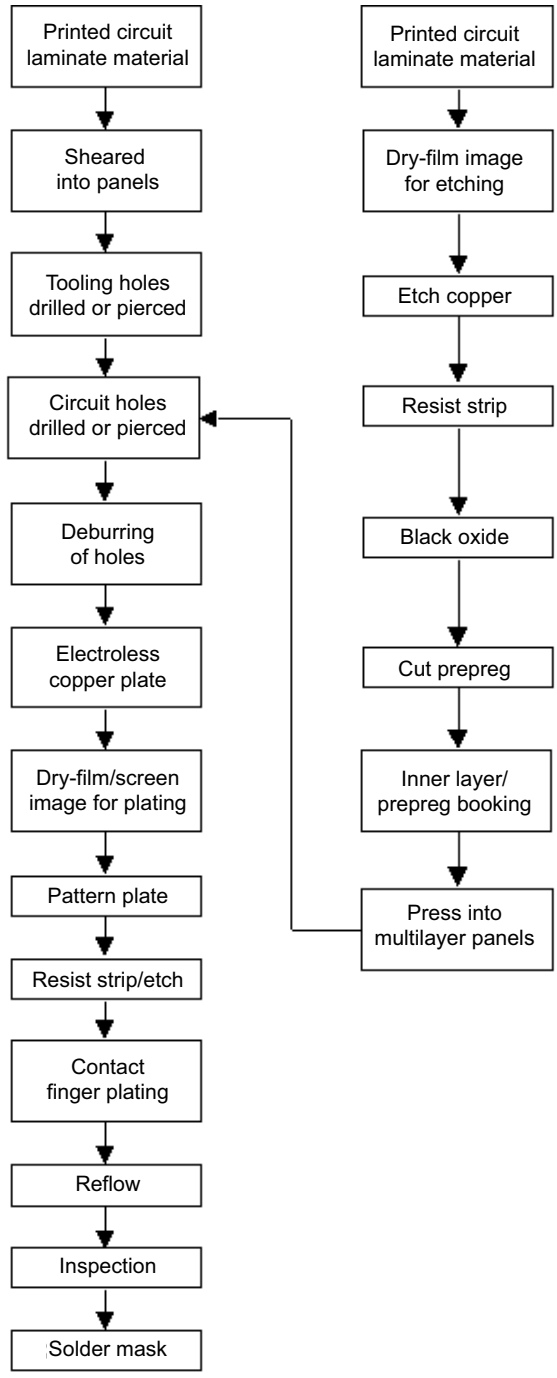

FIGURE 10A.1.4 Typical multilayer PWB fabrication process.

conductors are generally formed through both subtractive and additive processes. The partially cured laminate sheets, called *prepreg*, are cured and laminated with pressure and temperature.

The most common and least expensive resin system is FR-4 epoxy. This epoxy is a diglycidyl ether of tetrabromobisphenol A, with a glass transition temperature ranging from 135 to 180°C. Variations are

Alumina	N/A	8.90	.0002–.0015	6.8	8–12

sometimes introduced in the resin to tailor desirable mechanical and electrical properties, including glass transition temperature, dielectric constant, coefficient of thermal expansion, moisture absorption, and thermal conductivity.

Holes in conventional PWBs are typically mechanically drilled. Those holes that allow conduction through all layers are called *plated through-holes* (PTH) for through-hole leads. For surface-mount devices, the holes are referred to as *plated through-vias* (PTV). Blind vias begin at a surface layer of the board and end at an internal layer. Buried vias are located in internal layers and do not include the external layers.

The explosion of commercial wireless (1–2 GHz) and high-performance processors (>1 GHz) is challenging the limits of FR-4. The edge rates of the signals and clock are actually more critical to application design than the clock frequency. The dissipation factor correlates with signal distortion and the dielectric constant with the signal delay. Thus, the relatively high dielectric constant of FR-4 (4.2) and high dissipation factor (0.030) make FR-4 use increasingly difficult for high-frequency (>150-MHz board frequencies) and fast-edge-rate (less than 1–2 ns) applications. While polytetrafluoroethylene (PTFE) materials have been used in military and high-end commercial applications for three decades because of their low dielectric constant of 2.4 to 2.6, these materials tend to be about 15 times costlier than FR-4. New materials such as polyphenylene oxide (PPO)/epoxy have reduced the dissipation factor significantly. Higher performance resins, such as polyfunctional FR-4 epoxy, bismaleimide triazine/epoxy (BT), cyanate esters (CE), and polyimide, are also used for a variety of special applications. Some key parameters and the relative costs of common materials are summarized in Table 10A.1.7.

Printed wiring boards can also be connected by flexible dielectric materials called flex print. The rigid portion of printed wiring boards can be either organic or ceramic, while flexible circuits use thinner, flexible organic base materials, including polyester and polyimide. Flex print provides an interconnection between boards that can be electrically superior to conventional connectors.

High-Density Interconnect Technology

Driven by increasing component I/O densities, board technology is migrating to the high-density interconnection (HDI). While there are numerous processes to form HDI layers, these can be classified into two general categories: microvia and thin-film. The microvia approach offers many advantages, including high frequency, high clock-rate performance, high wiring densities, and high ratios of active device area to substrate area. While the increased density comes at a higher cost, the per-function cost can actually be significantly lower. Thin-film HDI technology has been used in space applications and supercomputer applications.

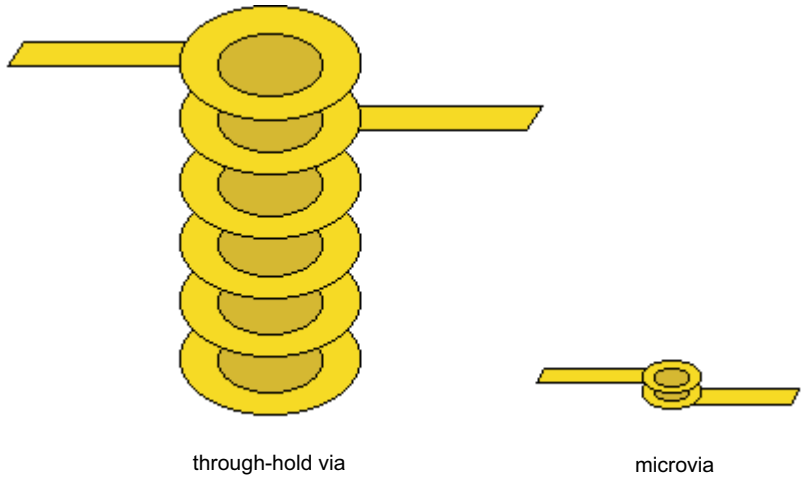

FIGURE 10A.1.5 Size advantage of microvia technology. (From IPC, *HDI and Microvia Technology,* Institute for Interconnecting and Packaging Electronic Circuits, Northbrook, IL, www.ipc.org/html/hdi.htm. With permission.)

Microvia HDI

Microvia HDI is becoming increasingly important with the advent of fine pitch array packaging. The Institute for Interconnecting and Packaging Electronic Circuits (IPC) defines a microvia as a blind or buried via of less than 150 μm, with a capture pad of less than 300 μm. Microvias can be used with conventional boards or chip-level packaging. In conventional boards, microvia technologies can be used selectively to redistribute difficult-to-route areas and enable components on both sides of the board. Ball grid arrays (BGAs) and CSPs with pitches of less than 1 mm typically require microvia redistribution layers. Figure 10A.1.5 shows the size advantage of microvias over conventional multilayer plated through-vias. Figure 10A.1.6 is a typical microvia stack-up; note that the microvia is actually included in the component solder pad. Current volume production yields exceed 99% in Japan and Taiwan. The microvias are generally formed by three basic approaches: plasma etch, photoimaging, and laser ablation. Laser ablation is a sequential technique, while plasma etch and photoimaging form vias simultaneously. Due to the high energy and difficulty of ablating glass fiber, the materials are typically not reinforced. Mechanical drilling can also be cost effective in material from 250 μm thick down to about 125 μm thick.[15]

Because there is no glass reinforcement, the dielectric constant of FR-4 epoxy is significantly lower than its reinforced counterpart. DYCOstrate®, developed by Dyconex of Zurich, Switzerland, is widely used in East Asia. An isotropic oxygen plasma is used to form vias that range from 75 to 150 μm in diameter. One advantage of this process is that the plasma removes all organic material, leaving the microvia clean.[17] The parallel processing and high yield make this process very cost effective.

A liquid- or dry-film photoimageable dielectric is generally an epoxy-acrylate material. Processing is similar to conventional soldermasking, followed by copper plating and patterning. Via diameters range from 50 to 250 μm.

Both CO_2 and ultraviolet (UV) lasers can be used to ablate the dielectric; UV can also burn through the copper layers. The CO_2 lasers are able to produce much smaller holes (10–25 μm) and are faster than the UV laser (25–200 μm). Laser vias can be formed in a variety of ways, including a two-pass process (first through copper, followed by a dielectric at a different frequency), a combination of conventional etching through the copper and laser ablation of the dielectric, and, finally, a deposited dielectric with laser via formation followed by an additive outer copper layer.[18] The remaining residue at the bottom of the ablated via can be removed with potassium permanganate or plasma etching for higher aspect ratio holes.

© 2001 by CRC Press LLC

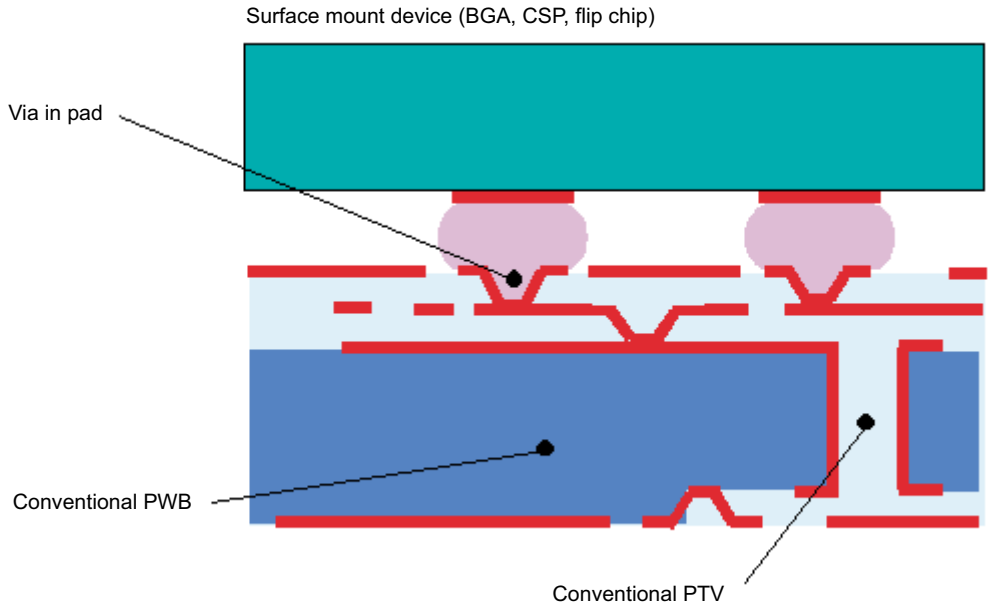

FIGURE 10A.1.6 Example of microvia technology. (From IPC, *HDI and Microvia Technology,* Institute for Interconnecting and Packaging Electronic Circuits, Northbrook, IL, www.ipc.org/html/hdi.htm. With permission.)

The reliability of the microvias is generally excellent, due to an aspect ratio of less than one. Other critical reliability factors are the hole diameter, plating thickness, hole cleanliness, and plating uniformity. In a sample of 15 different microvia test cases, only two test cases could not pass 2000 liquid-to-liquid thermal shock cycles (–55 to 125°C).[19] In another study of 18 U.S. and European fabricators, strong correlation was found between hole diameter and reliability. Holes of less than 150 μm were not reliable. Vias in solder pads were found to have no impact on solder-joint reliability.

Thin-Film HDI

All thin-film HDI approaches use deposited thin-film conductors with organic or inorganic interlayer dielectrics. The materials are sputtered with processes similar to semiconductor processing. Vias provide interconnection between conductor layers. Fully assembled modules using thin-film HDI are referred to as MCM-Ds.

Thin-film HDI can be classified into four generic types: overlay HDI, reach-through via HDI, beveled die-edge HDI, and conventional, chip-last, MCM-D, thin-film conductor and deposited dielectric HDI. A chip-last approach may employ wirebonding or other interconnects for die-to-substrate connectivity.

Table 10A.1.8 illustrates some of the many manufacturers and research institutions that make various types of HDI and MCM-D substrates. Typical design considerations, such as the number of metal layers, conductor line width, line spacing, via diameter, and via pitch, are listed in Table 10A.1.8 for each manufacturer. While many layers of dielectric and metal are possible, applications are often easily routed in two signal layers and a power-and-ground layer.

Ceramic Substrate Technology

Thick-film ceramic boards are formed by screen printing conductive, resistive, and dielectric paste onto a dielectric substrate and then firing. Typical thicknesses are in the range of 10 to 60 μm, depending on the materials. The classification "thin-film" refers to materials that are deposited in a sputtered vacuum process, similar to that used in semiconductor fabrication. Thin-film feature sizes are an order of

magnitude less than the thick-film structures. These hybrid composites can have multiple conductor layers and can include both thick- and thin-film processes.

10A.1.3 Printed Circuit Assembly Processes

The printed circuit assembly processes consist of placing components on the printed wiring board, soldering the components, and post-solder processing steps such as cleaning and conformal coating. Classification of soldering processes is based on the method of applying the solder and the heating processes involved. Two processes in common use are wave soldering and reflow soldering. Wave soldering is used primarily for through-hole technology, while reflow soldering is used for surface-mount assembly.

Through-Hole Assembly

Through-hole components can be placed manually or with automated insertion equipment. High-speed equipment can place more than a thousand devices per minute, crimp the leads on the opposite side of the board, and dress the lead to an appropriate length. In wave soldering, the board is passed over a jet of molten solder. The hydrostatic pressure of the solder from the nozzle wets the underside of the PWB and pushes the solder slightly up the plated through-hole. Subsequent capillary action, resulting from the surface tension between the solder and the walls of the plated through-hole, forces the molten solder to rise through the hole and wet the upper lands of the through-hole, securing the part in place.

Before soldering, boards must be fluxed and preheated. Fluxing consists of applying a chemical compound with activators, solvents, and detergents to the solder-joint locations to chemically clean the surfaces to be joined. Preheating reduces thermal shock to the components and the PWB, activates the flux, and evaporates any flux solvents to prevent the formation of blowholes (voids) in the solder joint.

SMT Assembly

The reflow soldering process consists of remelting solder previously applied to a PWB joint site (pad) in the form of a preform or paste. No solder is added during reflow. The first step in the process is to apply solder paste and any necessary adhesives to the land patterns on the printed wiring board. Adhesives are needed only if the components cannot be held in place by the tackiness of the solder paste. After

© 2001 by CRC Press LLC

component placement, the populated PWB is transported to the preheater to evaporate solvents in the solder paste. In this stage, the temperature of the board is raised to 100 to 150°C at a rate low enough to prevent solvent boiling and the formation of solder balls; 2°C/second has been accepted as an industry norm.[20]

The next stage in the reflow process is slow heating, which increases the temperature to the solder melting point and activates the flux in the solder paste. The activated flux removes oxides and contaminants from the surfaces of the metals to be joined. The next stage consists of melting the solder. During the melting stage, the temperature of the solder paste is raised to just above its melting point. When the solder melts, it replaces the liquid flux formed in the previous step. The temperature is held above the melting point while the solder coats the surfaces to be joined. The temperature must be regulated to allow the melted solder particles to coalesce and form a fillet around the component lead. Excessive temperatures increase the fluidity of the solder, causing it to move away from the desired joint location, while excessively long periods at the wetting temperature may lead to intermetallic formation and embrittlement. Fillet formation is the most critical part of the reflow process. The last stage involves cooling the solder joint, either by conducting the heat through the board layers or by natural or forced convection to the ambient air.

Reflow methods differ according to the method of heat transfer to the reflow site. Conductive, convective, and radiative heat transfers are variously used for this purpose. Conductive heat-transfer methods include the soldering iron, hot-bar reflow, and conductive-belt reflow. Radiative heat-transfer methodologies include infrared, laser, and optical fiber systems. Convective heat transfer is used in vapor-phase (or condensation) reflow systems. Each method has its own merits and limitations. The most common technique for mass reflow soldering is infrared heating/convection because it allows temperature control throughout the reflow soldering cycle. However, vapor-phase soldering is still considered the best way to limit the maximum temperature reached during reflow, as the temperature in the oven never rises above the temperature of the saturated vapor.

Connectors

Connectors can be classified based on the electronic elements being connected. Board-to-board connectors are used to connect two printed circuit boards; wire-to-board connectors are usually used to connect a source of power to a printed circuit board or to bus signals with high fidelity; and wire-to-wire connectors are generally used externally to the electronic equipment. In contemporary systems, connectors are a vital link in completing an electronic system. Connectors should be chosen carefully, taking into consideration current, voltage, impedance, EMI/EMR shielding, and allowable losses.

A connector is composed of four basic elements:[21] the contact interface, the contact finish, the contact spring, and the connector housing. The contact interfaces are of two kinds: separable and permanent. The separable connector allows for mating and unmating, while the permanent interface does not. The contact finish aids in establishing a contact interface and protecting the contact springs from corrosion. The contact spring is the electrically conducting element between the permanent connection to the subsystems and the separable interface that supplies the force necessary to maintain contact at the separable interface. The connector housing performs both mechanical and electrical functions by electrically insulating the individual contacts and supporting and locating them mechanically.

Board-to-board connectors are an important part of today's packaging. Commercial applications are making high-density connectors inexpensive. Mezzanine assemblies are gaining popularity, as processor modules become more complex in order to accommodate processor upgrades. One example is Intel's Pentium II® Mobile Module, which uses a 400-pin, 1.27-mm pitch connector.[22]

10A.1.4 Electronic Packaging Future

The future of electronic packaging promises an accelerating change. For several years now, industry roadmaps have assessed the capabilities, needs, direction, and future of electronic packaging. Hundreds

© 2001 by CRC Press LLC

of companies, government agencies, consortia, and universities have contributed to roadmaps. There are a number of these long-range plans, including the National Electronics Manufacturing Initiative (NEMI),[14] the Japan Printed Circuit Association's *Report on the Technology Roadmap for Advanced System Integration and Packaging*,[23] and IPC's *The National Technology Roadmap for Electronic Interconnections*.[24] Many large companies and research universities involved in packaging, such as the University of Maryland's CALCE Electronic Products and Systems Center, also have roadmaps that complement and fill research holes.

The most recent findings are that cost is king in nearly all applications. Cost, a major driver in the advancement of technology, is also driving the trend toward electronics manufacturing service (EMS) suppliers or contract manufacturers. Cost and business pressures are fueling the 25% annual increase in EMS providers. The advantages of EMS include optimizing manufacturing cycle times, reducing working capital, and improving quality. The NEMI roadmap suggests that a downside of this EMS trend will be a slowing of research and development, as the EMS providers will push to keep the *status quo* rather than advance to less proven areas. The NEMI roadmap predicts that this will also lead to shorter product cycles and more conservative, evolutionary packaging approaches. If the new technology cannot achieve cost parity with existing technologies, then industry acceptance will be delayed. One example of this is flip chip packaging, competing with those technologies that are now widely used: CSP and BGA.[25]

The NEMI, IPC, and the Semiconductor Industry Association roadmaps all predict a movement from peripheral to array packaging; consequently, peripheral packages will not decrease below a 0.5-mm pitch. The growth of flip chip interconnection was seen as a growing trend in the industry by all roadmaps. The NEMI roadmap sees integral passives (resistors and capacitors) as an important part of the future in portable electronics, whereas the IPC sees the enabling technologies as immature.[26]

Some recent predictions from the NEMI roadmap are summarized in Tables 10A.1.9 and 10A.1.10. The cost of I/O and labor to assemble packages will continue to fall dramatically. Substrate lines, spaces, and device I/O pitch will also shrink to keep pace with silicon integration. Noncontact test infrastructure

TABLE 10A.1.9 NEMI Predictions for the Future[25]

	1999	2003
IC package costs per I/O (¢)	0.7–0.9	0.4–0.6
Board assembly conversion (¢)	0.7–0.9	0.5
Substrate lines and spaces (μm)	70	35
Process test pads (mm)	0.5	Non-contact
Flip chip pad pitch (μm)	180	130

TABLE 10A.1.10 Package Forecast by Lead Count Range

I/O	1998	2003
4–18	28,495	38,768
20–32	16,347	20,489
36–68	8442	18,502
72–100	2043	5160
104–144	1551	3222
148–208	922	2378
212–304	405	1070
308+	511	1710
Total	58,716	91,299

© 2001 by CRC Press LLC

will be required to provide efficient and cost effective assurance that assemblies are functional. A shift to higher pin-count packages is also expected, as shown in Table 10A.1.10. While the current percentage of packages with a pin count greater than 304 is less than 1%, the percentage in the year 2003 will nearly double.

Electronic packaging technology will continue to enable many compact and high-speed products of the 21st century. The need for innovations in cost, yields, and productivity will certainly challenge those engineers involved in the many facets of packaging. These improvements will eventually touch and, it is hoped, enhance the quality of life of all the world's people.

11.1 Introduction

Nam P. Suh

Traditionally, the design field has been identified with particular end products, e.g., mechanical design, electrical design, ship design. In these fields, design work is largely based on specific techniques to foster certain product characteristics and principles. Examples include the principles of constant wall thickness, lightweight construction, and shortest load path. Also, the design field has been subdivided by an increasing reliance on specialized knowledge and the division of labor. Precision engineering and robotics are examples of subfields that are distinguished by the accuracy and reliability that the product must have. In the field of precision engineering, for instance, the dimensions of interest are nanometers, which are often encountered in the semiconductor industry. Each one of these fields also has its specific know-how and paradigms to support effective design have also sub-divided the design field.

There are three branches of design. The traditional school, which still dominates, believes that design requires experience and cannot be taught. The second group deals with optimization as a subset of design, using computer-based tools such as genetic algorithms, fuzzy logic, and the like. The third school of thought believes that there are axioms that govern good design decisions. A good designer needs to use all three methodologies.

11.2 Elements of the Design Process

Nam P. Suh

All design activities must do the following:

1. *Know* the "*customers' needs*."
2. *Define the essential problems* that must be solved to satisfy the needs.
3. *Conceptualize the solution through synthesis*, which involves the task of satisfying several different functional requirements using a set of inputs such as product design parameters within given constraints.
4. *Analyze* the proposed solution to establish its optimum conditions and parameter settings.
5. *Check the resulting design solution* to see if it meets the original customer needs.

Design proceeds from abstract and qualitative ideas to quantitative descriptions. It is an iterative process by nature: new information is generated with each step, and it is necessary to evaluate the results in terms of the preceding step. Thus, design involves a continuous interplay between *the requirements the designer wants to achieve* and *how the designer wants to achieve these requirements*.

Designers often find that a clear description of the design requirements is a difficult task. Therefore, some designers deliberately leave them implicit rather than explicit. Then they spend a great deal of time trying to improve and iterate the design, which is time consuming at best. To be efficient and generate the design that meets the perceived needs, the designer must specifically state the users' requirements before the synthesis of solution concepts can begin.

Solution alternatives are generated after the requirements are established. Many problems in mechanical engineering can be solved by applying practical knowledge of engineering, manufacturing, and economics. Other problems require far more imaginative ideas and inventions for their solution. The word "creativity" has been used to describe the human activity that results in ingenious or unpredictable or unforeseen results (e.g., new products, processes, and systems). In this context, creative solutions are discovered or derived by inspiration and/or perspiration, without ever defining specifically what one sets out to create. This creative "spark" or "revelation" may occur, since our brain is a huge information storage and processing device that can store data and synthesize solutions through the use of associative memory, pattern recognition, digestion and recombination of diverse facts, and permutations of events. Design will always benefit when "inspiration" or "creativity," and/or "imagination" plays a role, but this process must be augmented by amplifying human capability systematically through fundamental understanding of cognitive behavior and by the development of scientific foundations for design methods.

11.3 Concept of Domains

Nam P. Suh

Design is made up of four *domains*: the customer *domain*, the *functional domain*, the *physical domain*, and the *process domain* (see Figure 11.3.1). The domain on the left relative to the domain on the right represents "what the designer wants to achieve," whereas the domain on the right represents the design solution, or "how the designer proposes to satisfy the problem." Therefore, the design process can be defined as mapping from the "what" domain to the "how" domain. During product design, the mapping is from the functional domain to the physical domain. In manufacturing process design, the designer maps from the physical domain to the process domain.

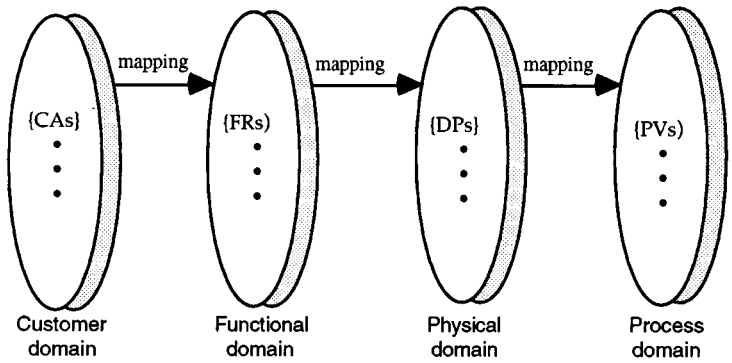

FIGURE 11.3.1 Four domains of the design world. {x} are characteristic vectors of each domain.

The customer domain is characterized by customer needs or the attributes the customer is looking for in a product, process, system, or material. In the functional domain, the designer formally specifies customer needs in terms of functional requirements (FRs). In order to satisfy these FRs, design parameters (DPs) are conceived in the physical domain. Finally, a means to produce the product specified in terms of DPs is developed in the process domain, which is characterized by process variables (PVs).

In mechanical engineering, design typically refers to product design and, often, hardware design. However, mechanical engineers also deal with other equally important designs such as software design, design of manufacturing processes and systems, and organizations. All designers go through the same thought process, although some believe that their design is unique and different from those of everyone else. In materials science, the design goal is to develop materials with certain properties (i.e., FRs). This is done through the design of microstructures (i.e., DPs) to satisfy these FRs, and through the development of material processing methods (i.e., PVs) to create the desired microstructures. To establish a business, the goals are {FRs}, and they are satisfied by structuring the organization in terms of its departments {DPs} and finding the human and financial resources {PVs} necessary to staff and operate the enterprise. Similarly, universities must define the mission of their institutions (i.e., FRs), design their organizations effectively to have an efficient educational and research enterprise (i.e., DPs), and must deal with human and financial resource issues (i.e., PVs). In the case of the U.S. government, the President of the United States must define the right set of {FRs}, design the appropriate government organization and programs {DPs}, and secure the resources necessary to get the job done {PVs}, subject to the constraints imposed by the Constitution and Congress. In all organizational designs the process domain represents the resources: human and financial.

Table 11.3 shows how seemingly different design tasks in many different fields can be described in terms of the four design domains. In the case of the product design, the customer domain consists of the customer requirements or attributes the customer is looking for in a product; the functional domain consists of functional requirements, often defined as engineering specifications and constraints; the

TABLE 11.3 Characteristics of the Four Domains of the Design World for Various Designs: Manufacturing, Materials, Software, Organizations, and Systems

Domains Character Vectors	Customer Domain {CAs}	Functional Domain {FRs}	Physical Domain {DPs}	Process Domain {PVs}
Manufacturing	Attributes which consumers desire	Functional requirements specified for the product	Physical variables which can satisfy the functional requirements	Process variables that can control design parameters (DPs)
Materials	Desired performance	Required properties	Microstructure	Processes
Software	Attributes desired in the software	Output	Input variables and algorithms	Subroutines
Organization	Customer satisfaction	Functions of the organization	Programs or offices	People and other resources that can support the programs
Systems	Attributes desired of the overall system	Functional requirements of the system	Machines or components, subcomponents	Resources (human, financial, materials, etc.)

physical domain is the domain in which the key design parameters {DPs} are chosen to satisfy the {FRs}; and the process domain specifies the manufacturing methods that can produce the {DPs}. It is indeed fortunate that all designs fit into these four domains, since in a given design task, mechanical design, software design, manufacturing issues, and organizational issues must often be considered simultaneously. Because of this logical structure of the design world, generalized design principles can be applied to all design applications, and the issues that arise in the four domains can be considered systematically and concurrently.

Customer needs are often difficult to define. Nevertheless the designer must make every effort to understand customer needs by working with customers to appreciate and establish their needs. Then these needs (or the attributes the customer is looking for in a product) must be translated into functional requirements (FRs). This must be done in a "solution neutral environment." This means that the FRs must be defined without bias to any existing or preconceived solutions. If the FRs are defined based on an existing design, then the designer will simply be specifying the FRs of that product and creative thinking cannot be done.

To aid the process of defining FRs, QFD (quality function deployment) has been used. In QFD customer needs and the possible functional requirements are correlated and important FRs are determined. Experience plays an important role in defining FRs, since qualitative judgment is often necessary for assessing customer needs and identifying the essential problems that must be solved.

11.4 The Axiomatic Approach to Design

Nam P. Suh

The creative process of mapping the FRs in the functional domain to DPs in the physical domain is not unique; the solution varies with a designer's knowledge base and creative capacity. As a consequence, solution alternatives may vary in their effectiveness to meet the customer's needs. The axiomatic approach to design is based on the premise that there are generalizable principles that form the basis for distinguishing between good and bad designs.

Suh (1990) identified two design axioms by *abstracting* common elements from a body of good designs, including products, processes, and systems. The first axiom is called the *Independence Axiom*. It states that the independence of *functional requirements* (FRs) must be always maintained, where FRs are *defined as the minimum set of independent functional requirements* that characterize the design goals. The second axiom is called the *Information Axiom*, which states that among those designs that satisfy the Independence Axiom the design that has the highest probability of success is the best design. During the mapping process (for example, mapping from FRs in the functional domain to DPs in the physical domain), the designer should make correct design decisions using the Independence Axiom. When several designs that satisfy the Independence Axiom are available, the Information Axiom can be used to select the best design.

Axioms are general principles or self-evident truths that cannot be derived or proven to be true; however they can be refuted by counterexamples or exceptions. Through axioms such as Newton's laws and the laws of thermodynamics, the concepts of force, energy, and entropy have been defined. One of the main reasons for pursuing an axiomatic approach to design is the generalizability of axioms, which leads to the derivation of corollaries and theorems. These theorems and corollaries can be used as design rules that precisely prescribe the bounds of their validity because they are based on axioms. The following corollaries are presented in Suh (1990).

Corollary 1: (Decoupling of Coupled Designs)
Decouple or separate parts or aspects of a solution if FRs are coupled or become interdependent in the designs proposed.

Corollary 2: (Minimization of (FRs)
Minimize the number of FRs and constraints.

Corollary 3: (Integration of Physical Parts)
Integrate design features in a single physical part if FRs can be independently satisfied in the proposed solution.

Corollary 4: (Use of Standardization)
Use standardized or interchangeable parts if the use of these parts is consistent with FRs and constraints.

Corollary 5: (Use of Symmetry)
Use symmetrical shapes and/or components if they are consistent with the FRs and constraints.

Corollary 6: (Largest Tolerance)
Specify the largest allowable tolerance in stating FRs.

Corollary 7: (Uncoupled Design with Less Information)
Seek an uncoupled design that requires less information than coupled designs in satisfying a set of FRs.

The ultimate goal of axiomatic design is to establish a science base for design and improve design activities by providing the designer with a theoretical foundation based on logical and rational thought processes and tools.

© 1999 by CRC Press LLC

The First Axiom: The Independence Axiom

The Independence Axiom may be formally stated as:

Axiom 1: The Independence Axiom
Maintain the independence of the functional requirements.

As stated earlier, functional requirements, FRs, are defined as the minimum set of independent requirements that the design must satisfy. A set of functional requirements is the description of design goals. The Independence Axiom states that when there are two or more functional requirements, the design solution must be such that each of the functional requirements can be satisfied without affecting any of the other requirements. This means that the designer must choose the correct set of DPs so that functional dependence or coupling is not introduced. When there is only one FR, the Independence Axiom is always satisfied. In this case, the given design alternatives should be optimized and the second axiom, the Information Axiom, is used to select the best design.

To apply the Independence Axiom, the mapping process from the design goals to the design solutions can be expressed mathematically. The set of functional requirements that define the specific design goals constitutes a vector {FRs} in the functional domain. Similarly, the set of design parameters in the physical domain that describe the design solution also constitutes a vector {DPs}. The relationship between the two vectors can be written as

$$\{\text{FRs}\} = [A]\{\text{DPs}\} \tag{11.4.1}$$

where [A] is the design matrix that characterizes the nature of the mapping. Equation (11.4.1) may be written in terms of its elements as $FR_i = A_{ij}DP_j$. Equation (11.4.1) is a design equation that may be used for the design of a product or the microstructure of a material. For the design of processes, the design equation may be written as

$$\{\text{DPs}\} = [B]\{\text{PVs}\} \tag{11.4.2}$$

where [B] is the design matrix that characterizes the process design.

Designs that satisfy the Independence Axiom must have either a diagonal or triangular design matrix (see Figure 11.4.1). When the design matrix [A] is diagonal, each of the FRs can be satisfied independently by adjusting one DP. Such a design is called an *uncoupled design*. When the matrix is triangular, the independence of FRs can be guaranteed if and only if the DPs are changed in a proper sequence. Such a design is called a *decoupled* or *quasi-coupled design*. Although the design matrix is a second-order tensor (note: stress, strain, and moment of inertia are also second-order tensors), the usual coordinate transformation technique cannot be applied to Equations (11.4.1) or (11.4.2) to find the invariants such as the diagonal matrix, since [A] and [B] typically involve physical phenomena and geometric relationships that are not amenable to coordinate transformation.

In addition to the Independence Axiom, the mapping of the design goals (FRs or DPs) to design solutions (DPs or PVs, respectively) is often subject to constraints, Cs. Constraints establish the bounds on the acceptable design solutions and differ from FRs in that they do not have to be independent. Cost, for example, is often considered a constraint since it is affected by all design decisions, but the design is acceptable as long as the cost does not exceed a set limit.

Example 1: Shaping of Hydraulic Tubes

In many applications (e.g., aircraft industry), steel tubes must be bent to complex shapes without changing the circular cross-sectional shape of the tube. To design a machine and a process that can achieve the task, the functional requirements can be formally stated as

FR1 = Bend the steel tube to prescribed curvatures.
FR2 = Maintain the circular cross section of the bent tube.

© 1999 by CRC Press LLC

$$\begin{Bmatrix} FR_1 \\ FR_2 \\ FR_3 \end{Bmatrix} = \begin{bmatrix} X & 0 & 0 \\ 0 & X & 0 \\ 0 & 0 & X \end{bmatrix} \begin{Bmatrix} DP_1 \\ DP_2 \\ DP_3 \end{Bmatrix}$$

a) Uncoupled design

$$\begin{Bmatrix} FR1 \\ FR2 \\ FR3 \end{Bmatrix} = \begin{bmatrix} X & 0 & 0 \\ X & X & 0 \\ X & X & X \end{bmatrix} \begin{Bmatrix} DP1 \\ DP2 \\ DP3 \end{Bmatrix}$$

b) Decoupled design

$$\begin{Bmatrix} FR1 \\ FR2 \\ FR3 \end{Bmatrix} = \begin{bmatrix} X & 0 & X \\ X & X & 0 \\ X & X & X \end{bmatrix} \begin{Bmatrix} DP1 \\ DP2 \\ DP3 \end{Bmatrix}$$

c) Coupled design

FIGURE 11.4.1 Examples of uncoupled, decoupled, and coupled designs.

One mechanical concept that can do the job is shown schematically in Figure 11.4.2 for a two-dimensional bending case. It consists of a set of matching rollers with semicircular grooves on their periphery. These "bending" rollers can counterrotate at different speeds and move relative to each other to control the bending process. The centers of these two bending rollers are fixed with respect to each other, and the contact point of the bending rollers can rotate about a fixed point. A second set of "feed" rollers, which counterrotate at the same speed, feed the straight tube feedstock into the bending rollers. As the tubes are bent around the rollers, the cross-sectional shape will tend to change to a noncircular shape. The deformation of the cross section is prevented by the semicircular cam profile machined on the periphery of the bending rollers. The DPs for this design are

DP1 = Differential rotation of the bending rollers to bend the tube
DP2 = The profile of the grooves on the periphery of the bending rollers

The kinematics of the roller motion needs to be determined. To bend the tube, one of the bending rollers must rotate faster than the other. In this case, the tube will be bent around the slower roller. The forward speed of the tube is determined by the average speed of the two bending rollers. The motion of these rollers can be controlled digitally using stepping motors.

The design shown in Figure 11.4.2 is an uncoupled design, since each of the proposed DPs only affects one FR. Is this the best design? The only way this question can be answered is to develop alternative designs that satisfy the FRs, constraints (Cs), and the Independence Axiom. Then the information content for each of the proposed designs must be computed so as to use the Information Axiom to select the best among the proposed designs.

Decomposition, Zigzagging, and Hierarchy

In the preceding example the design was completed when the two FRs in the functional domain were mapped to two DPs in the physical domain. However, in many designs both the FRs and DPs must be decomposed into hierarchies because the high level conceptual design ideas need further design details before they can be implemented. To create the hierarchies for the FRs and DPs, the designer must return to the functional domain from the physical domain. As shown in Figure 11.4.3, the design process requires the designer to alternate or zigzag between the functional domain and the physical domain.

© 1999 by CRC Press LLC

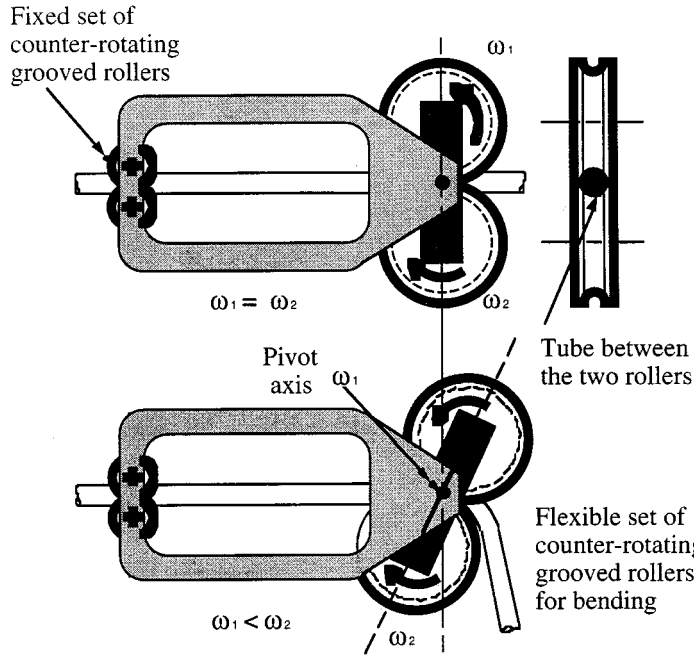

FIGURE 11.4.2 Concept for tube bending.

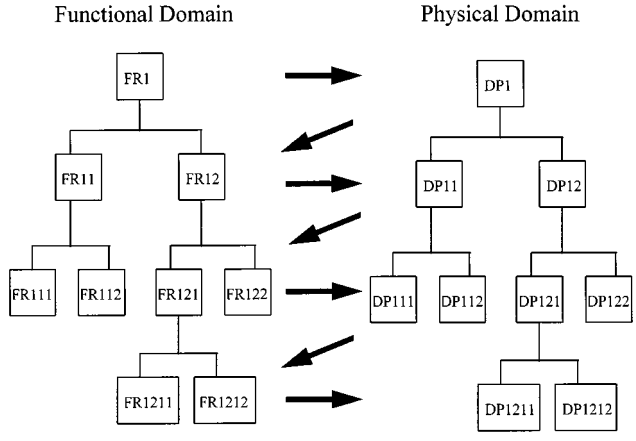

FIGURE 11.4.3 Hierarchical decomposition of FRs and DPs and zigzag mapping.

In many organizations, functional requirements or design specifications are decomposed without zigzagging by remaining only in the functional domain. This means that the designers are not working in a *solution-neutral environment*; they are specifying the requirements for an existing design. For example, assume that the design objective is to develop a vehicle that goes forward, stops, and turns. This vehicle has to satisfy these three FRs. These FRs cannot be decomposed until they are mapped to a set of DPs in the physical domain. This high-level mapping is often referred to as the *conceptual phase* of design. If, for instance, an electric motor is adopted as a means to move forward, then the FR "go forward" would be further decomposed in terms of this physical concept, and the evolving functional hierarchy will be different from that associated with the decision to use gas turbines. Therefore, to define the FRs in a solution-neutral environment, the designer needs to "zig" to the physical domain, and after proper DPs are chosen, the designer must then "zag" to the functional domain for further decomposition.

© 1999 by CRC Press LLC

This process of mapping and zigzagging must continue until the design is completed, resulting in the creation of hierarachical trees for both FRs and DPs. This will be illustrated in the following example.

Example 2: Refrigerator Design

Historically, humankind has had the need to preserve food. Now consumers want an electrical appliance that can preserve food for an extended time. The typical solution is to freeze food for long-term preservation or to keep some food at a cold temperature without freezing for short-term preservation. These needs can be formally stated in terms of two functional requirements:

FR1 = Freeze food for long-term preservation.
FR2 = Maintain food at cold temperature for short-term preservation.

To satisfy these two FRs, a refrigerator with two compartments is designed. The two DPs for this refrigerator may be stated as

DP1 = Freezer section
DP2 = Chiller (i.e., refrigerator) section

To satisfy FR1 and FR2, the freezer section should only affect the food to be frozen and the chiller (i.e., refrigerator) section should only affect the food to be chilled without freezing. In this case, the design matrix will be diagonal. However, the conventional freezer/refrigerator design uses one compressor and one fan which turns on when the freezer section temperature is higher than the set temperature, and the chiller section is cooled by controlling the opening of the vent (see Figure 11.4.4). Therefore, the temperature in the chiller section cannot be controlled independently from that of the freezer section.

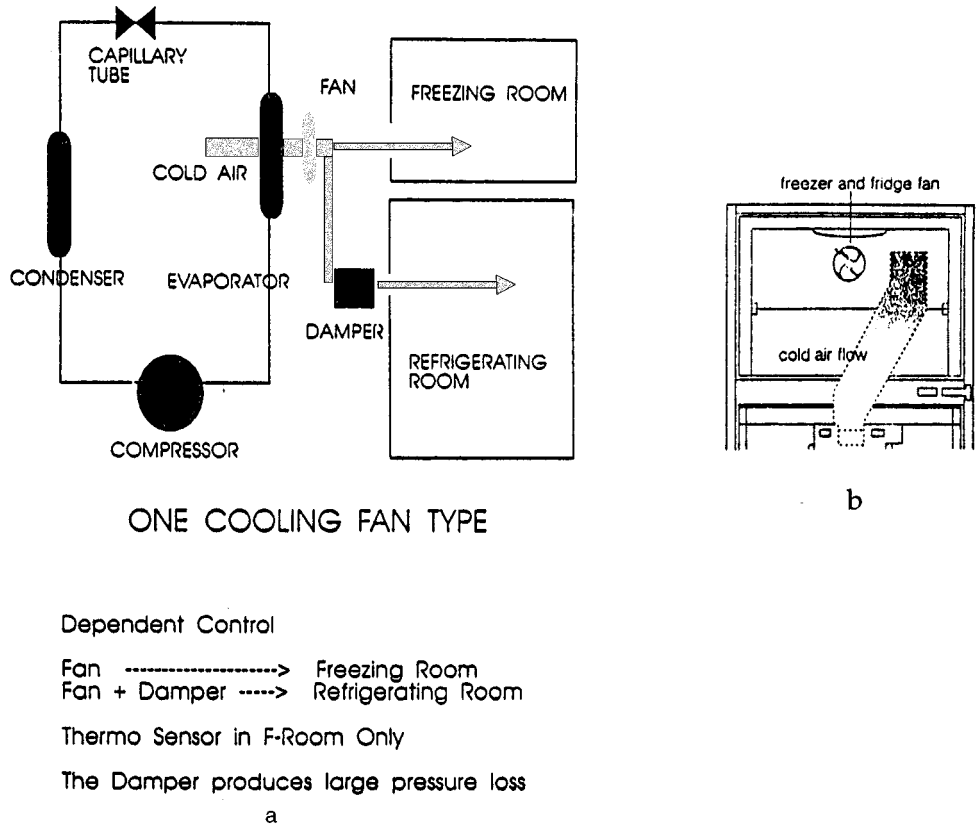

FIGURE 11.4.4 Conventional refrigerator/freezer cooling system.

© 1999 by CRC Press LLC

Having chosen DP1, FR1 can now be decomposed as

FR11 = Control temperature of the freezer section in the range of –18°C.
FR12 = Maintain the uniform temperature throughout the freezer section at the preset temperature.
FR13 = Control humidity to relative humidity of 50%.

FR2 may be decomposed in the context of DP2 as

FR21 = Control the temperature of the chilled section in the range of 2 to 3°C.
FR22 = Maintain a uniform temperature throughout the chilled section at a preset temperature to within 1°C.

To satisfy the second level FRs, i.e., FR11, FR12, FR21, etc., the designer has to conceive a design and identify the DPs for this level of decomposition. Just as FR1 and FR2 were independent from each other through the choice of proper DP1 and DP2, the FRs at this second level must also be independent from one another.

Suppose that the requirements of the freezer section will be satisfied by pumping chilled air into the freezer section, circulating the chilled air uniformly throughout the freezer section, and monitoring the returning air for temperature and moisture in such a way that the temperature is controlled independently from the moisture content of the air. Then the second level DPs may be chosen as

DP11 = Turn the compressor on or off when the air temperature is higher or lower than the set temperature, respectively.
DP12 = Blow the air into the freezer section and circulate it uniformly throughout the freezer section at all times.
DP13 = Condense the moisture in the returned air when its dew point is exceeded.

The design equation is written as

$$\begin{vmatrix} FR12 \\ FR11 \\ FR13 \end{vmatrix} = \begin{vmatrix} x & 0 & 0 \\ x & x & 0 \\ x & 0 & x \end{vmatrix} \begin{vmatrix} DP12 \\ DP11 \\ DP13 \end{vmatrix} \tag{11.4.3}$$

Equation (11.4.3) indicates that the design is a decoupled design.

The chilled section, where the food has to be kept in the range of 2 to 3°C, can now be designed. Here, again, a compressor may be used to control the air temperature within a preset range, and chilled air may be circulated to maintain a uniform temperature throughout the chilled section. This solution would result in a decoupled design as well. One of the design questions to be answered here is whether one compressor and one fan can be used to satisfy both {FR11, FR12, FR13} and {FR21, FR22}. Such a solution would minimize the information content without compromising functional independence (see Corollary 3). Most commercial refrigerators use only one compressor and one fan to achieve these goals (see Figure 11.4.4); however, many of these are coupled designs.

One can propose various specific design alternatives and evaluate the options in terms of the Independence Axiom. If a design allows the satisfaction of these FRs independently, then the design is acceptable for the set of specified FRs. If a solution that satisfies the Independence Axiom cannot be devised, then the designer must compromise the FRs by either eliminating some of the FRs or increasing the tolerance for temperature control, moisture control, etc.

One company has improved the preservation of food in their chilled section by providing one additional fan so as to be able to control the temperature of the chilled section more effectively (see Figure 11.4.5). This can be done since the evaporator was sufficiently cold to cool the air being pumped into the chiller section, even during periods when the compressor was not running. To maintain a uniform temperature distribution, extra vents were provided to insure good circulation of air. In this design, DP21 refers to

the fan for the chiller section, and DP22 represents the vents. The design matrix for the {FR21, FR22}–{DP21, DP22} relationship is diagonal as shown in the design equation:

$$\begin{vmatrix} FR21 \\ FR22 \end{vmatrix} = \begin{vmatrix} X & 0 \\ 0 & X \end{vmatrix} \begin{vmatrix} DP21 \\ DP22 \end{vmatrix} \tag{11.4.4}$$

© 1999 by CRC Press LLC

The company has compared the performance of the uncoupled design with that of competing coupled designs. For instance, the new design provides much more uniform temperature in the chiller section (Figure 11.4.6a) and much less temporal fluctuation than the existing coupled designs (Figure 11.4.6b). They also found that the uncoupled design saves electricity because air can be defrosted due to the air flow into the chiller section when the compressor is not operating. They also found that this new design enables the use of a quick refrigeration mode in the chilled section by turning on the fan of the chiller section as soon as food is put into the chiller section. To cool 100 g of water from 25 to 10°C it took only 37 vs. 58 min in a conventional refrigerator (Figure 11.4.7).

According to Corollary 3 (Integration of Physical Parts), the innovative idea of using two fans and uniformly positioned ducts may or may not be the best solution if the FRs can be satisfied independently using only one fan. If there is an alternative design that can satisfy the Independence Axiom, the Information Axiom and the detailed calculation of the information content must be used to determine the better of the two designs. As discussed in "The Second Axiom: The Information Axiom" (below), the best design is the one that has the minimum information content since it has the highest probability of success.

In the preceding example, the design matrices were formulated in terms of Xs and Os to model the nature of the relationship between each FR and each DP. In some cases, this simple, conceptual notation is sufficient to complete and implement the design. However, in many cases further steps should be taken to optimize the design. This means that the FR-DP relationships must be modeled more precisely after the conceptual design is represented in terms of Xs and Os.

Concurrent Design and Manufacturing Considerations

The previous section, Decomposition, Zigzagging, and Hierarchy, demonstrates use of the Independence Axiom during mapping from the physical domain to the process domain, i.e., product design. In order to implement the chosen DPs, the designer has to map from the physical domain to the process domain (i.e., process design) by choosing the process variables, PVs. This process design mapping must also satisfy the Independence Axiom, although sometimes the solution may simply involve the use of existing processes. When existing processes must be used to minimize capital investment in new equipment, the corresponding PVs must also be used to complete the mapping from the physical domain to the process domain. Therefore, the PVs act as constraints in choosing DPs. Since early design decisions may determine 70 to 80% of manufacturing productivity in many enterprises, the product design and process design (or selection) should be performed at the same time in order to develop designs that can be manufactured without incurring cost overruns and schedule slippage. This is sometimes called *concurrent design*.

The Second Axiom: The Information Axiom

When there is only one FR, the Independence Axiom is always satisfied, and the only task left is to optimize the given design. Various optimization techniques have been advanced to deal with optimization problems involving one objective function. However, when there are two or more FRs, some of these optimization techniques do not work. In these cases, we must first develop a design that is either uncoupled or decoupled. If the design is uncoupled, it can be seen that each FR can be satisfied and the optimum points can be found. If the design is decoupled, the optimization technique must follow a set sequence.

For a given set of FRs, it is most likely that every designer will come up with different designs, all of which are acceptable in terms of the Independence Axiom. However, one of these designs is likely to be the superior alternative. The Information Axiom provides a quantitative means for establishing the merits of a given design, and this value is used to select the best solution. Specifically, the Information Axiom may be stated as

Axiom 2: The Information Axiom
Minimize the information content.

Information is defined in terms of the information content **I** that is related, in its simplest form, to the probability of satisfying a given set of FRs. If the probability of success is p, the information content **I** associated with the probability is defined as

$$\mathbf{I} = -\log_2 p \tag{11.4.5}$$

Equation (11.4.5) defines information content in the units of binary digits or bits. In the general case of an uncoupled design with *n* FRs, **I** may be expressed as

$$I = -\sum_{i=1}^{n} \log_2 p_i = \sum_{i=1}^{n} I_i \tag{11.4.6}$$

where p_i is the probability of DP_i satisfying FR_i. Since there are *n* FRs, the total information content is the sum of all the individual measures. When all probabilities p_i are equal to one, the information content is zero. Conversely, the information content is infinite when one or more probabilities are equal to zero.

A design is called *complex* when its probability of success is low. The quantitative measure for complexity is the information content: complex systems require more information to make the system function (see Equation 11.4.5). Thus, a large system that is comprised of many subsystems and components is not necessarily complex. Even a small system can be complex if its probability of success is low.

Example 3: Cutting a Rod to a Length

Suppose we need to cut rod A to the length 1 +/– 0.000001 m and rod B to the length 1 +/– 0.1 m. Which task is more complicated?

The answer depends on the cutting equipment available for the job! However, most engineers with some practical experience would say that the one that has to be cut within 1 μm would be more difficult, because the probability of success associated with the smaller tolerance is lower than that associated

© 1999 by CRC Press LLC

with the larger tolerance. Therefore, the job with the lower probability of success is more *complex* than the one with higher probability. The Information Axiom links the notion of complexity with the specified tolerances for the FRs: the tighter the tolerance, the more difficult it may be to choose a design solution or a system that can satisfy the FRs.

In practice, the probability of success is a function of the intersection of the tolerances defined by the designer to satisfy the FRs and the ability of the chosen system to produce the part within the specified tolerances. This value can be computed by specifying the *design range* (*dr*) for an FR and by determining the *system range* (*sr*) that the proposed design can provide to satisfy the FR. Figure 11.4.8 illustrates these two ranges graphically. The vertical axis (the ordinate) is for the probability density function and the horizontal axis (the abscissa) is for either FR or DP, depending on the mapping domains involved. When the mapping is between the functional and the physical domains (as in product design), the abscissa is for FR, whereas for mapping between the physical and the process domains (e.g., process design), the abscissa is for DP.

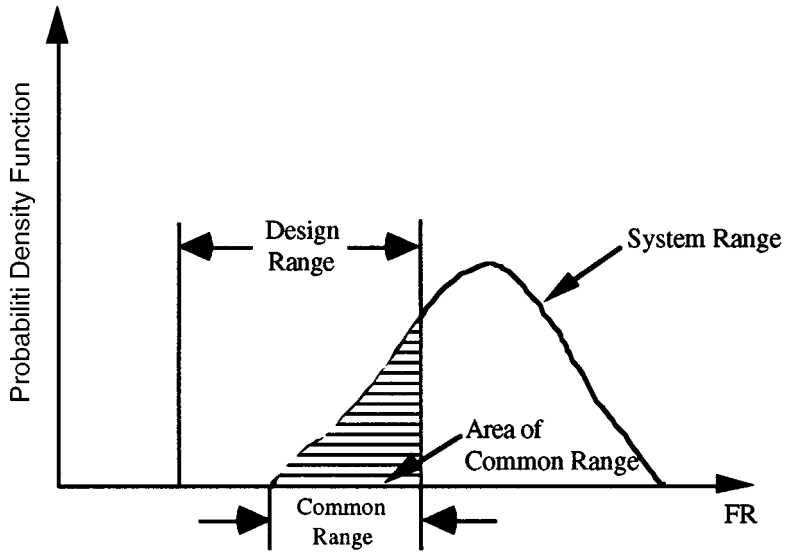

FIGURE 11.4.8 Design range, system range, and common range in a plot of the probability density function (pdf) of a functional requirement.

In Figure 11.4.8 the system range is plotted as a probability density function vs. the specified FR. The intersection of the design range and the system range is called the *common range* (*cr*), and this is the only region where the design requirements are satisfied. Consequently, the area under the common range divided by the area under the system range is equal to the design's probability of success. Then the information content may be expressed as

$$\mathbf{I} = \log_2\left(A_{sr}/A_{cr}\right) \tag{11.4.7}$$

where A_{sr} denotes the area under the system range and A_{cr} is the area within the common range. Furthermore, since A_{sr} =1.0 and there are *n* FRs to satisfy in most cases, the information content may be expressed as

$$I = -\sum_{i=1}^{n} \log_2\left(1/A_{cr}\right)_i \tag{11.4.8}$$

11.5 Algorithmic Approaches to Design

Leonard D. Albano

In addition to the axiomatic approach to design (see Section 11.4), there are many methods that are based on an algorithmic approach to design. In algorithmic design, the design process is identified or prescribed so that it leads the designer to a solution that satisfies the design goals. Algorithmic methods can be divided into several categories: pattern recognition, associative memory, analogy, experientially based prescription, extrapolation, interpolation, selection based on probability, etc. This section briefly discusses three common algorithmic methods for design: systematic design, the Taguchi method, and design for assembly (DFA).

Systematic Design

Systematic design methods prescribe how design should be done and provide standardized solutions for fulfilling certain functional requirements. Examples of systematic design methods include Pahl and Beitz (1988), Hubka and Eder (1988), and the German Standards Institute (VDI). This section describes the approach advanced by Pahl and Beitz.

The method of Pahl and Beitz (1988) divides the design process into a number of steps and prescribes methods for dealing with each step. Design starts with an appreciation of customers needs, which are then clarified in terms of an overall function. By definition, the overall function of an engineering system is to convert matter (e.g., energy, materials, signals). Energy, for example, can be converted from chemical energy to mechanical and thermal energy; materials can be shaped, finished, and coated to provide particular geometries and surface finishes; and signal conversion is often used to control the conversion of energy and materials. The overall function is an abstract formulation of customers needs and is defined in terms of inputs and outputs to a system.

Next, the overall function is decomposed into a hierarchy of generic subfunctions (i.e., energy, material, and signal conversions) that the product must perform in order to meet the overall function. The combination of subfunctions is termed a *function structure*. Use of the function structure facilitates the design task by breaking down the overall, complex function into smaller problems that can be divided among a number of experts. Construction of the function structure starts with the logical analysis of the functions that must appear in the solution if the overall function is to be satisfied. For example, a device for producing small, thermoplastic parts should include the following subfunctions: feed plastic pellets, melt plastic pellets, shape molten plastic into desired part geometry, cool part, dispense part, and control material flow. This function structure may be expanded during later steps of the design process as the designer gains additional insight.

Once a simple function structure is established, the designer searches for suitable solution principles to satisfy each of the subfunctions. Solution principles consist of some underlying physical principle or principles to effect the required conversion and some geometric form. Shear and torsion, for example, are physical principles for transferring mechanical energy, and the screw drive is a geometric form that embodies these effects. Published design catalogs, such as the VDI guidelines (VDI), provide a data base of standardized solution principles which facilitates the solution process. A design concept is obtained by integrating the solution principles for each subfunction.

The quality of the proposed design concept increases with the number of solution principles that are considered for each subfunction. Therefore, multiple solution principles should be identified for each subfunction, and these solution principles can be combined in various permutations to produce a rich solution field. Formulating the required subfunctions and the proposed principles in matrices provides a convenient scheme for organizing the results (see Figure 11.5.1). Each row of the matrix refers to a subfunction and the columns of the matrix contain combinations of solution principles.

The reduction of the solution field to a few promising proposals for further development involves a number of ad hoc strategies. One strategy relies on the experience of the designer to identify those

2	F_2	S_{21}	S_{22}		S_{2j}		S_{2m}
:	:	:	:		:		:
i	F_i	S_{i1}	S_{i2}		S_{ij}		S_{im}
:	:	:	:		:		:
n	F_n	S_{n1}	S_{n2}		S_{nj}		S_{nm}

FIGURE 11.5.1 Matrix approach for developing solution concepts based on mapping different principles S_{xy} to each subfunction F_x.

combinations of solution principles that are not compatible with customers needs or with one another. A second strategy is to use value analysis to evaluate and compare the solution variants generated by the matrix combination. The general procedure for value analysis involves identifying evaluation criteria and assigning relative weights to each criterion. Each solution variant is then assigned a value by combining its weighted value for each criterion. The solution variants are then compared on the basis of their total weighted value, and the best solution is selected.

The selected solution concept is then developed in terms of its layout and detail specifications. Much of the design development relies on design rules and knowledge readily available in handbooks and design guidelines. In addition to the development of production drawings and specifications, detail design often involves optimization of the solution principles and their geometric forms. The reader is referred to Pahl and Beitz (1988) for additional information.

The Taguchi Method

The Taguchi method (1987, 1993) provides a mathematical basis for analyzing product robustness and is intended as a guide for improving design quality. According to Taguchi, higher quality products satisfy customers needs with less variation and are manufactured at lower cost. This definition of quality is based on a cost model that emphasizes the costs associated with product variability. Costs due to variation include those incurred during manufacturing (such as the cost of materials, machine adjustments, and scraps) and those assumed by the customer (e.g., the cost to repair and/or replace the deficient product). The significance of the Taguchi cost model is the fact that it forces the designer to focus on *offline quality control* as a means to improve product quality.

Offline quality control (QC) is a strategy for reducing variability and improving quality during product design and process planning. It is an attempt to take advantage of the fact that most of the cost is committed during the early stages of product development, while only a very small percentage of the cost is actually expended. In contrast, the concept of *online quality control* has been used historically to advance quality products during manufacturing operations. However, during this stage of the product life cycle, much of the cost has been expended and committed. Statistical process control is an example of online quality control.

The practice of offline QC divides the design process into three stages: system design, parameter design, and tolerance design. System design refers to the conceptual phase of design when customers needs are formulated into a design problem and solutions are generated and evaluated. Once a solution is established and defined in terms of its characteristic attributes or parameters, parameter design is used to establish appropriate parameter settings so as to reduce the design's sensitivity to uncontrollable sources of variation. Taguchi refers to these conditions as *noise factors*. Environmental factors (e.g., people and ambient temperature) and time-dependent phenomena (such as tool wear and material

© 1999 by CRC Press LLC

shrinkage) are examples of noise factors. As a last step, tolerance design is used to enhance or fine-tune the quality improvements realized during parameter design. However, tolerance design often involves a trade-off between the improved quality and the increased production costs incurred by tightening tolerances.

Parameter and tolerance design rely on experimental and mathematical techniques to determine the best design, subject to various noise factors. Various strategies may be used to conduct the experiments. Consider a system that involves five design parameters and three levels of settings — high, medium, and low — for each parameter. The simplest strategy is to investigate all possible combinations of parameters and level settings, which would require $3^5 = 243$ sets of experiments. Instead, orthogonal arrays are an efficient and economical alternative to complete enumeration.

Figure 11.5.2 shows a portion of the L18 orthogonal array that enables a reduction in the work scope from 243 to 18 sets of experiments. The column headings A, B, C. D, and E correspond to each of the five design parameters or controllable factors, and the column entries refer to the three level settings 1, 2, and 3. Each row of the array defines an experiment as a unique combination of parameter settings. Any two columns have nine combinations of level settings — (1,1), (1,2), (1,3), (2,1), (2,2), (2,3), (3,1), (3,2), and (3,3) — and each combination appears with the same frequency. This balance is indicative of the array's orthogonality in a statistical sense because the influence of each control factor can be evaluated independently. The basic array can be extended to include the influence of noise factors and their level settings.

Experiment	Parameter Level Setting				
	A	B	C	D	E
1	1	1	1	1	1
2	2	2	2	2	2
3	3	3	3	3	3
4	1	1	2	2	3
5	2	2	3	3	1
6	3	3	1	1	2
7	1	2	1	3	2
8	2	3	2	1	3
9	3	1	3	2	1
10	1	3	3	2	2
11	2	1	1	3	3
12	3	2	2	1	1
13	1	2	3	1	3
14	2	3	1	2	1
15	3	1	2	3	2
16	1	3	2	3	1
17	2	1	3	1	2
18	3	2	1	2	3

FIGURE 11.5.2 Portion of L18 orthogonal array to investigate all combinations of five parameters with three level settings.

Analysis of variation techniques provide a mathematical basis for organizing and interpreting the experimental results. For each performance requirement, signal-to-noise (S/N) ratio is used to express how sensitive each design parameter is to uncontrollable noise (which is indicative of *design robustness*). A robust design has a high S/N ratio and performs well despite the influence of noise. Many equations are available for calculating S/N ratios, and the selection of the appropriate equation is a function of the type of cause–effect relationship under study. Examples include *higher-is-better, lower-is-better,* and *nominal-is-best*. The reader is referred to Taguchi (1987, 1993) for further information.

Design for Assembly

Design for assembly (DFA) supports the analysis and design of products for ease of assembly. Based on a collection of empirical time-study data, if–then rules, and design checklists, DFA methods and tools help the designer to focus on the relationship between the geometric features of a design and its

© 1999 by CRC Press LLC

components and the effort and resources necessary to assemble these components into the desired product. Philips International, Hitachi, Xerox, Ford, and General Electric have been industry leaders in the adoption and dissemination of DFA. In this section the most widely known method, advanced by Boothroyd and Dewhurst (1985), is considered. The method gives the total assembly time and design efficiency, and these measures are then used to guide redesign.

The method of Boothroyd and Dewhurst (1985) starts with the description of a product's assembly sequence in terms of components, component features, and the basic assembly tasks of handling and insertion (which includes fastening). For each component involved in the assembly sequence, a catalog of generic part features is used to classify the component with respect to its difficulty for handling and insertion. These classifications are then used to determine the time required for each assembly task, and the task times are added to give the total operation time for the component. Therefore, the total assembly time (TM) for the design is the sum of the operation times for each component.

Design efficiency is the ratio of an estimated, ideal assembly time to TM. The ideal assembly time is based on a theoretical minimum number of parts (NM). The estimation of NM relies on a checklist for identifying redundant components or components that may be combined to reduce parts count. For manual assembly, the ideal assembly time is specified as 3 sec per part, and design efficiency EM is given by the equation

$$EM = 3 \times NM/TM \tag{11.5.1}$$

The resulting values for assembly time and design efficiency provide the designer with a basis for redesign. Suggested strategies for redesign include reduction in parts count, use of symmetry to facilitate handling, and use of alternative fastening mechanisms to facilitate insertion (e.g., snap-fit elements are faster to insert than parts requiring screw tightening). The reader is referred to Boothroyd and Dewhurst (1985) for further information.

11.6 Strategies for Product Design

Michael Pecht

Requirements

The design team must have a clear appreciation of user requirements and constraints before a design can begin. Requirements are established within the context of product effectiveness attributes and include limits on parameters such as speed, miles per gallon, computations per second, and accuracy, as well as constraints on size, weight, reliability, and cost. Often, contractual requirements and company policy can dictate a product type, such as the use of an in-house technology or product, or the exclusion of a technology or product.

Requirements must be addressed holistically in the design of a product and must not be limited to those that affect the product's immediate performance. For example, the supportability of the product is a critical product requirement for many products in terms of the ease of maintenance and accessibility to the products, spares, support equipment, the time and required personnel to repair the product, and the ease of discovering or detecting where a problem occurs. A poor definition of requirements could lead to a design where, for example, the air conditioning compressor has to be removed to replace a spark plug, or where special tools are required to replace the oil in a car. Note also that the design team should be aware of the impact of administrative policies on the reliability of products as reflected in the product's scenario for use. For example, outdated standards can contribute to failures that are not the result of either faulty design or human error.

The Life Cycle Usage Environment

The life cycle usage environment or scenario for use of a product goes hand-in-hand with the product requirements. The life cycle usage information describes the storage, handling, and operating stress profiles and thus contains the necessary "load" input information for effective assessment and development of design guidelines, screens, and tests. The stress profile of a product is based on the application profile and the internal stress conditions of the product. Because the performance of a product over time is often highly dependent on the magnitude of the stress cycle, the rate of change of the stress, and even the time and spatial variation of stress, the interaction between the application profile and internal conditions must be specified. Specific information about the product environment includes absolute temperature, temperature ranges, temperature cycles, temperature gradients, vibrational loads and transfer functions, chemically aggressive or inert environments, and electromagnetic conditions. The life cycle usage environment can be divided into three parts: the application and life profile conditions, the external conditions in which the product must be stored, handled, and operated, and the internal product-generated stress conditions.

The application and life profile conditions include the application length, the number of applications in the expected life of the product, the product life expectancy, the product utilization or nonutilization (storage, testing, transportation) profile, the deployment operations, and the maintenance concept or plan. This information is used to group usage platforms (i.e., whether the product will be installed in a car, boat, satellite, underground), develop duty cycles (i.e., on–off cycles, storage cycles, transportation cycles, modes of operation, and repair cycles), determine design criteria, develop screens and test guidelines, and develop support requirements to sustain attainment of reliability and maintainability objectives. The external operational conditions include the anticipated environment(s) and the associated stresses that the product will be required to survive. The stresses include temperature, vibrations, shock loads, humidity or moisture, chemical contamination, sand, dust and mold, electromagnetic disturbances, radiation, etc.

The internal operational conditions are associated with product-generated stresses, such as power consumption and dissipation, internal radiation, and release or outgassing of potential contaminants. If

© 1999 by CRC Press LLC

the product is connected to other products or subsystems in a system, stresses associated with the interfaces (i.e., external power consumption, voltage transients, electronic noise, or dissipation) must also be included.

Characterization of Materials, Products, and the Manufacturing Processes

Design is intrinsically linked to the materials, products, interfaces, and manufacturing processes used to establish and maintain functional and structural integrity. It is unrealistic and potentially dangerous to assume defect-free and perfect-tolerance materials, products, and structures. Materials often have naturally occurring defects and manufacturing processes can induce additional defects to the materials, products, and structures. The design team must also recognize that the production lots or vendor sources for products that comprise the design are subject to change. Even greater variability in products characteristics is likely to occur during the fielded life of a product as compared to its design or production life cycle phases.

Design decisions involve the selection of products, materials, and controllable process techniques, using tooling and processes appropriate to the scheduled production quantity. Often, the goal is to maximize product and configuration standardization; increase package modularity for ease in fabrication, assembly, and modifications; increase flexibility of design adaptation to alternate uses; and utilize alternate fabrication processes.

Design Guidelines and Techniques

Generally, new products replace existing products. The replaced product can be used for comparisons (i.e., a baseline comparison product). Lessons learned from the baseline product can be used to establish new product parameters, to identify areas of focus in the new product design, and to avoid the mistakes of the past.

Once the products, materials, processes, and stress conditions have been characterized, design begins. In using design guidelines, there may not be a unique path to follow. Multiple branches may exist depending upon the input design constraints. The design team should explore enough of the branches to gain confidence that the final design is the best for the prescribed input information. The design team should also use guidelines for the complete design and not those limited to specific aspects of an existing design. This statement does not imply that guidelines cannot be used to address only a specific aspect of an existing design, but the design team may have to trace through the implications that a given guideline suggests.

Design guidelines that are based on physics of failure models can also be used to develop tests, screens, and derating factors. Tests can be designed from the physics of failure models to measure specific quantities and to detect the presence of unexpected flaws, manufacturing, or maintenance problems. Screens can be designed to precipitate failures in the weak population while not cutting into the design life of the normal population. Derating or safety factors can be determined to lower the stresses for the dominant failure mechanisms.

Preferred Products

In many cases, a product or a structure much like the required one has already been designed and tested. This is called a “preferred product or structure” in the sense that variabilities in manufacturing, assembly, and field operation that can cause problems have been identified and corrected. Many design teams maintain a list of preferred products and structures with acceptable performance, cost, availability, and reliability.

Redundancy

Redundancy permits a product to operate even though certain components and interconnections have failed. Redundant configurations can be classified as either active or standby. Elements in active redundancy operate simultaneously in performing the same function. Elements in standby redundancy are

© 1999 by CRC Press LLC

designed so that an inactive one will be switched into service when an active element fails. The reliability of the associated function is increased with the number of standby elements (optimistically assuming that the sensing and switching products of the redundant configuration are working perfectly, and failed redundant components are replaced before their companion component fails).

A design team may often find that redundancy is a way to improve product reliability if time is of prime importance, if the products requiring redundancy are already designed and the products are known to be of poor reliability.

On the other hand, in weighing its advantages, the design team may find that redundancy will

- Prove too expensive, if the products and redundant sensors and switching products are costly
- Exceed the limitations on size and weight, particularly in avionics, missiles, and satellites
- Exceed the power limitations, particularly in active redundancy
- Attenuate the input signal, requiring additional amplifiers (which increase complexity)
- Require sensing and switching circuitry so complex as to offset the reliability advantage of redundancy

Protective Architectures

It is generally desirable to include means in a design for preventing a product, structure, or interconnection from failing catastrophically, and instead allow it to fail safely.

Fuses and circuit breakers are examples used in electronic products to sense excessive current drain and disconnect power from a failed circuit. Fuses within circuits safeguard products against voltage transients or excessive power dissipation and protect power supplies from shorted parts. Thermostats may be used to sense critical temperature, limiting conditions and shutting down the product or a component of the system until the temperature returns to normal. In some products, self-checking circuitry can also be incorporated to sense abnormal conditions and operate adjusting means to restore normal conditions or activate switching means to compensate for the malfunction.

Protective architectures can be used to sense failure and protect against possible secondary effects. In other cases, means can be provided for preventing a failed product or structure from completely disabling the product. For example, a fuse or circuit breaker can disconnect a failed product from a product in such a way that it is possible to permit partial operation of the product after the failure, in preference to total product failure. By the same reasoning, degraded performance of a product after failure of a product is often preferable to complete stoppage. An example is the shutting down of a failed circuit whose design function is to provide precise trimming adjustment within a deadband of another control product. Acceptable performance may thus be permitted, perhaps under emergency conditions, with the deadband control product alone.

Sometimes the physical removal of a part from a product can harm or cause failure of another part of the product by affecting load, drive, bias, or control. In some cases, self-healing techniques can be employed to self-check and self-adjust to effect changes automatically to permit continued operation after a failure.

The ultimate design, in addition to its ability to act after a failure, would be capable of sensing and adjusting for drifts to avert failures.

In the use of protective techniques, the basic procedure is to take some form of action after an initial failure or malfunction, to provide perhaps reduced performance, and to prevent additional or secondary failures. Such techniques can be considered as enhancing product reliability, although they also affect availability and product effectiveness. No less a consideration is the impact of maintenance, repair, and product replacement. If a fuse protecting a circuit is replaced, what is the impact when the product is reenergized? What protective architectures are appropriate for postrepair operations? What maintenance guidance must be documented and followed when fail-safe protective architectures have or have not been included?

© 1999 by CRC Press LLC

Stress Margins

Products and structures should be designed to operate satisfactorily at the extremes of the parameter ranges, and allowable ranges must be included in the procurement or reprocurement specifications. To guard against out-of-tolerance failures, the design team must consider the combined effects of tolerances on products, subsequent changes due to the range of expected environmental conditions, drifts due to aging over the period of time specified in the reliability requirement, and tolerances in products used in future repair or maintenance functions.

Methods of dealing with product and structural parameter variations include statistical analysis and worst-case analysis. In statistical design analysis, a functional relationship is established between the output characteristics of the structure and the parameters of one or more of its products. In worst-case analysis, the effect that a product has on product output is evaluated on the basis of end-of-life performance values or out-of-specification replacement products.

Derating

The principle of derating is that there are no distinct stress boundaries for voltage, current, temperature, power dissipation, etc. above which immediate failure can occur and below which the product will operate indefinitely. Instead, the life of some products increases in a continuous manner as the stress level is decreased below the rated value. Practically, however, there are minimum stress levels below which increased derating will lower reliability, and the complexity required to step up performance will offset any gain in reliability.

Size and Weight Control

Methods to reduce product volume include:

- Eliminating unused space
- Selecting an exterior shape to require least possible volume when integrated with the intended installation structure
- Eliminating separable interconnections, using optimally shaped components and subassemblies
- Minimizing interconnection requirements
- Eliminating support components such as heat sinks, blowers, and special coolant flow passages
- Eliminating redundant components
- Using components and package elements to perform multiple functions

Methods to lower product weight include using high-strength lightweight materials, eliminating duplicate structures, and providing only that degree of strength required to reach a desired safety factor.

Potential Failure Sites and Failure Mechanisms

The design team must evaluate the potential failure mechanisms, failure stresses, failure sites, and failure modes, given a product architecture, the comprising products and materials, and the manufacturing processes. One approach to evaluation consists of the assessment of a list of candidate or "potential" failure mechanisms. The load conditions that cause the failure mechanisms to occur are then determined in light of the life cycle usage environment identified earlier. Table 11.6.1 presents various failure mechanisms and the associated load conditions.

Once the failure mechanisms and associated stresses have been identified, then failure sites are specified and a detailed reliability assessment is conducted for each location suspected to be a potential area of failure. Table 11.6.2 presents an example case of various failure sites, mechanisms, and load structures for a microelectronic product.

Failures can be categorized by their impact on end product performance. A critical failure is an event that reduces the performance of the end product to unacceptable levels. A noncritical failure, also called a fault, does not reduce performance to unacceptable levels. Failures can also be classified by the time

frame and manner in which the event occurs. The categories are catastrophic, intermittent, out-of-tolerance, and maladjustment.

1. **Catastrophic failures.** A catastrophic failure occurs when a product becomes completely inoperative or exhibits a gross change in characteristics. Examples are an open or shorted resistor or capacitor, a leaky valve, a stuck relay, or a broken switch.
2. **Intermittent failures.** Intermittent failures are nonperiodic failures that can occur within products, interconnects, or product interfaces including software. Examples include switch bouncing and poor transmission of signals. The design team must not only safeguard against the effects of intermittent failures, but also avoid creating possible modes of such failures (e.g., conditions permitting product-to-product or structural breakdowns).
3. **Out-of-tolerance failures.** Out-of-tolerance failures result from degradation, deterioration, drift, and wearout. Examples are the drifting of resistor and capacitor values and the wearing out of relays and solenoid valves and precision gears. The changes can arise as a result of time, temperature or temperature cycles, humidity, altitude, etc. When these changes, considered collectively, reach the point where product performance is below acceptable limits, we say that the product has failed.
4. **Maladjustment failures.** Maladjustment failures are often due to human error. Failures arise from improper adjustment of products, as well as abuse of adjusting products due to lack of understanding of the adjustments and the capabilities of the products. Such failures are hard to evaluate and difficult to avoid but must be considered if the reliability of the product is to be sustained.

Designing for the Application Environment

The design of modern products requires that the team be acquainted with the environmental factors affecting product performance over time. The environment is seldom forgiving and when a weak point exists, performance suffers. Design teams must understand the environment and its potential effects and then must select designs or materials that counteract these effects or provide methods to alter or control the environment within acceptable limits.

In addition, a product can create or perturb an environment. For example, many epoxies out-gas during cure, releasing corrosive or degrading volatiles or particulates into the product. Teflon may release fluorine and polyvinylchloride (PVC) may release chlorine. Certain solid rocket fuels are degraded into a jelly-like mass when exposed to aldehydes or ammonia, either of which can come from a phenolic nozzle cone. Common environmental considerations follow.

Temperature Control

Temperature is a powerful agent for electrical, chemical, and physical deterioration for two basic reasons:

- The physical properties of almost all known materials are modified by changes in temperature, temperature gradients, and temperature extremes.
- The rate of most chemical reactions is influenced by the temperature of the reactants.

Nevertheless, the effects of steady-state temperature and spatial and temporal temperature gradients must be clearly understood before a thermal control method is determined. A good practice is to develop a table of potential failure sites and failure mechanisms and the effects of temperature in its many forms.

Poor heat removal of dissipated I^2R losses, hysteresis, or eddy current losses can result in physical damage or accelerated chemical reaction rates. The latter occurrence, affecting certain types of materials, can cause general degradation and catastrophic or intermittent failures. But the fault is not always with the design; air intakes or outlets could be blocked because of faulty installation, or maintenance personnel might fail to clear or replace air filters.

Thermal management schemes for electronic equipment are selected, once the heat flux and the maximum temperature difference available for heat transfer have been identified. A complete thermal

© 1999 by CRC Press LLC

management strategy involves selecting an appropriate heat removal scheme for each level of packaging. For low heat fluxes, passive thermal management techniques can be used. Such techniques do not require the expenditure of external energy for the heat removal. Interest in such techniques is currently very strong, due to their design simplicity, low cost, and high reliability.

Examples of passive cooling techniques include conduction cooling using high thermal conductivity substrates and/or heat sinks and natural convection air cooling. Conduction cooling can be employed when the heat source is not directly exposed to the coolant. This method is desirable in dense electronic packages, where radiation and convection are not effective cooling means. Natural convection cooling relies on the buoyancy-induced flows generated due to heating. For a maximum temperature rise of 85°C above the environment, heat fluxes of up to about 0.1 W/cm^2 can be removed by natural convection air cooling under nominal sea-level environmental conditions.

For higher heat fluxes, a combination of passive and active techniques can sometimes be used. This may include, for example, a high thermal conductivity substrate at the board level, along with forced air cooling at the box level. For this range of heat fluxes, the use of cold plate technology, thermoelectrics, and flow-through cooling are also possible; other common techniques are the use of heat pipe or thermosyphon (see Chapter 4).

Besides the out-gassing of corrosive volatiles when subjected to heat, almost all known materials will expand or contract when their temperature is changed. This expansion and contraction causes problems with fit between product interface and interconnections. Local stress concentrations due to nonuniform temperature are especially damaging, because they can be so high. A familiar example is a hot water-glass that shatters when immersed in cold water. Metal structures, when subjected to cyclic heating and cooling, may ultimately collapse due to the induced stresses and fatigue caused by flexing. The thermocouple effect between the junction of two dissimilar metals causes an electric current that may induce electrolytic corrosion.

Plastics, natural fibers, leather, and both natural and synthetic rubber are all particularly sensitive to temperature extremes as evidenced by their brittleness at low temperatures and high degradation rates at high temperatures.

Shock and Vibration Control

Shock and vibration can harmfully flex leads and interconnects, dislodge parts or foreign particles into bearings, pumps, and electronics, cause acoustical and electrical noise, and lead to structural instabilities. Protective measures against shock and vibration stresses are generally determined by an analysis of the deflections and mechanical stresses produced by these environmental factors. This generally involves the determination of natural frequencies and evaluation of the mechanical stresses within components and materials produced by the shock and vibration environment. If the mechanical stresses so produced are below the acceptable safe working stress of the materials involved, no direct protection methods are required. If, on the other hand, the stresses exceed the safe levels, corrective measures such as stiffening, reduction of inertia and bending moment effects, and incorporation of further support members are indicated. If such approaches do not reduce the stresses below the acceptable safe levels, further reduction is usually possible by the use of shock-absorbing mounts.

Products are sometimes specially mounted to counter the destructive effects of shock and vibration. Shock mounts often serve this purpose, but effective means for attenuating shock and vibration simultaneously are complex. Isolation of a product against the effects of vibration requires that the natural frequency of the product be substantially lower than the undesired frequency of vibration.

Three basic kinds of isolators are available:

- Elastomers made of natural or synthetic rubber, used in a shear mode or in a diaphragm to dampen the induced shock or vibration.
- Metallic isolators, such as springs, metal meshes, or wire rope. Springs lack good damping qualities, but meshes and rope provide smooth friction damping.

© 1999 by CRC Press LLC

- Viscous dampers (similar to the type used on automobiles) which are velocity-sensitive, tend to become ineffective under high-frequency vibration. Resilient mounts must be used with caution, since they can amplify the intensity of shock and vibration if improperly placed. The ideal goal is to design a product to be resistant to shock and vibrations, rather than to provide complete isolation.

Another vibration protective technique is potting or encapsulation of small parts and assemblies. The potting material should be compliant enough to dampen vibrations. Some materials polymerize exothermically, and the self-generated heat may cause cracking of the casting or damage to heat-sensitive products. Another problem is shrinkage of the potting material. In some cases, molds are made oversized to compensate for shrinkage.

One factor that is not often considered is that the vibration of two adjacent components, or separately insulated subsystems, can cause a collision if maximum excursions and sympathetically induced vibrations are not accounted for in design. Another failure mode, fatigue (the tendency for a material to break under cyclic stress loads considerably below its tensile strength), includes high cycle fatigue, acoustic fatigue, and fatigue under combined stresses such as temperature extremes, temperature fluctuations, and corrosion.

In addition to using proper materials and configuration, it may still be necessary to control the amount of shock and vibration experienced by the product. Damping products are used to reduce peak oscillations and special stabilizers can be employed when unstable configurations are involved. Typical examples of dampeners are viscous hysteresis, friction, and air damping. Vibration isolators commonly are identified by their construction and material used for the resilient elements (rubber, coil spring, woven metal mesh, etc.). Shock isolators differ from vibration isolators in that shock requires a stiffer spring and a higher natural frequency for the resilient element. Some of the types of isolation mounting products are underneath, over-and-under, and inclined isolators. In some cases, however, even though an item is properly insulated and isolated against shock and vibration damage, repetitive forces may loosen the fastening products. If the fastening products loosen enough to permit additional movement, the product will be subjected to increased forces and may fail. Many specialized self-locking fasteners are commercially available.

Chemical Action Control

The earth's environment contains numerous deteriorators including oxygen, carbon dioxide, nitrogen, snow, ice, sand, dust, salt water spray, organic matter, and chemicals in general. Product specifications often state limits on temperature, humidity, altitude, salt spray, fungus, sunshine, rain, sand, and dust.

A material or structure can chemically change in a number of ways. Among them are interactions with other materials (i.e., metal migration, diffusion) and modifications in the material itself (recrystallization, stress relaxation, phase changes, or changes induced by irradiation). In addition to the deterioration problems associated with the external environments to which products are subjected, adhesives, batteries, and certain types of capacitors are susceptible to chemical aging and biological growths.

Materials widely separated in the electromotive series are subject to galvanic action, which occurs when two dissimilar metals are in contact in a liquid medium. The most active metal dissolves, hydrogen is released, and an electric current flows from one metal to the other. Coatings of zinc are often applied to iron so that the zinc, which is more active, will dissolve and protect the iron (a process known as *galvanization*). Galvanic action is known to occur within the same piece of metal, if one portion of the metal is under stress and has a higher free-energy level than the other. The part under stress will dissolve if a suitable liquid medium is present. Stress-corrosion cracking occurs in certain magnesium alloys, stainless steels, brass, and aluminum alloys. It has also been found that a given metal will corrode much more rapidly under conditions of repeated stress than when no stress is applied.

Corrosion-resistant materials should be used as much as possible. Although aluminum is excellent in this respect due to the thin oxide coating that forms when it is exposed to the atmosphere, it tends to

© 1999 by CRC Press LLC

pit in moist atmospheres. Furthermore, aluminum may corrode seriously in a salt-laden marine atmosphere. Either anodization or priming with zinc chromate can provide additional protection.

Magnesium is sometimes used to minimize the weight of products but must be protected by surface additives against corrosion and electrolytic reaction. A coating of zinc chromate serves both purposes. Because magnesium is the most reactive metal normally used for structural purposes, the grounding of the magnesium structure requires careful selection of another metal for making the connection. Zinc- or cadmium-plated steel are the more commonly chosen connective materials.

Copper, when pure, is quite resistant to corrosion. However, under certain conditions, copper-made products will become chemically unstable. Transformers have occasionally failed due to impurities in the insulation and moisture. These conditions favor electrolytic reaction, which causes the copper to dissolve and eventually results in an open circuit.

Iron and steel are used in many products and structures because of their good magnetic and structural properties; however, only certain stainless steels are reasonably resistant to corrosion. Various types of surface plating are often added, but since thin coatings are quite porous, undercoatings of another metal such as copper are often used as a moisture barrier. Cadmium and zinc plating in some marine environments corrode readily, and often grow "whiskers", which can cause short circuits in an electronic product.

Proper design of a product therefore requires trade-offs in

- Selecting corrosion-resistant materials
- Specifying protective coatings if required
- Avoiding use of dissimilar metallic contacts
- Controlling metallurgical factors to prevent undue internal stress levels
- Preventing water entrapment
- Using high-temperature resistance coatings when necessary
- Controlling the environment through dehydration, rust inhibition, and electrolytic and galvanic protective techniques

Biological Growth Control

High humidity and warm temperatures often favor the growth of fungus, which can lead to deterioration of many electrical and mechanical properties. Products designed for use under tropical conditions can receive a moisture- and fungus-proofing treatment, which consists of applying a moisture-resistant varnish containing a fungicide. Air-drying varnishes generally are not as moisture-proof as are the baked-on types. This treatment is usually quite effective, but the useful life of most fungicides is less than that of the varnish, and retreatments may be necessary.

Moisture Control

Moisture, and impurities that may be contained with it, are known to cause corrosion of many metal systems. In addition, mated products can be locked together, especially when moisture condenses on them and then freezes. Similarly, many materials that are normally pliable at low temperatures become hard and brittle if moisture has been absorbed and subsequently freezes. Condensed moisture acts as a medium for the interaction between many, otherwise relatively inert, materials. Most gases readily dissolve in moisture. The volume increase from water freezing (i.e., converting from a fluid to solid state) can also physically separate components, materials or connections. The chlorine released by PVC plastic, for example, forms hydrochloric acid when combined with moisture.

Although the presence of moisture may cause deterioration, the absence of moisture also may cause reliability problems. The useful properties of many nonmetallic materials such as leather and paper, which become brittle and crack when they are very dry, depend upon an optimum level of moisture. Similarly, fabrics wear out at an increasing rate as moisture levels are lowered, and fibers become dry and brittle. Environmental dust can cause increased wear, friction, and clogged filters due to lack of moisture.

© 1999 by CRC Press LLC

Moisture, in conjunction with other environmental factors, creates difficulties that may not be characteristic of the factors acting alone. For example, abrasive dust and grit, which would otherwise escape, can be trapped by moisture. The permeability (to water vapor) of some plastics (PVC, polystyrene, polyethylene, etc.) is related directly to their temperature. The growth of fungus is enhanced by moisture, as is the galvanic corrosion between dissimilar metals. Some design techniques that can be used separately or combined to counteract the effects of moisture are

- Elimination of moisture traps by providing drainage or air circulation
- Using desiccant products to remove moisture when air circulation or drainage is not possible
- Applying protective coatings
- Providing rounded edges to allow uniform coating of protective material
- Using materials resistant to moisture effects, fungus, corrosion, etc.
- Hermetically sealing components, gaskets, and other sealing products
- Impregnating or encapsulating materials with moisture-resistant waxes, plastics, or varnishes
- Separation of dissimilar metals or materials that might combine or react in the presence of moisture or of components that might damage protective coatings.

The design team also must consider possible adverse effects caused by specific methods of protection. Hermetic sealing, gaskets, protective coatings, etc. may, for example, aggravate moisture difficulties by sealing moisture inside or contributing to condensation. The gasket materials must be evaluated carefully for outgassing of corrosive volatiles or for incompatibility with adjoining surfaces or protective coatings.

Sand and Dust Protection

In addition to the obvious effect of reduced visibility, sand and dust can degrade a product by abrasion leading to increased wear, friction causing both increased wear and heat, and clogging of filters, small apertures, and delicate products. Thus, products having moving parts require particular care when designing for sand and dust protection. Sand and dust will abrade optical surfaces, either by impact when being carried by air or by physical abrasion when the surfaces are improperly wiped during cleaning. Dust accumulations have an affinity for moisture and when combined may lead to corrosion or the growth of fungus.

In relatively dry regions, such as deserts, fine particles of dust and sand can readily be agitated into suspension in the air, where they may persist for many hours, sometimes reaching heights of several thousand feet. Thus, even though there is virtually no wind present, the speeds of vehicles or vehicle-transport product through these dust clouds can also cause surface abrasion by impact.

Although dust commonly is considered to be fine, dry particles of earth, it also may include minute particles of metals, combustion products, and solid chemical contaminants. These other forms may provide direct corrosion or fungal effects on products, because this dust may be alkaline, acidic, or microbiological.

When products require air circulation for cooling or removing moisture, the question is not whether to allow dust to enter, but rather how much or what size dust can be tolerated. The problem becomes one of filtering the air to remove dust particles above a specific nominal size. The nature of filters, however, is such that for a given working filter area, as the ability of the filter to stop increasingly smaller dust particles is increased, the flow of air or other fluid through the filter is decreased. Therefore, the filter surface area either must be increased, the flow of fluid through the filter decreased, or the allowable particle size increased (i.e., invariably, there must be a compromise). Interestingly enough, for aircraft engines, the amount of wear is proportional to the weight of ingested dust, but inversely proportional to dust size.

Sand and dust protection must be planned in conjunction with protective measures against other environmental factors. For example, it is not practical to specify a protective coating against moisture if sand and dust will be present, unless the coating is carefully chosen to resist abrasion and erosion or is self-healing.

© 1999 by CRC Press LLC

Explosion Control

Protection against explosion is both a safety and reliability problem. An item that randomly exhibits explosive tendencies is one that has undesirable design characteristics and spectacular failure modes. This type of functional termination, therefore, requires extreme care in design and reliability analyses.

Explosion protection planning must be directed to three categories (not necessarily mutually exclusive) of products:

- Items containing materials susceptible to explosion
- Components located near enough to cause the explosive items to explode
- Product that might be damaged or rendered temporarily inoperative by overpressure, flying debris, or heat from an explosion

The first category includes products containing flammable gases or liquids, suspensions of dust in the air, compounds that spontaneously decompose in certain environments, product containing or subjected to high or low extremes of pressure (includes implosions), or any other products capable of creating an explosive reaction. Keep in mind that even basically inert materials such as glass or metals can explode when subjected to rapid environmental changes or extremes such as temperature or stress.

The second category includes many variations on methods for providing an energy pulse, a catalyst, or a specific condition that might trigger an explosion. A nonexplosive component, for example, could create a corrosive atmosphere, mechanical puncture, or frictional wear on the side of a vessel containing a high-pressure and thereby cause the container to explode.

The third category is important because a potentially explosive product (such as a high-pressure air tank) can be damaged or made to explode from another explosion. Thus, some reasoning must be applied when considering products not defined by the first two categories. From a practical standpoint, explosion protection for items in the third category should be directed to product that might possibly be near explosions.

The possibility of an explosive atmosphere leaking or circulating into other product compartments must also be recognized. Lead-acid batteries, for example, create hydrogen gas that, if confined or leaked into a small enclosure, could be exploded by electrical arcing from motor brushes, by sparks from metallic impacts, or by exhaust gases. Explosive environments, such as dust-laden air, might be circulated by air distribution products. Dust from common ingredients such as wheat flour has been the source of massive, catastrophic explosions.

Explosion protection and safety are very important for design and reliability evaluations and must be closely coordinated and controlled. Just as a safe product is not necessarily reliable, neither is a reliable product necessarily safe; but the two can be compatible.

Electromagnetic Radiation Control

Protection against the effect of electromagnetic radiation has become a sophisticated engineering field of electromagnetic compatibility design. The radiation environment in space near the earth is composed primarily of Van Allen, auroral, solar flare, and cosmic phenomena. Of lesser importance are solar wind, thermal energy atoms in space, neutrons, naturally occurring radon gas, albedo protons, plasma bremsstrahlung, and man-made nuclear sources. In the electromagnetic spectrum are gamma rays, X-rays, ultraviolet, and Lyman-alpha radiation. Damage near the surface of the earth is caused by the electromagnetic radiation in the wavelength range from approximately 0.15 to 5 m. This range includes the longer ultraviolet rays, visible light, and up to about the midpoint of the infrared band. The most direct approach to protection is to avoid the limited region in which high radiation levels are found. When exposure cannot be avoided, shielding and filtering are important protective measures. In other cases, material design changes or operating procedural changes must be instituted in order to provide protection.

© 1999 by CRC Press LLC

High Vacuum Control

In a high vacuum, materials with a high vapor pressure will sublimate or evaporate rapidly, particularly at elevated temperatures. In some plastics, the loss of plasticizer by evaporation will cause cracking, shrinking, or increased brittleness. Metals such as magnesium, which would normally evaporate rapidly (1 g/cm^2/year at 250°C), can be protected by inorganic coatings with low vapor pressures.

In a high vacuum, adjoining solid surfaces can become cold-welded after losing adsorbed gases. Some form of lubrication is therefore necessary. Conventional oils and greases evaporate quickly. Graphite becomes unsatisfactory (actually an abrasive) because of the loss of absorbed water. However, thin films of soft metals, such as lead, silver, or gold, are effective lubricants in a high vacuum. Thin films of molybdenum disulfide are often sprayed over chrome or nickel plating, forming easily sheared layers. The film also releases sulfur at interfaces during sliding, performing the same function as water vapor does for graphite.

Human Factors and Operability

Humans are active participants in the operating of many products, and can be traded as an external "stress." Consequently, the interaction of humans with products must be weighed against safety, reliability, maintainability, and other product parameters to assess product reliability, maintainability time and performance, system and subsystem safety analyses, and specific human engineering design criteria. For convenience and clarity, four types of human interactions with a product are identified:

- Design and production of a product
- Operators and repairers as mechanical elements (human engineering)
- Operators and repairers as decision elements (human performance reliability)
- Bystanders (this classification is not considered further because it is largely a safety matter, unless they consciously or inadvertently operate or affect the operation of a product)

Designing for Operability

While product design teams, planners, and managers would hope to have well-above-average people in every position associated with product operation, product design must accommodate the realities of the product's life cycle use. The complexity of the product that is presented to the operator, the array of components, including ancillary product, cable connectors, patch panels, switches, knobs, controls, panel markings, meters, oscilloscopes, horns, bells, panel lights, etc., must be of concern in design. The various components comprising the product should be clearly labeled for easy identification. Those items that must be manipulated in order to connect the product (cable connectors, patch panels, switches) should be arranged in a simple and logical order and should be plainly marked. Typical constraints are that

- An operator should be within the physical capabilities of the complete range of potential operators.
- A person should not be required to do something that his or her coordination will not allow him or her to do.
- In times of psychological stress, people cannot easily use, read, and respond to controls and displays.

Mock-ups under realistic conditions are very helpful in uncovering potential problems early in the design process. For example, if a product must be used at night in extremely cold weather, have a person try to use it in a freezing, poorly lit room for several hours.

Designing for Maintainability

Few operational products can be perfectly reliable while meeting other product trade-offs such as rust. Maintenance can thus be an important consideration in the long-term effectiveness of a product.

© 1999 by CRC Press LLC

Maintainability is the probability that, when a specified maintenance action is initiated, a failed product will be restored to operable conditions in a specified downtime. Thus, design features that will expedite maintenance will enhance maintainability. Designing for maintainability means inclusion in the design of those features that can be conceived to assist the maintenance technician. Specific features include the degree of accessibility for product replacement, facilities for fault isolation, special tools or test-product requirements, the level of servicing skills required, servicing documentation requirements, and spare-part stocking requirements.

Critical rating factors include grouping of components by electrical function, use of integral fault indication for basic modules; components or functional assemblies removable without interruption of permanent electrical connections; elimination of tool requirements for mechanical disassembly; direct access to removable assemblies; products commonality; and identification of replaceable components.

In checking out a product, the maintenance technician must often also operate it. Therefore, the design considerations relating to operability are, in general, also applicable to maintainability. In addition, many design considerations relating to maintenance are more complex than those relating to operation.

The design team needs to consider how the product actually will be repaired in the field, perhaps under the pressures of understaffed maintenance crews, many of whom are inexperienced, or by field service personnel with limited knowledge about the product. The design team must always keep in mind that a product may be used and repaired by people who have other things in mind than "babying" the product. The design team must also realize the difference between what people will probably do and what the design team thinks they ought to do.

The design team, in acknowledging that a product could fail if not maintained, should provide means for ease of maintenance, ease of removal of a failed unit, trouble shooting, access to the failed unit, and repair or replacement. Such means, in addition to improving maintainability, will also improve reliability through the averting of subsequent failure due to human errors during maintenance. Many design details are important to the maintenance technician. A list of "Do's" and "Don'ts" in designing for maintainability is presented in Table 11.6.3.

TABLE 11.6.3 Warning to Design Teams: Some Common Design Errors Affecting Maintainability

Don't place products or maintenance structures (e.g., oil filter) where they cannot be removed without removal of the whole unit from its case or without first removing other products
Don't put an adjustment out of arm's reach
Don't neglect to provide enough room for the technician to get his or her gloved hand into the unit to make an adjustment
Don't screw subassemblies together in such a way that the maintenance technician cannot tell which screw holds what
Don't use chassis and cover plates that fall when the last screw is removed
Don't make sockets and connectors for modules of the same configuration so that the wrong unit can be installed
Don't provide access doors with numerous small screws or attachments
Don't use air filters that must be replaced frequently; don't place these filters so that it is necessary to shut down power and disassemble the product to reach them
Don't omit the guide from a screwdriver adjustment, so that while the technician is adjusting and watching a meter, the screwdriver slips out of the slot
Don't design frequent failure or highly adverse impact failure items in least accessible locations
Don't unnecessarily subject nonwear components to failure stress caused by maintenance actions

The Design Team

During the entire period of design, reliability should be continuously monitored by the design team. The membership of the design team and the technical matters requiring their attention are shown in Table 11.6.4. A generic guiding list is given in Table 11.6.5.

© 1999 by CRC Press LLC

TABLE 11.6.4 Design Team

Members	Technical Considerations
Project engineer	Products lists and application
Electrical, mechanical, chemical, manufacturing, and design representations	Tolerance studies
Management representatives	Environmental and operational effects
Maintenance and logistics representatives	Drift, aging, and end-of-life parameters
User community representatives	Regression or worst-case analysis
	Reliability analysis
	Trade-off studies
	Maintenance factors
	Test data
	Availability and affordability analysis

TABLE 11.6.5 Design Reliability Check List Item

Are the requirements for performance, application, environment, and maintainability and reliability established for each product, interface, and structure?
Are the best available methods for reducing the adverse effects of operational environments on critical structures being utilized?
Have normal modes of failure and the magnitude of each mode for each component or critical product have been identified as to root cause?
Has shelf life of products chosen for final design been determined?
Have limited-life products been identified and inspection and replacement requirements specified?
Have critical products that require special procurement, testing, and handling been identified?
Are effective safety factors being used in the application of products, interfaces, and structures?
Have studies been made considering variability and degradation of parameters of products and structures?
Have all vital adjustments been classified as to factory, preoperational, or operator types?
Have adjustments been minimized?
Have stability requirements of all products and structures associated with each adjustment been established?
Are similar plugs and connectors adequately protected against insertion in wrong socket?
Are malfunction-indicating products being used extensively?
Are self-monitoring or self-calibration products installed in major products where possible?
Are mechanical support structures adequate?
Is there a concentrated effort to make the developmental model as near to the production model as possible?
Have packaging and mechanical layout been designed to facilitate maintenance and to reduce maintenance costs and downtime?

Summary

When a product is being designed, it is assumed that the required investment will be justified according to how well the product performs its intended function over time. This assumption cannot be justified when a product fails to perform upon demand or fails to perform repeatedly. It is not enough to show that a product can conduct a function but that it can do so repeatedly when needed by the product user.

The design of any product involves trade-offs, including, but not limited to, performance capability, size, weight cost, product maintenance activities, and other factors, depending upon the intended use. In cases where human life is at risk, reliability issues play a major role in design. However, it is equally important to ask how large can a safety factor be for a critical situation such as a spacecraft, where human life might be in jeopardy, yet weight is a governing element.

The demand for better performance over time, coupled with higher-life cycle costs and stricter legal liabilities, has made product reliability of great importance. As the attitude toward production of engineering products has changed, reliability has established itself as one of the key elements when designing and manufacturing a product. However, the application of reliability principles in the product design and manufacturing processes has not always kept pace with the evolution of highly complex and dynamic engineering products. The design team must understand reliability theory and techniques, in conjunction

© 1999 by CRC Press LLC

with design and manufacturing processes as well as the scenario for use of the product. The goal is to provide a scientific basis for design decisions considering product effectiveness requirements and the scenario for use, create a product design that will satisfy those requirements, and document those design decisions for both the hardware product and the recommended support product for sustaining product effectiveness during the life of the product.

11.7 Design of Manufacturing Systems and Processes

Leonard D. Albano

Design of Manufacturing Systems

Section 11.6 provides strategies for the design of products that meet the customer's needs, based on findings derived from market studies and product research and development. The success of such designs depends on the enterprise's ability to manufacture it, without compromising product performance or incurring noncompetitive production costs. Thus, the design of a manufacturing system must be done with a clear understanding of the functional requirements and physical design parameters for a product and an appreciation for the business goals and constraints.

The structure of a manufacturing system is hierarchical. At the highest level, there are two distinct subsystems: the *direct manufacturing operations* and the *indirect overhead functions*. The direct manufacturing operations consist of the employees and equipment needed to convert the input resource materials into the final desired products. The indirect overhead functions refer to the people, vendors, and capital that support and supervise the direct operations. At the lowest level, the manufacturing system is defined by many basic manufacturing operations, such as metal cutting and plastic forming, that are used to create specific part types (see Chapter 13).

Manufacturing systems can be classified in terms of the volume and variety of products produced. One possible classification scheme is as follows:

1. *Continuous flow processes*: high volume production of a single product type, such as sugar and oil refineries
2. *Assembly lines*: high volume production of a limited product variety; relies on standardized components and interchangeable parts; common system for automotive industry
3. *Batch processing*: relatively low volume production of multiple product types; concepts of group technology used to batch workpieces to increase efficiency of process routing; example applications include the manufacture of aircraft and heavy construction equipment
4. *Job shop*: low volume production of a variety of nonstandard parts; focuses on customized products; early reliance on craftsmen has shifted to cellular manufacturing systems in order to maximize flexibility and throughput

The design of a manufacturing system may be defined in terms of the concept of domains, as presented in Section 11.3, and the integration of three or more design fields; they are product design, organization design, and software design.

1. *Product design*: The design of the direct manufacturing operations is based on mapping the product's design parameters in the physical domain to process variables in the process domain.
2. *Organizational design*: The human and financial resources, which contribute to both direct operations and the indirect overhead, are provided to satisfy the goals and structure of the business organization.
3. *Software design*: Computer-based tools are easily available to control production and inventory levels, support information flow for decision-making, and automate manufacturing operations.

Several important advances in manufacturing can be identified from the above design model. *Concurrent engineering* refers to the integration of product design and manufacturing system design. This approach involves continuous mapping from the functional domain to the physical domain to the process domain. If the organizational structure changes to adapt to new customer needs, the single enterprise may be replaced by a highly flexible, virtual enterprise that pools resources from several qualified organizations for rapid response. This virtual enterprise corresponds to *agile manufacturing*. With a rationalized approach to system design, the role of the computers, information technology, robots, etc. can be better understood (see Chapter 13). Mitchell (1991) defines *computer-integrated manufacturing*

© 1999 by CRC Press LLC

as "the use of computers to achieve an integrated flow of manufacturing activities, based on integrated information flow that links together all organizational activities."

A designer may develop many different manufacturing systems that are technically feasible. The designer must have some basis for the selection of a system and the layout of the various elements that comprise it. The evaluation of economic feasibility is one criterion for decision-making. Economic feasibility depends on the planned production volume, fixed resources, total production costs, projected revenue stream, and the desired income. The latter case involves consideration of the investment strategy. Because of the interrelations among the system performance and the economic factors, the suggested design procedure is to consider economic feasibility as a design constraint. The ideal to be achieved is one involving the design and production of reliable products that satisfy the customer's needs, while providing the desired profit and return on investment. See Chapter 13 for information on manufacturing system and enterprise management.

Manufacturing Process Design

The principal objective of manufacturing process design is to produce an organized plan for converting raw materials into useful products. It involves the selection of timely and cost-effective methods to produce a product without compromising quality and reliability. As part of the product development process, good manufacturing process design contributes to the industrial competitiveness of a manufacturing enterprise, while poor process design contributes to cost and schedule overruns and the delivery of products that fail to meet some or all of the customers' needs.

Manufacturing process planning often requires the consideration of several manufacturing processes for a specific part. In addition to considering manufacturing costs and production time, rational planning should also involve evaluation of how well a particular process satisfies the design requirements, which are delineated within the engineering drawings and reference specifications. The suitability of a given process may be based on many factors, such as

1. The dimensions and geometric precision that can be obtained
2. The surface roughness that can be attained
3. The changes that may be produced in material properties and part performance

Unfortunately, there is seldom much time to conduct an exhaustive laboratory or computer-based study and evaluation of all solution alternatives. A systematic approach to design that provides fundamental principles for decision-making would facilitate process design while enabling the designer to consider all important factors. Section 11.4, for instance, describes the concept of axiomatic design as a scientific framework for design and decision-making.

Metals Processing

Metal shapes and components can be produced by various casting, forming, and metal-removal processes (see Chapter 13). In the case of metal removal, process planning involves selecting and sequencing the appropriate machine tools and operations so as to convert a solid piece part from its initial shape to a final, desired geometry. This involves matching machine and tool data to the design requirements, subject to certain constraints imposed by the manufacturing organization and facilities. In practice, it consists of five or more steps:

1. Interpretation of the engineering drawing and reference specifications
2. Selection of machining operations to form the specified surfaces
3. Selection of machine tools for each machining operation
4. Selection of jigs and fixtures to guide or facilitate machining
5. Sequencing the machining operations

© 1999 by CRC Press LLC

The initial material shape may be one of any number of geometries, ranging from simple bar stock to a complex casting. Basic machine tool operations are discussed in Chapter 13, and they include shaping, planing, turning, grinding, sawing, and drilling.

Process planning is performed by either experienced planners or automated software systems. There are at least two major difficulties associated with relying solely on human planners. First, they often rely on intuition gained through experience, and this experience requires a significant period of time to accumulate. Consequently, the number of truly skilled planners in any given industry is limited from generation to generation. Second, the capacity of a manufacturing enterprise to adopt new processes and new systems is limited by the knowledge background and creativity of the process planner. In order to address these problems, computer-aided process planning (CAPP) systems (see Chapter 13) have been developed.

The two fundamental strategies for CAPP are the *variant approach* and the *generative approach*. The variant approach is closely related to the automation of manual process planning techniques, i.e., the process plan for a specific part is created by computer-based retrieval of an existing process plan from a data base. Thus, the role of the computer in a variant system is primarily to manage a data base of process knowledge. Generative systems synthesize manufacturing and planning knowledge to generate specific process plans for a specific part. The reasoning mechanism for generative systems varies from algorithms to decision trees to artificial intelligence techniques. The variant approach is the basis for the overwhelming majority of computer codes for process planning because of a number of practical computational advantages. Nevertheless, several generative systems have been developed by industry, and this area will continue to be the focus of research and development, especially for large companies that can support the considerable investment needed for software development and hardware procurement.

Polymer Processing

There are basically two major categories of plastics: *thermoplastics* and *thermosetting resins* (see Chapter 12). Each group contains thousands of specific formulations with a wide range of mechanical, physical, and chemical properties. The scope of applications includes the automotive, houseware, and packaging industries. For example, government regulations pertaining to energy conservation have forced the automotive manufacturers to reduce the weight of automobiles. As a result, lightweight plastics have replaced traditional steel bumpers and outer panels while fulfilling specific performance requirements for mechanical strength, thermal resistance, and environmental durability.

To design with plastics, the product engineer selects an appropriate plastic material by considering a number of technical and economic factors in concert with specific data compiled in manufacturer's literature and encyclopedic data sources, such as the *Modern Plastics Encyclopedia*. To select the appropriate manufacturing process, the process engineer must understand the impact of the processing techniques on the material structure and, ultimately, the desired technical performance, e.g., mechanical strength and physical properties. Although a considerable number of plastic material alternatives are available, the variety of forming operations is limited. The basic set of processes includes compression molding, transfer molding, injection molding, extrusion, cold molding, thermoforming, and blow molding. The reader is referred to Chapter 13 for specific information on the production of thermoplastics and thermosetting resins.

Because of the interrelations between processing techniques and material structure, the axiomatic approach to design (see Section 11.4) provides helpful information for concurrent engineering. In this context, the use of plastic parts involves the successive mapping of engineering properties in the functional domain, to a plastic material structure in the physical domain, to processing techniques in the process domain. This mapping can be written in the form:

$$\{\mathbf{FRs}\} = [\mathbf{A}]\{\mathbf{DPs}\} \tag{11.7.1}$$

© 1999 by CRC Press LLC

$$\{\mathbf{DPs}\} = [\mathbf{B}]\{\mathbf{PVs}\} \tag{11.7.2}$$

in which the desired material properties are contained in the vector of functional requirements {**FRs**}, the material structure is described in {**DPs**}, and the manufacturing process is defined by {**PVs**}. Equations (11.7.1) and (11.7.2) display the general structure of the equations for materials design and process planning. The design matrices [**A**] and [**B**] are used to determine whether the proposed mapping satisfies the Independence Axiom: they must be either diagonal or triangular to allow for the manufacture of a plastic part with the desired properties (see Section 11.4.1, "The First Axiom: The Independence Axiom"). The production of microcellular plastics of MIT (Suh, 1990) is an example that illustrates design of a manufacturing process to yield the desired polymer structure.

11.8 Precision Machine Design

Alexander Slocum

Any machine, from a machine tool to a photocopier to a camera, is an assembly of components that are designed to work together to achieve a desired level of performance. Each machine has a budget for cost and performance, and achieving the best balance between the two, regardless of the function of the machine, is the essence of *precision machine design.*

In order to be able to effectively develop a design for a precision machine, the design engineer must simultaneously envision in his/her head the functions the machine must perform (e.g., milling, turning, or grinding) alongside a pictorial library of component technologies (e.g., bearings, actuators, and sensors), generic machine configurations (e.g., cast or welded articulated and/or prismatic structures), analysis techniques (e.g., back-of-the-envelope and finite element methods), and manufacturing methods (e.g., machine, hand, or replication finished). In addition, the machine design engineer must be aware of the basic issues faced by the sensor and electronics engineer, the manufacturing engineer, the analyst, and the controls engineer. Only by a simultaneous consideration of all design factors can a viable and effective design be rapidly converged upon. Awareness of current technological limitations *in all fields* can also help a design engineer to develop new processes, machines, and/or components.

The goal of the precision machine design engineer is to make all the components of a precision machine in proper proportion of each other, both in relation to their physical size and the capabilities of the servocontroller and power systems. If a component is oversized, it may increase the cost of the machine while performance may not be increased. If a component is too small, the rest of the machine's components may never reach their potential and machine performance will suffer. Note that size is a function of static and dynamic qualifiers. Components that behave well statically do not necessarily have good dynamic performance.

In today's world where rapid time to market is essential, the design of quality precision machines depends on the ability of the design and the manufacturing engineers to predict how the machine will perform before it is built. Kinematics of a machine are easily tested for gross functionality using mechanism synthesis and analysis software. Wear rates, fatigue, and corrosion are often difficult to predict and control, but for the most part are understood problems in the context of machine tool design. Hence perhaps the most important factors affecting the quality of a machine are the accuracy, repeatability, and resolution of its components and the manner in which they are combined. These factors are critical because they affect every one of the parts that will be manufactured using the machine. Accordingly, minimizing machine cost and maximizing machine quality mandate predictability of accuracy, repeatability, and resolution. As noted by Donaldson*: "A basic finding from our experience in dealing with machining accuracy is that machine tools are deterministic. By this we mean that machine tool errors obey cause-and-effect relationships, and do not vary randomly for no reason."

In this section, the design of precision machines will be studied by following a path of analysis of the overall system's potential for accuracy, as well as applying this perspective to the understanding of the operation of the components that make up a precision machine:

- Analysis of errors in a precision machine
- Structures
- Bearings

It is important to realize that the design of precision machines is like any other endeavor. The better one understands the fundamental principles and concepts, the better one will be able to integrate components into a precision system. In the light of understanding the science of design, one must always consider practical applied philosophy. A few broad design guidelines for the precision machine designer include:

* Donaldson, R. November 1972. The deterministic approach to machining accuracy. *SME Fabricat. Technol. Symp.* Golden, CO (UCRL Preprint 74243).

© 1999 by CRC Press LLC

- Subject all decisions to an “is there a better way” value analysis based on system considerations.
- Always picture in your mind how the system will be manufactured, assembled, used, and maintained.
- Minimize the number of parts in an assembly and minimize their complexity.
- Maximize the number of instances where reference surfaces and self-locating “snap together” parts can be used.
- Whenever possible, take advantage of kinematic design principles.
- Utilize new materials and technologies to their fullest potential.
- Read continuously and familiarize yourself with technologies in many areas.
- Observe continuously and familiarize yourself with products in many areas.

Analysis of Errors in a Precision Machine

The first step in the design of a precision machine is to understand the basic definitions and principles that characterize and govern the design of all precision machines. Some of the more basic definitions and principles include

- The principle of reversal
- Modeling the errors in a machine
- Determination of the relative errors between the tool and the workpiece
- Linear motion system errors
- Estimating position errors from modular bearing catalog data
- Axis of rotation errors
- Error budgets

Accuracy, Repeatability, and Resolution

There are three basic definitions to remember with respect to how well a machine tool can position its axes: *accuracy, repeatability (precision),* and *resolution. Accuracy* is the maximum translational or rotational error between any two points in the machine’s work volume. *Repeatability (precision)* is the error between a number of successive attempts to move the machine to the same position, or the ability of the machine to make the same motion over and over. Bidirectional repeatability is the repeatability achieved when the point is approached from two different directions. This includes the effect of backlash in a leadscrew. Accuracy is often defined in terms of the mean, and repeatability in terms of the standard deviation. For a set of N data points with a normal (Gaussian) distribution, the mean x_{mean} and the standard deviation σ are defined as

$$x_{\text{mean}} = \frac{1}{N}\sum_{i=1}^{N} x_i \qquad \sigma = \sqrt{\frac{1}{N-1}\sum_{i=1}^{N}\left(x_i - x_{\text{mean}}\right)^2} \tag{11.8.1}$$

The standard deviation is used in the determination of the probability of occurrence of an event in a system that has a normal distribution. Table 11.8.1 gives the percent chance of a value occurring within a number of standard deviations of its expected value.* One must be very careful not to confuse an offset of the mean with the allowed random variation in a part dimension. For example, precision-molded plastic lenses for cameras have their molds hand finished to make the mean size of lenses produced equal to the nominal size required.

* The equation for the computation of the percent chance was obtained from Drake, A. 1967. *Fundamentals of Applied Probability Theory.* McGraw-Hill, New York. p. 211. Values ϕ (k) were computed using Mathematics™. Another valuable reference to have is Natrella, M. *Experimental Statistics,* NBS Handbook 91.

© 1999 by CRC Press LLC

TABLE 11.8.1 Chance of a Value Falling within kσ of its Expected Value

k	% chance of occurrence
1.0	68.2689
2.0	95.4500
3.0	99.7300
4.0	99.9937
5.0	99.9999
6.0	100.0000

It is interesting to note, however, Bryan's* observation of the issue of using probabilistic methods to characterize repeatability: "The probabilistic approach to a problem is only a tool to allow us to deal with variables that are too numerous, or expensive to sort out properly by common sense and good metrology." One must not belittle probability, however, for it is a mathematical tool like any other that is available to the design engineer. Required use of this tool, however, might be an indication that it is time to take a closer look at the system and see if the system can be changed to make it deterministic and therefore more controllable. Often the key to repeatability is not within the machine itself, but in isolating the machine from variations in the environment.**

Resolution is the larger of the smallest programmable step or the smallest mechanical step the machine can make during point-to-point motion. Resolution is important because it gives a lower bound on the repeatability. When a machine's repeatable error is mapped, the resolution becomes important if the mapped errors are to be compensated for by other axes.

Amplification of Angular Errors

Perhaps the most overlooked error in machine design is the amplification of an angular error over a distance to create a large translational error at some point in the machine. Mathematically, this error has a magnitude equal to the product of the distance between the point and the rotation source and the sine of the included angle. Hence this type of error can be referred to as a *sine error.* This principle extends to locating bearing surfaces far from the workpiece area of the machine tool.*** Errors in the bearing's motion can be amplified by the distance between the bearing and the workpiece, and can be transmitted to the workpiece. This can result in horizontal and vertical straightness errors and axial position errors. The same is true for the effects of all other types of errors on machine components. A *cosine error*, on the other hand, is the error made when the measurement of the distance between a point and a line is not made along a path orthogonal to the line.

With respect to dimensional measurements. In the late 1800s, Dr. Ernst Abbe noted *"If errors in parallax are to be avoided, the measuring system must be placed coaxially with the axis along which displacement is to be measured on the workpiece."* The Abbe principle can be visualized by comparing measurements made with a dial caliper and a micrometer as shown in Figure 11.8.1. The dial caliper is often used around the shop because it is easy to use, the head slides back and forth to facilitate quick measurement. However, note that the measurement scale is located at the base of the jaws. When a part is measured near the tip of the jaws, the jaws can rock back slightly, owing to their elasticity and imperfections in the sliding jaw's bearing. This causes the caliper to yield a slightly undersize

** *"In designing an experiment the agents and phenomena to be studied are marked off from all others and regarded as the field of investigation. All others are called disturbing agents. The experiment must be so arranged that the effects of disturbing agents on the phenomena to be investigated are as small as possible."* James C. Maxwell.

*** See Bryan, J.B. 1989. The Abbe principle revisited — an updated interpretation, *Precis. Eng.* 1(3):129–132. An extension of the Abbe principle to this type of situation is referred to as the *Bryan principle*, which is discussed in Section 5.2.1 along with a discussion on where to mount sensors for various types of measurements.

© 1999 by CRC Press LLC

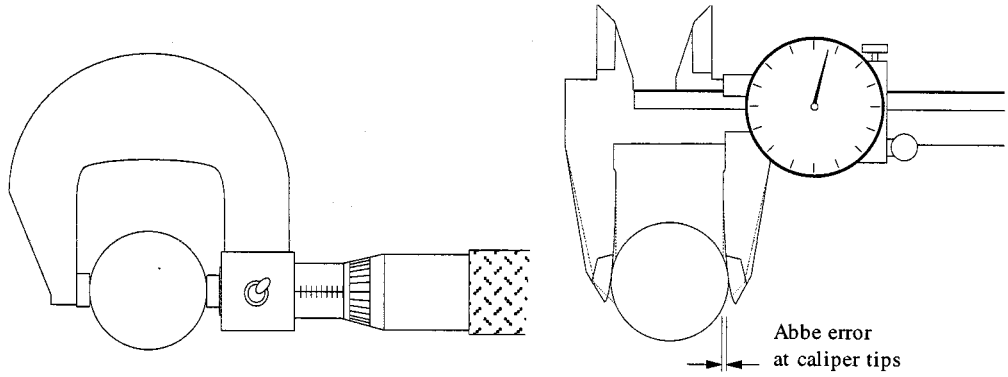

FIGURE 11.8.1 Abbe error illustrated through the use of a dial caliper and a micrometer.

measurement. The micrometer, on the other hand, uses a precision measuring device located in line with the part dimension, so there is no Abbe error. Both instruments are sensitive to how hard the jaws are closed on the part. A micrometer often has a torque limiting adjustment to provide a very repeatable measuring force. It is impossible to overstress the importance of Abbe errors.

The micrometer is more difficult to use and less versatile than the caliper, yet it has greater accuracy because of its more robust structural loop. So it is in the design of precision machines. Often one has to sacrifice ergonomics for performance. The goal, therefore, is to minimize the extent of the sacrifice.

Sensitive Directions

It is important to note that there are *sensitive directions* in a machine, and it is along these directions that the most effort must be expended to minimize errors. For example, as illustrated in Figure 11.8.2 an error motion ε of a tool tangent to the surface of a round part of radius r in a lathe results in a radial error in the workpiece of magnitude ε^2/r, which is much smaller than ε. Sensitive directions can be *fixed*, such as when the tool is stationary and the part is moving (e.g., a lathe), or *rotating*, such as when the tool is rotating and the part is fixed (e.g., a jig borer).

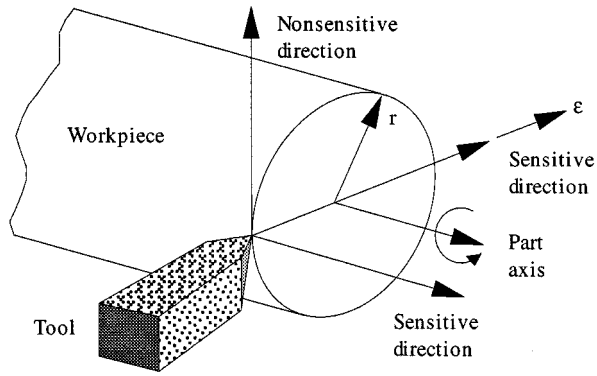

FIGURE 11.8.2 Illustration of sensitive directions.

The Reversal Principle

How were the first accurate machines developed? Machines were first made repeatable, which can be done by paying special detail to surface finish of bearings, prevention of lost motion (e.g., backlash), and by making the forces on the machine repeatable. Once a machine is made repeatable, it can be used to measure the accuracy of another component or machine using the principle of reversal. This is illustrated in Figure 11.8.3.

© 1999 by CRC Press LLC

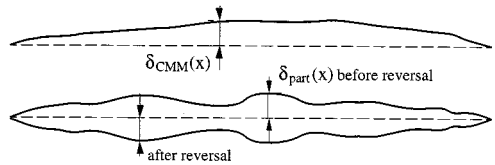

FIGURE 11.8.3 Illustration of the principal of reversal.

The machine is used to measure a part from one side, obtaining a reading of

$$Z_{\text{probe before reversal}}(x) = \delta_{CMM}(x) - \delta_{\text{part}}(x)$$

The part is then turned over, taking care to keep its axial position justified, then the machine is used to remeasure the part, obtaining a reading of

$$Z_{\text{probe after reversal}}(x) = \delta_{CMM}(x) - \delta_{\text{part}}(x)$$

By subtracting the measurements from each other, the repeatable error in the measuring machine is removed:

$$\delta_{\text{part}}(x) = \frac{-Z_{\text{probe before reversal}}(x) + Z_{\text{probe after reversal}}(x)}{2}$$

There are many variations (e.g., for roundness measurements), and the principle shows how repeatability is often the most important characteristic of a precision machine. In fact, the principle can be applied to the design of the machine itself. For example, two bearing rails can be ground side by side, and then placed end to end on a machine. If the carriage that rides on them has the same bearing spacing as the individual rail length, then as the carriage moves on the end-to-end rails, it will not pitch or yaw, it will only have a straightness error. This straightness error can then be more readily compensated for by the motion of an orthogonal axis via an error compensation algorithm in the controller.

Modeling the Errors in a Machine

In order to determine the effects of a component's error on the position of the toolpoint or the workpiece, the spatial relationship between the two must be defined. Figure 11.8.4 illustrates the issue: the tool is connected to the workpiece through the linkage that is the machine. Any errors between the machine's links create error between the tool and the workpiece. The essential goal of precision machine design is to be able to model and predict these errors, so they can be addressed during the design state of the machine.

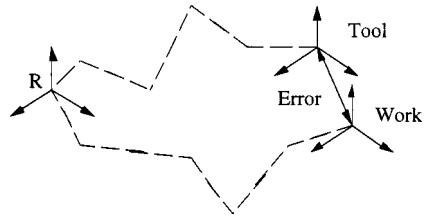

FIGURE 11.8.4 The goal is to be able to model the errors in the machine to predict the error between the tool and the work during the design phase so appropriate action can be taken before the machine is built.

© 1999 by CRC Press LLC

To represent the relative position of a rigid body in three-dimensional space with respect to a given coordinate system, a 4×4 matrix is needed. This matrix represents the coordinate transformation to the reference coordinate system (X_R Y_R Z_R) from that of the rigid body frame (X_n Y_n Z_n), and it is called the *homogeneous transformation matrix* (HTM).* The first three columns of the HTM are direction cosines (unit vectors i, j, k) representing the orientation of the rigid body's X_n, Y_n, and Z_n axes with respect to the reference coordinate frame, and their scale factors are zero. The last column represents the position of the rigid body's coordinate system's origin with respect to the reference coordinate frame. P_s is a scale factor, which is usually set to unity to help avoid confusion. The presuperscript represents the reference frame you want the result to be represented in, and the postsubscript represents the reference frame from which you are transferring:

$$R_{\mathbf{T}_n} = \begin{bmatrix} O_{ix} & O_{iy} & O_{iz} & P_x \\ O_{jx} & O_{jy} & O_{jz} & P_y \\ O_{kx} & O_{ky} & O_{kz} & P_z \\ 0 & 0 & 0 & P_s \end{bmatrix} \tag{11.8.2}$$

Thus, the equivalent coordinates of a point in a coordinate frame n, with respect to a reference frame R, are

$$\begin{bmatrix} X_R \\ Y_R \\ Z_R \\ 1 \end{bmatrix} = R_{\mathbf{T}_n} \begin{bmatrix} X_n \\ Y_n \\ Z_n \\ 1 \end{bmatrix} \tag{11.8.3}$$

For example, if the X_1 Y_1 Z_1 coordinate system is translated by an amount x along the X axis, the HTM that transforms the coordinates of a point in the X_1 Y_1 Z_1 coordinate frame into the XYZ reference frame is

$$XYZ_{\mathbf{T}_{X_1Y_1Z_1}} = \begin{bmatrix} 1 & 0 & 0 & x \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{11.8.4}$$

If the X_1 Y_1 Z_1 coordinate system is rotated by an amount θ_x about the X axis, the HTM that transforms the coordinates of a point in the X_1 Y_1 Z_1 coordinate frame into the XYZ frame is

$$XYZ_{\mathbf{T}_{X_1Y_1Z_1}} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos\theta_x & -\sin\theta_x & 0 \\ 0 & \sin\theta_x & \cos\theta_x & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{11.8.5}$$

Machine structures can be decomposed into a series of coordinate transformation matrices describing the relative position of each axis and any intermediate coordinate frames that may assist in the modeling

* The HTM representation of structures has existed for many decades. See, for example, Denavit, J. and Hartenberg, R. June 1955. A kinematic notation for lower-pair mechanisms based on matrices. *J. Appl. Mech.* Perhaps the most often referenced work with respect to its application to manufacturing tools is Paul, R. 1981. *Robot Manipulators: Mathematics, Programming, and Control.* MIT Press, Cambridge, MA.

© 1999 by CRC Press LLC

process, starting at the tip and working all the way down to the base reference coordinate system (n = 0). If N rigid bodies are connected in series and the relative HTMs between connecting axes are known, the position of the tip (Nth axis) in terms of the reference coordinate system will be the sequential product of all the HTMs:

$$ {}^{R}\mathbf{T}_{N} = \prod_{m=1}^{N} {}^{m-1}\mathbf{T}_{m} = {}^{0}\mathbf{T}_{1}\,{}^{1}\mathbf{T}_{2}\,{}^{2}\mathbf{T}_{3}\ldots \tag{11.8.6} $$

It can be difficult to determine how a part modeled as a rigid body actually moves; thus care must be taken when evaluating the error terms in the HTMs of systems with multiple contact points. Nonserial link machines (e.g., a four-bar linkage robot) require a customized formulation to account for interaction of the links.

Determination of the Relative Errors Between the Tool and the Workpiece

Ideally, the HTM products (Equation 11.8.6) for the position of the point on the workpiece the tool contacts and the location of the toolpoint with respect to the reference frame will be identical. The relative error HTM $\mathbf{E}_{\text{rel}}$, representing position and orientation errors between the tool and workpiece, is determined for ${}^{R}\mathbf{T}_{\text{work}} = {}^{R}\mathbf{T}_{\text{tool}}\mathbf{E}_{\text{rel}}$:

$$ E_{\text{rel}} = {}^{R}\mathbf{T}_{\text{tool}}\,{}^{-1}{}^{R}\mathbf{T}_{\text{work}} \tag{11.8.7} $$

The relative error HTM is the transformation in the toolpoint coordinate system that must be done to the tool in order to be at the proper position on the workpiece. For implementation of error correction algorithms on numerically controlled machines, as illustrated in Figure 11.8.5 one must consider how the axes will be required to move in order to create the desired motion, specified by Equation 11.8.7 in the tool reference frame. For the general case of a machine with revolute and translational axes (e.g., a five-axis machining center), one would have to use inverse kinematic solutions such as those developed for robot motion path planning. Most machine tools and CMMs have only translational axes, and thus the error correction vector ${}^{R}\mathbf{P}_{\text{correction}}$ with respect to the reference coordinate frame can be obtained from

$$ {}^{R}\begin{bmatrix} P_x \\ P_y \\ P_z \end{bmatrix}_{\text{correction}} = {}^{R}\begin{bmatrix} P_x \\ P_y \\ P_z \end{bmatrix}_{\text{work}} - {}^{R}\begin{bmatrix} P_x \\ P_y \\ P_z \end{bmatrix}_{\text{tool}} \tag{11.8.8} $$

Because of Abbe offsets and angular orientation errors of the axes, ${}^{R}\mathbf{P}_{\text{correction}}$ will not necessarily be equal to the position vector $\mathbf{P}$ component of $\mathbf{E}_{\text{rel}}$. ${}^{R}\mathbf{P}_{\text{correction}}$ does represent the incremental motions the X, Y, and Z axes must make on a Cartesian machine in order to compensate for toolpoint location errors.

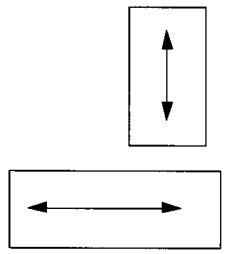

FIGURE 11.8.5 Repeatable error motions in one axis can be mapped and compensated for by motion of an orthogonal axis.

© 1999 by CRC Press LLC

Compensating for errors in a machine can be a good thing; however, electronic compensation can only do so much. One has to start with a good design. The error in a machine can be minimized in general by maximizing the efficiency of the machine's *structural loop*. The structural loop is defined as the structure that joins the tool to the fixture to which the workpiece is attached. During cutting operations, the contact between the tool and workpiece can change the structural loop's characteristics. Maximizing the efficiency of the structural loop generally requires minimizing the path length of the mechanism. As can be seen from Abbe's principle or the HTM analysis method, the shorter the path length, the less the error amplification and the total end point error.

Linear Motion System Errors

Consider the case of an ideal linear motion carriage shown in Figure 11.8.6 with x, y, and z offsets of a, b, and c, respectively, All rigid bodies have three rotational (ε_X, ε_Y, ε_Z) and three translational (δ_X, δ_Y, δ_Z) error components associated with their motion. These errors can be defined as occurring about and along the reference coordinate system's axes, respectively. Often the errors will be a function of the position of the body in the reference frame.

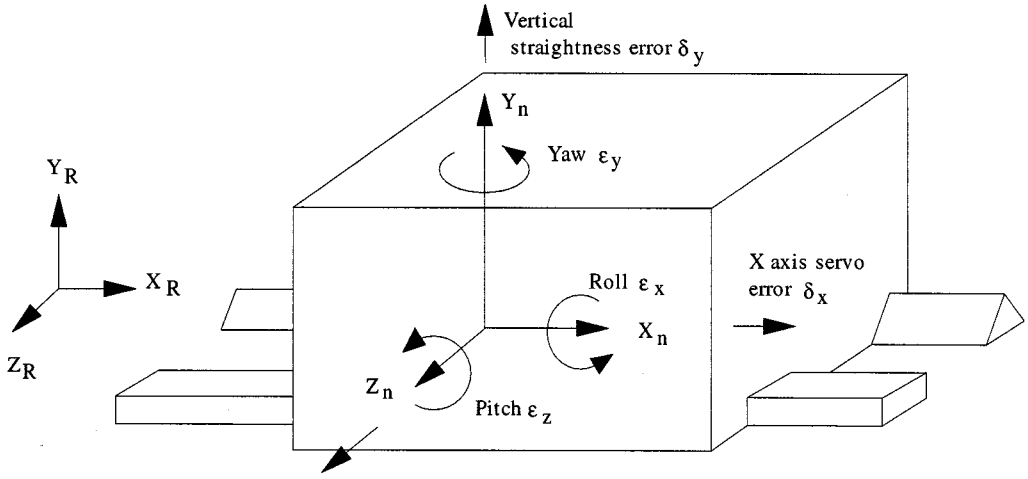

FIGURE 11.8.6 Motion and errors in a single-axis linear motion carriage (prismatic joint).

For the linear carriage, the HTM (see Equation (11.8.2)) that describes the effects of errors on carriage motion can be obtained in the following manner. Observing the right-hand rule, a rotation ε_X, about the X axis (*roll*) causes the tip of the Y-axis vector to move in the positive Z direction by an amount proportional to sin ε_X, and in the negative Y direction by an amount proportional to $1 - \cos \varepsilon_X$. Since the error terms are very small, at most on the order of minutes of arc, small-angle approximations are valid and will be used. Hence the element $o_{ky} = \varepsilon_X$. The roll error ε_X also causes the tip of the Z-axis vector to move in the negative Y direction, so that the element $o_{jz} = -\varepsilon_X$. A rotation ε_Y about the Y axis (*yaw*) causes the tip of the X-axis vector to move in the negative Z direction, so that $o_{kx} = -\varepsilon_Y$, and causes the tip of the Z-axis vector to move in the positive X direction, so $o_{iz} = \varepsilon_Y$. Similarly, a rotation ε_Z about the Z axis (*pitch*) causes the tip of the X-axis vector to move in the positive Y direction, so $o_{jx} = \varepsilon_Z$, and causes the tip of the Y axis vector to move in the negative X direction so that $o_{iy} = -\varepsilon_Z$. Translational errors δ_X, δ_Y, and δ_Z directly affect their respective axes, but care must be taken in defining them. Having neglected second-order terms, the HTM for the linear motion carriage with errors is

© 1999 by CRC Press LLC

$$ {}^{R}\mathbf{T}_{\text{nerr}} = \begin{bmatrix} 1 & -\varepsilon_Z & \varepsilon_Y & a+\delta_X \\ \varepsilon_Z & 1 & -\varepsilon_X & b+\delta_Y \\ -\varepsilon_Y & \varepsilon_X & 1 & c+\delta_Z \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{11.8.9} $$

Estimating Position Errors from Modular Bearing Catalog Data

The HTM method is powerful, but from where does one get estimates of the errors? For the linear motion system, the HTM assumes that the errors occur at the center of stiffness of the carriage. The *center of stiffness* is the point at which, when a force is applied to the system, no net angular motion results. For a symmetrical system, it is located at the center of the system. For other systems, the center of stiffness can be found in the same way that the *center of mass* is found:

$$ x_{\text{center of stiffness}} = \frac{\sum_{i=1}^{N} K_i x_i}{\sum_{i=1}^{N} K_i} \tag{11.8.10} $$

Indeed, the *center of friction* can also be defined, and when locating the point, where the actuation force of an axis is to be applied, one can see that ideally, the center of mass, the center of stiffness, and the center of friction should all be coincident. In the best case, they will also be concurrent with external loads applied to an axis.

Once the center of stiffness has been found, the error motions about the center of stiffness can be determined using the dimensions of the system and estimates for the errors in individual bearing elements (e.g., linear ball bearing catalogs often include data on the vertical and horizontal error motions that will occur between the bearing block and the rail). Figure 11.8.7 illustrates the model of a linear motion system supported by modular bearings.

It can be assumed that the translational errors are based on the average of the straightness errors experienced by the bearing blocks:

$$ \begin{aligned} \delta_x &= \delta_{\text{servo}} \\ \delta_y &= \frac{\delta_{y1}+\delta_{y2}+\delta_{y3}+\delta_{y4}}{4} \\ \delta_z &= \frac{\delta_{z1}+\delta_{z2}+\delta_{z3}+\delta_{z4}}{4} \end{aligned} \tag{11.8.11} $$

The angular errors are based on the differences in the average straightness errors experienced by pairs of bearing blocks acting across the carriage:

$$ \begin{aligned} \varepsilon_x &= \frac{\frac{\left(\delta_{y2}+\delta_{y3}\right)}{2} - \frac{\left(\delta_{y1}+\delta_{y4}\right)}{2}}{W} \\ \varepsilon_y &= \frac{\frac{\left(\delta_{z3}+\delta_{z4}\right)}{2} - \frac{\left(\delta_{z1}+\delta_{z2}\right)}{2}}{L} \\ \varepsilon_z &= \frac{\frac{\left(\delta_{y1}+\delta_{y2}\right)}{2} - \frac{\left(\delta_{y3}+\delta_{y4}\right)}{2}}{L} \end{aligned} \tag{11.8.12} $$

© 1999 by CRC Press LLC

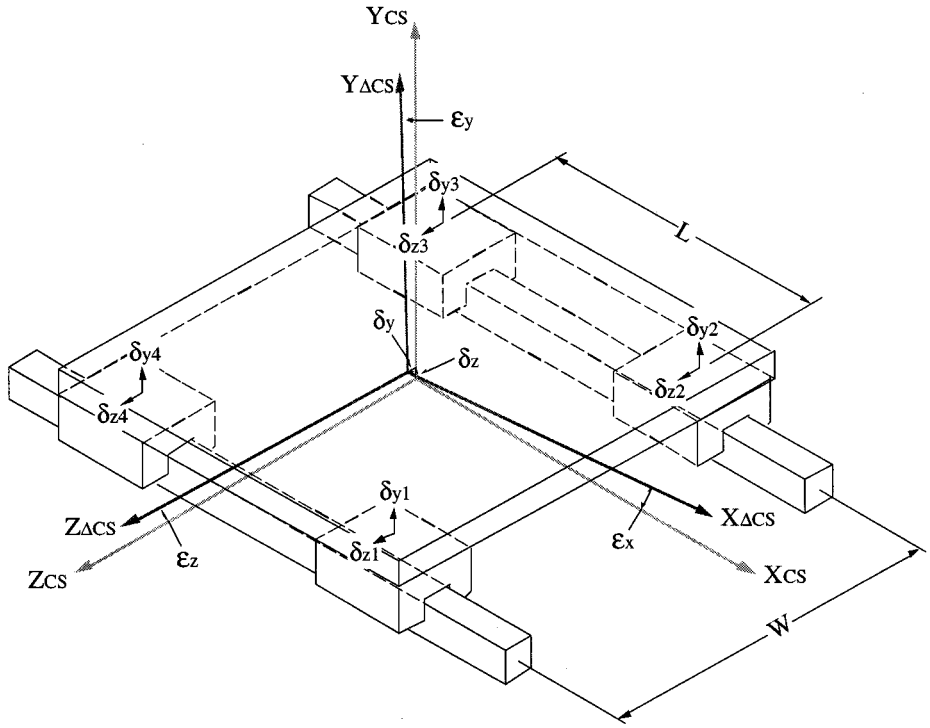

FIGURE 11.8.7 A linear motion system will have errors that act about the center of stiffness of the system.

When the bearing blocks are moving in unison to create the straightness error, they would not be creating the angular errors. However, to be conservative when modeling the errors in a machine, since it cannot be known which errors are going to occur, one should simultaneously incorporate both translational and angular error estimates into the error model of the machine.

Once a machine has been built, the error motions would be measured and analyzed to verify whether the machine meets its performance criteria. This is also a good time to evaluate the effectiveness of the model. For example, Figure 11.8.8 shows the straightness measurements for a linear motion axis supported by cam followers running on a vee and a flat. It is very difficult to tell what the source of the error is. Figure 11.8.9 shows a Fast Fourier Transform of the straightness data. Note that the FFT is plotted in terms of amplitude and wavelength (as opposed to the more commonly seen power and frequency plots used by electrical engineers). It can help identify the dominant sources of error, so design attention can be properly allocated. It can also show, as in this case, that the errors from a number of different sources are of similar magnitude, so if greater performance is required, one should probably seek an alternate design.

Axis of Rotation Errors*

Consider the rotating body shown in Figure 11.8.10. Ideally, the body rotates about its axis of rotation without any errors; however, in reality the axis of rotation revolves around an axis of the reference coordinate frame with radial errors δ_X and δ_Y, an axial error δ_Z, and tilt errors ε_X and ε_Y. All of these errors may be a function of the rotation angle θ_z. For a point in the spindle coordinate frame $X_nY_nZ_n$,

* Definitions used in this section were condensed from those provided in *Axis of Rotation: Methods for Specifying and Testing*. ANSI Standard B89.3.4M-1985, American Society of Mechanical Engineers, United Engineering Center, 345 East 47th Street, New York, NY 10017. This document also contains appendices which describe measurement techniques and other useful topics pertaining to axes of rotation.

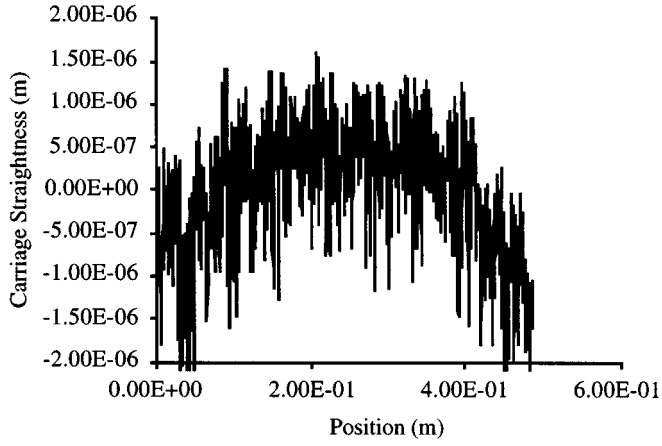

FIGURE 11.8.8 Strightness of a linear motion system.

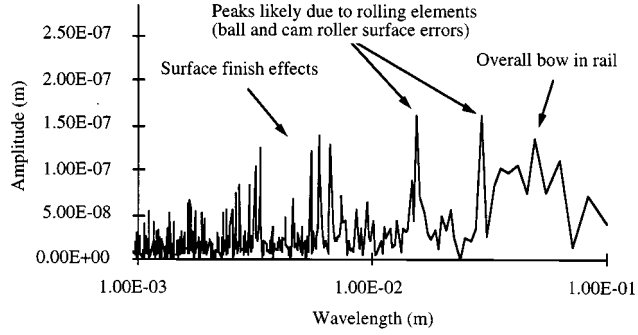

FIGURE 11.8.9 Fourier transform of the straightness of a linear motion system.

one would first use the rotation angle θ_z to transform the point roughly the reference frame. Then, since the other error motions are small, the order of multiplication of their HTMs would not be critical.

With the operators S = sine and C = cosine, the general result is

$$ {}^{R}\mathbf{T}_{\text{nerr}} = \begin{bmatrix} C\varepsilon_Y C\theta_Z & -C\varepsilon_Y S\theta_Z & S\varepsilon_Y & \delta_X \\ S\varepsilon_X S\varepsilon_Y C\theta_Z & C\varepsilon_X C\theta_Z - S\varepsilon_X S\varepsilon_Y S\theta_Z & -S\varepsilon_X C\varepsilon_Y & \delta_Y \\ -C\varepsilon_X S\varepsilon_Y C\theta_Z + S\varepsilon_X S\theta_Z & S\varepsilon_X C\theta_Z + C\varepsilon_X S\varepsilon_Y S\theta_Z & C\varepsilon_X C\varepsilon_Y & \delta_Z \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{11.8.13} $$

Note that this general result may also be used for the case of a linear motion carriage if ε_Z is substituted for θ_Z. Most often, second-order terms such as $\varepsilon_X\varepsilon_Y$ are negligible and small-angle approximations (i.e., cos ε = 1, sin ε = ε) can be used, which leads to

$$ {}^{R}\mathbf{T}_{\text{nerr}} = \begin{bmatrix} \cos\theta_Z & -\sin\theta_Z & \varepsilon_Y & \delta_X \\ \sin\theta_Z & \cos\theta_Z & -\varepsilon_X & \delta_Y \\ \varepsilon_X \sin\theta_Z - \varepsilon_Y \cos\theta_Z & \varepsilon_X \cos\theta_Z + \varepsilon_Y \sin\theta_Z & 1 & \delta_Z \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{11.8.14} $$

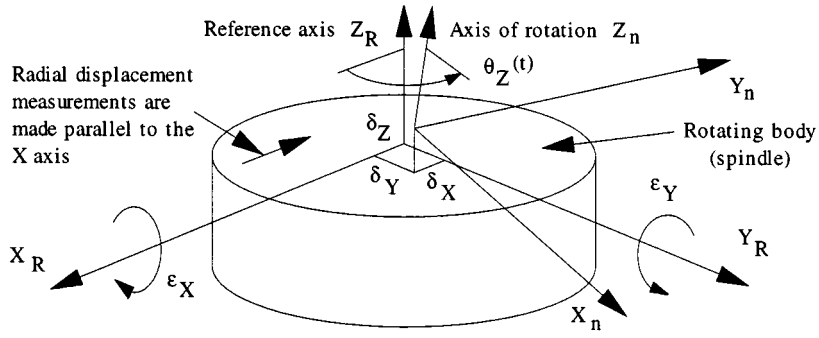

FIGURE 11.8.10 Motion and errors about an axis of rotation (revolute joint).

However, since this matrix is usually evaluated using a spreadsheet, it is best to use the exact form. When nanometer performance levels are sought, second-order effects can start to become important.

In the context of evaluating errors of rotating bodies, particularly when making measurements and discussing the results, it is necessary to consult the axis of rotation standard ANSI B89.3.4M. The "*error motion* of a spindle is the change in position, relative to the reference coordinate axes, of the surface of a perfect workpiece with its center line coincident with the axis of rotation." This definition excludes thermal drift errors. The *runout* is the total displacement measured by an instrument sensing against a moving surface or moved with respect to a fixed surface. The term total indicator reading (TIR) is equivalent to runout. Unfortunately, all too often an imperfect workpiece is eccentrically mounted to a spindle and used to evaluate the performance of a spindle; hence the runout can be a misleading measurement. The "*axial motion* is the error motion colinear with the Z reference axis." "Axial slip", "end camming", and "drunkenness" are nonpreferred terms which have been used in the past. The *tilt motion* is the error motion in an angular direction relative to the Z reference axis. Tilt motion creates sine errors on the spindle which is why the radial error motion is a function of Z position and face motion is a function of radius. Note that "coning", "wobble", and "swash" are sometimes used to describe tilt motion, but they are nonpreferred terms.

These errors are measured and then plotted using polar plots. The *error motion polar plot* is a polar plot of error motion made in synchronization with the rotation of the spindle. Error motion polar plots are often decomposed into plots of various error components. Some of the various types of error motion polar plots are shown in Figure 11.8.11. The *total error motion polar plot* is the complete error motion polar plot as recorded. The *average error motion polar plot* is the mean contour of the total error motion polar plot averaged over the number of revolutions. Note that asynchronous error motion components do not always average out to zero, so the average error motion polar plot may still contain asynchronous components. The average error motion value is a measure of the best roundness that can be obtained for a part machined while being held in the spindle (or the roundness of a hole the spindle is used to bore). The *fundamental error motion polar plot* is the best-fit reference circle fitted to the average error motion polar plots. The *residual error motion polar plot* is the deviation of the average error motion polar plot from the fundamental error motion polar plot. For radial error motion measurements, this represents the sum of the error motion and the workpiece (e.g., ball) out-of-roundness. The workpiece out-of-roundness can be removed using a reversal technique.* The *asynchronous error motion polar plot* is the deviation of the total error motion polar plot from the average error motion polar plot. Asynchronous in this context means that the deviations are not repetitive from revolution to revolution. Asynchronous

* The former was developed by Bob Donaldson at LLNL, and the latter by Spragg and Whitehouse. See Appendix B of ANSI B89.3.4M-1985 and the various cited references. Also see the ANSI standard *Measurement of Out-of-Roundness*, ANSI B89.3.1-1972(R1979).

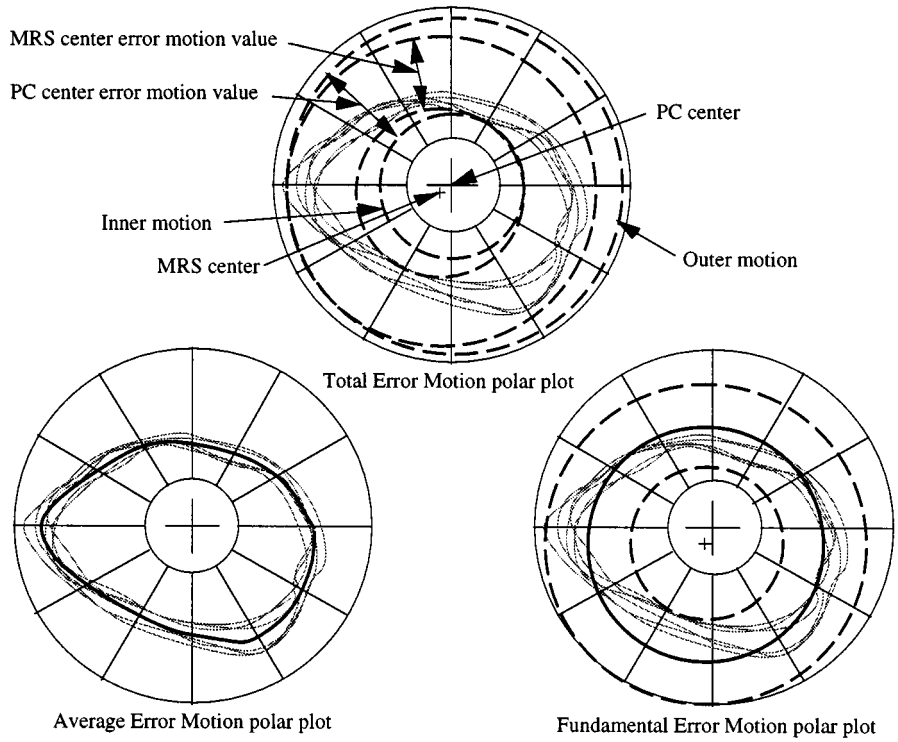

FIGURE 11.8.11 Examples of error motion and error motion component polar plots.

error motions are not necessarily random (in the statistical sense), but they do provide an indication of the attainable surface finish of the part.

Once again, the FFT is a vital tool for identifying the source of errors so that the designer can seek to minimize them. Figure 11.8.12 shows an FFT of a grinding spindle's error motion. The spindle speed was 1680 rpm (28 Hz), the bearing inner diameter was 75 mm, the outer diameter was 105 mm, the number of balls was 20, and the ball diameter was 10 mm. One of the dominant errors occurs at twice the rotation frequency, indicating that the bore in which the bearing is placed is most likely out-of-round.

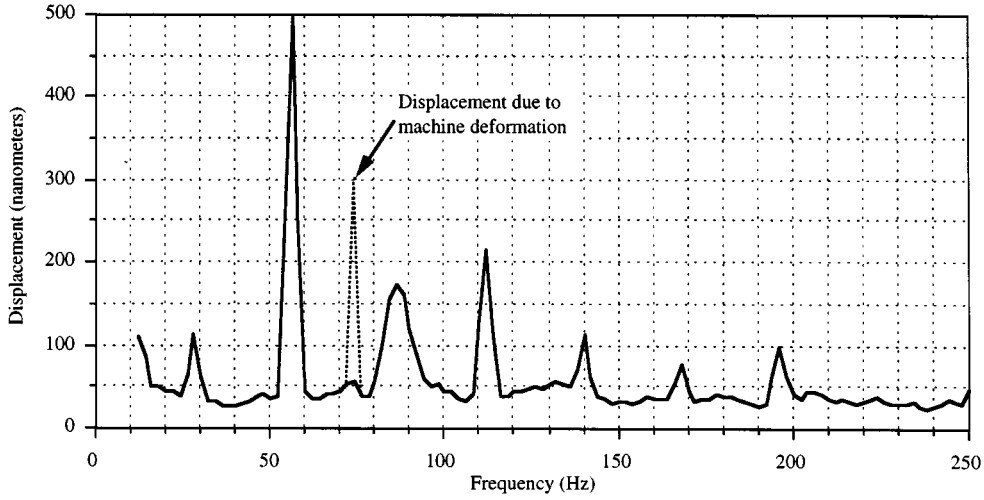

FIGURE 11.8.12 FFT of grinding spindle error motion.

Error Budgets

To define the relative position of one rigid body with respect to another, six degrees of freedom must be specified. To further complicate matters, error in each of the six degrees of freedom can have numerous contributing components. In fact, considering all the interacting elements in a typical machine tool, the number of errors that must be kept track of can be mindboggling. Therefore, the best way to keep track of and allocate allowable values for these errors is to use an *error budget*. An error budget, like any other budget, allocates resources (allowable amounts of error) among a machine's different components.* The goal is to allocate errors such that the ability of any particular component to meet its error allocation is not exceeded.

An error budget is formulated based on connectivity rules that define the behavior of a machine's components and their interfaces, and combinational rules that describe how errors of different types are to be combined. The first step in developing an error budget is to develop a kinematic model of the proposed system in the form of a series of homogeneous transformation matrices (HTM). The next step is to analyze systematically each type of error that can occur in the system and use the HTM model to help determine the effect of the errors on the toolpoint position accuracy with respect to the workpiece. The result is a list of all end point error components, their sources, and amplification-at-the-toolpoint factors (called the *error gains* or *sensitivities*). Different combinational rules can then be applied to yield upper and lower bound estimates of the total error in the machine.

Perhaps the most important step in assembling the error budget for a machine is the placement of the coordinate frames and the assignment of linear and angular errors corresponding to the axes. Angular motion errors suffer no ambiguity in their definition since they are unaffected by other errors and therefore can be defined with respect to any set of axes. Linear motion errors, on the other hand, must be carefully defined in terms of linear motion caused directly and linear motion that is the result of an Abbe error. During the design phase, the coordinate systems must be located at the origin of the angular errors, where pitch, yaw, and roll errors are the center of stiffness as defined above.

Combinational Rules for Errors

Different types of errors do not mix unless handled properly. Once all error components are multiplied by their respective error gains, a final combination of errors can then be made to yield an educated guess as to the machine's expected performance. There are three common types of errors, which are defined as:**

1. "*Random* — which, under apparently equal conditions at a given position, does not always have the same value, and can only be expressed statistically."
2. "*Systematic* — which always have the same value and sign at a given position and under given circumstances. (Wherever systematic errors have been established, they may be used for correcting the value measured.)" Systematic errors can generally be correlated with position along an axis and can be corrected if the relative accompanying random error is small enough.
3. "*Hysteresis* — is a systematic error (which in this instance is separated out for convenience). It is usually reproducible, has a sign depending on the direction of approach, and a value partly dependent on the travel. (Hysteresis errors may be used for correcting the measured value if the direction of approach is known and an adequate pretravel is made.)" Backlash is a type of hysteresis error that can be compensated for to the extent that is repeatable.

Systematic and hysteresis errors can often be compensated for to a certain degree using calibration techniques. Random error cannot be compensated for without real-time measurement and feedback into a correcting servoloop. Thus, when evaluating the error budget for a machine, three distinct *subbudgets*

---

** These definitions are from the CIRP Scientific Committee for Metrology and Interchangeability, 1978. A proposal for defining and specifying the dimensional uncertainty of multiaxis measuring machines. *Ann. CIRP.* 27(2):623–630.

© 1999 by CRC Press LLC

based on systematic, hysteresis, and random errors should be kept. Often inputs for the error budget are obtained from manufacturers' catalogs (e.g., straightness of linear bearings), and they represent the peak-to-valley amplitude errors e_{PV}. A peak-to-valley error's equivalent random error with uniform probability of occurrence is given by $\varepsilon_{equiv.\ random} = \varepsilon_{PV}/K_{PV}$. If the error is Gaussian, then $K_{PVrms} = 4$ and there is a 99.9937% probability that the peak-to-valley error will not exceed four times the equivalent random error.

In the systematic subbudget, errors are added together and sign is preserved so cancellation may sometimes occur. The same is true for the hysteresis subbudget. In the random subbudget, both the sum and the root-mean-square error should be considered, where the latter is given by

$$\varepsilon_{irms} = \left(\frac{1}{N} \sum_{i=1}^{N} \varepsilon_{irandom}^2 \right)^{1/2} \tag{11.8.15}$$

Note that in the random subbudget, all the random errors are taken as the 1σ values. For the final combination of errors, the 4σ value is typically used, which means that there is a 99.9937% chance that the random error component will not exceed the 4σ value. In this case the total worst-case error for the machine will be

$$\varepsilon_{iworst\ case} = \sum \varepsilon_{isystematic} + \sum \varepsilon_{ihysteresis} + 4 \sum \varepsilon_{irandom} \tag{11.8.16}$$

The best-case error for the machine will probably be

$$\varepsilon_{ibest\ case} = \sum \varepsilon_{isystematic} + \sum \varepsilon_{ihysteresis} + 4 \left(\sum \varepsilon_{irandom}^2 \right)^{1/2} \tag{11.8.17}$$

In practice, the average of these two values is often used as an estimate of the accuracy the design is likely to achieve.

Type of Errors

There are many types of errors that occur in a machine including:

Straightness. *Straightness* is the deviation from true straight-line motion. One generally thinks of the straightness error as primarily dependent on the overall geometry of the machine and applied loads. As shown in Figure 11.8.13 straightness error can be considered the deviation from a straight line motion along a linear axis. The unofficial term *smoothness* can be used to describe straightness errors that are dependent on the surface finish of the parts in contact, the type of bearing used, and the bearing preload. In other words, the smoothness of motion would be the deviation from the best-fit polynomial describing the straightness of motion. Smoothness is not intended to be a descriptor of surface finish, but rather a descriptor of high-frequency straightness errors whose wavelength is typically on the order of the magnitude of the error, normal to the surface of two moving bodies in contact.

Kinematic Errors. Kinematic errors are defined here as *errors in the trajectory of an axis that are caused by misaligned or improperly sized components.* For example, kinematic errors include orthogonality (squareness or perpendicularity) and parallelism of axes with respect to their ideal locations and each other. Translational errors in the spatial position of axes are also a form of kinematic error. The dimensions of an axis's components can also cause the tool or workpiece to be offset from where it is supposed to be and is also classified as a kinematic error.

As shown in Figure 11.8.14 given two machine axes of motion in the XZ plane with one machine axis aligned with the X reference axis, the orthogonality error is defined as the deviation ε_y from 90° between the machine's other axis and the reference X axis. This is a straightforward definition which is simple to specify on a drawing, but is not necessarily simple to measure or control in production. Parallelism between two axes has horizontal and vertical forms that define the relative taper and twist

© 1999 by CRC Press LLC

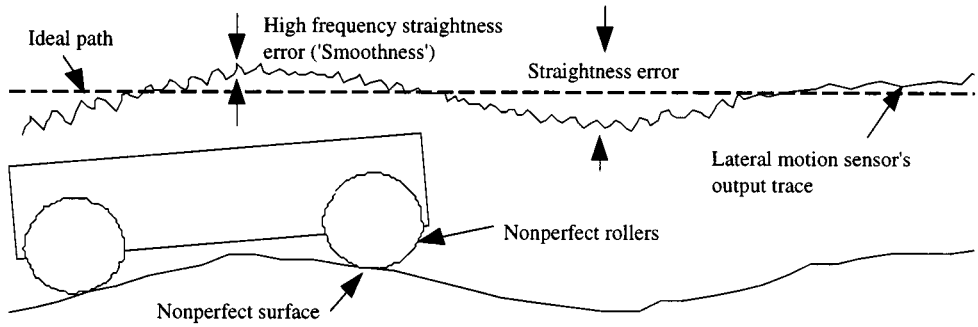

FIGURE 11.8.13 Strightness errors caused by surface form and finish errors.

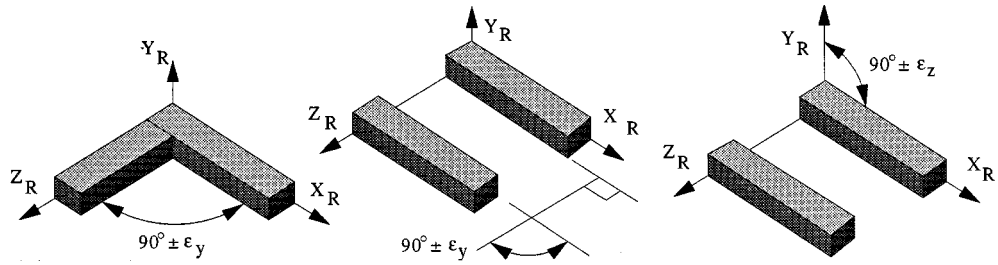

FIGURE 11.8.14 Orthogonality and horizontal and vertical parallelism errors.

between the two axes, respectively. An example of horizontal parallelism error (taper) would be an axis on a lathe that was not parallel to the spindle's axis of rotation. Using this axis to move a tool along the outer surface of a part would result in the part becoming tapered along its length. An example of vertical parallelism error is two axes used to support a milling machine bed. If one end of one of the axes is high, the bed itself will be warped when bolted to the axes, and parts machined while bolted to the bed will wobble.

Kinematic errors in a well-designed and manufactured machine would be very repeatable and can be compensated for if the controller is well designed. However, the fundamental principle of modern precision machine design is still to *maximize mechanical performance for a reasonable cost before using special controllers, algorithms, and sensors to correct for mechanical errors.*

External Load-Induced Errors. External loads that cause errors in a machine include gravity loads, cutting loads, and axis acceleration loads. The difficulty in modeling load-induced errors lies in their often distributed and/or varying effects. The types of errors discussed thus far have been geometrically induced and were a function of position. Thus, they could be relatively easily included in the HTM model of a machine. Load-induced errors, on the other hand, are often distributed throughout the structure. In order to incorporate them into the HTM model, a method for lumping them at discrete points must be devised. Depending on the structure, the bearing interface is often the most compliant part of the structure, and it can make sense to lump load-induced errors at the bearing interfaces. For more complex structures, it may be necessary to introduce additional coordinate frames into the HTM model.

In addition to increasing accuracy for enhancement of quality, machines are being required to move at greater speeds in order to increase productivity. Machine tools are usually thought of as big, bulky, slow-moving structures. The next generation of machine tools, however, will probably require axes to have acceleration capabilities in excess of 1 g. Deflections caused by accelerating the mass are acceptable for many drilling operations which would allow high spindle speeds and high axis feed rates to be used to increase productivity. Acceleration and deceleration rates of high-speed manufacturing equipment's

© 1999 by CRC Press LLC

axes may one day routinely approach several g. In designing this type of equipment, accuracy along the path of motion may or may not be critical. However, final placement and settling time, where the maximum accelerations and inertial forces are present, will be important. Note that in the design of this type of machinery, cutting forces are often insignificant compared to inertial forces.

Another major contributor to load-induced errors in machine tools and some robots are cutting forces. Fortunately, high-speed cutting processes often generate low cutting forces, so the problems of high acceleration and high cutting force usually do not occur simultaneously. However, cutting forces are applied at the tool tip and act on every element in the machine. In order to estimate forces generated by the cutting process, actual cutting forces on machines with similar tools should be measured or appropriate handbooks consulted. In many cases, the rapid advance of new types of cutting tool materials and tool shapes will require the design engineer to consult with a tooling manufacturer or make experimental tests.

Load-Induced Errors from Machine Assembly. Even if all machine components are within required tolerance prior to assembly, additional load-induced errors can be introduced during assembly. The first type of error is forced geometric congruence between moving parts. An example is the bolting of a leadscrew to a carriage, where the nonstraightness of the leadscrew shaft creates a straightness error in the carriage with a period equal to the lead of the screw. A common example is mounting a mirror at its four corners, which often creates a visible distortion. The second type of error is the effect of the assembly process on the stiffness of the structure itself, and how the stiffness can be evaluated and incorporated into the HTM model. A third type of error, one that can be predicted, is the deformation of the machine when forces are applied to preload bearings and bolts. In addition, errors may also be caused by clamping or locking mechanisms.

Thermal Expansion Errors[*]. The need for ever-increasing accuracy and greater machine speeds makes thermal errors ever more important to control. Errors caused by thermal expansion are among the largest, most overlooked, and misunderstood form of error in the world of machine design. Thermal errors affect the machine, the part, and the tool. Even the warmth of a machinist's body can disrupt the accuracy of an ultraprecision machine. Figure 11.8.15 shows the thermal effects that must be accounted for in the design of a precision machine.[**] Thermal errors are particularly bothersome because they often cause angular errors that lead to Abbe errors.

Temperature changes induce thermal elastic strains ε_T, that are proportional to the product of the coefficient of expansion α, of the material and the temperature change, ΔT, experienced by the material:

$$\varepsilon_T = \alpha \Delta T$$

In addition, temperature gradients often cause angular errors, which lead to Abbe errors. If a machine, a tool, and a workpiece all expanded the same amount and could all be kept at the same temperature, then the system might expand uniformly with respect to the standard (always measured at 20°C) and everything would be within tolerance when brought back to standard temperature. However, different metals manufactured at different temperatures can experience serious dimensional metrology problems. Fortunately, standards have been developed (e.g., ANSI B89.6.2[***]) that define in great detail the effects of temperature and humidity on dimensional measurement and how measurements of these effects should be made. Although thermal strains can be minimized by using materials that do not expand very much,

[*] C° denotes temperature difference, whereas °C denotes an absolute temperature. This helps to avoid confusion, particularly when reference is made to temperature increases above ambient.

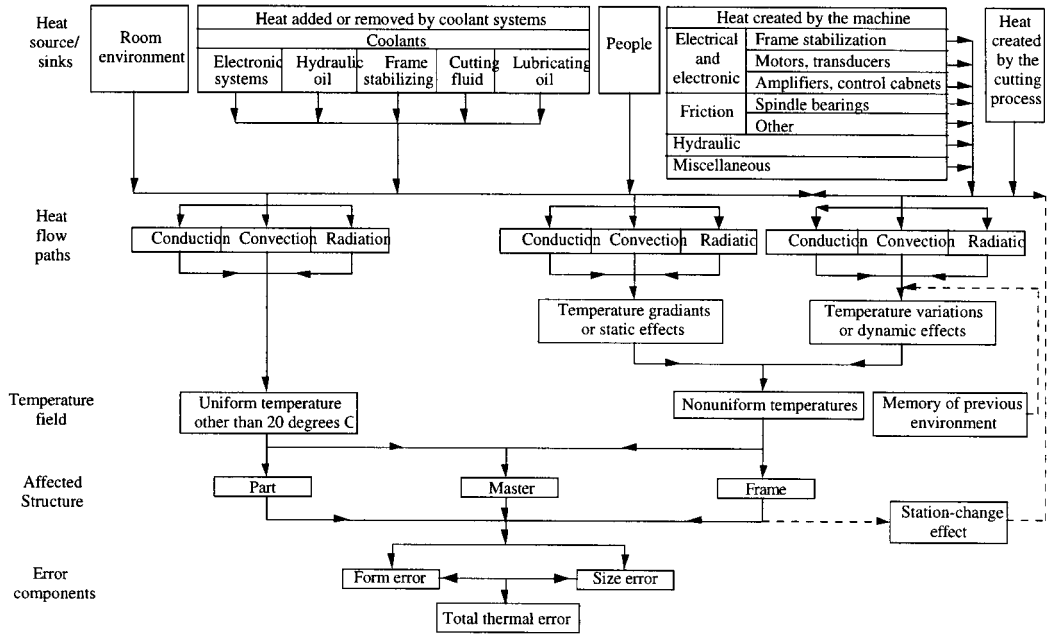

FIGURE 11.8.15 Thermal effects in manufacturing and metrology. (After Bryan.)

and by accurately controlling the environment; in practice, however, these can be difficult solutions to implement for economic reasons.

Structures

The detailed design of the machine structure requires an understanding of the errors in a machine and how they interact with the envisioned assemblage of components. When designing the structure, the engineer must have an overall philosophy in mind with respect to how to assemble the system and address principle types of errors.

For a precision machine, the engineer must first develop a strategy for attaining accuracy (these issues were addressed in the context of 11.8.1 “Analysis of Errors in a Precision Machine”):

- Accuracy obtained from component and assembly accuracy
  - Inexpensive once the process is perfected.
  - Accuracy is strongly coupled to thermal and mechanical loads on the machine.
- Accuracy obtained by error mapping a repeatable system
  - Inexpensive once the process is perfected.
  - Accuracy is moderately coupled to thermal and mechanical loads on the machine.
- Accuracy obtained from a metrology frame (measure the position of an inaccurate machine with respect to an accurate reference frame)
  - Expensive, but sometimes the only choice.
  - Accuracy is uncoupled to thermal and mechanical loads on the machine.

Next, a direction should be set regarding dynamic performance and how much is needed, by considering the following:

© 1999 by CRC Press LLC

- System bandwidth requirements
- Effects of changing system parameters
- Methods to add damping
- Experimental modal analysis

Thermal errors are among the most difficult to predict and control, and an approach to address them should be established early on:

- Passive temperature control
- Active temperature control

With design approaches to the above, the next step is to consider structural materials and different machine configurations that are available:

- Materials
- Existing configurations

Finally, a decision should be made regarding the overall approach to be used with regard to how all the components are assembled:

- Elastically averaged design
- Kinematic design
- Bolted joint design
- Kinematic coupling design

These issues are discussed in greater detail below. Proper consideration of all the details takes a great deal of study* and practice, but these highlights should be useful as an introduction, or as a refresher.

Dynamic System Requirements

Engineers commonly ask "how stiff should the structure be?" A minimum specified static stiffness is a useful but not sufficient specification. For example, the machine can be made to not deflect too much under its own weight or the weight of a part. Fortunately, it can be predicted with reasonable accuracy. To obtain good surface finish or dynamic performance, the dynamic stiffness needs to be specified.

The dynamic stiffness of a system is the stiffness measured using an excitation force with a frequency equal to the damped natural frequency of the structure. The dynamic stiffness of a system is also equal to the static stiffness divided by the amplification at dynamic resonance. It takes a large amount of damping to reduce the amplification factor to a low level. There are several damping quantifiers that are used to describe energy dissipation in a structure. The quantifiers include:

η	Loss factor of material
η_s	Loss factor of material (geometry and load dependent)
$Q = A_r$	Resonance amplification factor
ϕ	Phase angle ϕ between stress and strain (hysteresis factor)
δ_{Ld}	Logarithmic decrement**
ΔU	The energy dissipated during one cycle
ζ	The damping factor associated with second-order systems

* See, for example, Slocum, A. 1997. *Precision Machine Design.* Society of Manufacturing Engineers, Dearborn, MI. Much of the contents of this section was derived from this book.

** Most texts on vibration refer to the log decrement as δ, however, to avoid confusion with discussions on displacement termed δ, the log decrement will be referred to here as δ_{Ld}.

© 1999 by CRC Press LLC

The various damping terms are related (approximately) in the following manner:

$$\eta = \frac{1}{A_r} = \frac{\delta}{\pi} = \phi = \frac{\Delta U}{2\pi U} \tag{11.8.18}$$

The logarithmic decrement δ_{Ld} is an extremely useful measure of the relative amplitude between N successive oscillations of a freely vibrating system (one excited by an impulse):

$$\delta_{Ld} = \frac{-1}{N}\log_e\left(\frac{a_N}{a_1}\right) \tag{11.8.19}$$

The logarithmic decrement can also be related to the damping factor ζ, velocity damping factor b, mass m, and natural frequency ω_n of a second-order system model:

$$\zeta = \frac{\delta_{Ld}}{\sqrt{4\pi^2 + \delta_{Ld}^2}} \tag{11.8.20}$$

Note that the amplification at resonance of a second-order system is given by

$$Q = A_r = \frac{1}{2\zeta\sqrt{1-\zeta^2}} \quad (\zeta \le 0.707) \tag{11.8.21}$$

For example, Figure 11.8.16 shows the time decay of a fairly well-damped system. For this system, n = 4, $a_5 = 0.5$, $a_1 = 1.5$, $\delta_{ld} = 0.275$, $\zeta = 0.44$, and Q = 11.5.

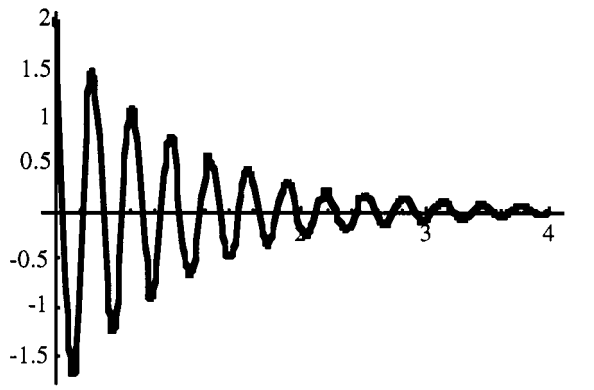

FIGURE 11.8.16 Time decay signal from a fairly well-damped system struck with an impulse.

Machines with good dynamic performance achieve damping by material selection and by the bolted joints and bearing interfaces in the structure. Unfortunately, material and joint damping factors are difficult to predict and are often too low. Thus the designer must consider the stiffness, mass, and damping of the system, and be prepared to alter them to achieve the desired level of performance. For high speed or high accuracy machines, damping mechanisms may have to be designed into the structure in order to meet realistic damping levels. The first step, however, is to try and determine the bandwidth required with an initial estimate of the stiffness, mass, and damping in the system. Then with these goals, one can try to change the parameter that has the greatest impact on performance.

© 1999 by CRC Press LLC

System Bandwidth Requirements. An estimate of the system's servo bandwidth can be made by considering the motions the system is required to make. Most systems null high frequency disturbance forces with their own mass or added damping; however, lower frequency forces must be offset by forces from the controller/actuator. As a result, the servo bandwidth required is primarily a function of the types of moves that the system will be required to make. For start and stop moves (e.g., in a wafer stepper), the bandwidth should be on the order of

$$\omega(\text{hz}) = \frac{10}{2\pi t_{\text{settling time}}} \tag{11.8.22}$$

When contouring, the X and Y axis moves according to x = Rsinωt and y = Rcosωt, the frequency ω is a function of the linear velocity of the cutter through the material, and the radius of the contour:

$$\omega(\text{hz}) = \frac{v_{\text{linear}}}{2\pi r_{\text{path radius}}} \tag{11.8.23}$$

For example, for a large circle (e.g., 200 mm D) being cut at modest speeds (e.g., 0.1 m/sec), the bandwidth required is only 0.16 Hz. On the other hand, for a sharp turn in a corner, the radius of the cutter path trajectory may only be 1 mm, so ω > 16 Hz. The latter is a reasonable requirement for a large machine tool, where the spindle axis may weigh 1000 kg and thus require a critically damped system stiffness of 10 N/μm, which means a design stiffness on the order of 100 N/μm when one considers the limited damping that is obtainable.

In order to make a better assessment of what system parameters should be, a simple model can be used in the early stages of design. For example, a system with a motor driving a carriage can be modeled as shown in Figure 11.8.17.

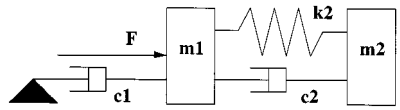

FIGURE 11.8.17 Effect of changing system mass on dynamic performance.

In this model:

- m_1 is the mass of a linear motor forcer or m_1 is the reflected inertia of the motor rotor and leadscrew (or just a linear motor's moving part):

$$M_{\text{reflected}} = \frac{4\pi^2 J}{l^2}$$

- m_2 is the mass of the carriage.
- c_1 is the damping in the linear and rotary bearings.
- c_2 is the damping in the actuator-carriage coupling and the carriage structure.
- k_2 is the stiffness of the actuator and actuator-carriage-tool structural loop.

The equations of motion of this system are

$$\begin{vmatrix} m_1 & 0 \\ 0 & m_2 \end{vmatrix} \begin{vmatrix} \ddot{x}_1 \\ \ddot{x}_2 \end{vmatrix} + \begin{vmatrix} c_1 + c_2 & -c_2 \\ -c_2 & c_2 \end{vmatrix} \begin{vmatrix} \dot{x}_1 \\ \dot{x}_2 \end{vmatrix} + \begin{vmatrix} k_2 & -k_2 \\ -k_2 & k_2 \end{vmatrix} \begin{vmatrix} x_1 \\ x_2 \end{vmatrix} + \begin{vmatrix} F(t) \\ 0 \end{vmatrix} \tag{11.8.24}$$

© 1999 by CRC Press LLC

The transfer function x_2/F (dynamic response of the carriage) is

$$\frac{x_2}{F} = \frac{k_2 + c_2 s}{c_1 s\left(k_2 + c_2 s + m_2 s^2\right) + \left(m_1 + m_2\right) s^2 \left(k_2 + c_2 s\right) + m_1 m_2 s^4} \tag{11.8.25}$$

Note that the product of the masses term tends to dominate the system. To illustrate the design implications, consider four different calculated design options for a linear motion system shown in Figure 11.8.18.

Actuator	ballscrew	lin. motor	lin. motor	lin. motor
Bearings	linear ball	linear ball	air	air
Structural damping	no	no	no	yes
material damping zeta	0.005	0.005	0.005	0.1
actuator to ground zeta	0.05	0.03	0	0
m1 (actuator) (kg)	50	5	5	5
m2 (carriage), kg	50	50	50	50
c1 (N/m/s)	187	355	0	0
c2 (N/m/s)	19	19	19	374
k1 (N/m)	1.75E+08	1.75E+08	1.75E+08	1.75E+08
Bandwidth (Hz)	25	100	30	100

FIGURE 11.8.18 Calculated parameters of four possible linear motion systems.

As a guideline, the servo bandwidth of the system is generally limited by the frequency at which the servo can drive the system without exciting structural modes. Without special control techniques, the servo bandwidth can be no higher than the frequency found by drawing a horizontal line 3 dB above the resonant peak to intersect the response curve. This method is used only to initially size components. A detailed controls simulation must be done to verify performance and guide further system optimization. As an example, consider the response of the ballscrew-driven carriage supported by rolling element linear bearings, as shown in Figure 11.8.19. In this case, since preloaded linear guides and a ballnut are used, damping to ground will be high. The inertia of the ballscrew will lower the system frequency considerably (note the $m_1 m_2 s^4$ term in the transfer function). Going up 3 dB from the resonance peak and projecting to the left to intersect the response curve gives an estimate of the maximum bandwidth the machine can be driven at, without danger of exciting a resonance, of about 25 Hz.

Effects of Changing the System's Mass. Decreasing the mass of the system will enhance the ability of the machine to respond to command signals. However, the trade-off is that the system will lose the ability to attenuate high frequency noise and vibration as shown in Figure 11.8.20.

A system with decreased mass offers a higher natural frequency, which means that higher speed controller signals can be used without compromising the accuracy of the system. A low mass system also shows improved damping, a result of the increased loss factor [the loss factor $\zeta = c/(2m)$], but a low mass system shows less noise rejection at higher frequencies. This suggests that the machine will be less able to attenuate noise and vibration. Considering all the issues, in conclusion, the mass should be minimized to reduce controller effort and improve the frequency response and loss factor (ζ).

Effects of Changing the System's Stiffness. A system with higher stiffness will give a flatter response at low frequencies and give smaller displacements for a given force input. More importantly, the compromise of decreased noise attenuation is not as dramatic as is the case with lowering the system mass. This is shown by the similar shapes in the three curves at high frequencies in Figure 11.8.21. However, acoustical noise may be worsened by adding stiffness. In conclusion, the stiffness of the machine structure should be maximized to improve positioning accuracy.

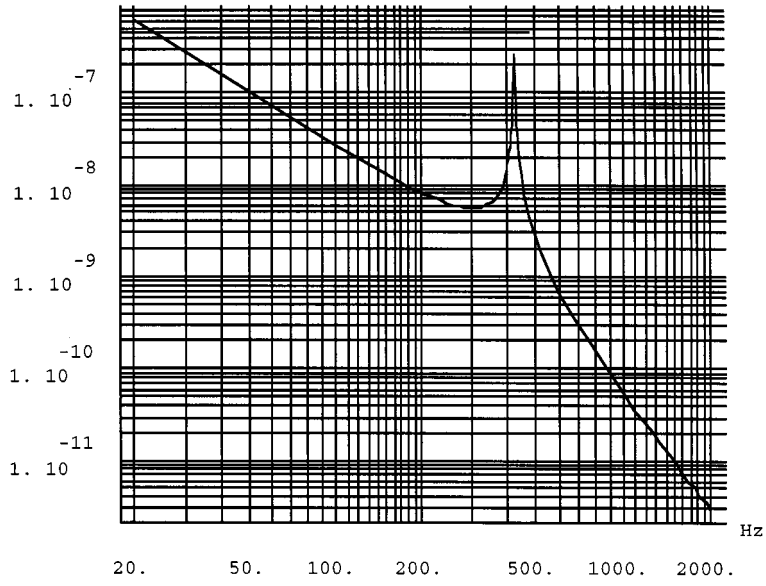

FIGURE 11.8.19 Frequency response of a ballscrew-driven system.

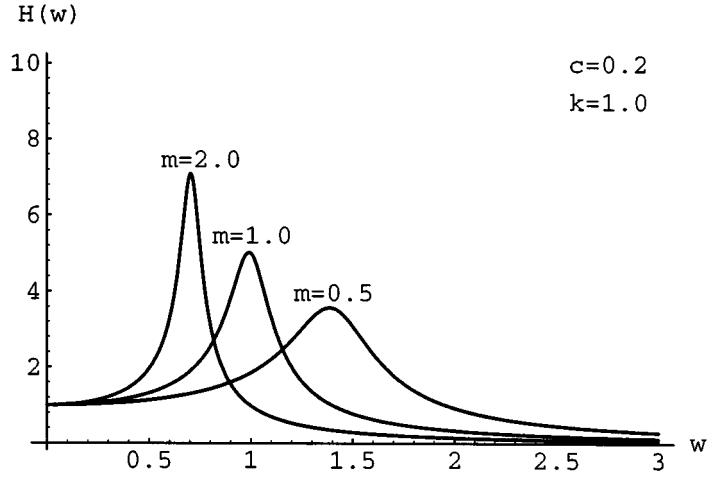

FIGURE 11.8.20 Effect of changing system mass on dynamic performance.

Effects of Changing the System's Damping. Increasing the system's damping can make a dramatic improvement in the system's response. The trend is for decreasing amplification of the output at resonance with increasing damping, although a damping coefficient of 0.4 may be difficult to obtain in practice. Figure 11.8.22 shows the dramatic improvement available by doubling the system's damping.

Methods of Achieving Damping

Although it has been extensively studied, the mechanism of damping in a material is difficult to quantify and one must generally rely on empirical results.* In fact, damping is highly dependent on alloy

* A discussion of the many different microstructural mechanisms that generate damping in materials is beyond the scope of this book. For a detailed discussion see Lazan, B.J., *Damping of Materials and Members in Structural Mechanics*. Pergamon Press, London.

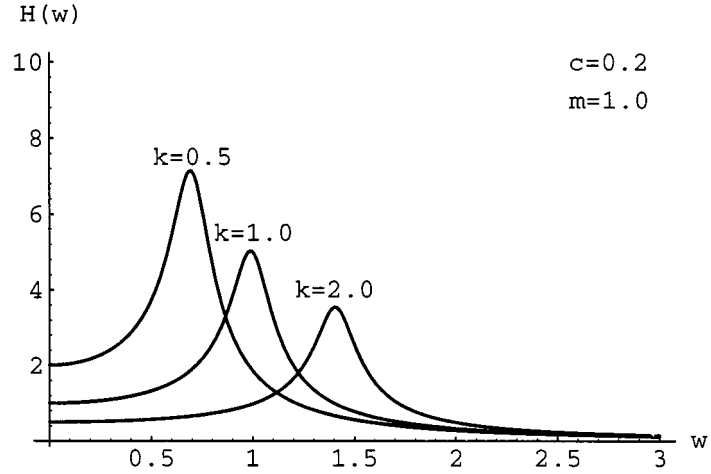

FIGURE 11.8.21 Effect of changing system stiffness on dynamic performance.

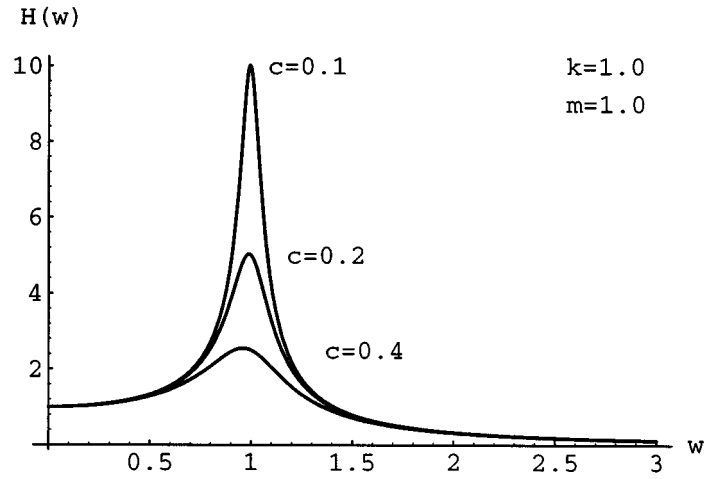

FIGURE 11.8.22 Effect of changing system damping on dynamic performance.

composition, frequency, stress level and type, and temperature. Structural damping levels are often quite low, and frequently the dominant source of damping is the joints in an assembly. In fact, one must be extremely wary of damping data that are presented in the literature, because often it is presented without a discussion of the design of the test setup.

The amount of damping one obtains from a material is very low compared to the amount of damping that one can obtain with the addition of a damping mechanism. Damping mechanisms can range from simple sand piles to more complex shear dampers or tuned mass dampers as discussed below. In general, cast iron is the best damped structural metal. Polymer concrete or granite make well-damped structures that tend to be more monolithic in nature; but ceramics have very poor damping.

Tuned Mass Dampers. In a machine with a rotating component (e.g., a grinding wheel), there is often enough energy at multiples of the rotational frequency (harmonics) to cause resonant vibrations in some of the machine's components. This often occurs in cantilevered components such as boring bars and some grinding wheel dressers. The amplification at a particular frequency can be minimized with the use of a tuned mass damper. A tuned mass damper is simply a mass, spring, and damper attached to a structure at the point where vibration motion is to be decreased. The size of the mass, spring, and damper

© 1999 by CRC Press LLC

are chosen so they oscillate out of phase with the structure and thus help to reduce the structure's vibration amplitude.

Consider the single-degree-of-freedom system shown in Figure 11.8.23. The system contains a spring, mass, and damper. For a cantilevered steel beam, the spring would represent the beam stiffness, the mass would be that which combined with the spring yielded the natural frequency of the cantilevered beam, and the damper would be that which caused a 2% energy loss per cycle. As also shown in Figure 11.8.23, a second spring-mass-damper system can be added to the first to decrease the cantilevered beam's amplitude at resonance. The equations of motion of the system are

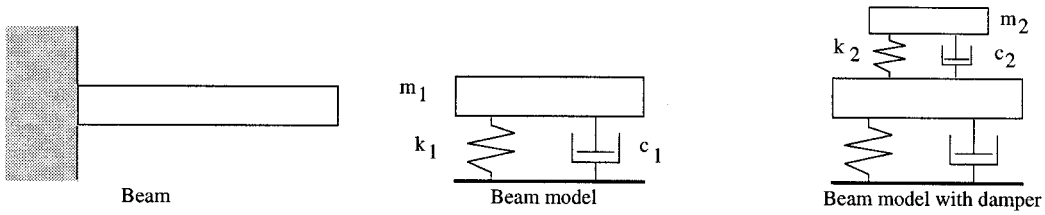

FIGURE 11.8.23 Cantilever beam, model, and model with tuned mass damper.

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} \ddot{x}(t) + \begin{bmatrix} c_1 + c_2 & -c_2 \\ -c_2 & c_2 \end{bmatrix} \dot{x}(t) + \begin{bmatrix} k_1 + k_2 & -k_2 \\ -k_2 & k_2 \end{bmatrix} x(t) \tag{11.8.26}$$

In the frequency domain, in order to present a solution for the motion of the system, the following notation is introduced:

$$Z_{ij}(\omega) = -\omega^2 m_{ij} + i\omega c_{ij} + k_{ij} \qquad i, j = 1, 2 \tag{11.8.27}$$

The amplitudes of the motions of the component and the damper as a function of frequency are given by*

$$X_2(\omega) = \frac{-Z_{12}(\omega) F_1}{Z_{11}(\omega) Z_{22}(\omega) - Z_{12}^2(\omega)} \tag{11.8.28}$$

The design of a tuned mass damper system for a machine component may involve the following steps:

- Determine the space available for the damper and calculate the mass (m_2) that can fit into this space.
- Determine the spring size (k_2) that makes the natural frequency of the damper equal to the natural frequency of the component.
- Use a spreadsheet to generate plots of component amplitude as a function of frequency and damper damping magnitude (c_2).

Constrained Layer Dampers. The structural joints in a machine tool have long been known to be a source of damping by the mechanisms of friction and microslip. A study of structural joint damping has shown that numerous theories are available for predicting damping by these mechanisms,** however, the amount of damping obtained is still less than what is required for critical damping, and controlling the surface interface parameters at the joint to achieve uniform results from machine to machine is difficult. In addition, as far as the accuracy of the machine is required, it would be best if the joints behaved as

* Ibid., p 115.

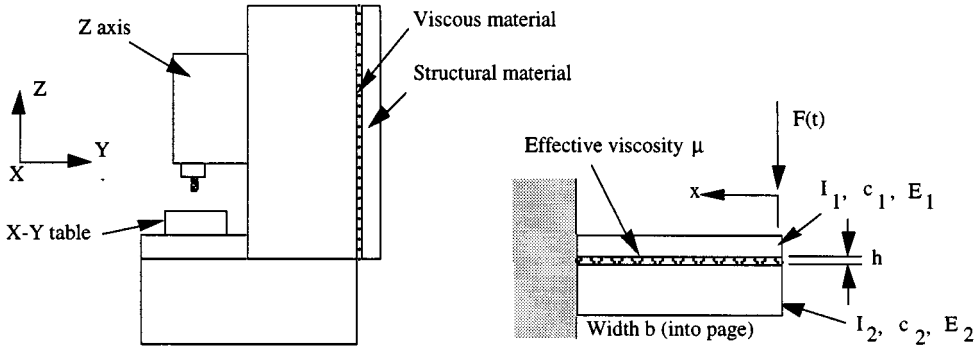

FIGURE 11.8.24 Increasing structural damping by adding alternate layers of viscous and structural materials.

a rigid interface which, as discussed below, can be obtained by bolting and grouting (or bonding) a joint. A better method is to add damping by applying alternate layers of viscoelastic and structural materials to a machine tool structure,* as illustrated in Figure 11.8.24.

Experimental Modal Analysis of a Machine's Dynamic Performance

The manner in which a machine behaves dynamically has a direct effect on the quality of the process. It is vital to be able to measure a machine's dynamic performance to enable engineers to determine exactly which parts of a machine need to be strengthened or made to be better damped.

Experimental modal analysis allows the study of vibration modes in a machine tool structure. An understanding of data acquisition, signal processing, and vibration theory is necessary to obtain meaningful results. For a modest-sized company (50 employees), it is feasible and reasonable to have one person dedicated to metrology, including experimental modal analysis. Companies routinely invest $100,000 or more in precision measurement devices (e.g., gauges, autocollimator, laser interferometer, ball bar, surface roughness, etc.). The dynamic performance of a machine is every bit as important, and requires only a modest investment (about $40K).

When a company's metrologist is trained in modal analysis, results can be rapidly obtained and presented to the design department. For example, suppose a new machine is being designed where axial stiffness of the drive system is of extreme importance (e.g., a centerless grinder). The design engineer wants to know if a rollerscrew will give better performance than a ballscrew. Not completely trusting catalog data, and not knowing the primary source of compliance (the mounting, the bearings, the shaft, or the nut), the engineer replaces a ballscrew — in a known good machine — with a rollerscrew. The metrologist does the modal analysis and the engineer learns in "real time" what the result is. Similarly, the engineer can look to other machines on the shop floor for physical models of elements to be used in a new design, and the metrologist can make the measurements in a short time.

All too often a modal analysis is done after a design is complete to help solve a problem. The results can often be used to help repair the problem; however, done before hand, modal testing of similar machines or test-subassemblies would have led to a better design approach that in the end would have resulted in a better integrated system. The results of a modal analysis yield important information regarding the machine's dynamic properties, including:

- Modal natural frequencies
- Modal damping factors
- Vibration mode shapes

* See, for example, Haranath, S., Ganesan, N., and Rao, B. 1987. Dynamic analysis of machine tool structures with applied damping treatment. *Int. J. Mach. Tools Manuf.* 27(1):43–55. Also see Marsh, E.R., Slocum, A.H. 1996. An integrated approach to structural damping. *Precis. Eng.*, 18(2,3):103–109.

© 1999 by CRC Press LLC

This information is vital to a designer, who may use the information to

- Locate sources of compliance in a structure.
- Characterize machine performance.
- Optimize design parameters.
- Identify the weak links in a structure for design optimization.
- Identify modes which are being excited by the process (e.g., an end mill) so that structure can be modified accordingly.
- Identify modes (parts of the structure) which limit the speed of operation (e.g., in a coordinate measuring machine).

A manager may ask "why should we start doing this if we have not done it in the past, and were very successful?" The engineering answer is that faster and more accurate machines are needed in the future, and the materials being processed are getting harder and harder (e.g., ceramics). The business answer is that the problems are getting tougher to solve, and engineering time is expensive. Also, international competition is more widespread and much tougher. History has shown that application of new advanced tools virtually always guarantees an increase in performance and competitive edge.

Identification, Control, and Isolation of Heat Sources*

Heat that causes thermal errors is introduced into the machine from a number of sources including moving parts (e.g., high-speed spindles, leadscrew nuts, linear bearings, transmissions), motors, the material removal process, and the external environment (e.g., sunshine through a window, direct incandescent lighting, heating ducts, the floor, operators' body heat, etc.). Heat transfer mechanisms in a machine include conduction, convection, evaporation,** and radiation. They are executed by recirculating lubricating oil and cutting fluid, chips from the cutting process, conduction through the frame of the machine, convection of air in and around the machine, and internal and external sources of radiation.

There are three schools of thought regarding minimization of thermally induced errors. The first is to prevent thermal expansion in the first place. The second is to minimize the time it takes for the machine to reach its equilibrium temperature, or in some cases, bring the entire machine to a uniform temperature (e.g., circulate, temperature-controlled fluid through the machine), which can help to minimize differential expansion. The third is to disregard the effects of thermal errors and simply map them, which is a very difficult and often impractical thing to do. Regardless of the methodology followed, a thorough understanding of the effects of heat sources and transfer mechanisms is required, which is beyond the scope of this work.

The manner in which the temperature of a machine is to be controlled can have a large impact on the machine's design. In summary, there are many options available to the design engineer:

- Passive temperature control:
  - Minimize and isolate heat sources.
  - Minimize coefficient of thermal expansion.
  - Maximize thermal conductivity to minimize thermal gradients.
  - Maximize thermal diffusivity to quickly equilibrate transient thermal effects.
  - Minimize thermal emissivity of the structure to minimize radiant coupling to the environment, or maximize the emissivity to couple the structure to an environmental control enclosure.

* An important reference to have that discusses many of the issues discussed here in greater detail is *Temperature and Humidity Environment for Dimensional Measurement*, ANSI Standard B89.6.2-1973.

** Evaporation cooling occurs when aqueous fluids are used. Evaporative cooling is usually uneven and represents one of the biggest temperature control problems facing the precision machine design engineer.

© 1999 by CRC Press LLC

- Active temperature control:
  - Air showers
  - Circulating temperature-controlled fluid within the machine
  - Oil showers
  - Thermoelectric coolers for localized temperature control of hot spots

Each conceptual design option must consider how the temperature within the machine will vary if each of these different temperature control strategies were applied.

Material Considerations

For the conceptual design phase, one should design the structure using differently available materials, and then also design a multimaterial hybrid. For example, cast iron can be made into virtually any shape, so the design engineer has greater freedom, but large sections are expensive to thermally anneal, which must be done to achieve material homogeneity and stability. Granite is usually used in the form of simple rectangular, circular, or planar shapes. Ships are made from welded steel plate and thus conceivably any size of machine tool could also be welded together. Polymer concrete can be cast into virtually any shape and requires no stress relief or prolonged aging cycle. With new ceramics and composite materials, the choices become even more varied, so one really must be alert and consider all options.

Cast Iron Structures

The good general properties of cast iron and the ease with which parts can be cast have made cast iron the foundation of the machine tool industry. Generally, when a machine tool component is smaller than a compact car, it is a candidate for being made of cast iron, although castings weighing hundreds of tons have been made. For larger parts or where economy is of prime importance, one should consider welding together plates and standard structural shapes (e.g., boxes, angles, I-beams, and channels), as discussed below.

Sand casting can be used to make virtually any size part, and it basically involves making a pattern out of a suitable material (e.g., foam, wood, or metal) and packing sand around it. Parting lines are used to allow the sand mold components to be disassembled from around the pattern and then reassembled after the part is removed. Sand cores are often inserted into the mold to form cavities inside the mold (e.g., the cylinders of an engine casting). Regardless of the design of the part, one must also consider that as the metal cools it shrinks (on the order of 5 to 10% for most metals), and that in order to remove the part from the mold without breaking the mold, a taper (draft) of about 1:10 is required. In addition, extra metal should be added to surfaces that will have to be machined (a machining allowance), and locating surfaces should be added so that the part can be fixtured to facilitate machining. Thus in order to specify a casting, there are a few basic guidelines one needs to know in order to minimize the work that a professional mold design engineer has to do to clean up your design. These guidelines are discussed below.*

Granite Structures**

Granite is used as a structural material in machines that are generally used in dry environments because granite can absorb moisture and swell. Thus it may not be appropriate to use granite in a machine where cutting fluid splashes all over it, although there is some debate as to how susceptible to swelling granite actually is. Granite can be sawed into a part of virtually any shape or size (deviations from round slabs

* See, for example, the handbook *Casting Design as Influenced by Foundry Practice.* Mechanite Metal Corp., Marietta, GA.

** A good source of design information about what shapes and sizes can be made is available from Rock of Ages Corp., Industrial Products Group, P.O. Box 482, Barre, VT 05641.

© 1999 by CRC Press LLC

or rectilinear shapes can be expensive). Since it is a brittle material, sharp corners are not allowed, and most structures are built from pieces that are bolted (using inserts) and grouted or bonded together. Since granite is brittle, threaded holes cannot be formed, and thus threaded inserts must be glued or press-fit into round holes in the granite. Common applications of granite components in machine tools include structural members and air-bearing ways in coordinate measuring machines and other inspection machines. Note that the porosity of some granite makes it unsuitable for air bearings even after it has been polished.

The low thermal conductivity of granite makes it slow to absorb heat. This makes granite, particularly black granite, susceptible to thermal distortions caused by the top surface absorbing heat from overhead lights. Granite's coefficient of thermal expansion is less than that of most metals, so in the process of manufacture, shipping, and use, one must consider how differential thermal expansion will affect a machine's performance if metal components have been bolted to it. Although granite has been sitting in the ground for millions of years and thus may seem to possess the ultimate stability, one must consider the effects of relieving the stress upon the granite's dimensional stability after it has been quarried. There are suppliers of very stable granite components, so the design engineer must carefully shop around. A very desirable property of granite (or any other brittle material) is that it will chip when banged instead of forming a crater with a raised lip (Brinell). Granite is also relatively inexpensive to quarry, cut, and lap. Hence granite is often the material of choice for coordinate measuring machine tables.

Welded Structures*

Welded structures can be made from any weldable alloy (e.g., iron alloys such as 1018 structural steel or Invar). Welded structures (weldments) are commonly used, for example, where (1) the cost of a large structure is to be minimized, (2) a high degree of material damping is not needed or the structure will be filled with a damping material, and/or (3) the part is too large to be cast and thermally stress relieved economically. If welded properly, so that the weld material is in a metallurgically stable form, residual stresses can sometimes be removed using vibratory stress-relief methods.

A welded structure is similar to a cast structure, in that strength and stiffness are achieved through the use of sections that are reinforced with ribs; consequently, structural analysis can be difficult and beyond the conceptual design phase often requires the use of finite element methods. Damping and heat transfer characteristics across welded joints are also difficult to model because they are dependent on depth of weld penetration, composition of the weld material, and contact pressure between member surfaces at the joints where the weld does not penetrate. One solution is to specify full penetration welds. To minimize the cost of welded structures, the number of parts and linear meters of weld must be minimized. Furthermore, the more welds that are made, the greater the thermal distortion that is likely to occur as a result of the manufacturing process. However, if too few ribs are used, large plate sections can vibrate like drums. Damping and thermal performance of a welded structure can improve greatly if a viscous temperature-cooled fluid is recirculated throughout the structure, or if damping mechanisms are used as described above. A welded structure can also be used as a mold for a polymer concrete casting which creates a heavy but well-damped and stiff structure, but care must be taken to avoid bimaterial thermal deformation problems.

Ceramic Structures**

The first introduction of a machine that was made almost entirely of ceramics was in 1984 at the Tokyo machine tool show. Although all-ceramic machines generally perform admirably, they have yet to compete economically with machines made from cast iron or polymer concrete. However, in the future,

* A good reference to have is Blodgett, O. 1963. *Design of Weldments*. James F. Lincoln Arc Welding Foundation, P.O. Box 3035, Cleveland, OH 44104.

** See, for example, Ormiston, T. September 1990. Advanced Ceramics and Machine Design. *SME Tech. Paper* EM90-353.

© 1999 by CRC Press LLC

as more and more ceramic components are made for use in consumer products (e.g., automobiles), it is likely that precision machines will contain more and more ceramic components.*

Hard materials (e.g., ceramics) offer advantages over conventional materials in terms of dimensional stability, strength, and stiffness over a wide range of temperatures. In applications ranging from adiabatic internal combustion engines for maximum efficiency to X-ray mirrors for X-ray photolithography, the ability to manufacture components from hard materials is clearly of vital importance to the future of the manufacturing industry. Unfortunately, most ceramic components are finish machined on machines built from cast iron and the abrasive nature of ceramics limits the life of these machines. Thus a new family of machine tools and machine tool components will have to be developed specifically for the manufacture of ceramic components. Consider several key properties of some ceramic materials that can help guide the design process for new machines:

- Most ceramic materials (e.g., aluminum oxide and silicon nitride) will not corrode in any fluid environment that might be used in the manufacture of ceramic components (i.e., fluids from oil to water).** Thus ceramics are key materials for water hydrostatic bearings.
- The more brittle a material is, the less plastic deformation that is generated during finish grinding or lapping; hence the surface is more likely to have a negative skewness. A surface with a negative skewness minimizes the need for a lubricant that has good wetting properties that allows for water to be considered as a lubricant. A surface with a negative skewness will also suffer less damage in the event that the lubricant is lost.
- The more brittle a material is, the less plastic deformation that is generated during finish grinding; hence the surface is less likely to contain high residual stress levels that can lead to dimensional instability. In addition, a precision machine should not be subjected to shock loads in the first place. For general machine tool applications, such as bearing rails, the element geometry generally provides more than enough strength to withstand impact loads generated when a machine crashes.
- Generous radii must be used in all corners, and threaded steel inserts must be used if parts are to be bolted to ceramic components. To bond two ceramic components together, conventional adhesives can be used, or for high-performance applications, ceramic parts can be frit bonded. In frit bonding, a glass powder is applied to the two mating surfaces and then fused by heating the parts above the melting point of the glass. The bond will not be as strong as the ceramic, but it will be almost as stiff.
- Unlike some metals, elements do not precipitate out of a ceramic material's microstructure with time (e.g., carbides do not form like in some iron alloys) so dimensional stability is enhanced. Thus ceramic components can also have virtually unmatched dimensional stability. For metrology masters (e.g., squares and straight edges), ceramics are much lighter than conventional materials, they are less likely to be damaged (dropped) in the first place, and they are less likely to become scratched or worn in everyday use.
- Most ceramics are pure and thus the achievable surface finish is limited only by the size of the grain structure formed during the sintering process; however, most advanced ceramic materials have submicron sizes and this effect is usually not a problem the way it can be with metals. Also note that metals contain discrete hard particles that are dragged across the softer surface during machining which degrades surface finish.

* Furukawa, Y. et al. 1986. Development of ultra precision machine tool made of ceramics. *Ann. CIRP.* 35(1): 279–282.

** Aluminum oxide components are subject to stress corrosion cracking in aqueous environments and thus care must be taken to minimize tensile stresses. Note that silicon-based ceramics, which have predominantly covalent molecules, are far less reactive with water. Only at high temperature and pressure do silicon-based ceramics become appreciably affected by aqueous environments.

© 1999 by CRC Press LLC

- Ceramic materials have a high modulus that is good for machine stiffness, but some have poor thermal properties (e.g., alumina) that can lead to increased thermal deformations of the machine. Note that silicon carbide has very good thermal properties but it is considerably more expensive than alumina
- Ceramic materials in intimate contact will not gall or fret the way many metals often do; thus they make excellent bearing surfaces. However, when ceramic materials are in intimate sliding contact, traction forces can cause the local tensile strength to be exceeded, which produces surface cracks that lead to spalling. In such situations, it may be desirable to use a ceramic material with a high fracture toughness and tensile strength (e.g., silicon nitride). Thermal stresses can also initiate local or gross failure.
- Ceramic materials have a higher modulus of elasticity and lower density than do bearing steels; hence ceramic rolling elements have a smaller contact zone that leads to less heat generation. Hybrid bearings (e.g., metal rings and ceramic rolling elements) generate 30 to 50% less heat than do steel bearings. This means that grease can be used to lubricate the bearings at much higher speeds.* In general, for smaller diameter ultraprecision bearings, hybrid bearings can have up to three times the DN value of steel bearings (i.e., 4.5 million vs. 1.5 million).
- Aluminum oxide has good overall properties for structural applications such as fluidstatic bearing rails and CMM structures. Zirconia is very tough, and its coefficient of thermal expansion matches that of steel, so it can be used as a bearing rail liner for rolling element bearings without worrying about bimaterial expansion problems. However, most zirconias are multiphase materials and thus are not well suited for applications where high-dimensional stability is required (e.g., in precision bearings). Silicon nitride has the best overall properties including very high toughness, which makes it ideal for rolling element bearings, but it is too expensive to use for large structural components. Silicon carbide and tungsten carbide are extremely hard and wear-resistant and they are often used in cutting tool applications.
- Aluminum oxide components can be made by cold pressing followed by machining, firing, and grinding. Note that there is significant volume shrinkage during the firing process. Hence designing ceramic structural parts often requires assistance from the manufacturer. In general, the same shape design rules apply as for metal castings, and the wall thickness should not be greater than about 25 mm. Ceramics components (e.g., those made from silicon nitride) can also be made by hot pressing followed by grinding and lapping.

Polymer Concrete Castings**

Portland cement-based concrete is not dimensionally stable enough, due to its own internal structural variations with time and its hygroscopic nature, to allow it to be used for the main structure of a precision machine tool. Although in many applications, properly cured reinforced concrete on a stable, dry subgrade can provide a reasonably stable foundation for very large machines that are not self-supporting, unreinforced Portland cement concrete itself is not dimensionally stable due to (1) reaction shrinkage from cement hydration; (2) shrinkage due to loss of excess nonstoichiometric water, which leaves conduits for humidity-induced expansion or contraction; and (3) nonelastic dimensional changes (e.g., creep and microcracking in the inherent brittle/porous structure). Overall, strain variations with time may be as high as 1000 μm/m.

* Steel bearings require oil mist lubrication at higher speeds. Introducing an oil mist (oil dripped into a high-pressure air stream) into a bearing increases the chance that water and dirt particles might be introduced into the bearing, which can lead to premature failure. Actually, a precision bearing cooled by an oil mist should have its air cleaned and dried to a level usually associated with air bearings (e.g., 3-μm filter and H_2O < 50 to 100 ppm).

Fortunately, a number of different types of polymer-based concretes have been developed which can be used to cast machine tool quality structures. For example, Fritz Studer AG, a prominent manufacturer of precision grinders in Switzerland, discovered that special polymers can be used to bind together specially prepared and sized aggregate to yield a stable, essentially castable, granite-like material with a damping coefficient much higher than that of cast iron.* By carefully controlling the manufacturing process and selection of binder and aggregate, properties can be varied somewhat to suit the user. The polymer concrete material and process developed by Studer is known as Granitan™ and its composition and manufacturing process was patented. Numerous companies have licensed the process and will make castings from Granitan™ to order. Other companies have developed their own proprietary polymer concretes with similar high performance properties.

For polymer concrete castings, the same rules for draft allowance apply as for metal castings if the mold is to be removed. Instead of ribs, polymer concrete structures usually use internal foam cores to maximize their stiffness-to-weight ratio. Unlike metal castings, a polymer concrete casting will not develop hot spots while curing even in thick, uneven sections. Polymer concrete castings can readily accommodate cast-in-place components such as bolt inserts, conduit, bearing rails, hydraulic lines, etc. It should be noted that a bolt will fail before a bonded-in-place insert.

With appropriate section design, polymer concrete structures can have the stiffness of cast iron structures and much greater damping than cast iron structures.** However due to polymer concretes' lower strength, heavily loaded machine substructures (e.g., carriages) are still best made from cast iron. Polymer concretes do not diffuse heat as well as cast iron structures and thus attention must be paid to the isolation of heat sources to prevent the formation of hot spots in a polymer concrete structure. In addition, their modulus of elasticity is about one fifth that of steel, and their strength is an order of magnitude less, so they are used primarily for machine bases.

Structural Configurations

For proper functioning of moving axes and operational stability, often it is important to minimize thermal and elastic structural loops. By this it is meant that the path length from the toolpoint to the workpiece through the structure should be minimal. The less material that separates the part of the structure that holds the tool and the part of the structure that holds the part, the more likely the entire system will quickly reach and maintain a stable equilibrium.

Open-Section (C or G) Frames

Most small machines are designed with an open frame, as shown in Figure 11.8.25 which greatly facilitates workzone access for fixturing and part handling. Note that the machine could be designed with the spindle oriented in the horizontal or the vertical direction. Unfortunately, open section frames are the least structurally and thermally stable. The lack of symmetry leads to undesirable thermal gradients and bending moments. The fact that a critical part of the structure is cantilevered means that Abbe errors abound; hence great care must be used when designing a precision machine with an open frame. Note that there are many different variations on this design for different types of machines (e.g., milling machines and lathes). The common feature of all is the fact that the structural loop is open.

Closed-Section (Bridge or Portal) Frames

Most large machines are designed with a closed frame as shown in Figure 11.8.26. When the Z motion is built into the bridge, a second actuator must often be slaved to the primary actuator that moves the

bridge. This prevents the bridge from yawing (walking). Note that there are many different variations on this design for different types of machines (e.g., milling machines and lathes). The common feature of all is the fact that the structural loop is closed.

Tetrahedral Frames

Nature invented the tetrahedron and found it to be an immensely stable and powerful form (e.g., diamonds). In engineering and architecture, the tetrahedron represents the three-dimensional application of the age-old structure of stability, the triangle. Lindsey of NPL in England took these basic building blocks of nature and added well-engineered damping mechanisms to yield a major advancement in the

© 1999 by CRC Press LLC

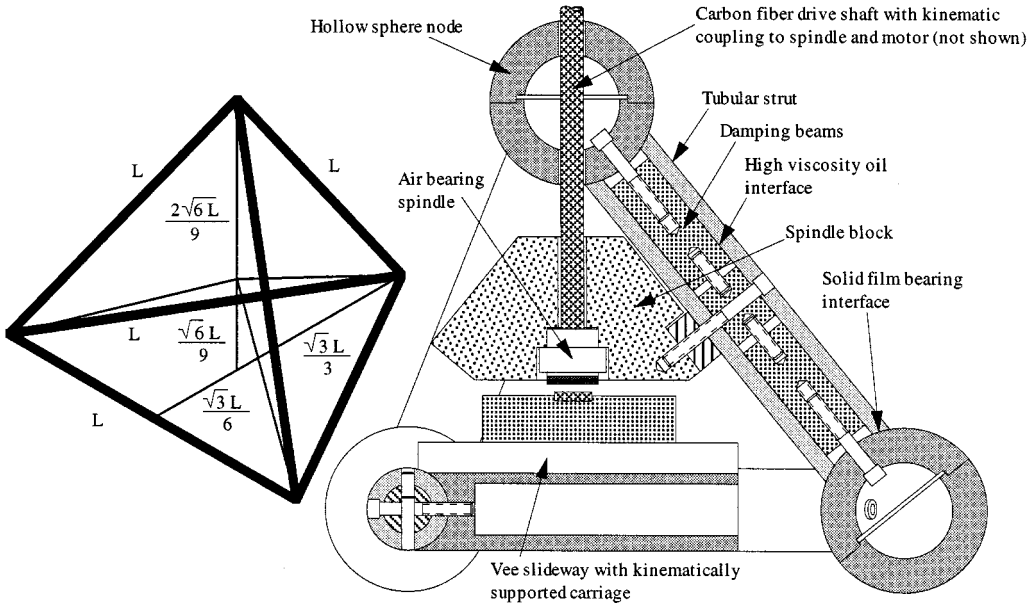

FIGURE 11.8.27 Tetraform structural concept for machine tools and instruments developed by Lindsey. (Courtesy of the National Physical Laboratory.)

structure of machine tools. The *Tetraform* machine tool concept is shown in Figure 11.8.27. The structures owes its exceptional dynamic performance to the following:*

- Damping in the legs is achieved through the use of inner cylinders which dissipate energy through viscous shear. Energy is dissipated via squeeze film damping and relative sliding motion damping.
- Damping at the joints is achieved by a sliding bearing (PTFE) interface.
- Microslip at the joints does not affect the dimensional stability of the machine because the minimum energy form of the tetrahedron wants to be preserved. Unlike a plane joint which can continue to slip and lead to dimensional instability, the tetrahedron's legs' spherical ends want to stay on the spherical joint nodes.

The latter point has even more profound consequences, in that it makes the use of composite materials in the structure an attractive alternative to metals or ceramics. Wound carbon fiber tubes can be designed to have a zero coefficient of thermal expansion along their length and they can have stiffness-to-weight ratios two times higher than are obtainable with metals. It would be difficult to design a conventional machine tool that made economical use of the desirable properties of carbon fibers.

Counterweights and Counterbalances

Counterweights, shown in Figure 11.8.28 can be used to minimize gravity loads. This helps minimize the holding torque required of servomotors, which in turn minimizes motor size and heat input to the machine. For a very high precision machine, however, the bearings used to guide the counterweights and support the pulley bearings should have negligible static friction. Counterweights also increase the mass of the system, which can decrease dynamic performance. In the case of quasistatic axes (e.g., large gantry-type surface grinders), the counterweight can increase the load on the structure that supports the axes, and if the structure is cantilevered, then as the counterbalanced axis moves, the deflection errors

* This concept is protected by worldwide patients. See, for example, U.K. patent 8,719,169, or contact the British Technology Group, 101 Newington Causeway, London, SE1 6BU, England.

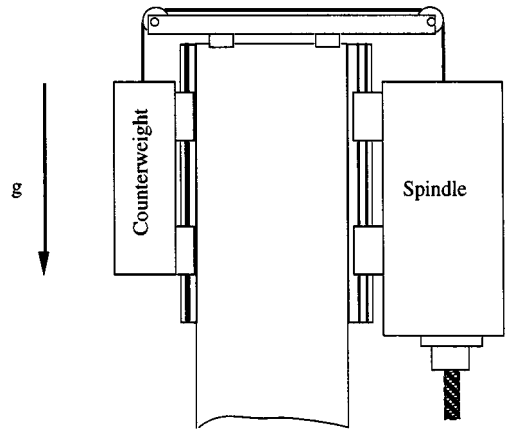

FIGURE 11.8.28 Use of a counterweight to balance the deadweight of an axis.

caused by the weight of the counterbalanced axis will change. Alternatively, a separate frame and low-accuracy slave carriage can be used to support the counterweights.

A counterbalance can be any passive means used to support the weight of an axis that moves in a vertical direction. Pistons have been used successfully but they can impart frictional and misalignment forces. A very effective counterbalance method is to use a float. This also provides viscous damping if the fluid used is a viscous oil.

Compensating Curvatures

All structures have finite stiffness, and when loads are applied, lateral and angular displacements will result. To compensate for these effects, it is possible to shape the otherwise straight ways of an axis so that the sum of the deflections and the intentional nonstraightness results in minimal net straightness error. This type of correction is known as a *compensating curvature*. Usually, it is very difficult to also compensate for angular errors. If the error budget is properly assembled, it can be used to plot the total error as a function of the position of an axis. Once the plot is found, it can be used to help design a shape (ideally, the inverse of the plot) that will cancel the lateral and hopefully also angular errors for the given bearing design. Compensating curvatures can easily be measured using an autocollimator.

When the load does not greatly change on parts moving along axes that are curvature compensated (e.g., axes that carry a measuring head), the method can be effective. If the loads do change greatly (e.g., a table carrying different weight parts and fixtures), the compensating curvature can sometimes decrease performance. One of its main attractions, however, is that once the correct compensated curvature and manufacturing process is found for a particular machine, it can be the least expensive way to correct for straightness errors.

With modern mapping techniques, compensating curvatures are used primarily on very large structures or when angular errors caused by deflection are too large and cannot be corrected for by another axis. For example, they might be used in a situation where otherwise the toolpoint would enter the workpiece at an angle rather than being perpendicular. A rotary axis would be required to compensate for this type of angular error, as opposed to just another linear axis, which can only be used to compensate for an Abbe error.

Structural Connectivity

The principle of kinematic design states that point contact should be established at the minimum number of points required to constrain a body in the desired position and orientation (i.e., six minus the number of desired degrees of freedom). This prevents overconstraint, and thus an “exact” mathematically continuous model of the system can be made. Kinematic locating mechanisms range from simple pins to Gothic arch-grooved three-ball couplings shown in Figure 11.8.29. Kinematic designs, however, are

© 1999 by CRC Press LLC

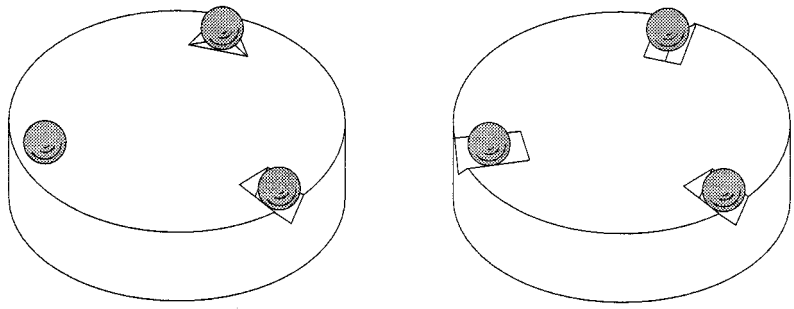

FIGURE 11.8.29 Flat-groove-tetrahendron (Kelvin clamp) and three-vee-groove kinematic couplings. In both cases, the balls are mounted to an upper plate (not shown) which is held in position with respect to the lower plate by the coupling.

subject to high-contact stresses, which often may require the use of ceramic components (e.g., silicon nitride balls and grooves) if the highest level of performance is to be achieved. If stress and corrosion fatigue are controlled, repeatability of a kinematic system can be on the order of the surface finish of the points in contact if the loads are repeatable or the preload high enough. Finite contact areas do exist, and they effectively elastically average out the local errors due to surface roughness. In addition, note that friction and microindentation will limit the accuracy of the kinematic model.

Kinematic support of a structure is often desired to ensure that the structure is not deformed by inaccuracies or instabilities of the mounting surface. For a small instrument, only one of the kinematic mounting points may be rigidly connected and the other two may consist of flexures that will allow for differential thermal growth between the instrument and the mounting surface. Friction does exist in kinematic couplings, and thus forces can be transmitted between a mounting surface and an instrument.

The principle of *elastic averaging* states that to accurately locate two surfaces and support a large load, there should be a very large number of contact points spread out over a broad region. Examples include curvic or Hirth couplings, which use meshed gear teeth (of different forms, respectively) to form a coupling. The teeth are clamped together with a very large preload. This mechanism is commonly used for indexing tables and indexing tool turrets. Figure 11.8.30 shows an indexing and clamping mechanism for a lathe tool turret. Note that many different types of clamping preload systems exist. However, this type of mechanism causes the system to be overconstrained; on the other hand, if an elastically averaged system is properly designed, fabricated, and preloaded, the average contact stress will be low, high points will wear themselves in with use, and errors will be averaged out by elastic deformation. The system itself will then have very high load capacity and stiffness. For a worn-in elastically averaged system, the repeatability is on the order of the accuracy of the manufacturing process used to make the parts divided by the square root of the number of contact points (i.e., teeth in a tooth coupling). Still, because of the large number of contact points, the chance of dirt contaminating the interface increases.

With respect to the connectivity between structural elements (e.g., a headstock and a bed), elements of a structure can either be connected together via:

- Kinematic design
  - Deterministic
  - Less reliance on manufacturing
  - Stiffness and load capacity limited
- Elastically averaged design
  - Nondeterministic
  - More reliance on manufacturing
  - Stiffness and load capacity not limited

© 1999 by CRC Press LLC

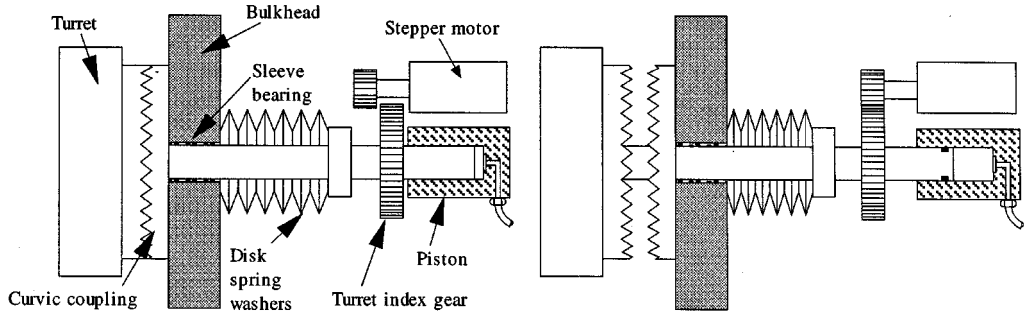

FIGURE 11.8.30 Typical turret indexing and locking mechanism in engaged and disengaged positions.

It should be noted that overconstrainted systems cannot accommodate differential thermal growth and hence are more prone to warping. Furthermore, finite deformation of the contact surface leads to micromechanical constraints that limit the true kinematicity of the structure. The use of hard materials (e.g., ceramics) helps to minimize the latter problem. For permanently connected components, one can align them using a kinematic location system and then inject epoxy or grout to create a bond between all the surfaces in close proximity, although with this method, one must make sure that the shrinkage of the bond material does not warp the components.

Bolted Joints*

Bolts can be used to prevent two parts from separating or sliding relative to one another. For the former, the tensile forces across the joint are transferred through the bolt shaft. For the latter, sliding motion is resisted by frictional forces generated from the normal load on the joint produced by tightening of the bolt and the coefficient of friction between the joint's parts. Because more than one bolt is usually used at a joint, it would be virtually impossible to ensure a tight fit of the bolt shafts in the holes, so it is not even worth trying. Sufficient lateral stiffness is usually provided by bolt preload and joint friction. For better resistance to shock loads, parts can be bolted in place and then holes drilled, reamed, and pinned with hardened steel dowels or roll pins. *In situ* drilling and reaming of the holes through both parts while they are bolted together maintains hole alignment, so multiple pins can be used.

Figure 11.8.31 illustrates the cross section of a typical portion of a bolted joint. A common bolt configuration used to bolt bearing rails for T-slides is shown in Figure 11.8.32. Many rails have a double row of bolts. In general, the cantilevered length should not exceed the bedded length. Ideally, the bedded length should be about 1.5 times the cantilevered length, but sadly this often takes up too much room. Furthermore, the stress cones under the boltheads should ideally overlap to maximize stiffness and minimize rail waviness. In practice, however, as shown in Figure 11.8.33 adequate stiffness can be obtained from a wider bolt spacing. The total stiffness for N segments of a bearing rail (e.g., N segments under a bearing pad) is given by**

$$K_{\text{Rail}} = \frac{N_{\text{Segments}}}{\dfrac{1}{K_{\text{Rail bend \& shear}}} + \dfrac{1}{K_{\text{Joint}} + \dfrac{1}{\dfrac{1}{K_{\text{Flange comp}}} + \dfrac{1}{K_{\text{Flange shear}}} + \dfrac{1}{K_{\text{Bed Shear}}} + \dfrac{1}{K_{\text{Bolt}}}}}}$$

* For a more detailed discussion, see, for example, Bickford, J.H. 1981. *An Introduction to the Design and Behavior of Bolted Joints.* Marcel Dekker, New York; as well as A. Blake's book.

** The theory and practical implementation implications of bolted joints for machine tool applications are beyond the scope of this work. These are discussed in greater detail in Slocum, A. 1997. *Precision Machine Design.* Society of Manufacturing Engineers, Dearborn, MI.

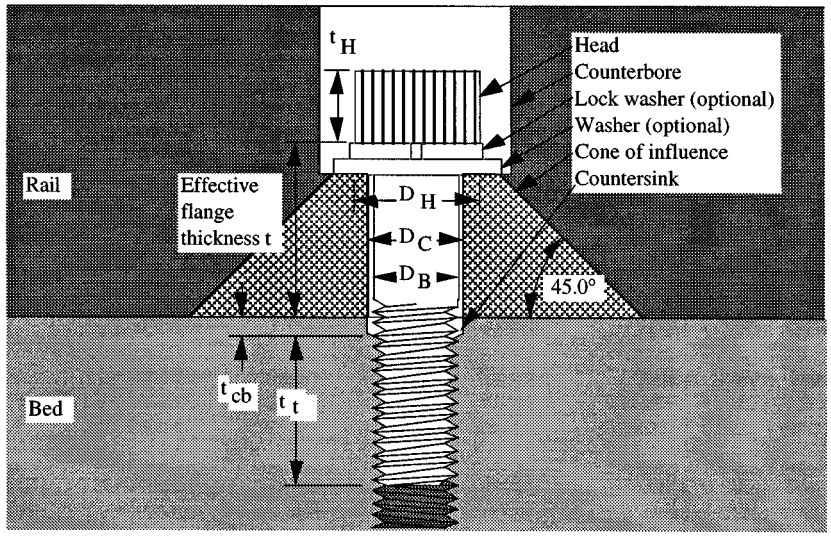

FIGURE 11.8.31 Typical components of a bolted assembly.

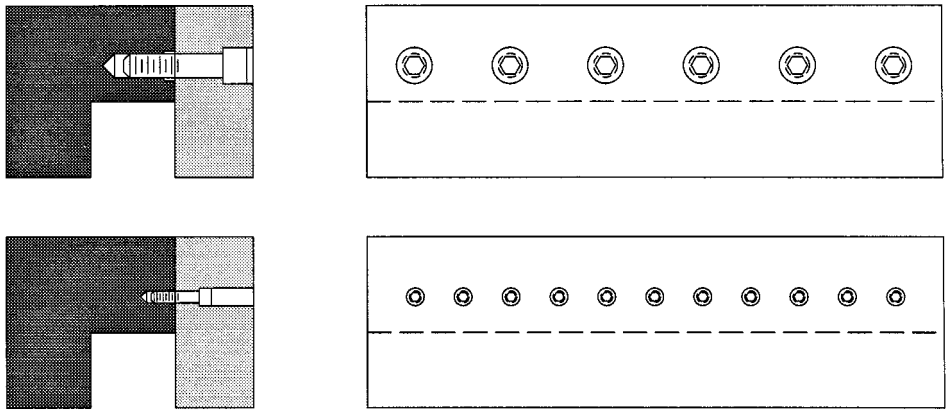

FIGURE 11.8.32 Counterbored and bolted bearing rails with equal stiffness.

Bolt diameter is not a sensitive parameter for stiffness when bolt spacing is made a function of the bolt diameter. When the length of the bolt and the cone are expressed as bolt lengths, bolt joint stiffness becomes linearly dependent on the bolt diameter. As a result, bolt diameter cancels out as shown in Figure 11.8.33.

Bearings

Since bearings are such a critical element in precision machines, one must *think* about the seemingly innumerable number of bearing design considerations that affect the performance of a machine, including:

- Speed and acceleration limits
- Range of motion
- Applied loads
- Accuracy
- Repeatability
- Sealability
- Size and configuration
- Weight
- Support equipment
- Maintenance

© 1999 by CRC Press LLC

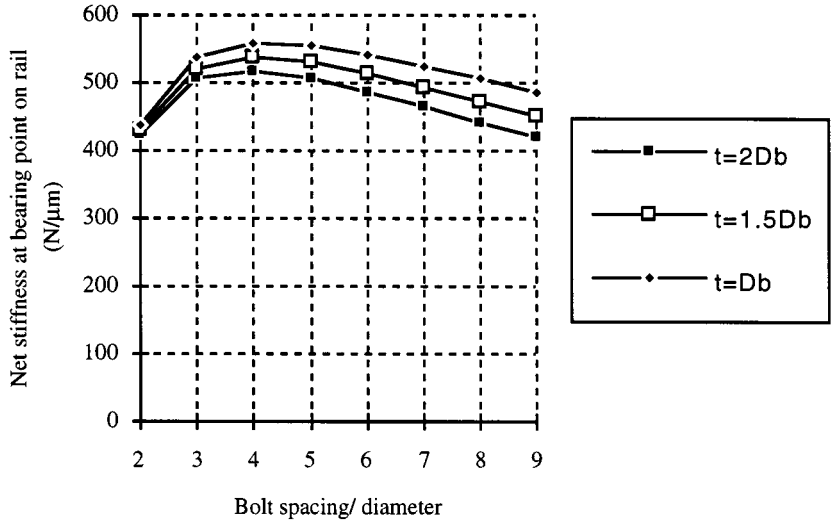

FIGURE 11.8.33 Relationships among stiffness and bolt spacing.

- Resolution
- Preload
- Stiffness
- Vibration and shock resistance
- Damping capability
- Friction
- Thermal performance
- Environmental sensitivity
- Material compatibility
- Mounting requirements
- Required life
- Availability
- Designability
- Manufacturability
- Cost

Because there are always design trade-offs in choosing a bearing for a precision machine, all of these factors must be considered simultaneously by the design engineer. In addition, there are several issues that are common to most types of bearings. These issues include surface roughness, preload, and replication of bearings in place.

Surface Roughness

Surface roughness is a characterization of the profile of the surface and often has an effect (although difficult if not impossible to characterize) on the smoothness of a bearing's motion. In terms of the manufacturing process, smoothness of motion of a bearing can only be quantified in terms of the surface roughness and bearing design:

- Sliding contact bearings tend to average out surface finish errors and wear less when the skewness is negative. A positive skewness (defined below) can lead to continued wear of the bearing.
- For rolling element bearings, if the contact area is larger than the typical peak-to-valley spacing, an elastic averaging effect will occur and a kinematic arrangement of rollers will produce smooth motion. If this condition is not met, the effect will be like driving on a cobblestone street. If numerous rolling elements are used, the effects of elastic averaging can help to smooth out the motion.
- Hydrostatic and aerostatic bearings are insensitive to surface finish effects when they are considerably less than the bearing clearance.
- Flexural and magnetic bearings are not sensitive surface finish.

© 1999 by CRC Press LLC

There are three common parameters for specifying the surface finish or roughness*: the *root mean square* (rms or R_q), the *centerline average* (R_a), and the International Standards Organization (ISO) 10-point height parameter (R_z). The latter is with respect to the five highest peaks and five lowest valleys on a sample. A surface profile measurement yields a jagged trace. If a best fit straight line is drawn through a section of the trace of length L, then the R_q, R_a, and R_z, surface finishes are defined, respectively, from deviations y from the line as a function of distance x along the sample:

$$R_q = \sqrt{\frac{1}{L}\int_0^L y^2(x)\,dx} \qquad R_a = \frac{1}{L}\int_0^L y(x)\,dx \qquad R_z = \frac{\sum_{i=1}^{5} y_{\text{peak}}(i) - y_{\text{valley}}(i)}{5} \tag{11.8.29}$$

Unfortunately, these measures do not provide any information as to the topographical characteristics of the surface. As shown in Figure 11.8.34 the surface topography can be characterized by the *skewness*. The skewness is the ratio of the third moment of the amplitude distribution and the standard deviation σ from the mean line drawn through the surface roughness measurements. Hence the skewness provides a measure of the shape of the amplitude distribution curve. For a contact-type bearing, valleys separated by wide flat planes may be acceptable. This form would have a negative skewness value and is typically in the range –1.6 to –2.0 for bearing surfaces. Sharp spikes would soon grind off, creating wear debris and more damage, and hence positive skewness values are unacceptable for contact-type bearing surfaces. The skewness is defined mathematically from:

$$\text{skew} = \frac{\mu_3}{\sqrt{\mu_2}} = \frac{\mu_3}{\sigma} \qquad \mu_n = \int_{-\infty}^{\infty} (y-\mu)^n f(y)\,dy \qquad \mu = \int_{-\infty}^{\infty} y f(y)\,dy \tag{11.8.30}$$

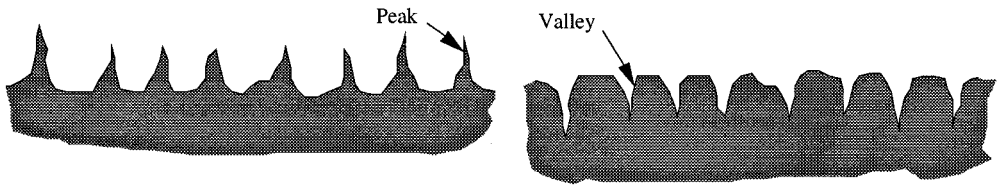

FIGURE 11.8.34 Surfaces with positive (left) and negative (right) skewness.

Numerous other methods exist for defining the shape and intensity of surface roughness features. For example, the autocorrelation function is used to check for the degree of randomness in a surface. This can be used to help track down periodic components (e.g., those caused by tool chatter), which can then sometimes be reduced in subsequently made parts. A frequency spectrum analysis can also be used to accomplish this. The science of surface metrology is constantly evolving as surface finish requirements increase, and the interested reader should consult the literature.**

Bearing Preload

A preloaded bearing is one where one bearing pushes against another, thereby squeezing the bearing rail. This allows the bearing to resist bi-directional loads without motion nonlinearity (e.g., backlash) when the load reverses direction. As the force on a pair of opposing pads preloaded against each other is applied, one bearing pushes harder on the rail by an amount equal to the product of the pad stiffness and the carriage deflection, and one pushes less by the same amount.

Insufficient preload is synonymous with at least some of the bearing points periodically losing contact with the bearing surface. This results in difficult-to-map error motions and decreased stiffness, possibly leading to chatter of the tool. Tool chatter, in turn, degrades the surface finish of the part. However, with contact-type bearings, preload can accelerate wear and can lead to stiction, which decreases controllability. These issues lead to the desirability of externally pressurized fluid film bearings (air or fluid) where preload will not change with time.

Unless the axes of the machine are designed to utilize the weight of the machine itself as a preload, in many cases the preload will change with time. This is particularly true if contact-type bearing surfaces wear and if the structure relaxes, due to internal stress needed to maintain the preload. In an effort to counter these effects, the classic method has been to use a device known as a gib to generate the preload. In general, a gib can be defined as a mechanical device that can apply preload to a bearing. In the classical sense, a gib was a wedge-shaped part that was advanced by the action of a screw. When a gibbed machine wears, the gibs, bearings, and sometimes the ways must be rehand-finished and the gibs adjusted to provide the proper preload.

In many machines it is common to use modular rolling bearing components whose preload is set by using oversized balls or rollers, or by tightening bolts that push on a plate contacting the rollers. When the latter type of system wears, it is often discarded and replaced with a new unit. Hence large economies of scale can be obtained by some bearing component manufacturers.

Replicated Bearings*

Replication is a process whereby a very low shrinkage polymer is poured or injected around a master shape that has been coated with mold release. When the polymer cures, it has the shape of the master, which can then be removed and used again. This process can be used to form a bearing surface itself, such as a sliding bearing or a hydrostatic bearing with a pocket, or to form a mating surface between a modular bearing carriage and rough surface of a structure such as a casting.

Because hardening of many polymer resins is an exothrmic reaction, one of the important aspects of this process is to minimize the amount of polymer used, and to maximize the stiffness and thermal diffusivity of the master and the part. This is required to prevent the heat of polymerization from heating the structure, deforming it, and then the polymer hardening to the thermally deformed shape. Unlike bolted assemblies, once the polymer cures to form the desired shape (e.g., a trough in which a linear bearing rail is placed), alignment is no longer possible.

Figure 11.8.35 shows schematic details of surface preparation required to ensure the debonding does not occur. This sawtooth pattern can be obtained in a number of different ways. In addition to the rough surface finish required, the surface must also be thoroughly cleaned and a mold release applied to the master.

Sliding Contact Bearings

Sliding contact bearings are the oldest, simplest, least expensive bearing technology, and they still have a wide range of applications, from construction machinery to machines with atomic resolution. Sliding bearings are thus a very important element in the machine design engineer's tool kit. Sliding contact bearings utilize a variety of different types of lubricants between various interface materials. Lubricants

* See, for example, Devitt, A. October 1989. Replication techniques for machine tool assembly. In *East Manuf. Tech. Conf.* Springfield, MA. Available from Devitt Machinery Co., Twin Oaks Center, Suite G, 4009 Market Street, Aston, PA 19104.

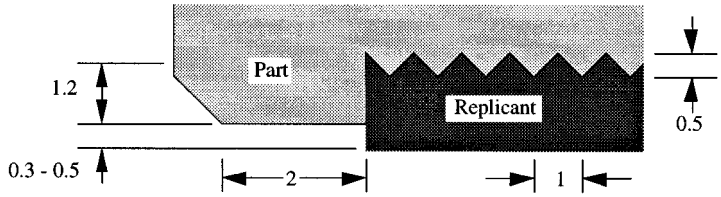

FIGURE 11.8.35 Details of surface and region for replication (dimensions are in mm).

range from light oil to grease to a solid lubricant such as graphite or a PTFE polymer. Because they often distribute loads over a large area, contact stresses and space requirements are often low, while stiffness and damping are usually high. In this section, general properties of sliding contact bearings are discussed followed by a discussion of design considerations.

There are numerous types of sliding contact bearings available and in the context of discussing their general properties, some specific categories will be discussed. In general, one should note that all sliding contact bearings have a static coefficient of friction that is greater (to some degree, no matter how small) than the dynamic coefficient of friction (static μ > dynamic μ). The difference between the static and dynamic friction coefficients will depend on the materials, surface finish, and lubricant.

Rolling Element Bearings

Figures 11.8.36 and 11.8.37 show representative types of ball and roller bearings. Typical linear rolling element bearing configurations are shown in Figure 11.8.38. Note that, in general, it is easier to make a ball spherical than a roller cylindrical; hence ball bearings are more commonly used in precision machines than are roller bearings, the exception being when very high loads must be withstood. A good roller bearing may be better than a moderate ball bearing, and hence in the end the most important thing is to compare manufacturers' specifications.

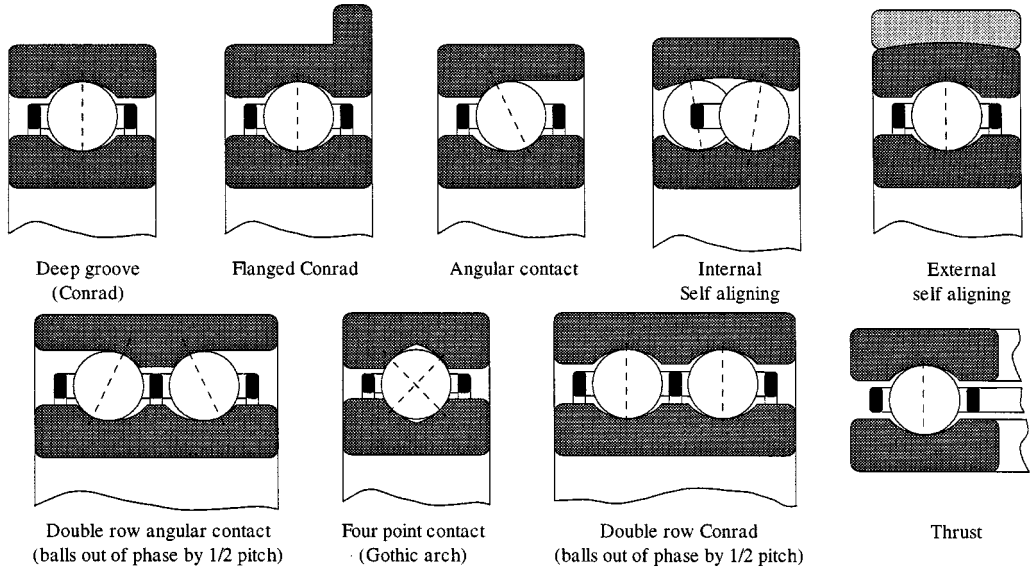

FIGURE 11.8.36 Typical ball bearing configurations for rotary motion bearings.

For linear motion applications, it is more difficult to maintain quality control of a curved surface a ball rides on than a planar surface a roller rides on because the latter can be self-checking. Note that machine-made linear bearing rails will have the same errors as the linear bearings on the machine that

© 1999 by CRC Press LLC

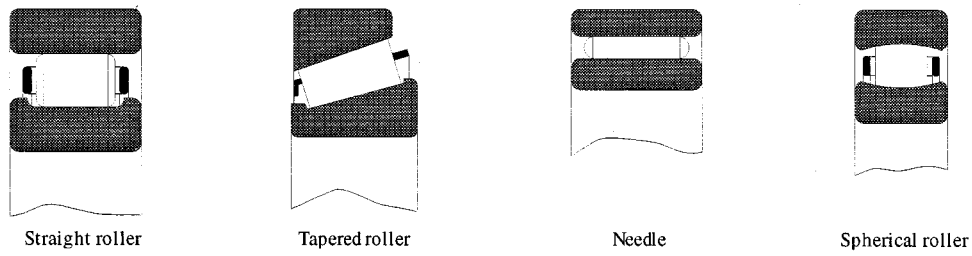

FIGURE 11.8.37 Typical roller bearing configurations for rotary motion bearings.

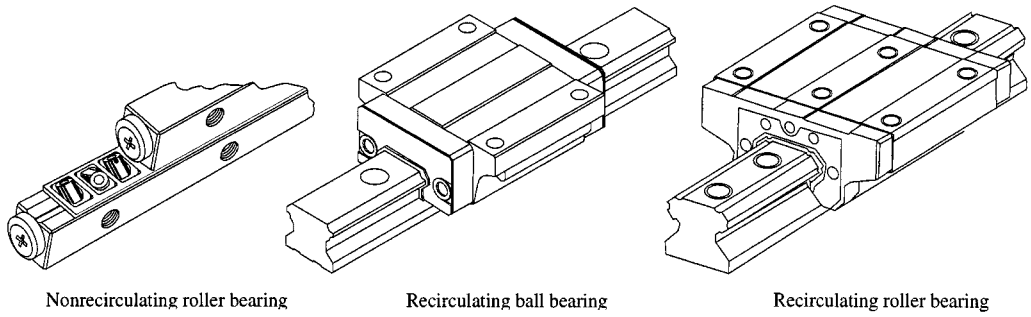

FIGURE 11.8.38 Typical linear rolling element bearing configurations.

was used to make them. For rotary axes, the raceway and the grinding tool can both be rotating at different speeds, which, combined with the random nature of precision spindle radial error motions, means that the form of the raceway can be uniform around is circumference. Thus rotary motion rolling element bearings can be made more accurate than linear motion rolling element bearings. Typical total radial error motion on a precision spindle is on the order of $^1/_4$ to 1 μm. For higher-performance linear or rotary motion bearings, one would typically move into the realm of aerostatic, hydrostatic, or magnetic bearings.

The design and production of a rolling element bearing requires careful analysis, materials selection, manufacturing quality control, and testing. Few companies other than bearing manufacturers have the resources for this type of effort. Whenever possible, one should use off-the-shelf bearing components. In addition, whenever possible, one should use modular components such as spindles and linear axes, particularly for nonsubmicron machines made in small lots (less than about 10 to 20 machines). The savings in design time, prototype testing, spare parts inventory, and repair and replacement costs often far outweigh the potential of saving a few dollars in manufacturing costs.

Designing with rolling element bearings can be intimidating because there are so many subtle details that can ruin a design if they are not considered. The best way to learn about how to handle these details is to think carefully about the physics of their design and the application and/or to work with others with experience, and if possible to experiment. In addition, manufacturers of precision bearing components are also usually willing to work with design engineers to integrate their bearing components into a design. Mapping and metrology frames can be used to increase accuracy given adequate repeatability, resolution, and controllability of the machine *if* the machine is designed with these error-reducing methods in mind.

Rolling Element Linear Motion Bearings

After the rotary motion rolling element ball bearing, the linear motion rolling element bearing ranks on the list of major inventions. Although not found in consumer products with anywhere near the frequency

© 1999 by CRC Press LLC

of rotary ball bearings, linear rolling element bearings are vital for the manufacturing industry. They are critical elements in the design of today's high performance machine tools and factory automation systems.

Flexural Bearings*

Sliding, rolling, and fluid film bearings all rely on some form of mechanical or fluid contact to maintain the distance between two objects while allowing for relative motion between them. Since no surface is perfect and no fluid system is free from dynamic or thermal effects, all these bearings have an inherent fundamental limit to their performance. *Flexural bearings* (also called *fllexure pivots*), on the other hand, rely on the stretching of atomic bonds during elastic motion to attain smooth motion. Since there are millions of planes of atoms in a typical flexural bearing, an average effect is produced that allows flexural bearings to achieve atomically smooth motion. For example, flexural bearings allow the tip of a scanning tunneling microscope to scan the surface of a sample with subatomic resolution.** There are two categories of flexural bearings, monolithic and clamped-flat-spring, as shown in Figures 11.8.39 and 11.8.40.

Hydrostatic Bearings

Hydrostatic bearings utilize a thin film of high-pressure oil to support a load. In general, bearing gaps can be rather large, on the order of 5 to 100 μm. There are five basic types of hydrostatic bearings: single pad, opposed pad, journal, rotary thrust, and conical journal/thrust bearings. All operate on the principle of supporting a load on a thin film of high-pressure oil that flows continuously out of the bearing; hence a method is needed for supplying the pressurized oil and collecting and recirculating the oil that flows out of the bearing.

11.9 Robotics

Leonard D. Albano

The field of robotics is concerned with the design and development of mechanical devices that can be programmed to perform certain functions. Robots have been developed for a large variety of applications, such as material transport, automated assembly, and operations in controlled environments, such as high temperature and caustic surroundings. The semiconductor industry, for example, uses advanced robotic technology to fabricate IC chips. Many robots are simply relied on as a cost-effective alternative to human workers for certain highly repetitive tasks, such as spot welding and painting. For these applications, the robot must be able to undergo a range of accelerated motions while demonstrating the ability to position accurately its end effector. This must be done with minimum breakdowns and rapid repair. The control strategy involves solving the governing dynamic equations as the robot arm and end effector move through their operations. See Chapter 14 for further information.

11.10 Computer-Based Tools for Design Optimization

The range of computer applications in engineering design covers procedures from preliminary conceptual design to the production of manufacturing drawings and specifications (see Chapter 13). Most computer applications intended for production use can be classified into five or more major categories: analysis, computer-aided drafting and design, geometric modeling, data base management systems, and artificial intelligence. Traditional software for design optimization may be categorized as analytical applications, based on rational principles of mathematics and linear programming. Emerging computer-based tools for design optimization are an offshoot of research in artificial intelligence, capable of processing a variety of algorithmic, symbolic, deterministic, probabilistic, and fuzzy knowledge.

Design Optimization with Genetic Algorithms

Mark Jakiela

Introduction

One broad use of computer-based tools in design is to automate the design process itself. This is commonly done by modeling a design problem (or class of design problems) as a search problem. Such a model requires a representation and a search process. A representation is some set of parameters, either continuous or discrete, which can represent every possible design with appropriate values assigned to each parameter. We can call each possible parameter setting a design, and the set of all possible designs (possibly infinite in number) is called the design space. The search process is some method to investigate the design space and find some design that is acceptable or desired. When some acceptable designs are more desirable than others, the search process can be used to perform optimization.

Traditionally, the search and optimization technique that has been used most frequently for mechanical engineering problems has been a gradient-based search with continuous variables. When this representation and search method agrees with the problem being solved (the optimization model functions should be smooth and the objective preferably unimodal), this technique works exceedingly well. Currently, however, a variety of important problems are not amenable to this well-established technique because they cannot be modeled with only continuous variables (discrete or mixed discrete problems) and/or the objective and constraint functions do not exhibit appropriate characteristics. Other techniques are therefore required.

This subsection will provide an introduction to genetic algorithms ("GAs"), a search and optimization process that mimics the natural process of evolution. First, a brief tutorial on the fundamentals of GAs is given. This is followed by several examples drawn from a range of engineering problem domains. We hope that the variety of examples demonstrates the real strength and advantage of genetic algorithms: their versatility. They can be used to address almost any type of optimization problem. Requirements for their use are discussed in the tutorial. Some general and philosophical remarks conclude the subsection.

Genetic Algorithm Tutorial

Genetic algorithms are a simulation of a simplified process of evolution (Holland, 1975). The fundamental object of data used by a GA is referred to as a chromosome. Some number of chromosomes exist simultaneously in a population. The GA transforms one population into a succeeding population, creating a generation of children from a generation of parents. It does this with operators that are analogous to the biological operators of reproduction, recombination, and mutation. A measure of the quality of each chromosome, analogous to the fitness of a biological organism in an environment, is created and used to probabilistically select chromosomes that will serve as parents. With an increasing number of generations, the overall (e.g., average, single best) fitness of the population increases and the diversity represented in the population decreases.

© 1999 by CRC Press LLC

For engineering purposes (see e.g., Goldberg, 1989), the chromosome is some type of encoding of the characteristics of a possible design. There is the notion, therefore, of a genotype (chromosome space) to phenotype (design space) mapping. Consider, as a simple example, a GA that is used to evolve optimal values of a set of parameters. A chromosome might be set up as a string of binary digits (i.e., bits), with concatenated substrings being binary encodings for each parameter. This is shown in Figure 11.10.1. Each bit position can be thought of as a gene and the value found there can be though of as an allele. The number of bits used to encode the parameter defines a resolution of the representation accuracy.

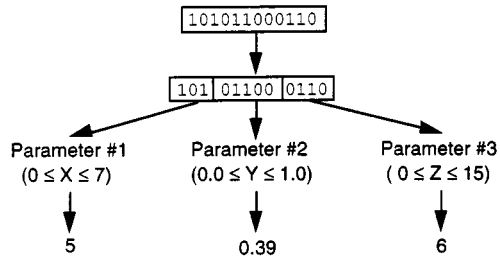

FIGURE 11.10.1 Binary chromosome representation.

Continuing with the explanatory parameter optimization example, the various processes of one iteration (i.e., generation) would proceed as follows. In a given generation, all chromosomes would be decoded to yield possible values for the parameters. These parameters would be used in an objective function of interest to yield a value measuring the quality of that set of parameters. This objective function value is used as the fitness measure of the chromosome. The probability of choosing a chromosome to serve as a parent is influenced by its fitness value: as in nature, the fittest are more likely to reproduce. Pairs of parents are randomly chosen with these weighting probabilities and mated. Copies of the parent chromosomes (i.e., reproduction) are used to build the chromosomes of the children. This is done by performing some type of recombination operation on them.

Figure 11.10.2 shows a simple one-point crossover recombination operation. First, a crossover point is randomly selected along the length of the chromosomes. Then, the front of one chromosome is appended to the back of the other chromosome and vice versa. This creates two children from two parents. Performing crossover with all the pairs of parents will create a tentative population of children that can replace the parents. The final step is to perform mutation on these children with a very low probability. One bit per 1000, for example, can be randomly chosen and inverted in value as an aid to maintaining diversity in the population. Finally, replacing the parents with the children brings the algorithm to the next generation.

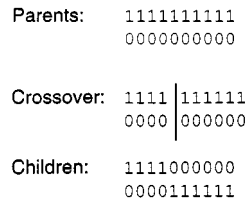

FIGURE 11.10.2 One-point crossover.

The procedure described above is commonly referred to as a "simple" GA (Goldberg, 1989) and can be thought of as a basic or canonical approach. In practice, several runtime parameters are required in its implementation. These include the probability of crossover (will two parents recombine, or will they proceed into the next generations unaltered?), the probability of mutation (on average, what fraction of genes are mutated?), a fitness scaling coefficient (an adjustment limiting the range of fitness values that

© 1999 by CRC Press LLC

helps to prevent premature convergence), and population size (the number of chromosomes in a population). Note that a simple GA has the disadvantage of requiring a large number of function calls. This can be mitigated somewhat by using an "overlapping" population, in which a smaller number of parents will be chosen (i.e., fewer of the best) and the resulting children will replace the worst members of the parents' population. Regardless of the amount of overlap, note that a GA requires no derivative computations; the search is directed by the zeroth-order sampling of fitness function values. Because of this, a GA can perform well in ill-behaved multimodal search spaces (see Goldberg, 1989) and is relatively unlikely to become trapped in local suboptima. Equally important is the high degree of general flexibility of a chromosome representation. Although a binary encoding makes clear the general operation mechanisms and actually is used for a variety of problems, several other types of representations have been used and found to work well. In almost all cases, the evolutionary optimization strategy succeeds in producing improved designs. A variety of representations and fitness/objective functions will be described in the following examples.

Examples

Truss Parameter Selection. As a first example, we describe a problem that could readily be formulated as a continuous optimization problem (see Arora, 1989, pp. 23–31). The following genetic algorithm formulation, condensed from Wallace et al. (1995), will highlight the different approaches that are needed for a GA-based optimization.

Consider the symmetric truss shown in Figure 11.10.3. The truss is to be made of medium strength structural steel. We will assume that the load W and the truss height h are specified. The designer wishes to determine the truss base s and the inside and outside diameters of the members 1 and 2. A possible list of design variables and associated upper and lower limits for this problem are shown in Table 11.10.1. Note that the variables r_1 and r_2 allow the cross sections to vary continuously from solid rod stock to thin-walled pipe.

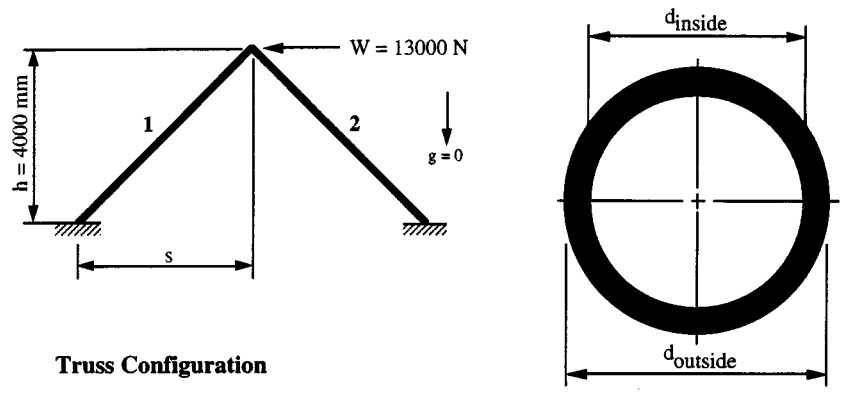

FIGURE 11.10.3 Definition of a simple two-member truss problem (gravity is assumed to be zero to simplify buckling calculations).

TABLE 11.10.1 Design Variables or Parameters to be Optimized in the Truss Problem

Design Variable	Limits
$d_{1(outside)}$	$0 < d_{1(outside)} < 100$ mm
$r_1 = d_{1(inside)}/d_{1(outside)}$	$0 < r_1 < 1$
$d_{2(outside)}$	$0 < d_{2(outside)} < 100$ mm
$r_2 = d_{2(inside)}/d_{2(outside)}$	$0 < r_2 < 1$
s	1000 mm < s < 3000 mm

© 1999 by CRC Press LLC

In a continuous gradient-based formulation, the next step would be to model the relationships of interest as objective and constraint functions. Lagrange variables could then be introduced and the lagrangian would be subjected to the first- and second-order (constrained) optimality conditions to find a set of local optima. In addition to the upper and lower variable limits already listed, the other relationships of interest would include the normal stresses in members 1 and 2, the buckling stress in member 1, and the material cost as the objective function.

A genetic algorithm formulation does not use any derivatives. Instead, an objective function augmented with penalty terms for each potentially active constraint is used in an unconstrained optimization search. Wallace et al. (1995) formalize the notion of "design specifications" as a means to formulate such GA design optimization problems in a consistent and simplified way. The basic idea is that specifications indicate the probability that a particular performance level will be deemed acceptable. For the truss optimization the performance specifications considered are shown in Table 11.10.2. It is also possible to use other goal, objective, or preference formulations, such as the utility theory (Keeney and Raiffa, 1976).

The performance specifications on normal stress in the two members, $n_{\sigma 1}$ and $n_{\sigma 2}$, are modeled as safety factors. The specification distribution indicates that a safety factor for either member less than 1.5 is unacceptable (i.e., it will be accepted with a probability of zero, also see discussion below), and a safety factor greater than 2.0 is acceptable with certainty. To actually use this probabilistic specification, the design variables shown in Table 11.10.1 are decoded from a chromosome and used to compute values for $n_{\sigma 1}$ and $n_{\sigma 2}$, resulting in turn in two acceptance probabilities. A buckling safety factor for member 1 is treated in a similar manner (note that member 2 is always in tension). In addition to the upper and lower limits on r_1 and r_2, an additional performance specification is provided that indicates a strong preference for solid rod or thin-walled tube. This specification has, in effect, made the acceptable ranges of r_1 and r_2 discontinuous. Finally, the cost objective function is also provided to the problem as a probabilistic specification. If a full acceptance probability is achieved, the problem can be resolved with a lower material cost certainty point. In the solutions presented below, we assume that rod is 1/2 the price of pipe on a unit volume basis.

Once all individual acceptance probabilities are computed, a composite acceptance probability is used as the fitness function for the GA search. Intuitively, it seems as though the overall probability of acceptance is simply the product of the individual acceptance probabilities. Such a model does not work well in the GA-based search since a low score on a single characteristic will leave the overall design with a zero acceptance probability (in this case, the GA will consider "infeasible" designs with r_1 and/or r_2 between 0.2 and 0.7). The other characteristics of the designs could be very good and worthy of consideration in future generations. We therefore transform the multiplicative probability maximization into an additive information content minimization by taking the log of each probability term. The resulting objective is a generalized from of Suh's "Information Axiom" see Section 11.4.

$$I = \sum_{i=1}^{n} \log_2 \left(\frac{1}{p_i} \right) \tag{11.10.1}$$

where

n = number of design specifications or criteria
p_i = probability of being acceptable as defined by the i^{th} specification*
I = design information content in bits

Results for the solved truss problem are shown in Figure 11.10.4. Member 1 is under compression and thus is tubular (for buckling stiffness), while the tensile member 2 is made of less expensive rod stock. Convergence to a solution typically occurred in 80 generations requiring 2.5 sec on a Silicon Graphics

* For small values of p_i, a minimum nonzero value is used in Equation 11.10.1 to prevent division by zero.

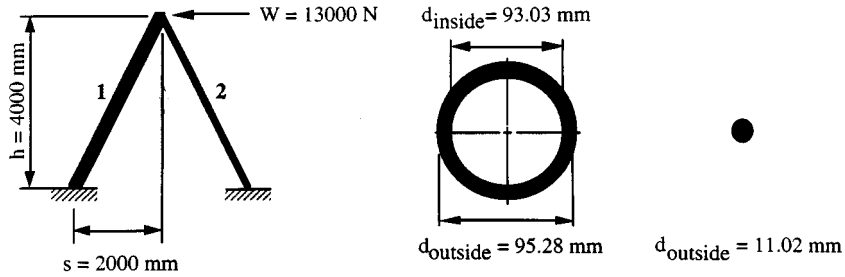

FIGURE 11.10.4 (a) Configuration of the optimized truss design.

Indigo[2] Extreme[2]. This search involved the evaluation of 2400 candidate designs (30 per generation). The search space for this problem contains $\approx 1.1 \times 10^{12}$ points (five parameters at 8-bit resolution gives 2^{40} points).

It must be noted that the search converged to this solution using rod stock for member 2 in only 17% of 60 consecutive optimizations. The more frequent solution shown in Figure 11.10.5 is nearly as good.

Topology Optimization. In this example, we will address planar stress/strain problems and the generation of optimal structural topologies. As shown in Figure 11.10.6, a design domain defines the allowable extents of any possible design. This domain is discretized into a rectangular grid, with each square element of the grid assigned a value of "material" or "void". Treating each grid element as a binary variable leads to a large combinatorial search space. The grid is used to create a finite element mesh for structural analysis. In our case, each material element contains four triangular finite elements made from the five nodes located at the four corners and the center of each material element. The genotype corresponding to this phenotype is a simple binary two-dimensional array chromosome, or a binary string, as described below.

Phenotypically, certain material elements are required to always contain material, regardless of the bit value in the genome. We refer to these as material constraints. These are elements that serve as structural boundary conditions. In Figure 11.10.6, examples would be the highest and lowest elements bordering the wall, and the element that is used to apply the load. Thus, the genotype is not always a completely accurate representation of the actual structure.

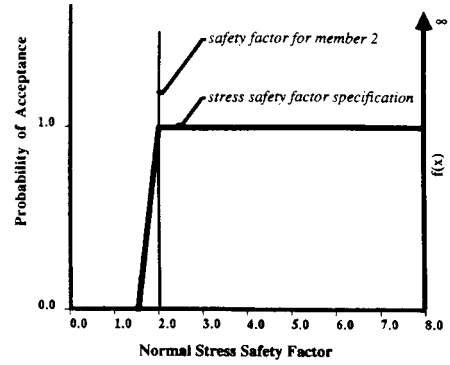
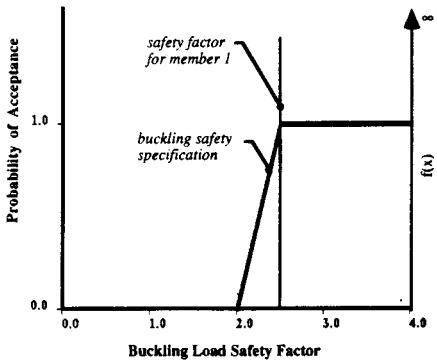
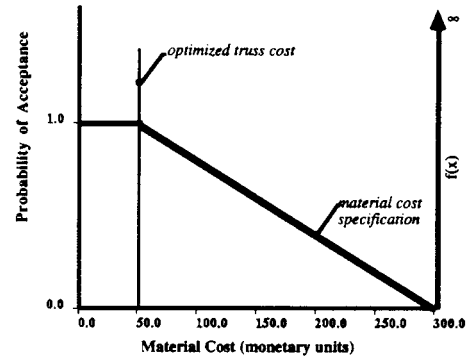
$n_{\sigma 1}$ = 7.09, $p_{acceptable}$= 1.0



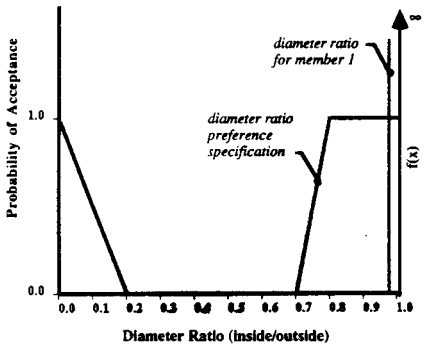
$n_{\sigma 2}$ = 2.03, $p_{acceptable}$= 1.0



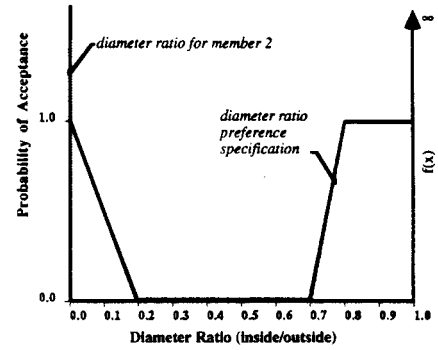
n_{Bl} = 2.50, $p_{acceptable}$= 1.0



C = 51.02 units, p = .9958



r_1 = 0.9764, $p_{acceptable}$ = 1.0



r_2 = 0.0, $p_{acceptable}$ = 1.0

FIGURE 11.10.4 (b) Comparison of truss performance variables to design specifications.

The genotype can also differ from the phenotype because of connectivity analysis. Connectivity analysis requires that all elements that are included in the structural analysis be connected to other elements by at least one edge–edge connection, as opposed to only a corner connection. In addition, all elements considered connected must be linked to one of the material constraint elements by a path of edge connections. Any elements not so connected are removed from the mesh for the purposes of structural analysis: they are considered to have no stiffness and no mass. Since we are addressing planar problems, the rationale for connectivity analysis is that elements connected at corners cannot transfer

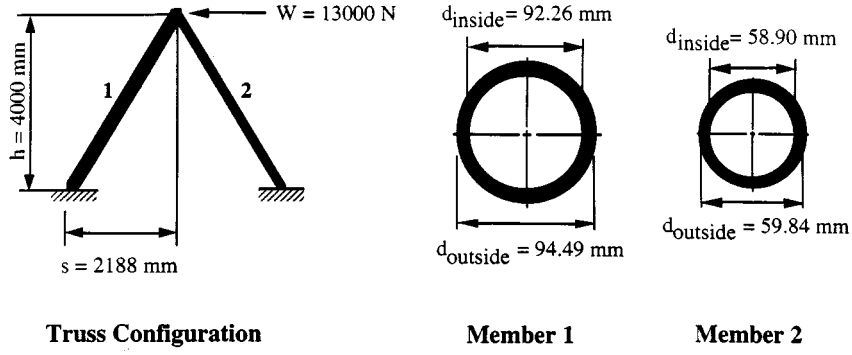

FIGURE 11.10.5 A result that did not find the better solution using cheaper rod stock for member 2. The cost is 56.73 units, giving $p_{acceptable}$ = 0.9728 (compared to 0.9958 for the solution using rod for member 2). $n_{\sigma 1}$ = 7.49, $n_{\sigma 2}$ = 2.01, $n_{\beta 1}$ = 2.50.

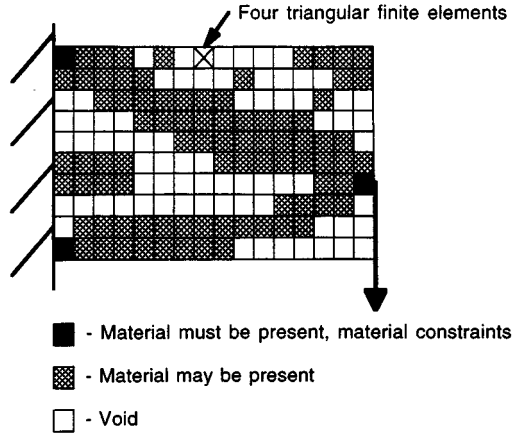

FIGURE 11.10.6 Typical design domain.

moments about those corners (since the finite element model treats corners as kinematic pin joints). It is less likely, therefore, that "disconnected" elements will contribute to enhanced structural performance. We have found that this is true empirically (see Chapman et al., 1993 for further discussion of this topic). Figure 11.10.7 shows the structure of Figure 11.10.6 after connectivity analysis. It is important to note that we do not penalize structures with more disconnected elements; we simply reward structures based upon the performance caused by their connected elements. This allows disconnected elements to in some sense be "recessive", in that crossover could cause them to combine with the (possibly disconnected) elements from another structure to yield a structure of connected elements of much improved performance.

As fitness, we are interested primarily in structural performance. In this study, this will be represented by two characteristics, mass and deflection. Generally, we wish the genetic algorithm to evolve structures that are both lightweight and deflect small amounts under a given load. The deflection, δ, will be measured with a finite element simulation and the mass m will be proportional to the number of connected material elements. These two characteristics can be used to create an unconstrained fitness, such as maximizing the following ratio:

$$\text{fitness} = \frac{1}{(\delta)(m)} \tag{11.10.2}$$

© 1999 by CRC Press LLC

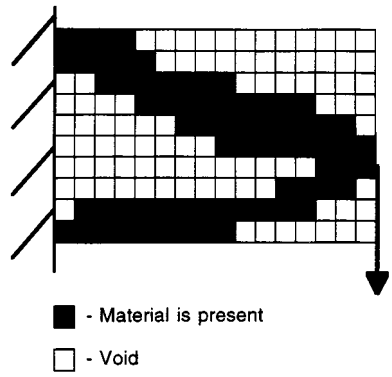

FIGURE 11.10.7 After connectivity analysis.

Alternatively, one of these characteristics can be optimized while treating the other as a constraint. Chapman and Jakiela (1995) provide some guidelines for using penalty functions for structural optimization that address many different characteristics (e.g., reducing the number of macroscopic holes in the topology).

In this example, we will use two different types of chromosomes to represent the material array. The first is a one-dimensional string chromosome made by concatenating the rows of the material array. The second is a two-dimensional binary array precisely matching the material array. For a two-dimensional array chromosome, a single-point crossover can be done as shown in Figure 11.10.8. A position is randomly selected along both dimensions, defining a point in the array. Complementary parts from both parents, diagonal about the point, contribute to the chromosomes of the children. Note that this approach can be extended to any dimension.

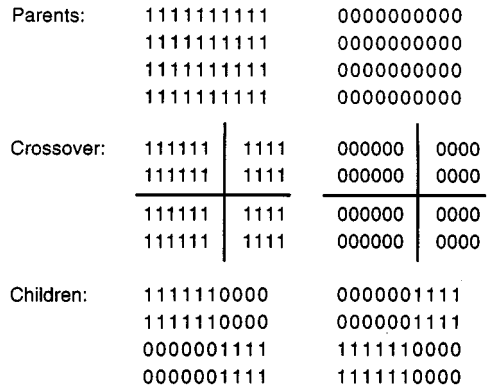

FIGURE 11.10.8 One-point crossover on 2D arrays.

Using the binary string chromosome, Figure 11.10.9 shows results for three different material discretizations. The loading and material constraints were as described in Figure 11.10.6. All three cases display a uniformly distributed porosity with an overall shape arising implicitly from the topological optimization.

Hierarchial Shape Packing. Effective material utilization is important to virtually all industries. A specific problem in this area that can be modeled as a combinatorial optimization problem is the arrangement of planar shapes to be cut out from a piece of material so as to minimize scrap. This problem has great economic significance in the garment, sheet metal, shipbuilding, and other industries. A common instance involves a "blank" of stock material of fixed width, such as would result from a roll of material.

© 1999 by CRC Press LLC

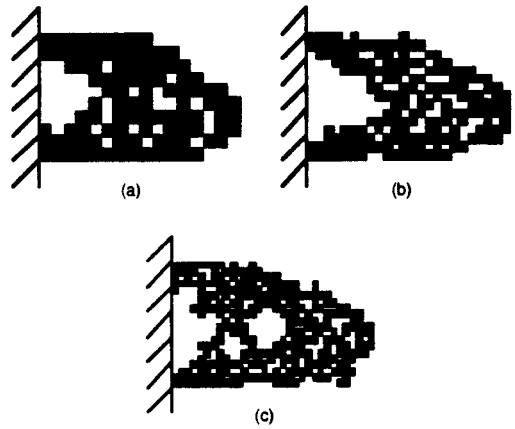

FIGURE 11.10.9 Results of (a) 10 × 16, (b) 15 × 24, and (c) 20 × 32 optimizations.

The part shapes must be arranged to minimize the length of material required from the roll. We have solved this problem with a two-level hierarchical genetic algorithm. A more complete description of this approach can be found in Dighe and Jakiela (1995a).

The approach of the lower level is shown in Figure 11.10.10. The blank of fixed width is considered analogous to a box into which the shapes will be packed. One by one, in a particular order, the shapes will be placed into the box so as to minimize the accrued height required. To pack a particular shape, a location and orientation is specified, as shown in Figure 11.10.10b, and the shape is "dropped" straight down until it contacts one of the previously packed shapes or the bottom of the box. The "dropping into a box" metaphor does not extend to include dynamic effects. Note, for example, that part D in Figure 11.10.10c would not rotate and slide to settle in a lower final position; it is in its final location for the values of x and θ chosen. Figure 11.10.10d shows a much better choice of parameters for x and θ. The lower level uses a genetic algorithm to optimize the values of x and θ and therefore is used each time a shape is packed.

The overall success of this packing strategy depends on the order in which the objects are placed. The higher-level GA searches the space of possible orders to find those that work well with the packing strategy of the lower-level GA. The chromosome representation for a packing order, and associated crossover and mutation operators are shown in Figure 11.10.11. The chromosome is simply a list of part labels, with the left-to-right order indicating the packing order. If we try to perform a single point crossover on these strings, Figure 11.10.11 shows that invalid offspring often result. Some labels are missing and others appear more than once. To remedy this problem, we use a simple order-based crossover as shown in Figure 11.10.11b. For positions to the left of the crossover point, each child receives the order from one of the parents. The order of the remaining parts is obtained from the order in which those remaining parts appear in the other parent's chromosome. Finally, mutation simply changes the location of a part label, usually by moving it to the left.

Note that this crossover operator tends to not disrupt the leftmost parts of the chromosomes. In particular, without mutation, the very leftmost position in any chromosome must have a label that was present in that position in the initial population. Hence, mutation is performed with a leftward bias.

Figure 11.10.12 shows some typical arrangements produced using this approach. Figures 11.10.12a and 11.10.12b show two configurations in the same optimization run. These ten objects were chosen such that their characteristic sizes varied by about a factor of 10. Figure 11.10.12 shows a jigsaw puzzle that we have used as a benchmark test for the packing system. Taking into account deliberate gaps between the parts, the density of the correct jigsaw arrangement is 0.92, not 1.00. Two arrangements from the same optimization run are shown in Figures 11.10.12d and 11.10.12e. It is clear that the simple "height-based" lower-level GA cannot match a human's visual processing and reasoning ability.

© 1999 by CRC Press LLC

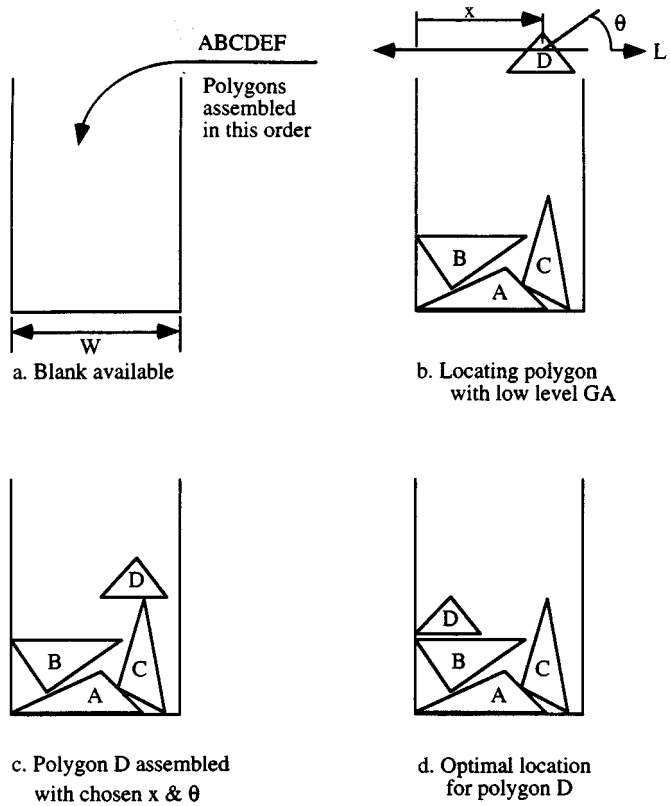

FIGURE 11.10.10 Lower-level GA for hierarchical shape packing.

Integrating a GA-based search with heuristics derived from observation of human experts is the subject of ongoing work in this area (see Dighe and Jakiela, 1995b).

Optimization in Multidisciplinary Design

Kemper Lewis, Farrokh Mistree, and J. R. Jagannatha Rao

Introduction

The design of complex systems is a difficult task of integrating disciplines, each with their own analysis, synthesis, and decision process. Optimizing such a system on a global scale is realistically impossible, but finding a solution that is "good enough" and robust is achievable. Several approaches to formulating and solving a multidisciplinary design problem have arisen in a rather ad hoc fashion since the inception of multidisciplinary design optimization (MDO). These approaches include single-level and multilevel formulations, hierarchical and nonhierarchical system decomposition methods, and numerous optimization and analysis processes and approaches at the system and subsystem levels. Designers are referred to as decision makes and objectives as goals or rewards. With only one decision maker, the problem becomes a scalar or vector optimization problem. But in MDO, many decision makers may exist, and each decision maker's strategy to optimize his/her rewards could depend on the strategies and decisions of other decision makers. The modeling of strategic behavior based on the actions of other individuals is known as a *game*. Therefore, the focus in this section is on problems characterized by

- Single decision makers who have multiple rewards
- Multiple decision makers who have multiple rewards

This focus in optimization theory is shown as the shaded region in Figure 11.10.13. Typical courses in optimization focus on the upper-left quadrant, namely, scalar optimization problems with one objective and one decision maker. In this section, the focus is on the other three quadrants as a means to expand the application of optimization theory to problems that frequently occur in engineering design.

Classification of MDO Formulations

Simultaneous and Nested Analysis and Design. With the advent of MDO and its various applications, a structure of problem approaches and formulations is necessary. In Cramer et al. (1994) and, more recently, Balling and Sobieski (1994) and Lewis and Mistree (1995), various classes and classifications of problem formulations are presented. Figure 11.10.14 is a generic representation of a coupled, three-discipline system.

Depending on the level of analysis, the modules in Figure 11.10.14 may refer to disciplines, components, or processes. It is the decomposition of the system, subsystem coupling and solution, and system synthesis that pose major research and application problems in MDO. The terms used in the figure, as well as other common terms, and are defined below.

s_1, s_2, s_3: disciplinary *state variables* which comprise the *state equations*
y_1, y_2, y_3: the *state equations*
r_1, r_2, r_3: *residuals* in the state equations
y_{12}, y_{13}, y_{21}, y_{23}, y_{31}, y_{32}: *coupling functions*, y_{ij} contains those functions computed in discipline i which are needed in discipline j

$y^*_{12}, y^*_{13}, y^*_{21}, y^*_{23}, y^*_{31}, y^*_{32}$: *coupling variables*
x: *system design variables* needed by more than one discipline
x_1, x_2, x_3: *disciplinary design variables*
g_1, g_2, g_3: *design constraint functions*
f_1, f_2, f_3: *design objective functions*

The primary task at hand is summarized as follows: *Determine the values of the design, state, and coupling variables which satisfy the state equations, the coupling equalities, the design constraints, and the design objective functions.*

Based on this, six classifications for fundamental approaches to MDO problem formulation and solution are presented by Balling and Sobieski, which depend on three criteria:

1. System vs. multilevel decomposition
2. Simultaneous (SAND) vs. nested analysis and design (NAND) at the *system* level.
3. Simultaneous (SAND) vs. nested analysis and design (NAND) at the *subsystem* or *discipline* level.

At the discipline level, SAND implies that the disciplinary design and state variables are determined simultaneously by the optimizer, while NAND implies that the optimizer determines only the disciplinary design variables and requires determination of the state variables at each iteration. At the system level, SAND implies that the system design variables and coupling variables are determined simultaneously by the system optimizer, while NAND implies that the system optimizer determines only the system design variables and requires calls to a system analysis routine to determine the coupling variables at each iteration. The "optimizers" at the system level or discipline level could be gradient based or heuristic in nature, depending on the problem formulation. Further classifications can be generated if these approaches are combined or linked sequentially within one design problem.

Each approach has a three-part name consisting of the overall decomposition descriptor, the solution approach at the system level, and the solution approach at the subsystem level. The first part indicates whether the approach is a single-level or multilevel approach. The middle and last parts of the name indicate whether the SAND or NAND approach is used at the system and discipline levels, respectively.

Example

These terms are illustrated based on a simple example from aeroelastic MDO problem in Cramer et al. (1994). This aeroelastic problem involves two disciplines, aerodynamics and structures. This problem is extremely difficult, as the solution of either of these disciplines *alone* involves heavy analysis and computation. For simplicity, it is assumed that a *single-level* scheme is to be used. The first formulation choice is SAND or NAND at the system level. If a SAND formulation is used, the discipline-level formulation must be determined. These formulations are illustrated below.

Single-SAND-SAND. In this formulation, feasibility is *not* sought for the analysis problem in any sense until convergence in the solver is reached. The analysis "codes" for aerodynamics and structures in this formulation perform a simple function; they evaluate the *residuals* of the analysis equations, rather than solving some set of equations. This is illustrated in Figure 11.10.15. The *optimizer* controls the calculation of the objective functions, f, and the constraints, g, based on the residuals, r_i, from the disciplines. The optimizer sends system and disciplinary design variables, X and X_i, to the disciplinary analysis routines.

Single-SAND-NAND. In this formulation, feasibility *is* enforced for each individual discipline, while the optimizer drives the individual disciplines toward multidisciplinary feasibility and optimality by controlling the coupling functions between the disciplines. This is illustrated in Figure 11.10.16. The optimizer sends design and coupling variables, X and y^*_{ij}, to the disciplinary analysis routines, while these routines return coupling functions, y_{ij}, which are functions of the design variables and the disciplinary state variables, y_i.

Single-NAND-NAND. In this formulation, multidisciplinary feasibility is required at each iteration of the optimizer. Therefore, an aeroelastic analysis solver combines the information from the aerodynamics

and structures disciplines and ensures that the two disciplines are feasible concurrently. This is illustrated in Figure 11.10.17. The optimizer only controls the objective functions and constraints, while the coupling functions are handled by the aeroelastic analysis solver which becomes a "black box" from the perspective of the optimization code. In each discipline, an analysis code solves a set of equations. The resulting *state equations* are fed into the other disciplines. This process continues until convergence among the disciplines, and the optimizer is once again invoked.

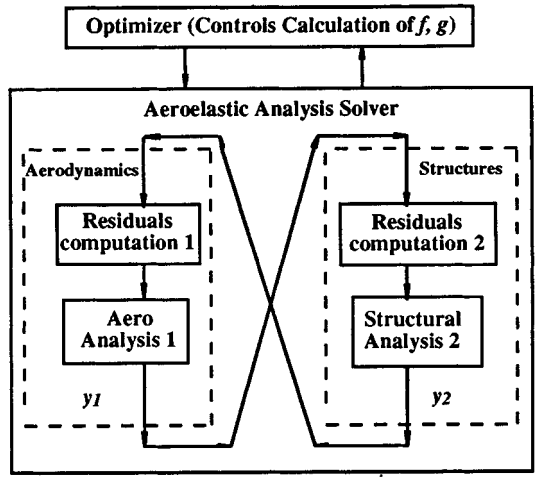

FIGURE 11.10.17 Single-NAND-NAND formulation.

Modeling Design Decisions: The Mathematical Programming Background

Decision-based design (DBD) is offered as a starting point for the creation of design methods that are based on the notion that the principal role of an engineer in the design of a product or process is to make decisions. Therefore, the process of design in its most basic sense is a series of decisions.

It is recognized that the implementation of DBD can take many forms; one implementation is the decision support problem (DSP) technique. Within the DSP technique there exist three types of decisions a designer can make: selection, compromise, or heuristic. In this section, the focus is on the compromise DSP, which is used to model multiobjective trade-offs in the solution of a mathematical model.

Compromise DSP. A compromise DSP is a hybrid formulation that incorporates concepts from both traditional mathematical programming and goal programming, and makes use of some new ones (Mistree et al., 1993). It is similar to goal programming in that the multiple objectives are formulated as system goals (involving both system and deviation variables) and the deviation function is solely a function of the goal deviation variables. This is in contrast to traditional mathematical programming where multiple objectives are modeled as a weighted function of the system variables only. The concept of system

© 1999 by CRC Press LLC

constraints, however, is retained from the traditional constrained optimization formulation. Special emphasis is placed on the bounds on the system variables, unlike in traditional mathematical programming and goal programming. In effect the traditional formulation is a subset of the compromise DSP — an indication of the generality of the compromise formulation. The compromise DSP is stated in words as follows:

Given

An alternative that is to be improved through modification
Assumptions used to model the domain of interest
The system parameters
All other relevant information

n	Number of system variables
p + q	Number of system constraints
p	Equality constraints
q	Inequality constraints
m	Number of system goals
$g_i(X)$	System constraint function

$$g_i(\underline{X}) = C_i(\underline{X}) - D_i(\underline{X})$$

$f_k(d_i)$	Function of deviation variables to be minimized at priority level k for the preemptive case
W_i	Weight for the Archimedean case

Find

The values of the independent *system variables* (they describe the physical attributes of an artifact)

$$X_j \quad j = 1,\ldots, n$$

The values of the *deviation variables* (they indicate the extent to which the goals are achieved)

$$d_i^-, d_i^+ \quad i = 1,\ldots, m$$

Satisfy

The *system constraints* that must be satisfied for the solution to be feasible, there is no restriction placed on linearity or convexity

$$g_i(\underline{X}) = 0; \quad i = 1,\ldots, p$$

$$g_i(\underline{X}) \geq 0; \quad i = p+1,\ldots, p+q$$

The *system goals* that must achieve a specified target value as far as possible; there is no restriction placed on linearity or convexity

$$A_i(\underline{X}) + d_i^- - d_i^+ = G_i; \quad i = 1,\ldots, m$$

The lower and upper *bounds* on the system

$$X_j^{\min} \leq X_j \leq X_j^{\max}; \quad j = 1,\ldots, n$$

$$d_i^-, d_i \geq 0 \quad \text{and} \quad d_i^- \cdot d_i^+ = 0$$

© 1999 by CRC Press LLC

Minimize

The *deviation function* which is a measure of the deviation of the system performance from that implied by the set of goals and their associated priority levels or relative weights:

Case a: Preemptive (lexicographic minimum)

$$Z = \left[f_1\left(d_i^-, d_i^+\right), \ldots, f_k\left(d_i^-, d_i^+\right) \right]$$

Case b: Archimedean

$$Z = \sum_{i=1}^{m} W_i\left(d_i^- + d_i^+\right); \qquad \sum W_i = 1; \quad W_i \geq 0$$

A graphical representation of a two-variable compromise DSP is shown in Figure 11.10.18. The difference between a system variable and a deviation variable is that the former represents a distance in the i^{th} dimension from the origin of the design space, whereas the latter has as its origin the surface of the system goal. The value of the i^{th} deviation variable is determined by the degree to which the i^{th} goal is achieved. It depends upon the value of $A_i(X)$ alone (Since G_i is fixed by the designer), which in turn is dependent upon the system variables X. The set of discrete variables can be continuous, Boolean, or a combination of types.

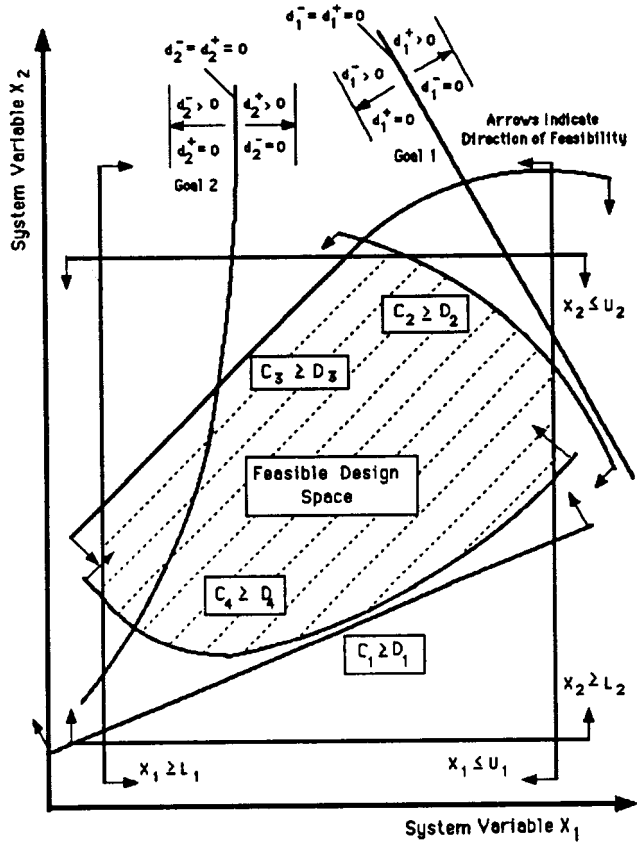

FIGURE 11.10.18 The compromise DSP.

© 1999 by CRC Press LLC

The compromise DSP is fundamentally different from the traditional mathematical optimization model. This difference is depicted in Figure 11.10.19 where the optimization model on the left occurs when designer's aspirations can be met by the system achievement and therefore an optimum can be found. But when a designer's aspirations do not overlap with the actual achievements, a solution which is "good enough" or *satisficing*[*] must be found. This is depicted and modeled in the compromise DSP on the right of Figure 11.10.19. When the aspiration space overlaps with the feasible design space (center of Figure 11.10.19), the optimization model and compromise DSP are the same.

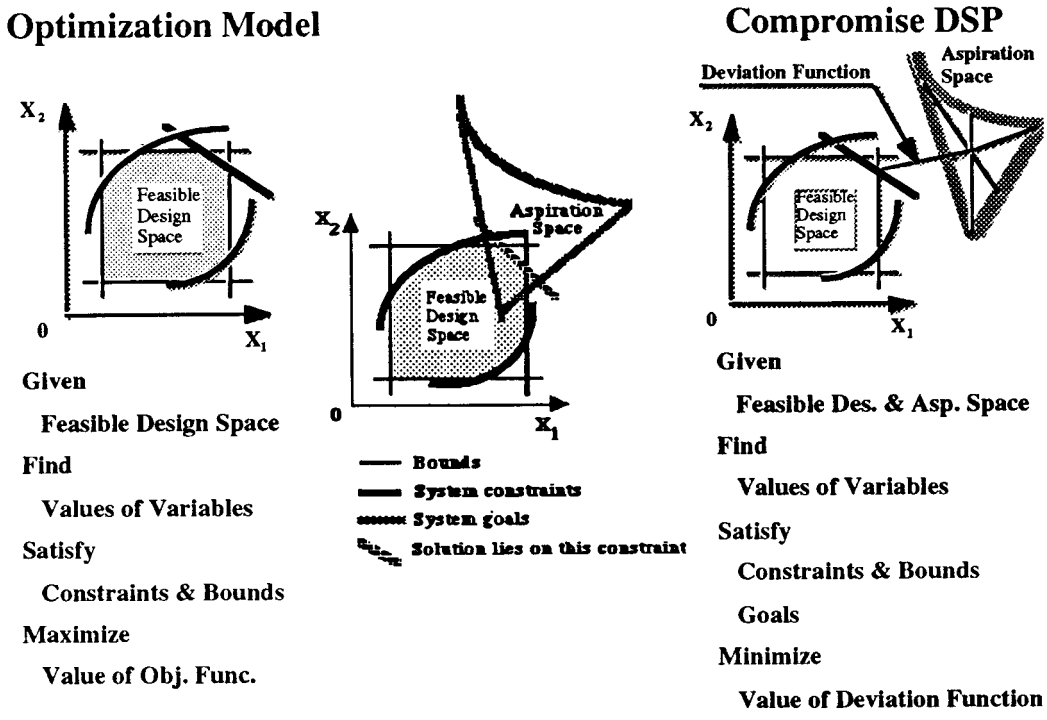

FIGURE 11.10.19 The optimizing and satisficing models.

Deviation Variables and Goals. In a **goal** one can distinguish the aspiration level, G_i, of the decision maker and the actual attainment, $A_i(X)$, of the goal. Three conditions need to be considered:

1. $A_i(X) \le G_i$; one wishes to achieve a value of $A_i(X)$ that is equal to or less than G_i.
2. $A_i(X) \ge G_i$; one wishes to achieve a value of $A_i(X)$ that is equal to or greater than G_i.
3. $A_i(X) = G_i$; one wishes to achieve a value of $A_i(X)$ equal to G_i.

Next, the concept of a **deviation variable** is introduced. Consider the third condition, namely, one would like the value of $A_i(X)$ to equal G_i. The deviation variable is defined as

$$d = G_i - A_i(\underline{X})$$

The deviation variable d can be negative or positive. In effect, a deviation variable represents the distance (deviation) between the aspiration level and the actual attainment of the goal. Considerable simplification

[*] Satisficing — not the "best", but "good enough" (the first use of this term, in the context of optimization, is attributed to Herbert Simon (Simon, 1982).

© 1999 by CRC Press LLC

of the solution algorithm is affected if one can assert that all the variables in the problem being solved are positive. Hence, the deviation variable d is replaced by two variables:

$$d = d_i^- - d_i^+$$

where

$$d_i^- \cdot d_i^+ = 0 \quad \text{and} \quad d_i^-, d_i^+ \geq 0$$

The preceding ensures that the deviation variables never take on negative values. The product constraint ensures that one of the deviation variables will always be zero. The system goal becomes

$$A_i(\underline{X}) + d_i^- - d_i^+ = G_i; \quad i = 1, 2, \ldots, m \tag{11.10.3}$$

subject to

$$d_i^-, d_i^+ \geq 0 \quad \text{and} \quad d_i^- \cdot d_i^+ = 0 \tag{11.10.4}$$

If the problem is solved using an algorithm that provides a vertex solution as a matter of course, then the constraint is automatically satisfied making its inclusion in the formulation redundant. Since some algorithms use solution schemes which provide a vertex solution, it is assumed that this constraint is satisfied. For completeness this constraint is included in the mathematical forms of the compromise decision support problem given previously in this chapter and for brevity will be omitted from all subsequent formulations.

Note that a goal (Equation 11.10.3) is always expressed as an equality. When considering Equation (11.10.3), the following will be true:

if $A_i \leq G_i$ **then** $d_i^- > 0$ and $d_i^+ = 0$.
if $A_i \geq G_i$ **then** $d_i^- = 0$ and $d_i^+ \geq 0$.
if $A_i = G_i$ **then** $d_i^- = 0$ and $d_i^+ = 0$.

How are the three conditions listed using Equation (11.10.3)?

1. To satisfy $A_i(X) \leq G_i$, the positive deviation d_i^+ must be equal to zero. The negative deviation d_i^- will measure how far the performance of the actual design is from the goal.
2. To satisfy $A_i(X) \geq G_i$, the negative deviation d_i^- must be equal to zero. In this case, the degree of overachievement is indicated by the positive deviation d_i^+.
3. To satisfy $A_i(X) = G_i$, both deviations, d_i^- and d_i^+, must be zero.

At this point it is established what is to be minimized. In the next section means for minimization of the objective in goal programming are introduced.

The Lexicographic Minimum and the Deviation Function. The objective of a traditional single objective optimization problem requires the maximization or minimization of an objective function. The objective is a function of the problem variables. In a goal programming formulation, each of the objectives is converted into a goal (Equation 11.10.3) with its corresponding deviation variables. The resulting formulation is similar to a single objective optimization problem but with the following differences:

The objective is always to minimize a function.
The objective function is expressed using deviation variables only.

The objective in the goal programming formulation is called the achievement function. As indicated earlier the deviation variables are associated with goals and hence their range of values depend on the

© 1999 by CRC Press LLC

goal itself. Goals are not equally important to a decision maker. Hence to effect a solution on the basis of preference, the goals may be rank-ordered into priority levels.

One should seek a solution which minimizes all unwanted deviations. There are various methods of measuring the effectiveness of the minimization of these unwanted deviations. The *lexicographic minimum* concept is a suitable approach, and it is defined as follows (see Ignizio, 1982; Ignizio, 1985).

Given an ordered array $\boldsymbol{f} = (f_1, f_2, \ldots, f_n)$ of nonnegative elements f_k, the solution given by $f^{(1)}$ is preferred to $f^{(2)}$ iff

$$f_k^{(1)} < f_k^{(2)}$$

and all higher-order elements (i.e., $f_1, \ldots, f_{k-1}$) are equal. If no other solution is preferred to $\boldsymbol{f}$, then $\boldsymbol{f}$ is the lexicographic minimum.

As an example, consider two solutions, $\boldsymbol{f}^{(r)}$ and $\boldsymbol{f}^{(s)}$, where

$$\boldsymbol{f}^{(r)} = (0,\ 10,\ 400,\ 56)$$

$$\boldsymbol{f}^{(s)} = (0,\ 11,\ 12,\ 20)$$

In this example, note that $\boldsymbol{f}^{(r)}$ is preferred to $\boldsymbol{f}^{(s)}$. The value 10 corresponding to $\boldsymbol{f}^{(r)}$ is smaller than the value 11 corresponding to $\boldsymbol{f}^{(s)}$. Once a preference is established, then all higher-order elements are assumed to be equivalent.

The Use of Coupled DSPs in Modeling and Solving Systems

Coupled compromise DSPs can be used to model multiobjective problems. These types of problems may involve the analysis and synthesis of problems from multiple disciplines, but in this section, the primary notion is *shared* design variable vectors. It is common in the design of complex systems, such as aircraft, for multiple design teams to include the same design variables in their design process. For example, consider the design of aircraft. The design variable, wing area, is used by the aerodynamics group to control the lift force. It is used by the structural group to control the structural framework of the wing. It is used by the propulsion group to control the amount of fuel needed. It seems advantageous to model systems this way, but this introduces an added level of complexity in a system model. Different disciplines are also dependent on the decisions made in other disciplines. Therefore, another focus is modeling the coupling of state variables between disciplines.

To begin the discussion, suppose that a designer (i.e., a decision maker) is investigating a typical engineering system such as a load-bearing structure, a high-speed mechanism, or an automotive transaxle. Assuming that this system is unambiguously described by a finite-dimensional variable vector $x \in \mathcal{R}^n$ (includes both the so-called "state" and "design" variables), then the general descriptive mathematical model can be characterized by a set of *parameters* p, which are fixed quantities over which the designer has no control, and the multifunction X, which represents the state equations and variational inequalities (derived from the natural laws such as the conservation principles) as well as the performance constraints for this system. Numerical approaches to such problems have been studied in Outrata (1990) and Outrata and Zowe (1995). If the only goal of the designer is to obtain a satisfying or a feasible design, then his/her task is simply to find a design x^o that satisfies the constraints and meets the goals as close as possible for a given p. On the other hand, if the designer wishes to find the design which minimizes the deviation between the goal achievement and aspiration with respect to several objective functions such as $f_i(x,p)$, i = 1, …, r, then the problem is to find a design x* that solves the following multiobjective formulation:

$$\underset{x \in X(p) \subset \Re^n}{\text{minimize}}\, d(x,p) = \left\{ d_1(x,p), \ldots, d_r(x,p) \right\} \tag{11.10.5}$$

© 1999 by CRC Press LLC

where d_i represents the deviation from the objective f_i, to its target value, f_{iTV}. In other words, the problem is to minimize the deviation between what a designer wants and what a designer can achieve.

At this general level of discussion, one readily asserts that a model such as in Equation (11.10.5) is the typical starting point for much of the current education, research, and practice in mechanical systems modeling and applied optimization, and yet in specific design instances, this assertion should be boldly challenged. For example, since the designer only controls *x* and another foreign party controls *p*, how is *p* chosen? Can the designer assume that the foreign decision maker will always select the vector that is most advantageous to the design (as is tacitly assumed, it is argued later, by most justifications of existing engineering models)? If not, how should the designer respond to this conflict? A two-player strategic game has just been described (see, e.g., Von Neumann and Morgenstern, 1944; Aubin, 1979; Dresher, 1981) where one player controls *x* and the other player controls *p* and where *p* represents all decisions which are outside the scope of the designer. By the classical definition, a "game" consist of multiple decision makers or players (or designers, in this case) who each control a specified subset of system variables and who seek to minimize their own deviation functions subject to their individual constraints. To continue this argument further, consider a typical schedule of a product design and manufacture, as shown in Figure 11.10.20.

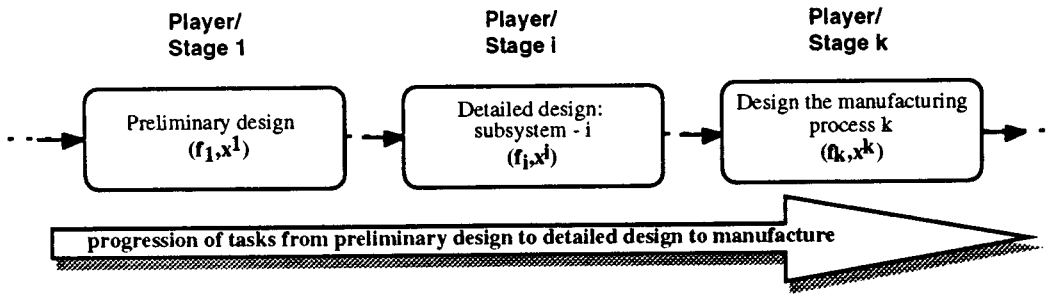

FIGURE 11.10.20 Different stages in a design time-line.

The decision makers at each of the several stages or stations in the time line are referred to as different players, even though they could be the same human designer. Each of the players controls and minimizes his own deviation function.

In the context where multiple decision makers collectively influence the final design, one must pose the following question: what mathematical formulation is appropriate for modeling the system in order to study the decisions made by *more than one player along the above time line?* Clearly, the conventional model of Equation (11.10.5) does not adequately represent the multiplayer scenario of the time line shown in Figure 11.10.20. This inadequacy is most acute when the players engage in strategic behavior which is anything other than total cooperation (e.g., dominance and noncooperation, among others). Thus, the major point of departure can be summarized as: (1) instead of formulating a single mathematical model at a single stage of the time line, as is done conventionally, these models represent one or more decision makers who determine the final design; and (2) each of the r decision makers has his own objective functions and one player's decision is influenced by the other. Thus, the final design could very well depend on whether the players compete, cooperate, or dominate one another — thus necessitating a study of the strategic interaction between the players. In short, a goal here is to model the design of Figure 11.10.20 as a *strategic game*, this figure perhaps being representative of a general engineering system design process at a high level of abstraction.

Mathematical modeling of such strategic behavior, where one decision maker's action depends on decisions by others, is well-established in wide-ranging applications from economics, business, and military (Aubin, 1979; Dresher, 1981; Fudenberg and Tirole, 1991; Mesterton-Gibbons, 1992). Such models are widely used in designing markets and auctions, and in predicting the outcome of encounters between competing companies or trading nations. As specific examples, consider automobile manufac-

© 1999 by CRC Press LLC

turers who interact strategically in order to set prices and production schedules of cars; or the strategic behavior that occurs between drivers as they try to pass each other on a busy undivided highway.

Victor A. Greenhut

Introduction — Nature and Properties of Pure Metals

Metals achieve engineering importance because of their abundance, variety, and unique properties as conferred by metallic bonding. Twenty-four of the 26 most abundant elements in the Earth's crust are

0-8493-9418-X/98/$0.00+$.50
© 1998 by CRC Press LLC

metals, with only two nonmetallic elements, oxygen and silicon, exceeding metals in frequency. The two most abundant metallic elements, iron (5.0%) and aluminum (8.1%), are also the most commonly used structural metals. Iron is the most-used metal, in part because it can be extracted from its frequently occurring, enriched ores with considerably less energy penalty than aluminum, but also because of the very wide range of mechanical properties its alloys can provide (as will be seen below). The next 15 elements in frequency, found at least in parts per thousand, include most common engineering metals and alloys: calcium (3.6%), magnesium (2.1%), titanium (0.63%), manganese (0.10), chromium (0.037%), zirconium (0.026%), nickel (0.020%), vanadium (0.017%), copper (0.010%), uranium (0.008%), tungsten (0.005%), zinc (0.004%), lead (0.002%), cobalt (0.001%), and beryllium (0.001%). The cost of metals is strongly affected by strategic abundance as well as secondary factors such as extraction/processing cost and perceived value. Plain carbon steels and cast irons, iron alloys with carbon, are usually most cost-effective for ordinary mechanical applications. These alloys increase in cost with alloying additions.

A variety of metal properties are unique among materials and of importance technologically. These properties are conferred by metallic bonding, in which the "extra" outer valence electrons are "shared" among all metal ion cores. This bonding is different from other types of solids in that the electrons are free to acquire energy, and the metallic ions are relatively mobile, and quite interchangeable with regard to their positions in the crystal lattice, the three-dimensional repeating arrangement of atoms in a solid. This section of the chapter will concentrate on the mechanical properties of metals, for which metallic bonding provides ductile deformation, i.e., shows substantial permanent shape change under mechanical load prior to fracture. The ductility of metals at low and moderate temperature makes them formable as solids and also confers safety (fracture toughness) in mechanical applications, in that under impact loading the metal will absorb energy rather than break catastrophically.

Metals are good conductors of heat and electricity because thermal and electrical energy can be transferred by the free electrons. These two properties tend to parallel each other. For example, the pure noble metals (e.g., copper, silver, gold, platinum) are among the best electrical and thermal conductors. As a broad generalization, metallic elements with an odd number of valence electrons tend to be better conductors than those with an even number. These behaviors can be seen in Table C.6A of the Appendix. Thermal conductivity and electrical resistivity (inverse conductivity) have a reciprocal relationship and follow the indicted trends. As metals are alloyed with other elements, are deformed, contain multiple phases, and contain crystalline imperfections, their electrical and thermal conductivity usually decreases significantly from that of the pure, perfect, unalloyed metal. The specific values of thermal conductivity and electrical resistivity for several common engineering alloys is given in Table C.6B of the Appendix. Electrical and thermal conductivities tend to decrease proportionately to each other with increasing temperature for a specific metal. These conductivities may be altered if heating introduces metallurgical change during annealing (see subsection on mechanical forming).

Metals are opaque to and reflective of light and most of the electromagnetic spectrum, because electromagnetic energy is transferred to the free electrons and immediately retransmitted. This gives most metals a characteristic reflective "metallic color" or sheen, which if the metal is very smooth yields a mirror surface. At very short wavelengths (high energies) of the electromagnetic spectrum, such as X rays, the radiant energy will penetrate the material. This is applied in radiographic analysis of metals for flaws such as cracks, casting porosity, and inclusions.

Metals are almost always crystalline solids with a regular repeating pattern of ions. A number of atomic-level defects occur in this periodic array. A large number of atomic sites are "vacancies" (point defects) not occupied by atoms (Figure 12.1.1). The number and mobility of vacant sites increase rapidly with temperature. The number and mobility of vacancies in metals are quite high compared with other materials because there are no charge balance or local electron bond considerations. This means that solid metal can undergo significant changes with only moderate thermal excitation as vacancy motion (diffusion) provides atom-by-atom reconstruction of the material. Vacancies allow solid metals to homogenize in a "soaking pit" after casting and permit dissimilar metals to diffusion bond at moderate temperatures and within short times. In the process, substitutional metallic atoms (ions) shown in Figure

© 1999 by CRC Press LLC

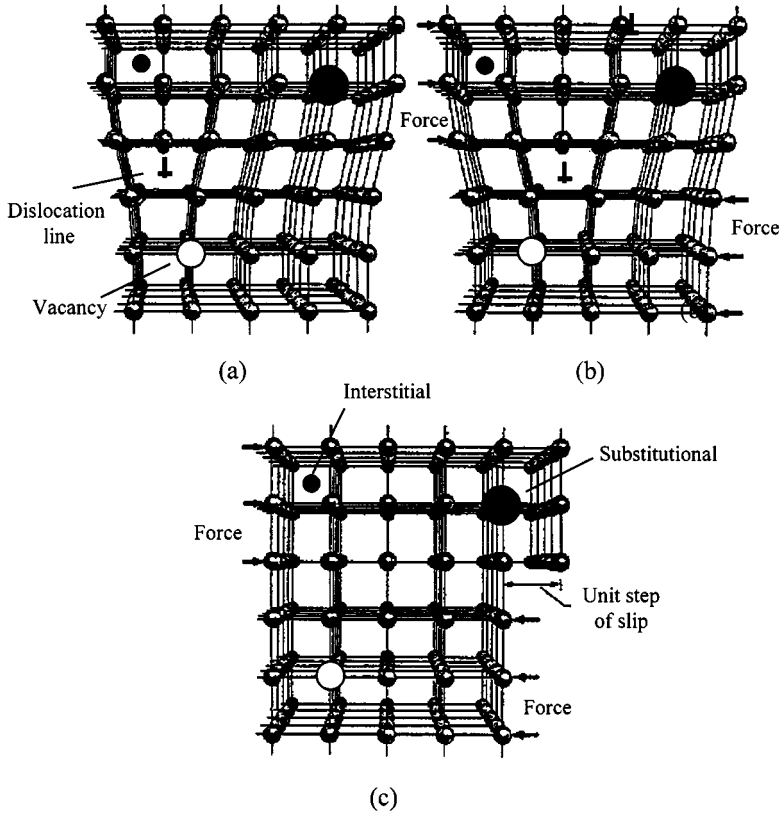

FIGURE 12.1.1 Point defects exist in the metal crystal structure: vacancies, substitutional atoms (ions), ions, and interstitial atoms (ions). A dislocation (⊥) line moves under an applied shear force until a surface step of plastic deformation is produced on the surface.

12.1.1 move via vacancy jumps while small interstitial atoms such as carbon (Figure 12.1.1) move from interstice to interstice. Vacancy mobility gives rise to major changes in mechanical properties during annealing (see subsection on mechanical forming) and is an important mechanism in creep deformation under load at elevated temperature (see subsection on corrosion and environmental effects).

At a slightly larger level, linear atomic packing defects known as dislocations, give rise to the ability of metallic materials to deform substantially under load. When a plane of atoms in the lattice ends, it gives rise to an edge "dislocation" such as that shown in Figure 12.1.1a. Such a dislocation can break and remake bonds relatively easily in a metal and thereby shift an atomic distance (Figure 12.1.1b). The process can continue until a surface step results. Many dislocations moving in this fashion can give rise to significant shape change in the material at moderate stresses. The onset of such massive dislocation motion in a metal is termed *yield* and occurs at the "yield stress" or "elastic limit" (see subsection on strength and deformation). Dislocations explain why the yield stress can be as low as about 100 Pa (10 psi) in a pure, pristine, single crystal of metal. Dislocations also explain how a fine-grained polycrystalline metal containing many microstructural features which interfere with dislocation motion may have a yield stress as great as 10 gPa (1000 ksi). Dislocations interact with each other in three dimensions and multiply. Therefore, dislocation motion can cause a major increase in dislocation density and yield stress, termed *cold work*. Vacancies can rearrange these dislocation tangles, restoring the metal to a condition closer to its original state, thereby lowering the yield stress. This can occur at moderate annealing temperatures (see subsection on mechanical forming).

The interaction of deformation, alloying elements, temperature, and time can cause a wide variety of microstructures in a solid metal down to near atomic levels with mechanical (and other) properties which

© 1999 by CRC Press LLC

can vary over a very wide range. It is possible to manipulate the properties of a single metal composition over a very wide range in the solid state — a behavior which can be used to mechanically form a particular metal and then use it in a demanding load-bearing application. The use of minor alloying additions can provide a yet wider range of properties with appropriate thermal and mechanical treatment.

Casting

One of the important technological advantages of metals is their ability to incorporate a wide variety of secondary elements in a particular metal and thereby create alloys of the metal. Alloying can increase the strength of a metal by several orders of magnitude and permit the strength and ductility to be varied over a wide range by thermal and/or mechanical treatment, resulting in ease of mechanical forming or resistance to deformation.

Several metal phases may exist together in the solid as grains (crystals), or secondary phases may occur as smaller entities on grain (intercrystal) boundaries or within grains. Often the strengthening phase is submicroscopic and cannot be detected by optical metallography (reflection optical microscopy). The size and distribution of secondary phases is manipulated by thermomechanical (thermal and/or mechanical) treatment of the solid metal as well as the original casting procedure.

Casting methods include expendable mold casting (investment/precision, plaster mold, dry sand, and wet sand casting), permanent mold casting (ingot, permanent mold, centrifugal, and die casting), and continuous casting (direct chill and "splat" casting). These are listed in approximate order of cooling rate in Figure 12.1.2. As cooling rate increases, the grain (crystal) size tends to be smaller and the strength increases while compositional segregation decreases, providing more uniform properties. At the extremely high casting rates (10^5 to 10^6/sec) of continuous splat casting, it is possible to produce homogeneous metals not possible in terms of phase diagrams, and many metals have been produced in the amorphous state, yielding unusual metallic glasses. Ingot casting and continuous direct chill casting are primarily used to produce solid metal which will be extensively mechanically formed to final shape. The other casting methods are used to produce shapes near final dimensions, but to varying extends may receive extensive machining, forming, or finishing prior to use. For the latter group, grain refiners are frequently added to reduce solidification grain size. Metal tends to solidify directionally, with grains elongated in the direction of heat flow. This gives rise to directional mechanical properties which should be accounted for in design.

Comparison of Casting Methods

	Solidification Rate	Grain Size	Strength	Segregation
Expendable mold	Slow	Coarse	Low	Most

casting practice. With the exception of investment (lost wax, precision) casting and to a lesser extent die casting, it is difficult to achieve very exacting tolerances and fine surface finish without postfinishing or forming of a casting.

Strength and Deformation, Fracture Toughness

Figure 12.1.3 shows a typical stress–strain diagram for a metal. The first portion is a linear, spring-type behavior, termed *elastic*, and attributable to stretching of atomic bonds. The slope of the curve is the "stiffness" (given for various metals in Table C.3 of the Appendix). The relative stiffness is low for metals as contrasted with ceramics because atomic bonding is less strong. Similarly, high-melting-point metals tend to be stiffer than those with weaker atomic bonds and lower melting behavior. The stiffness behavior is frequently given quantitatively for uniaxial loading by the simplified expressions of Hooke's law:

$$\varepsilon_x = \sigma_x / E \qquad \varepsilon_y = \varepsilon_z = -\upsilon\sigma_x / E \tag{12.1.1}$$

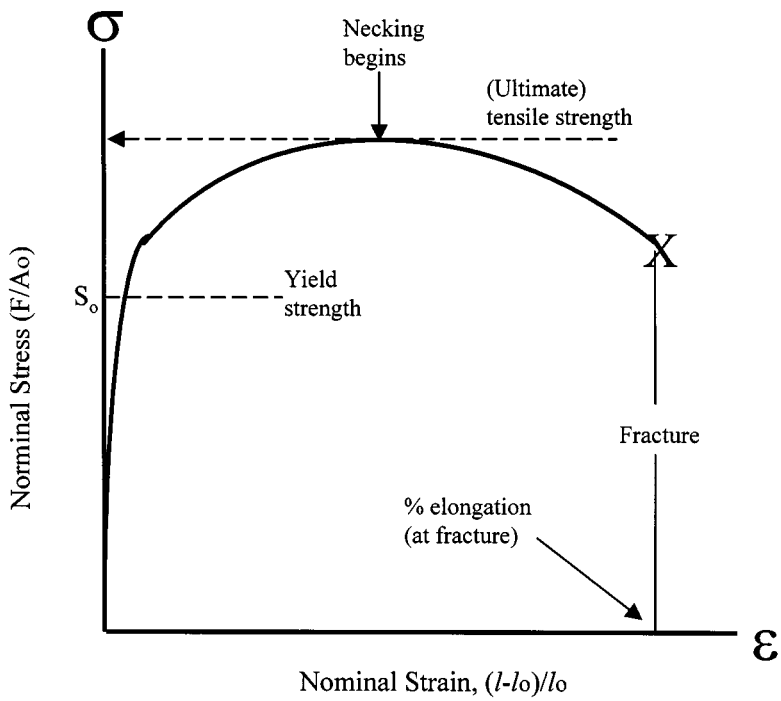

FIGURE 12.1.3 Typical engineering stress–strain curve for a metal.

Where σ_x is the stress (force per unit area, psi or Pa) in the *x* direction of applied unidirectional tensile load, ε_x is the strain (length per unit length or percent) in the same direction ε_y and ε_z are the contracting strains in the lateral directions, *E* is Young's modulus (the modulus of elasticity), and υ is Poisson's ratio. Values of the modulus of elasticity and Poisson's ratio are given in Table C.6A of the Appendix for pure metals and in C.6B for common engineering alloys. It may be noted that another property which depends on atomic bond strength is thermal expansion. As the elastic modulus (stiffness) increases with atomic bond strength, the coefficient of linear expansion tends to decrease, as seen in Table C.6.

The relationship of Equation (12.1.1) is for an isotropic material, but most engineering metals have some directionality of elastic properties and other structure-insensitive properties such as thermal expansion coefficient. The directionality results from directional elongation or preferred crystal orientation,

© 1999 by CRC Press LLC

which result from both directional solidification and mechanical forming of metals. In most cases two elastic moduli and a Poisson's ratio are required to fully specify behavior. A principal modulus might be given in the rolling direction of sheet or plate with a secondary modulus in the transverse direction. A difference of 2 to 5% should ordinarily be expected, but some metals can show an elastic modulus difference as great as a factor of 2 in the principal directions of heavily formed material. Such directional differences should be accounted for when spring force or dimensional tolerance under load (or change of temperature) is critical in a design.

At a critical stress the metal begins to deform permanently, as seen as a break in the straight-line behavior in the stress-strain diagram of Figure 12.1.3. The stress for this onset is termed the yield stress or elastic limit. For engineering purposes it is usually taken at 0.2% plastic strain in order to provide a predictable, identifiable value. An extensive table of yield values and usual applications for commercial metals and alloys is given in Appendix C.5. In the case of steel a small yield drop allows for clear identification of the yield stress and this value is used. The onset of yield is a structure-sensitive property. It can vary over many orders of magnitude and depends on such factors as grain size and structure, phases present, degree of cold work, and secondary phases in grains or on grain boundaries as affected by the thermal and mechanical treatment of the alloy. The extension to failure, the ductility, and maximum in the stress–strain curve, the "ultimate stress" or "tensile strength" (see Appendix C.5) are also structure-sensitive properties. The strength and specific strength (strength-to-weight ratio) generally decrease with temperature.

The ductility usually decreases as the strength (yield or ultimate) increases for a particular metal. Reduction in the grain size of the metal will usually increase yield stress while decreasing ductility (Figure 12.1.4). Either yield or ultimate strength are used for engineering design with an appropriate safety factor, although the former may be more objective because it measures the onset of permanent deformation. Ductility after yield provides safety, in that, rather than abrupt, catastrophic failure, the metal deforms.

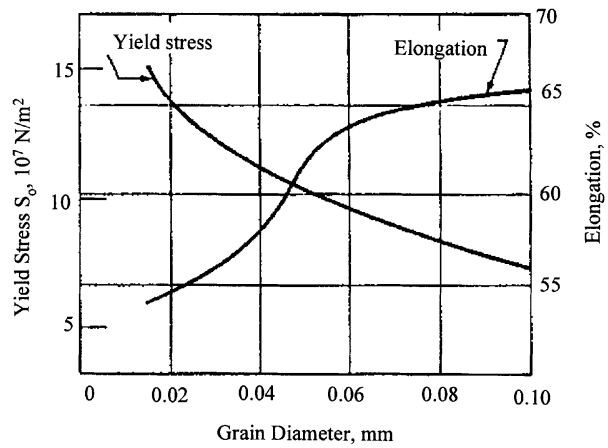

FIGURE 12.1.4 The effect of grain (crystal) size on yield stress and elongation to failure (ductility) for cartridge brass (Cu–30 Zn) in tension.

A different, independent measure is needed for impact loads — "toughness." This is often treated in design, materials selection, and flaw evaluation by extending Griffith's theory of critical flaw size in a brittle material:

$$\sigma_f = K_{1c} / \gamma c^{1/2} \tag{12.1.2}$$

© 1999 by CRC Press LLC

where σ_f is the failure stress, K_{Ic} is a structure-sensitive materials property, the "fracture toughness" or "stress intensity factor" for a normal load, γ is a constant depending on orientation, and c is the depth of a long, narrow surface flaw or crack (or half that of an internal flaw). This is a separate design issue from that of strength. It is of particular importance when a metal shows limited ductility and catastrophic failure must be avoided. In some applications the growth of cracks, c is monitored to prevent catastrophic failure. Alternatively, as a performance test sufficient energy absorption as characteristic of a metal is determined when it is fractured in a Charpy or Izod impact test. Many metals will show a rapid decline in such energy absorption below a nil ductility temperature (NDT), which may establish a lowest use temperature for a particular metal in a particular state and for a particular application. Welds are often qualified by impact tests as well as strength testing. Care must be taken to apply the impact test appropriate to an application.

Hardness, the resistance of the near surface of a metal to penetration by an indentor, is also employed as a mechanical test. Increased hardness can often be correlated with an increase in yield and ultimate strengths. Typical hardness values for a large number of commercial metals and alloys are provided in Appendix C.5. A hardness indent is frequently done to "determine" the strength of a steel, using "equivalency" tables. Great caution must be taken in applying such tables because while hardness is an easy test to perform, it measures a complex and interactive set of properties, increasing with strength, elastic modulus, and work hardening rate. It is also an observation of surface properties which may not be characteristic of the bulk metal — particularly thick-gauge steel used in tension. Surface-hardening treatments can make the simplistic use of an "equivalency" table particularly dangerous. Application to nonferrous metals is also problematic. If a hardness tested part is to be put into service, the placement of hardness indents (surface flaws) can cause permanent failure.

A summary of important engineering metals can be found in Appendix C.5. This extensive table provides strength, hardness, and applications information for many commercial metals in varied heat treatments.

Mechanical Forming

Hot working is used when major shape change, cross-section reduction, or texture (directional) properties are desired. Cold working is preferred when close tolerances and fine surface finish are needed. The cold-worked form of a metal typically shows higher yield and tensile strength, as can be seen for several alloys listed in Appendix C.5. Rolling, forging, and extrusion are primarily done hot, while shape drawing, extrusion, deep drawing, stretching, spinning, bending, and high-velocity forming are more commonly performed cold. Hot rolling between parallel rollers is used to reduce ingots to plates, sheets, strips, and skelp, as well as structural shapes, rail, bar, round stock (including thick-walled pipe), and wire. Sheet metal and threads on round or wire stock may be rolled to shape cold. Closed die hot forging employs dies with the final part shape, while open die forging (including swaging and roll forging) uses less-shaped dies. Coining, embossing, and hobbing are cold-forging operations used to obtain precision, detailed surface relief or dimensions. Generally, extrusion and die drawing require careful control of die configuration and forming rate and, in the latter case, lubricant system. Impact extrusion, hydrostatic extrusion, and deep drawing (thin-walled aluminum cans) permit very large precise dimensional and cross-section changes to be made cold in a single pass. Stretching, spinning, bending are usually used to shape sheet or plate metal and the spring-back of the metal due to elastic modulus must be accounted for to obtain a precise shape.

Solute, Dispersion, and Precipitation Strengthening and Heat Treatment

Alloying additions can have profound consequences on the strength of metals. Major alloying additions can lead to multiphase materials which are stronger than single-phase materials. Such metal alloys may also give very fine grain size with further strengthening of material. Small alloying additions may also

© 1999 by CRC Press LLC

substantially increase strength by solute strengthening as solid solution substitutional or interstitial atoms and or by particle strengthening as dispersion or precipitation hardening alloys.

Substitutional solute strengthening of copper by various atoms is shown in Figure 12.1.5. As the amount of an alloying element in solution increases, the strength increases as dislocations are held in place by the "foreign" atoms. The greater the ionic misfit (difference in size — Sn is a much larger ion than Ni), the greater the strengthening effect. The strength increase can be quite dramatic — as much as a 20-fold increase with a 1.5% addition to copper. Alternatively, a large addition of a very soluble element such as nickel can give major strengthening — monel, the Cu–70Ni alloy is more than four times stronger than pure copper (Figure 12.1.6). Interstitial solid solution carbon contributes to the strength of iron and is one contributor to strength in steels and cast irons. Solute strengthening can become ineffective in strengthening at elevated temperature relative to the absolute melting point of a metal as a result of rapid diffusion of substitutional and interstitial elements. The addition of more than one solute element can lead to synergistic strengthening effects, as this and other strengthening mechanisms can all contribute to the resistance of a metal to deformation.

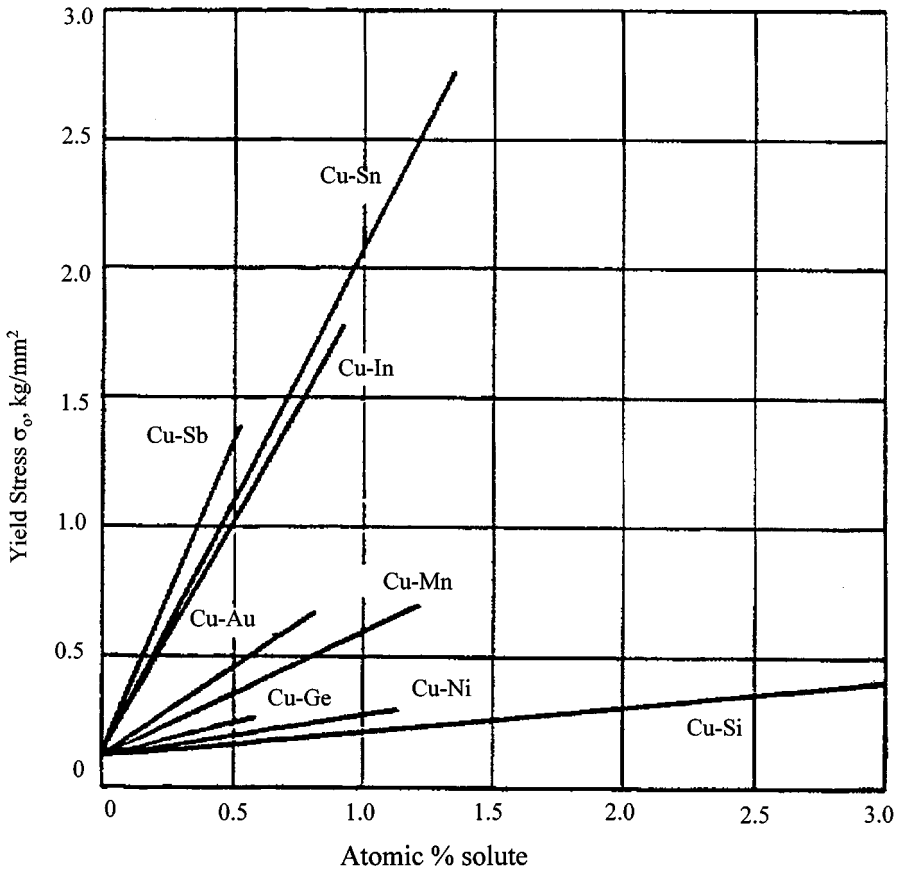

FIGURE 12.1.5 Effect of various substitutional atoms on the strength of copper. Note that as the ionic size of the substitutional atom becomes larger the strengthening effect becomes greater.

Ultrafine particles can also provide strengthening. A second phase is introduced at submicroscopic levels within each crystal grain of the metal. This may be done by a variety of phase-diagram reactions, the most common being precipitation. In this case the solid alloy is heated to a temperature at which the secondary elements used to produce fine second-phase particles dissolve in the solid metal — this is termed *solution heat treatment*. Then the metal is usually quenched (cooled rapidly) to an appropriate

© 1999 by CRC Press LLC

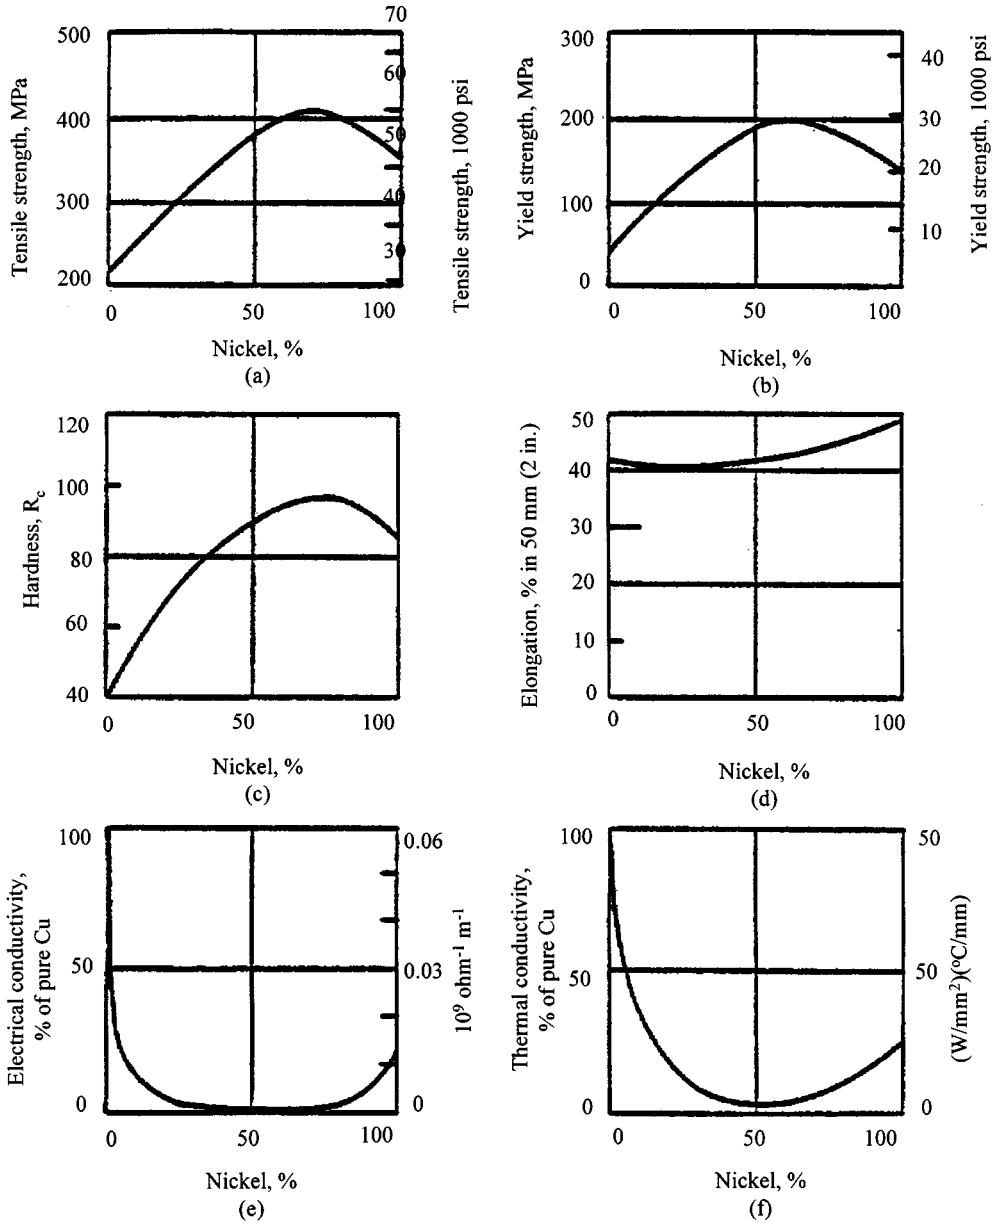

FIGURE 12.1.6 Variation in properties for copper–nickel random solid solution alloys. Note that over time at low temperature alloys (monel) may become nonrandom with significant strength increases.

temperature (e.g., room temperature or ice brine temperature) and subsequently held at an elevated temperature for a specified "aging" time during which particles precipitate and grow in size at near atomic levels throughout the solid metal. Temperature, time, alloy composition, and prior cold work affect the size and distribution of second-phase particles. The combination of treatments can be quite complex, and recently "thermomechanical treatments" combining temperature, time, and dynamic working have resulted in substantial property improvements. Heat treatment can be performed by the user, but it is difficult to achieve the optimum properties obtained by a sophisticated metallurgical mill. The heat treatment can manipulate structure and properties to obtain maximum strength or impact resistance. When metal is to be cold worked, a "softening treatment" can be employed which provides low yield

© 1999 by CRC Press LLC

stress and high ductility. The difference between the "dead soft" and maximum strength conditions can be over an order of magnitude — a useful engineering property change.

Alternative surface diffusion methods such as nitriding and carburizing, which introduce particles for fracture and wear resistance, are presented in the subsection on metal surface treatments.

In the case of dispersion strengthening (hardening), the fine strengthening particles are a discontinuous second phase without atomic continuity with the matrix. The behavior of such particles is shown schematically in Figure 12.1.7a as a function of increasing aging time or aging temperature (fixed time) which result in larger, more widely spaced dispersed-phase particles. Under stress, dislocations must move around (bypass) such particles, so that yield strength decreases with increased aging. Long aging times may be used to decrease yield strength ("soften") of the metal for fabrication. A short aging time, would be used for maximum strength. The dispersed phase can also provide some enhancement of ductility. A dispersion-strengthened metal for which the dispersed phase is stable at elevated temperatures can provide both high-temperature strength and creep resistance (subsection on high-temperature effects). Surface diffusion treatments usually produce dispersion hardening.

Precipitation strengthening (hardening) employs particles which have at least some atomic continuity with the matrix metal. Thus, when the metal is deformed, dislocations can either bypass or pass through (cut) the particles. The resulting behavior is shown in Figure 12.1.7b. As aging time or temperature increases (particles grow larger and more widely spaced), the yield stress increases to a maximum and then decreases. The maximum is termed *critically aged*, and when this designation is part of an alloy treatment, precipitation strengthening may be assumed. For fabrication by cold working, the lower-strength, higher-ductility *underaged* condition is usually employed. There are different possible combinations of thermal and mechanical treatment which will provide a maximum critical aging treatment. Usually the best optimum for strength is given in handbooks and data sheets. However, improved treatments may be available, particularly of the combined thermomechanical type.

Strengthening of Steels and Steel Heat Treatment

Steels, perhaps the most important of all engineering metals, are alloys of iron and carbon usually containing about 0.02 to 1.0 $^{w}/_{o}$ carbon. The binary Fe–C phase diagram is important in describing this behavior and is shown in Figure 12.1.8. This diagram shows what phases and structures will occur in quasi equilibrium at various carbon contents and temperatures (under atmospheric pressure). Steel forming and heat treatment center on the transformation from austenite, γ phase, at elevated temperature to ferrite (α phase) plus cementite (iron carbide, Fe_3C) below 727°C (1340°F), the Ac_1 temperature, a eutectoid transformation. If there are no other intentional alloying elements, the steel is a "plain carbon" steel and has an AISI (American Iron and Steel Institute) designation 1002 to 10100. The first two characters indicate that it is a plain carbon steel, while the latter characters indicate the "points" of carbon.* Alloy steels, containing intentional alloying additions, also indicate the points of carbon by the last digits and together with the first digits provide a unique designation of alloy content. In the phase diagram (Figure 12.1.8) iron carbide (Fe_3C, cementite) is shown as the phase on the right. This is for all practical purposes correct, but the true thermodynamically stable phase is graphite (C) — relevant when the eutectic at 1148°C (2048°F) is used to produce cast irons (alloys greater than 2 $^{w}/_{o}$ C).

The solid-state eutectoid transformation is promoted by the magnetic effect in iron as nonmagnetic austenite transforms below the eutectoid (Ac_1) temperature to the two magnetic solid phases ferrite (iron with solid solution carbon) and cementite solid phase.** At the eutectoid composition, 0.77 $^{w}/_{o}$ carbon,

* Plain carbon steels contain about 0.2 $^{w}/_{o}$ Si, 0.5 $^{w}/_{o}$ Mn, 0.02 $^{w}/_{o}$ P, and 0.02 $^{w}/_{o}$ S.

** It should be noted that austenitic stainless steels (300 and precipitation hardening, PH, series designations), nonmagnetic alloys with considerable chromium and nickel content to provide corrosion resistance, do not ordinarily transform from austenite to the lower-temperature phases. They are not intentionally alloyed with carbon, are not magnetic, and do not show the phase transformation strengthening mechanisms of steels. The term *steel* is something of a misnomer for these alloys.

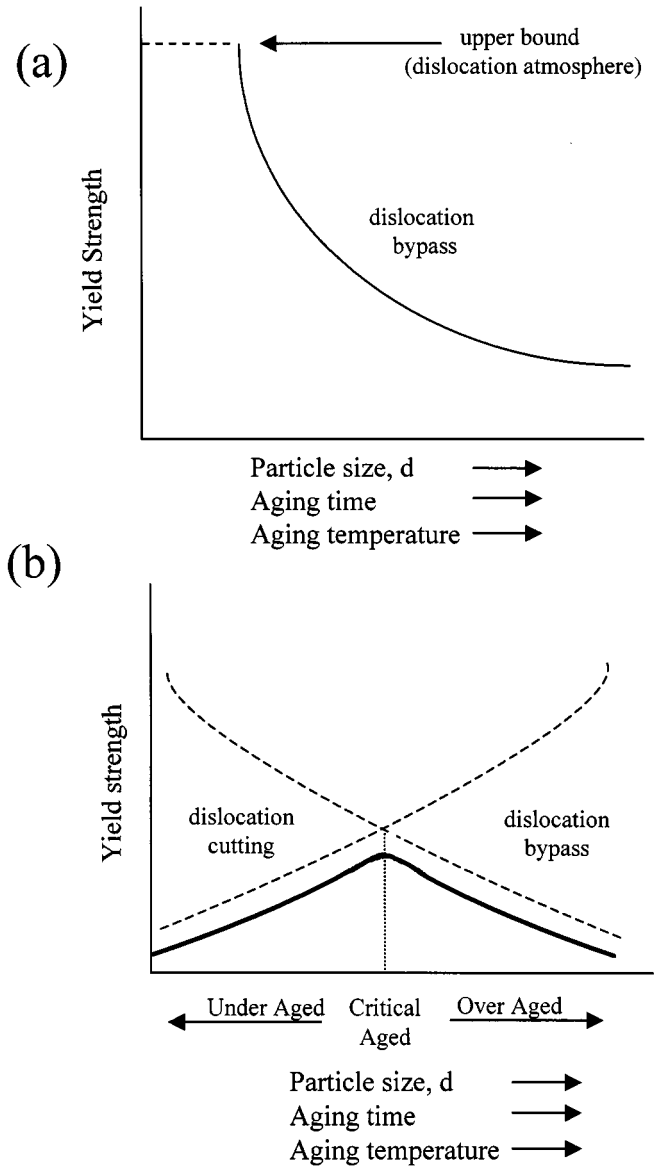

FIGURE 12.1.7 Effect of aging on dispersion- and precipitation-strengthened alloys for a fixed second–phase addition. (a) Dispersion strengthening: as aging time or temperature increases (dispersed phase particles larger and more separated), yield strength increases. A lower bound exists for near atomic size particles. (b) Precipitation hardening: two behaviors can occur giving a composite curve with a maximum at the critical aging time or temperature (optimum size and spacing of particles).

the two phases form as a fine alternating set of plates (lamellae) termed *pearlite* because of their pearllike appearance in a metallographic microscope. This two-phase structure of metal (ferrite) and carbide (cementite) provides strength (very slowly cooled — about 65 ksi, 14% tensile elongation), which increases as a more-rapid quenching yields a finer pearlite microstructure (to about 120 ksi). As strength increases, ductility and fracture toughness decrease. With yet more rapid quenching and more local atomic diffusion, the austenite transforms to bainite, a phase of alternating carbon and iron-rich atomic planes. This has yet higher strength (to about 140 ksi) and lower ductility. When the metal is quenched so rapidly that carbon diffusion is prevented, the austenite becomes unstable. Below a critical temperature,

© 1999 by CRC Press LLC

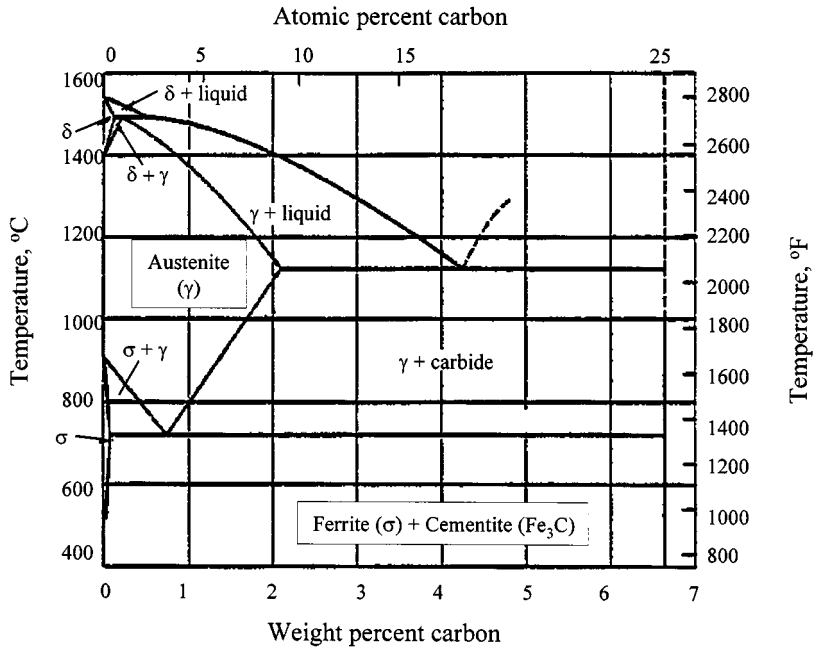

FIGURE 12.1.8 Iron–carbon phase diagram relevant for steel. The steel composition range is from about 0.02 to 1.00 $^{w}/_{o}$ carbon. Steel strengthening treatments require heating into the austenite region (above the Ac_3) and then quenching.

the martensitic start temperature (M_s), the metal transforms spontaneously by shear to martensite. Full transformation occurs below the martensite finish temperature (M_f). The formation of this hard phase introduces enormous microscopic deformation and residual stress. The strength is very much higher (about 300 ksi) but there is almost no ductility. This rapidly cooled material can spontaneously fail from "quench cracking," which results from residual stresses and the martensite acting as an internal flaw. To relieve stresses and provide some fracture toughness, martensitic steel is "tempered" at an intermediate temperature such as 500°C for about an hour to provide some ductility (about 7%) while sacrificing some strength (about 140 ksi). Tempering for shorter times or at lower temperatures can give intermediate properties. High-carbon steels are often used for cutting tools and forming dies because of their surface hardness and wear resistance. When a high-carbon steel (>0.7 $^{w}/_{o}$ C) requires fabrication at lower temperature, it may be held at a temperature just under the eutectoid for an extended time (e.g., for 1080 steel: 700°C, 1300°F — 100 hr) either after or without quenching to provide a soft condition (<60 ksi, 20% extension). A variety of different quenching temperatures, media, and procedures can be used to vary required combinations of the microstructures above and mechanical properties. The discussion above centered on eutectoid steel and holds for other high-carbon steels. Increasing carbon content favors the formation of martensite in steels, thereby providing increased strength, hardness, and wear resistance. However, such steels can be quite brittle.

At lower carbon content, "primary ferrite" forms (Figure 12.1.8) as the steel is quenched from above the boundary of austenitic (γ) region, the Ac_3. Subsequently, pearlite (ferrite and cementite), bainite, and/or martensite can form. Lower carbon content increases the amount of primary ferrite, a weaker/ductile phase, and decreases the tendency to form martensite, a stronger/brittle phase. The result is a more fracture tough, ductile ("safer") steel, but strength is lower. Such steels are also mechanically more forgiving if welded. Thus, a 1010 steel (0.10 $^{w}/_{o}$ C) might be used for applications where extreme "formability" and "weldability" are required, such as for car bodies and cans, while a 1020 steel (0.20 $^{w}/_{o}$ C) might be used for construction materials for which some increased strength is desired while

© 1999 by CRC Press LLC

maintaining safety. A medium-carbon steel such as a 1040 would be used when a balance of strength and toughness (and ease of welding) is needed.

In order to quench (and temper) steels continuous cooling transformation (CCT) diagrams are used such as that in Figure 12.1.9 for a 1040, medium-carbon steel. The steel is quenched from above the Ac_3. Vertical lines indicate quenching rates as shown in the lower left inset of the diagram. The cooling rate for the center of a round bar of given diameter quenched in air, oil, and water is given below the diagram. Solid lines on the diagram indicate percent transformation (start, 10%, 50%, 90%, finish of transformation), and a dotted line separates the region where primary ferrite forms from that of transformation to pearlite. The lower diagram shows the indentation hardness to be expected, as this and other mechanical behavior can be predicted from the CCT curve. As an example, the center of a 15 mm ($\sim^1/_2$ in.) diameter bar quenched in air would be about 25% primary ferrite and 75% fine pearlite, with a Rockwell C hardness (HRC) of about 15. If quenched in oil, the bar center would be chiefly bainite with a small amount of martensite (HRC $\cong$ 25). The same bar quenched in water would be all martensite (HRC $\cong$ 55) before tempering. The transformation at other positions in the bar and for other engineering shapes (sheet, pipe, square rod, etc.) can be obtained from conversion curves.

It should be noted that layers in the steel closer to the quenched surface cool more quickly and are therefore displaced toward the left of the CCT diagram. There is a variation in structure and mechanical properties from the quenched surface to the center. One result is that the surface of the steel tends to be stronger, harder, and more wear resistant than the center. A steel beam undergoing bending has maximum strength at the near surface which undergoes the greatest stresses, while the center provides safety because of its relative fracture toughness and ductility. A thin knife edge cools quickly and can be resistant to deformation and wear, while the thick back prevents the blade from snapping in half when bent.

Many elements may be incorporated in steels to promote specific properties. Almost all common additions (other than cobalt) tend to promote strengthening by the formation of martensite (or bainite) instead of pearlite. When alloying additions tend to promote martensite throughout a thick section independent of cooling rate, the alloy is said to have *high hardenability.* Some elements such as chromium, molybdenum, and nickel also may help to provide high-temperature strength and environmental resistance. One class of alloys with relatively small alloying additions are termed *HSLA* steels (high strength, low alloy) and usually show somewhat superior mechanical properties to their plain carbon steel equivalents. As steel is alloyed, the relative cost increases substantially. A useful strategy in steel selection (and steels are usually the first engineering candidate on a cost basis) is to start by determining if a medium-carbon steel will do. If greater safety and formability are needed, a lower carbon content may be used (with slightly lower cost); alternatively, a higher-carbon steel would be chosen for greater strength and wear resistance. Heat treatment would be used to manipulate the properties. If plain carbon steels prove unsatisfactory, the HSLA steels would be the next candidate. For very demanding applications, environments, and long-term operations, specialty alloy steels would be selected insofar as they are cost-effective.

Fatigue

Fatigue is the repeated loading and unloading of metal due to direct load variation, eccentricity in a rotating shaft, or differential thermal expansion of a structure. Even substantially below the yield point (elastic limit) of a metal or alloy this repeated loading can lead to failure, usually measured in terms of the number of cycles (repeated load applications) to failure. Some studies have suggested that well over 80% of all mechanical failures of metal are attributable to fatigue.

High-stress, low-cycle fatigue usually occurs at stresses above the yield point and lifetimes are tens or hundreds of cycles (to about a thousand cycles). Failure occurs as a result of the accumulation of plastic deformation, that is, the area (energy) under the stress–strain curve (Figure 12.1.3). A simple lifetime predictive equation can be used to predict lifetime:

© 1999 by CRC Press LLC

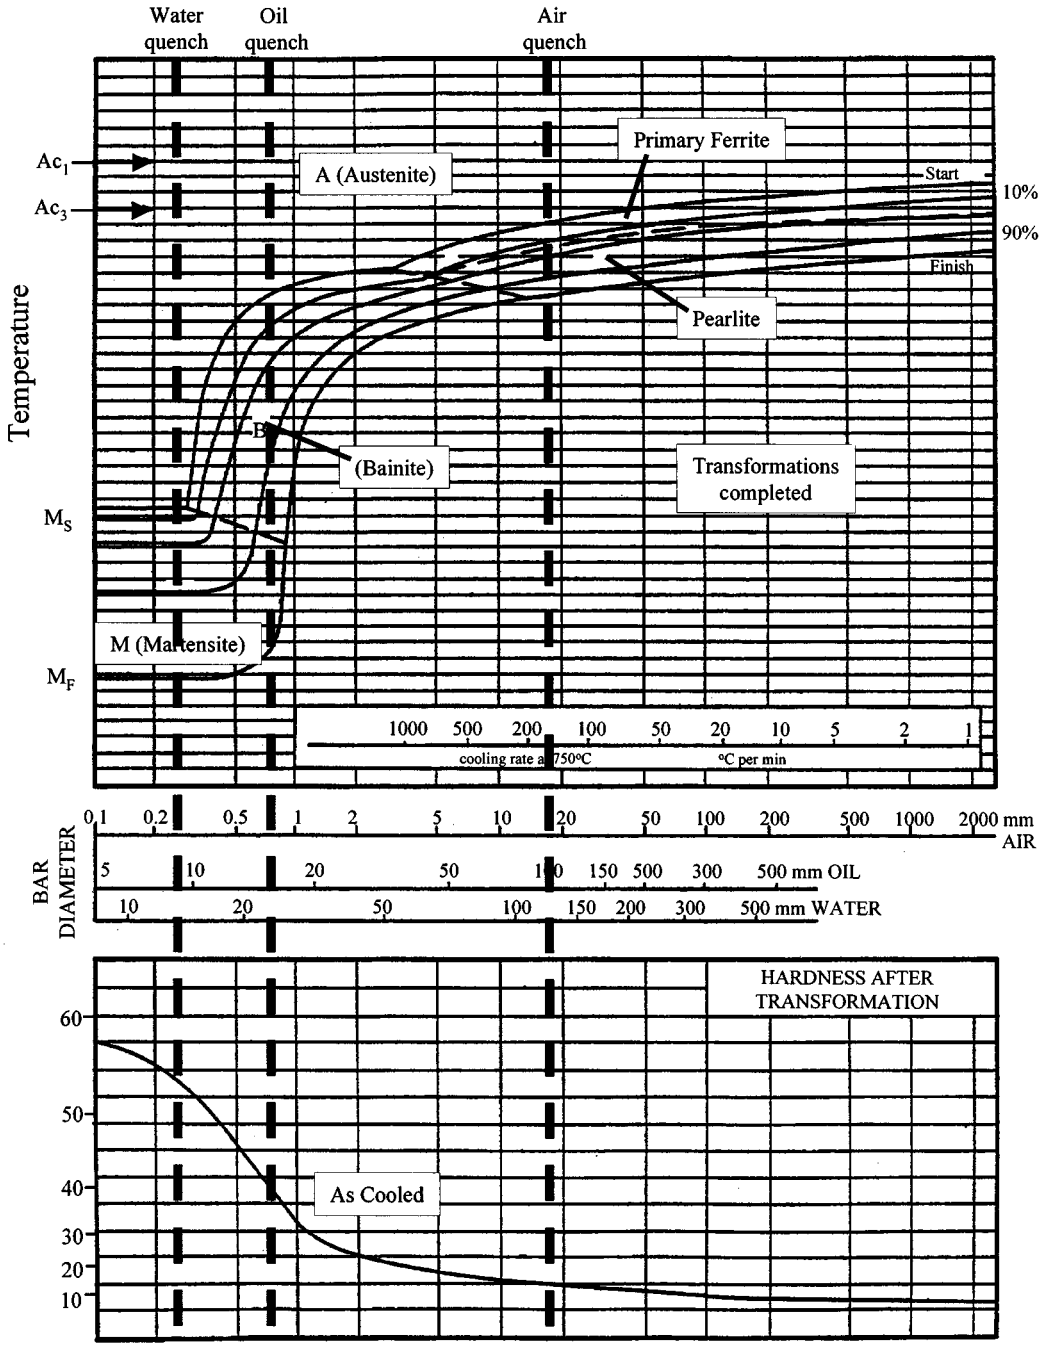

FIGURE 12.1.9 CCT diagram for 1040 steel. A 15-mm round bar air quenched from above the Ac_3 will be chiefly fine pearlite (ferrite and iron carbide, cementite) with about a quarter of the structure primary ferrite at the center. Quenching in oil will yield bainite with about 10% martensite. Water quenching will produce wholly martensite at the center. (After Atkins, M., *Atlas of Continuous Cooling Transformation Diagrams for Engineering Steels*, ASM International, Materials Park, OH, 1980.)

© 1999 by CRC Press LLC

$$N \approx \left[\varepsilon_u / 2\varepsilon_{pf}\right]^2 \tag{12.1.3}$$

where N is the number of cycles to failure, ε_u is total strain from the stress–strain curve, and ε_{pf} is the plastic strain amplitude in each fatigue cycle.

More commonly, metals are used well below their yield point and fail after many, many cycles of repeated loading in low-stress, high-cycle fatigue. There is microscopic, local plastic deformation (cold working) and vacancy generation (recovery effects) during such cyclic loading which result in "fatigue hardening" (strengthening) of unworked metal and "fatigue softening" of unworked metal. Some have even found success relieving residual stressed with a vibratory anneal. Early in the fatigue process surface flaws or in some cases severe internal flaws begin to propagate. The fatigue crack propagates in areas of high stress a small, usually submicroscopic, distance with each tensile loading. The propagation on each cycle frequently leaves identifiable marking on the failure surface termed *fatigue striations* which mark the progress of the subcritical crack. When the crack becomes so large that the fracture toughness criterion is exceeded (Equation 12.1.2), catastrophic overload failure occurs. When the future fatigue loading can be predicted and the cyclic crack propagation rate is known, fatigue cracks can be inspected or monitored in different applications such as aircraft structures and pressure vessels to decommission or replace parts before fatigue failure. This must be done cautiously because a change to a more aggressive (corrosive, oxidative, elevated temperature) environment can increase the crack propagation rate. If a harmonic resonance occurs in the metal part, vibratory maxima can cause premature fatigue failure. Harmonics can change as fatigue cracks propagate. Harmonic vibration can be prevented with vibratory (dynamic) design concepts and/or direct monitoring.

Figure 12.1.10 shows typical metal *S–N* curves (stress vs. number of cycles to failure) for a high-strength aluminum and for a titanium alloy. Note that the convention is to make stress the vertical axis and to plot the number of cycles to failure on a logarithmic scale. For high-stress, low-cycle fatigue ($<10^3$ cycles) the curve is flat and linear, consistent with the model of Equation12.1.3. For high cycle fatigue the lifetime is a rapidly varying function of stress until very low stresses (long lifetimes occur). The actual fatigue life varies statistically about the mean value shown in approximate proportion to the number of cycles to failure. These curves are for testing in ambient air. Fatigue life would be longer in an inert environment and may be shortened drastically in an aggressive environment. Iron- and titanium-based alloys, such as the example shown, usually have an "endurance limit," a stress below which lifetime is ostensibly infinite. In air, at room temperature, the endurance limit is about half the tensile strength for most iron and titanium alloys. Other metals appear to show no stress below which they last indefinitely. Therefore, a "fatigue limit" is designated — usually the stress at which the fatigue life is 10^8 cycles. This may be a long lifetime or not depending on the frequency of loading and engineering lifetime. The fatigue limit is generally about 0.3 times the tensile strength for metals with strengths below about 100 ksi (700 MPa). The factor is somewhat poorer for higher-strength metals. It is apparent that on a relative strength basis, iron- and titanium-based alloys are fatigue-resistant metals when compared with others. Dispersion-strengthened alloys have been seen to provide some lifetime advantage in fatigue.

A number of mathematical relationships have been proposed to predict fatigue life, but none works with complete success and all require experimental data. Perhaps the most successful of the so-called fatigue "laws" are the "cumulative damage" laws. The simplest is Miner's law:

$$\sum i\left[n_i / N_i\right] = 1 \tag{12.1.4}$$

where n_i is the number of cycles applied and N_i is the number of cycles for failure at a particular stress level, σ_i. The conceptual basis is that the number of fatigue cycles at a stress level uses up its relative fraction of total fatigue lifetime and may be correlated to fatigue crack propagation (striation spacing). Modifications of this model account for the order and relative magnitude of loads. Several techniques

© 1999 by CRC Press LLC

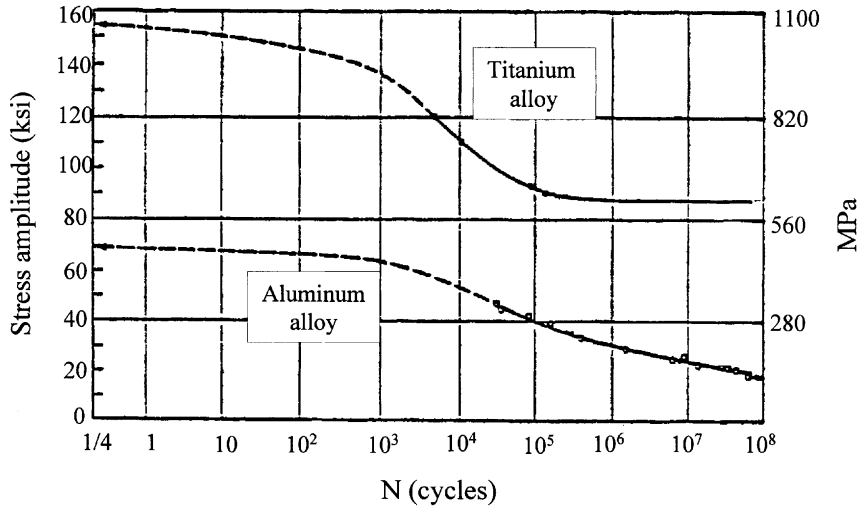

FIGURE 12.1.10 *S–N* (fatigue) curves for high-strength titanium (upper curve) and aluminum alloys. Note that titanium (and iron) alloys show an endurance limit, a stress below which the metal lasts indefinitely.

have met with partial success in increasing fatigue lifetime beyond that predicted by the cumulative damage models:

1. Coaxing — intermittent or continuous, superimposed vibration at very low stress,
2. Overstressing — intermittent or superimposed compressive loading,
3. Surface compression — intermittent shot peening or surface rolling,
4. Surface removal — chemical or mechanical surface polishing.

All but 1 are thought to close or eliminate fatigue cracks and surface damage. Coaxing has been said to introduce more of the vacancy-related recovery effects associated with fatigue.

High-Temperature Effects — Creep and Stress Rupture

Elevated temperature can cause a significant loss of strength and elastic modulus, so that a metal part may fail as a result of overheat even at loads which appear small at room temperature. High temperature is a relative matter and is usually judged as a fraction of the melting point measured on the absolute temperature scale. Thus, even moderate temperature excursions can be important for low-melting-point metals and alloys. As indicated in several sections above, many alloying and cold work strengthening methods depend upon heat treatment; an alloy can undergo metallurgical change due to overheat or to long-term holds at moderate temperatures and thereby alter properties significantly. Thus, the thermal stability of the microstructure should be determined. For example, metallographic replica techniques have been developed for determining in the field if microstructure has coarsened, making the metal weak.

Creep deformation is the continued deformation of a metal under load at elevated temperature, usually at a design stress well below the yield point. While measurable creep can occur at low temperatures over very long times or at very high (compressive) loads, creep usually becomes of engineering importance above about two thirds the melting point (absolute) of an alloy. Thus, both lead, which creeps at room temperature, and tungsten, which creeps in an incandescent light bulb at white heat, require a mechanical support or creep-resistant alloying additions. Figure 12.1.11 shows a schematic creep curve plotting creep strain* vs. time, *t*, at a particular tensile load and temperature. After the immediate elastic

* If a constant extension is applied to an object, the force it generates will decline over time due to creep. This is called *stress relaxation* and can be treated in a similar way.

© 1999 by CRC Press LLC

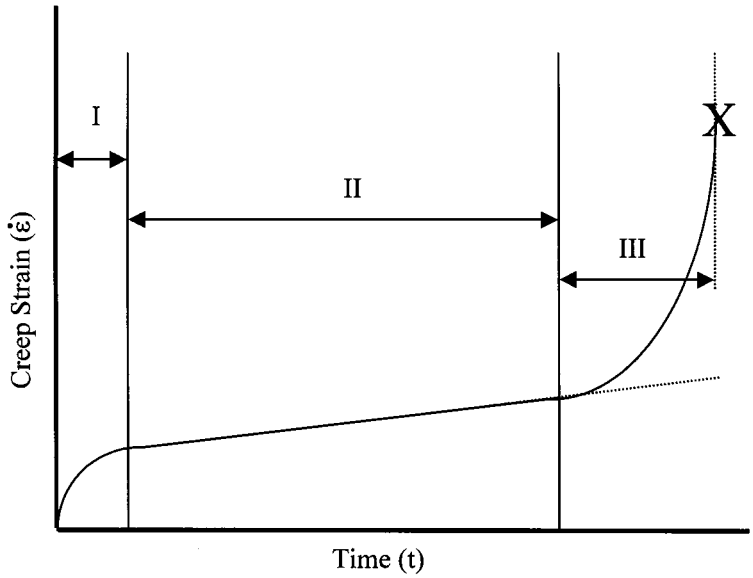

FIGURE 12.1.11 Schematic creep curve showing transient creep (I), steady-state creep (II), and tertiary creep (III). Note that the slope of the straight-line portion is the steady-state creep rate (minimum creep rate).

strain (t = 0), "transient creep" occurs in Region I. At elevated temperature this usually follows a $t^{1/3}$ behavior (Andrade creep). The majority of the curve has a straight-line behavior (Region II) in which the extension with time is constant. The slope of this part of the curve is termed the *steady-state strain rate* or *minimum creep rate*. It is used to calculate the creep extension which could cause functional failure when dimensional tolerances are exceeded. A simplified predictive model is

$$\varepsilon' = A\sigma^m e^{-h/kT} \tag{12.1.5}$$

where ε' is the minimum creep rate, A is a constant, σ is the applied stress, m is the stress dependence exponent (often 4 to 8), h is the activation enthalpy for creep, and T the absolute temperature.

In Region III the creep rate accelerates as the metal necks down severely in a local area, thereby increasing the local stress. The steady-state rate would continue (dotted line) if the load were adjusted to give constant load at the minimum cross section. Since loads do not readjust to compensate for necking in real applications, a final accelerated stage can be experienced. For example, a blowout can occur in late creep of a pressurized high-temperature piping system. The time to failure is termed the *stress rupture lifetime*. Predictive models are developed from Equation (12.1.5) to provide lifetime information.

Lowering use temperature or applied stress decreases susceptibility to creep deformation and increases stress rupture lifetime. Frequently, a moderate temperature decrease is most effective in this regard. Higher-melting-point metals are more creep resistant, so that the refractory metals tungsten and molybdenum can be used but require an inert atmosphere or protective coating to prevent rapid oxidation. In air or other active atmosphere, niobium-, nickel-, titanium-, and iron-based alloys may be used for creep resistance. Dispersion hardening, particularly with a high-temperature stable phase, such as an oxide, nitride, or carbide, can confer a degree of creep resistance.

Corrosion and Environmental Effects

Corrosion usually involves the slow removal of metal due to chemical and/or electrochemical reaction with an environment. Most metallic corrosion involves a galvanic, that is, electrochemical, component and localized attack in the form of pitting, attack in crevices, grain boundary attack, selective leaching

© 1999 by CRC Press LLC

of one phase, and exfoliation (attack parallel to the surface causing layers to peel away). Uniform corrosion is less common and also less of a concern as long as the rate of material removal is gradual and predictable.

Galvanic corrosion requires a medium, usually liquid (water), often containing a specific agent which promotes corrosion, a potential difference, and a complete electrical circuit, as well as an anode and a cathode. The anode will be the attacked, corroded, portion of the system. One cause for potential corrosion is dissimilar metals. For example, the galvanic series in seawater shows magnesium alloys as most anodic followed by zinc, aluminum, iron, nickel, brass, and copper alloys which are progressively more cathodic. When coupled electrically, the more-anodic metal would be corroded and the more cathodic would promote corrosion. One way of preventing corrosion is to isolate with insulator material the metal parts electrically so that a circuit is interrupted. The surfaces can be isolated from the corroding medium with paint, protective metal, conversion coatings, or a corrosion inhibitor additive to the liquid. In this situation it is more important to coat the cathode (noncorroding metal) since it impresses corrosion on the anodic metal dependent on exposed area. When in doubt, all parts should be painted repeatedly to prevent pinholes. Other possibilities include cathodic protection with an impressed electrical counterpotential or use of a sacrificial anode which is attacked instead of the metal components. Some metals such as stainless steels and aluminum alloys provide protection via an oxide coating, a *passive film*, which will form under specific, controlled electrochemical conditions providing *anodic protection.*

Another source for an anode and cathode can be the solution itself. Differences in temperature, ion concentration, oxygen content, and pH can all lead to a potential difference which results in corrosion. Often corrosion occurs far more rapidly for a specific range of solution concentration — indeed, sometimes dilution may accelerate corrosive attack. An oxygen deficiency cell under dirt or in a crevice frequently causes attack at the resulting anode. Potential differences can also exist in the metal itself: between different phases, inclusions, or grain chemistries; between grains and grain boundaries; between surface films and metal; and between different grain orientations. Selective leaching such as dezincification of high-zinc brasses (Cu–Zn) is an example for composition differences, while exfoliation corrosion of aluminum alloys and sensitized stainless steel are examples of grain boundary attack. Cold-worked metal tends to be anodic to annealed material so that a heavily formed part of a metal part may corrode preferentially.

Another important environmental cause of failure is stress corrosion cracking (SCC). A combination of applied or residual tensile stress and environmental attack results in progressive slow crack propagation over a period of time. Eventually, the crack becomes critical in size (Equation 12.1.2) and catastrophic failure occurs. There need be no evidence of corrosion for SCC to occur. When the loading is of a cyclic nature the effect is termed *corrosion fatigue*. To prevent these long-term crack propagation effects the environment and/or the source of tensile load may be removed. Considerable effort has been made to identify an ion concentration below which stress corrosion cracking will not occur (e.g., Cl for austenitic stainless steels), but there may be no level for complete immunity, merely a practical maximum permissible level.

Hydrogen embrittlement and hydrogen cracking can occur in the presence of stress and a hydrogen source. Embrittlement results when hydrogen diffuses into the metal and/or acts on the crack tip altering the fracture toughness. Hydrogen cracking may be regarded as a special case of stress corrosion cracking. Either environmental effect can lead to catastrophic failure. The source of hydrogen can be an acid solution, hydrogen evolved during corrosion, electrochemical treatment (plating, electropolishing), or hydrocarbons. Often isolation from the hydrogen source is difficult because hydrogen diffuses quickly through most materials and barrier coatings. Glass coating has met with some success.

Metal Surface Treatments

A number of treatments are employed to strengthen the surface of steels and make them more resistant to failure or wear. Some of the techniques may also be applied to selected nonferrous alloys. Flame, induction, and laser hardening provide intense heat to the outer surface of a medium- or high-carbon

© 1999 by CRC Press LLC

(hardenable) steel bringing it into the austenitic region, above Ac_3 (see subsection on fatigue). The bulk of the metal is not heated so that the surface can then be quenched rapidly forming hardening phases and a compressive surface stress. This provides strength and wear resistance. Another surface-hardening technique is carburizing. This can also be used on steels with lower carbon content. The metal is exposed to a controlled balance of carbon monoxide and carbon dioxide or is packed in graphite. At elevated temperature (usually above the Ac_3) carbon diffuses into the surface, converting it to a high-carbon steel. The steel is then either quenched directly from the carburizing temperature or reaustenitized and quenched. The result is similar to flame hardening, but higher hardness and surface compression can be accomplished compared with flame hardening. The center of the piece, with much lower carbon content, can provide fracture toughness, ductility, and safety. Nitriding exposes steel containing appropriate alloying elements (chromium, aluminum, vanadium, …) to monatomic nitrogen in the form of cracked ammonia, cyanide, or high-energy dissociated nitrogen gas. This is done below the eutectoid (lower transformation) temperature. Dispersed-phase nitrides are formed as nitrogen diffuses into the surface which harden the surface without a need for further heat treatment. The effects of both carburizing and nitriding can be introduced by carbonitriding above the transformation temperature and quenching or nitrocarburizing below the transformation to austenite.

12.2 Polymers

James D. Idol and Richard L. Lehman

Introduction

Polymers constitute a wide range of materials which are derived at least in part from organic, usually petroleum-based, raw materials; they consist of repeating molecular units and have special properties obtained by engineering the form of the molecular structures. The term *polymer* is derived from Greek roots and means "having many parts," a term which aptly describes the infinite number of compounds which can be synthesized from a relatively limited number of monomer units. The term *plastic* is often used in describing polymers, although this term is not in current usage since it is a general descriptive which refers to the forming rheology of many polymers but is too general to accurately describe this group of materials.

Polymers are used as engineering materials in the neat form, i.e., as the pure material, or in combination with a large diversity of additives, both organic and inorganic. These additives may be, among others, plasticizers which reduce the rigidity or brittleness of the material, fillers which increase strength and load deflection behavior under load, or stabilizers which protect the polymer against ultraviolet radiation.

The following discussion will separate polymers into two groups, thermoplastic and thermosetting, based on the distinctly different thermal processing behavior of these two broad classes of polymers. Thermoplastic polymers soften when heated and can be reshaped, the new shape being retained on cooling. The process can be repeated many times by alternate heating and cooling with minimal degradation of the polymer structure. Thermosetting polymers (or thermosets) cannot be softened and reshaped by heating. They are plastic and moldable at some state of processing, but finally set to a rigid solid and cannot be resoftened. Thermosets are generally stronger and stiffer than thermoplastic.

Table 12.2.1 of this section gives an overview of the physical properties of the most commonly used industrial polymers. Table 12.2.2 provides an overview of properties such as chemical resistance, ease of machining, and compressive strength for thermoplastic and thermosetting plastics, while Table 12.2.3 is a selection guide for polymers by application. A detailed summary of polymer properties, including electrical properties, thermal properties, optical properties, and fabrication, is presented in Table 12.2.4.

Thermoplastic Polymers

Acetal and Polyacetal

These combine very high strength, good temperature and abrasion resistance, exceptional dimensional stability, and low coefficient of thermal expansion. They compete with nylon (but with many better properties) and with metal die castings (but are lighter). Chemical resistance is good except for strong acids. Typical applications are water-pump parts, pipe fittings, washing machines, car instrument housings, bearings, and gears.

Acrylics (Methylmethacrylate, PMMA)

These are noted for their optical clarity and are available as sheet, rod, tubings, etc., as Perspex (U.K.) and Plexiglas (U.S., Germany, etc.). They are hard and brittle and quite resistant to discoloring and, especially, weathering. Applications include outdoor display signs, optical lenses and prisms, transparent coverings, drafting instruments, reflectors, control knobs, baths, and washbasins. They are available in a wide range of transparent and opaque colors.

Acrylonitrile-Butadiene-Styrene (ABS)

This combination of three monomers gives a family of materials which are strong, stiff, and abrasion resistant with notable impact-resistance properties and ease of processing. The many applications include

Phenol formaldehyde (mica filled)	1600–1900	38–50	0.5	17–35	36	Good
Acetals (glass filled)	1600	58–75	2–7	7	27	Good

Note: BHN = Brinell hardiness number, ρ = density, *E* = Young's modulus.

TABLE 12.2.2 Relative Properties of Polymers

Material	Tensile Strength[a]	Compressive Strength[b]	Machining Properties	Chemical Resistance
Thermoplastics				
Nylon	E	G	E	G
PTFE	F	G	E	O
Polypropylene	F	F	E	E
Polystyrene	E	G	F	F
Rigid PVC	E	G	E	G
Flexible PVC	F	P	P	G
Thermosetting plastics				
Epoxy resin (glass-fiber filled)	O	E	G	E
Formaldehyde (asbestos filled)	G	G	F	G
Phenol formaldehye (Bakelite)	G	G	F	F
Polyester (glass-fiber filled)	E	G	G	F
Silicone (asbestos filled)	O	G	F	F

Note: O = outstanding, E = excellent, G = good, F = fair, P = poor.

[a] Tensile strength (typical): E = 55 Nmm^{-2}; P = 21 Nmm^{-2}.

[b] Compressive strength (typical): E = 210 Nmm^{-2}; P = Nmm^{-2}.

pipes, refrigerator liners, car-instrument surrounds, radiator grills, telephones, boat shells, and radio and television parts. Available in medium, high, and very high impact grades.

Cellulosics

"Cellulose nitrate" is inflammable and has poor performance in heat and sunlight. Its uses are therefore limited. Cellulose acetate has good strength, stiffness, and hardness and can be made self-extinguishing. Glass-filled grades are made. Cellulose acetate-butyrate (CAB) has superior impact strength, dimensional stability, and service temperature range and can be weather stabilized. Cellulose proprionate (CP) is similar to CAB, but has better dimensional stability and can have higher strength and stiffness. Ethyl cellulose has better low-temperature strength and lower density than the others. Processing of cellulose

TABLE 12.2.3 Selection Guide for Polymers by Application

Application or Service	Properties Required	Suitable Plastics
Chemical and thermal equipment	Resistance to temperature extremes and to wide range of chemicals; minimum moisture absorption; fair to good strength	Fluorocarbons, chlorinated polyether, polyvinylidene fluoride, polypropylene, high-density polyethylene, and epoxy glass
Heavily stressed mechanical components	High-tensile plus high-impact strength; good fatigue resistance and stability at elevated temperatures; machinable or moldable to close tolerance	Nylons, TFE-filled acetals, polycarbonates, and fabric-filled phenolics
Electrostructural parts	Excellent electrical resistance in low to medium frequencies; high-strength and -impact properties; good fatigue and heat resistance; good dimensional stability at elevated temperatures	Allylics, alkyds, aminos, epoxies, phenolics, polycarbonates, polyesters, polyphenylene oxides, and silicones
Low-friction applications	Low coefficient of friction, even when nonlubricated; high resistance to abrasion, fair to good form stability and heat and corrosion resistance	Fluorocarbons (TFE and FEP), filled fluorocarbons (TFE), TFE fabrics, nylons, acetals, TFE-filled acetals, and high-density polyethylenes
Light-transmission components, glazing	Good light transmission in transparent or translucent colors; good to excellent formability and moldability; shatter resistance; fair to good tensile strength	Acrylics, polystyrenes, cellulose acetates, cellulose butyrates, ionomers, rigid vinyls, polycarbonates, and medium-impact styrenes
Housings, containers, ducts	Good to excellent impact strength and stiffness; good formability and moldability; moderate cost; good environmental resistance; fair to good tensile strength and dimensional stability	ABS, high-impact styrene, polypropylene, high-density polyethylene, cellulose acetate butyrate, modified acrylics, polyester–glass and epoxy–glass combinations

plastics is by injection molding and vacuum forming. Applications include all types of moldings, electrical insulation, and toys.

Ethylene-Vinyl Acetate (EVA)

This material gives tough flexible moldings and extrusions suitable for a wide temperature range. The material may be stiffened by the use of fillers and is also specially formulated for adhesives. Applications include all types of moldings, disposable liners, shower curtains, gloves, inflatables, gaskets, and medical tubing. The material is competitive with polyvinyl chloride (PVC), polyethene, and synthetic rubbers, and is also used for adhesives and wax blends.

Fluorocarbons

This class of polymers, characterized by fluorine substitution, has outstanding chemical, thermal, and electrical properties and is characterized by the following four main classes of structures.

Polytetrafluoroethylene (PTFE), known commercially as Teflon or Fluon, is the best-known material and resists all known chemicals, weather, and heat, has an extremely low coefficient of friction, and is "non-stick." These materials are inert with good electrical properties. They are nontoxic, nonflammable, and have a working temperature range of –270 to 260°C. They may be glass filled for increased strength and rigidity. They do not melt and they must be formed by sintering of powders. Applications include chemical, mechanical, and electrical components, bearings (plain or filled with glass and/or bronze), tubing, and vessels for "aggressive" chemicals.

Fluoroethylenepropylene (FEP), unlike PTFE, can be processed on conventional molding machines and extruded, but thermal and chemical resistance properties are not quite as good.

Ethylenetetrafluoroethylene (ETFE) possess properties similar to but not as good as those of PTFE. However, the material exhibits a thermoplastic character similar to that of polyethylene which gives it a very desirable molding behavior.

TABLE 12.2.4 Properties of Polymers (continued)

Properties of Polymers [continued]

Chemical class	Polyketone							
	aliphatic thermoplastic							
	neat resin							
ELECTRICAL PROPERTIES								
D.C. resistivity, ohm-cm	103							
Dielectric constant, 60 cps	5-6							
Dielectric constant, 10^6 cps								
Dissipation factor, 60 cps								
Dissipation factor, 10^6 cps	0.04							
MECHANICAL PROPERTIES								
Modulus of elasticity, 10^3 psi	250							
Tensile strength, psi	>9000							
Ultimate elongation, %	300							
Yield stress, psi	9000							
Yield strain, %	2.2							
Rockwell hardness								
Notched Izod impact strength, ft lb/in.	4							
Specific gravity	1.24							
THERMAL PROPERTIES								
Burning rate								
Heat distortion, 264 psi. C	105-110							
Specific heat, cal/g								
Linear thermal expansion coefficient, 10^{-5}, C	9-11							
Maximum continuous service temperature, C								
CHEMICAL RESISTANCE								
Mineral acids, weak	Good							
Mineral acids, strong	Fair							
Oxidizing acids, concentrated	Fair							
Alkalies, weak	Good							
Alkalies, strong	Good							
Alcohols	Excellent							
Ketones	Excellent							
Esters	Excellent							
Hydrocarbons, aliphatic	Excellent							
Hydrocarbons, aromatic	Excellent							
Oils: vegetable, animal, mineral								
MISCELLANEOUS PROPERTIES								
Clarity	translucent							
Color	white crystals							
Refractive index, n_D								
FABRICATION								
Cl—calendering, Cs—casting, E—extrusion, F—hot forming or drawing, I—impregnation, MC—blow molding, MC—compression molding, MI—injection molding, S—spreading	E, MI							

© 1999 by CRC Press LLC

Perfluoroalkoxy (PFA) is the fourth group of fluorinated polymers. These materials have the same excellent properties as PTFE, but the compound is melt processible and, therefore, suitable for linings for pumps, valves, pipes, and pipe fittings.

Ionomers

These thermoplastics are based on ethylene and have high melt strength, which makes them suitable for deep forming, blowing, and other similar forming processes. They are used for packaging, bottles, moldings for small components, tool handles, and trim. They have a high acceptance of fillers.

Polymethylpentene

Polymethylpentene (TPX) is a high-clarity resin with excellent chemical and electrical properties and the lowest density of all thermoplastics. It has the best resistance of all transparent plastics to distortion at high temperature — it compares well with acrylic for optical use, but has only 70% of its density. It is used for light covers, medical and chemical ware, high-frequency electrical insulation, cables, microwave oven parts, and radar components. It can withstand soft soldering temperatures.

Polyethylene Terephthalate

Polyethylene terephthalate (PETP) and modified versions thereof have high strength, rigidity, chemical and abrasion resistance, impact resistance in oriented form, and a low coefficient of friction. It is attacked by acetic acid and concentrated nitric and sulfuric acids. It is used for bearings, tire reinforcement, bottles, automotive parts, gears, and cams.

Polyamides (Nylons)

The polyamides are a family of thermoplastics, e.g., Nylon 6, Nylon 66, and Nylon 610, which are among the toughest engineering plastics with high vibration-damping capacity, abrasion resistance, inherent lubricity, and high load capacity for high-speed bearings. They have a low coefficient of friction and good flexibility. Pigment-stabilized types are not affected by ultraviolet radiation and chemical resistance is good. Unfilled nylon is prone to swelling due to moisture absorption. Nylon bearings may be filled with powdered molybdenum disulfide or graphite. Applications include bearings, electrical insulators, gears, wheels, screw fasteners, cams, latches, fuel lines, and rotary seals.

Polyethylene

Low-density polyethylene (orinally called *polythene*) is used for films, coatings, pipes, domestic moldings, cable sheathing, and electrical insulation. High-density polyethylene is used for larger moldings and is available in the form of sheet, tube, etc. Polyethylene is limited as an engineering material because of its low strength and hardness. It is attacked by many oxidizing chemical agents and some hydrocarbon solvents.

Polyketone, Aliphatic

Aliphatic polyketones are relatively strong, tough, ductile polymeric resins derived from equal proportions of ethylene and carbon monoxide with an additional few percent of higher olefin for property and processibility adjustment. Their physical, thermal, and mechanical properties are similar to polyamides and polyacetals. Mechanical properties are characterized by preservation of high levels of stiffness, toughness, and strength over a broad temperature range. Resistance to hydrolysis, swelling, and permeation provides broad chemical resistance. Relatively new in commercial supply, they find application in gears, machine components, and similar engineering applications. Tribological performance is very good, and in particular they have a low coefficient of friction and a low wear factor against steel. The electrical properties of the neat polyketone are typical of those of polar, semicrystalline thermoplastics.

Polyethersulfone

Polyethersulfone is a high-temperature engineering plastic — useful up to 180°C in general and some grades have continuous operating ratings as high as 200°C. It is resistant to most chemicals and may

© 1999 by CRC Press LLC

be extruded or injection molded to close tolerances. The properties are similar to those of nylons. Applications are as a replacement for glass for medical needs and food handling, circuit boards, general electrical components, and car parts requiring good mechanical properties and dimensional stability.

Polystyrene

This polymer is not very useful as an engineering material because of brittleness in unmodified forms, but it is well known for its use in toys, electrical insulation, refrigerator linings, packaging, and numerous commercial articles. It is available in unmodified form as a clear transparent resin and also in clear and opaque colors. High-impact forms are achieved by compounding with butadiene or other rubbery resins and heat-resistant forms are achieved by the use of fillers. Polystyrene can be stabilized against ultraviolet radiation and also can be made in expanded form for thermal insulation and filler products. It is attacked by many chemicals, notably aromatic hydrocarbon solvents, and by ultraviolet light.

Polysulfone

Polysulfone has properties similar to nylon, but these properties are retained up to 180°C compared with 120°C for nylon, which greatly expands the range of applications. Its optical clarity is good and its moisture absorption lower than that of nylon. Applications are as a replacement for glass for medical needs and chemistry equipment, circuit boards, and many electrical components.

Polyvinyl Chloride

This is one of the most widely used of all plastics. With the resin mixed with stabilizers, lubricants, fillers, pigments, and plasticizers, a wide range of properties is possible from flexible to hard types, in transparent, opaque, and colored forms. It is tough, strong, with good resistance to chemicals, good low-temperature characteristics and flame-retardant properties. PVC does not retain good mechanical performance above 80°C. It is used for electrical conduit and trunking, junction boxes, rainwater pipes and gutters, decorative profile extrusions, tanks, guards, ducts, etc.

Polycarbonate

Polycarbonate is an extremely tough thermoplastic with outstanding strength, dimensional stability, and electrical properties, high heat distortion temperature and low-temperature resistance (down to –100°C). It is available in transparent optical, translucent, and opaque grades (many colors). Polycarbonates have only fair resistance to chemicals as evidenced by the stress cracking caused by many solvents. The weathering tendencies can be stabilized against ultraviolet radiation by the use of proper additives. Polycarbonate compounds are used for injection moldings and extrusions for glazing panels, helmets, face shields, dashboards, window cranks, and gears. Polycarbonate is an important engineering plastic.

Polypropylene

Polypropylene is a low-density, hard, stiff, creep-resistant plastic with good resistance to chemicals, good wear resistance, low water absorption, and is relatively low cost. Polypropylene can be spun into filaments, converted into weaves, injection molded, and is commonly produced in a large variety of forms. Glass-filled polypropylene is widely used for its enhanced mechanical properties. It is used for food and chemical containers, domestic appliances, furniture, car parts, twine, toys, tubing, cable sheath, and bristles.

Polyphenylene Sulfide

Polyphenylene sulfide is a high-temperature plastic useful up to 260°C. Ambient temperature properties are similar or superior to those of nylon. It has good chemical resistance and is suitable for structural components subject to heat. Glass filler improves strength and enables very high heat resistance to 300°C. Uses are similar to those of nylon, but for higher temperatures.

© 1999 by CRC Press LLC

Polyphenylene Oxide

This is a rigid engineering plastic similar to polysulfone in uses. It can be injection molded and has mechanical properties similar to those for nylon. It is used for automotive parts, domestic appliances, and parts requiring good dimensional stability. Frequently, the commercially available product is blended (or "alloyed") with polystyrene which acts as a cost-effective extender.

Thermosetting Polymers

Alkyds

There are two main groups of alkyds: diallyphthalate (DAP) and diallylisopthalate (DIAP). These have good dimensional stability and heat resistance (service temperature 170°C; intermittent use 260°C), excellent electrical properties, good resistance to oils, fats, and most solvents, but limited resistance to strong acids and alkalis. The mechanical properties are improved by filling with glass or minerals. The main uses are for electrical components and encapsulation. A wide range of colors and fast-curing grades are available.

Amino Resins

These are based on formaldehyde reacted with urea or melamine and are formulated as coatings and adhesives for laminates, impregnated paper textiles, and molding powders. The resins are usually compounded with fillers of cellulose, wood flour, and/or other extenders. As composites with open-weave fabric, they are used for building panels. Uses also include domestic electrical appliances and electric light fittings; the melamine type is used for tableware. The strength is high enough for use in stressed components, but the material is brittle. Electrical, thermal, and self-extinguishing properties are good.

Epoxies

Epoxy resins are used extensively across industry as engineering polymers and as adhesives. They can be cold cured without pressure using a "hardener" or may be heat cured. Inert fillers, plasticizers, flexibilizers, and extenders give a wide range of properties from soft flexible to rigid solid materials. Bonding to nearly all materials, e.g., wood, metal, glass, is excellent as are the mechanical, electrical, and chemical properties. Epoxies are used in all branches of engineering, including large castings, electrical parts, circuit boards, potting, glass and carbon fiber structures, flooring, protective coatings, and adhesives. Importantly, they exhibit little or no shrinkage on cure.

Phenolics (Phenol Formaldehyde, PF)

PF, the original "Bakelite," is usually filled with 50 to 70% wood flour for molded nonstressed or lightly stressed parts. Other fillers are mica for electrical parts, asbestos for heat resistance, glass fiber for strength and electrical properties, nylon, and graphite. Phenolics represent one of the best polymers for low-creep applications. Moldings have good strength, good gloss, and good temperature range (150°C wood filled; intermittent use 220°C), but are rather brittle. Applications include electrical circuit board, gears, cams, and car brake linings (when filled with asbestos, glass, metal powder, etc.). The cost is low and the compressive strength very high.

Polyester

Polyester resins can be cured at room temperature with a hardener or alone at 70 to 150°C. It is used unfilled as a coating, for potting, encapsulation, linings, thread locking, castings, and industrial moldings. It is used mostly for glass-reinforced-plastic (GRP) moldings.

© 1999 by CRC Press LLC

Polyimides

Polyimides are noted for their unusually high resistance to oxidation and service temperatures up to 250°C (400°C for intermittent use). The low coefficient of friction and high resistance to abrasion make them ideal for nonlubricated hearings. Graphite or molybdenum disulfide filling improves these properties. They are used for high-density insulating tape. Polyimides have high strength, low moisture absorption, and resist most chemicals, except strong alkalis and ammonia solutions.

Silicones

These may be cold or heat cured and are used for high-temperature laminates and electrical parts resistant to heat (heat distortion temperature 450°C). Unfilled and filled types are used for special-duty moldings. Organosilicones are used for surface coatings and as a superior adhesive between organic and nonorganic materials.

Laminated Polymer Structures

A wide range of composite structures are prepared from polymer resins combined with fibers. The reader is referred to Section 12.6 for a more extensive discussion of polymer composites. Laminated polymer structures consist of layers of fibrous material impregnated with and bonded together usually by a thermosetting resin to produce sheets, bars, rods, tubes, etc. The laminate may be "decorative" or "industrial," the latter being of load-bearing mechanical or electrical grade.

Phenolics

Phenolic plastics can be reinforced with paper, cotton fabric, asbestos paper fabric or felt, synthetic fabric, or wood flour. They are used for general-purpose mechanical and electrical parts. They have good mechanical and electrical properties.

Epoxies

These are used for high-performance mechanical and electrical duties. Fillers used are paper, cotton fabric, and glass fiber.

Tufnol

"Tufnol" is the trade name for a large range of sheet, rod, and tube materials using phenolic resin with paper and asbestos fabric and epoxy resin with glass or fabric.

Polyester

This is normally used with glass fabric (the cheapest) filler. The mechanical and electrical properties are inferior to those of epoxy. It can be rendered in self-colors.

Melamine

Fillers used for melamine are paper, cotton fabric, asbestos paper fabric, and glass fabric. Melamines have a hard, nonscratch surface, superior electrical properties, and can be rendered in self-colors. They are used for insulators, especially in wet and dirty conditions, and for decorative and industrial laminates.

Silicone

Silicone is used with asbestos paper and fabric and glass fabric fillers for high-temperature applications (250°C; intermittent use 300°C). It has excellent electrical but inferior mechanical properties.

Polyimide

Polyimide is most often used with glass fabric as filler. Polyimides have superior thermal and electrical properties with a service temperature similar to that for silicones but with two to three times the strength and flexibility.

© 1999 by CRC Press LLC

Foam and Cellular Polymers

Thermoplastics

Polyurethane Foams. The "flexible" type is the one most used. It is "open cell" and used for upholstery, underlays, thermal and vibration insulation, and buoyancy. It can be generated *in situ*. The rigid type has "closed cells" and is used for sandwich construction, insulation, etc. Molded components may be made from rigid and semirigid types.

Expanded Polystyrene. This material is produced only in rigid form with closed cells. It can be formed *in situ*. The density is extremely low, as is the cost. Chemical resistance is low and the service temperature is only 70°C. It is used for packaging, thermal and acoustic insulation, and buoyancy applications.

Cellular Polyvinyl Chlorides. The low-density type is closed cell and flexible. It is used for sandwich structures, thermal insulation, gaskets, trim, to provide buoyancy, and for insulating clothing. The moderate- to high-density open-cell type is similar to latex rubber and is used as synthetic leather cloth. The rigid closed-cell type is used for structural parts, sandwich construction, thermal insulation, and buoyancy. Rigid open-cell PVC (microporous PVC) is used for filters and battery separators. In general, cellular PVC has high strength, good flame resistance, and is easy to work.

Polyethylene Foams. The flexible type is closed cell and has low density with good chemical resistance and color availability, but is a poor heat insulator and is costly. The flexible foams are used for vibration damping, packaging, and gaskets. The rigid type has high density and is used for filters and cable insulation. A structural type has a solid skin and a foam core.

Ethylene Vinyl Acetates. These are microcellular foams similar to microcellular rubber foam, but are much lighter with better chemical resistance and color possibilities.

Other Types. Other types of thermoplastics include cellular acetate, which is used as a core material in constructions; expanded acrylics, which have good physical properties, thermal insulation, and chemical resistance; expanded nylon (and expanded ABS), which are low-density, solid-skin constructions; expanded PVA, which has similar properties to expanded polystyrene; and expanded polypropylene, which gives high-density foams.

Thermosets

Phenolics. These can be formed *in situ*. They have good rigidity, thermal insulation, and high service temperature, but are brittle.

Urea Formaldehyde (UF) Foam. This is readily formed *in situ* and has good thermal insulation. It has open pores and is used for cavity-wall filling.

Expanded Epoxies. These have limited use because of their high cost. They give a uniform texture and good dimensional stability and are used for composite forms, e.g., with polystyrene beads.

Silicon Foams. These are rigid and brittle with a high service temperature (300°C; 400°C intermittent use). Their use is limited to high-temperature-resistant sandwich constructions. The flexible closed-cell type is costly but will operate up to 200°C and is used for high-temperature seals and gaskets.

Elastomers

Cellular Rubbers. There are three types: *sponge*, solid rubber blown to give an open-cell structure, *foam*, a liquid rubber expanded to form open or closed cells which is stiffer than sponge; and *expanded*, a solid rubber blown with mainly closed cells, also it is stiffer than sponge. Uses include gaskets, seals, thermal insulation, cushioning, shock absorption, sound and vibration damping, buoyancy, and sandwich constructions.

© 1999 by CRC Press LLC

Elastomers

Elastomers, or rubbers, are essentially amorphous polymers with linear chain molecules with some cross-linking, which ensures elasticity and the return of the material to its original shape when a load is removed. They are characterized by large strains (typically 100%) under stress. The synthetic rubber styrene butadiene is the most-used elastomer, with natural rubber a close second. The following describes the commonly used elastomers and gives some applications and properties.

Natural Rubbers (Polyisoprene, NR)

These elastomers have high strength, flexibility, and resilience, but have poor resistance to fuels, oils, flame, and sunlight aging. They are more costly than synthetic rubbers, which often replace them. "Soft-rubber" contains 1 to 4% sulfur as a vulcanizer. Wear resistance is increased by inclusion of fillers such as carbon black, silicon dioxide, clay, and wood flour. "Hard rubber" may contain up to 25% sulfur. Applications include vehicle tires and tubes, seals, antivibration mountings, hoses, and belts. Full vulcanization of 45% produces ebonite. Shore hardness: 30 to 90. Temperature range: –55 to 82°C.

Synthetic Rubbers

Styrene Butadiene Rubbers (SBR, GRS, BUNAS). These are similar to natural rubbers in application, but are usually inferior in mechanical properties, although cheaper. They are used in car brake hydraulic systems and for hoses, belts, gaskets, and antivibration mountings. Shore hardness: 40 to 80. Temperature range: –50 to 82°C.

Butadiene Rubbers (Polynutadiene, BR). These are used as substitutes for natural rubber, but are generally inferior. They have similar applications as natural rubber. Shore hardness: 40 to 90. Temperature range: –100 to 93°C.

Butyl Rubbers (Isobutylene Isoprene, GR 1). These are extremely resistant to water, silicon fluids and grease, and gas permeation. They are used for puncture-proof tires, inner tubes, and vacuum seals. Shore hardness: 40 to 90. Temperature range: –45 to 150°C.

Nitrile Rubbers (Butadiene Acrylonitrile, BUNA, N.NBR). These have good physical properties and good resistance to fuels, oils, solvents, water, silicon fluids, and abrasion. They are used for O rings and other seals, petrol hoses, fuel-pump diaphragms, gaskets, and oil-resistant shoe soles. Shore hardness: 40 to 95. Temperature range: –55 to 82°C.

Neoprene Rubbers (Polychloroprene, Chloroprene). These are some of the best general-purpose synthetic rubbers. They have excellent resistance to weather aging, moderate resistance to oils, and good resistance to refrigerants and mild acids. Shore hardness: 40 to 95. Temperature range: –40 to 115°C.

Chlorosulfonated Polyethylene Rubbers (CSM). These have poor mechanical properties but good resistance to acids and heat with complete resistance to ozone. They are used in chemical plants, tank linings, and high-voltage insulation. Shore hardness: 45 to 100. Temperature range: –100 to 93°C.

Ethylene Propylene Rubbers (EP, FPM). These specialized rubbers are especially resistant to weather aging heat, many solvents, steam, hot water, dilute acids and alkalis, and ketones, but not petrol or mineral oils. They are used for conveyor belts, limited automotive applications, silicone fluid systems, and electrical insulation. Shore hardness: 40 to 90. Temperature hardness: –50 to 177°C.

Fluorocarbon Rubbers. These comprise a wide range of rubbers with excellent resistance to chemical attack, heat, acids, fuels, oils, aromatic compounds, etc. They have a high service temperature. They are particularly suitable for vacuum applications. Shore hardness: 60 to 90. Temperature hardness: –23 to 260°C.

Isoprenes (Polyisoprene, IR). These are chemically the same as natural rubber but are more costly. The properties and applications are similar to those of natural rubber. Shore hardness: 40 to 80. Temperature hardness: –50 to 82°C.

Polyacrylic Rubbers (ACM, ABR). This is a group of rubbers with properties midway between nitrile and fluorocarbon rubbers with excellent resistance to mineral oils, hypoid oils, and greases and good resistance to hot air and aging. The mechanical strength is low. They are often used for spark plug seals and transmission seals. Shore hardness: 40 to 90. Temperature hardness: –30 to 177°C.

© 1999 by CRC Press LLC

Polysulfide Rubbers. These have poor physical properties and heat resistance, but good resistance to oils, solvents, and weathering and are impermeable to gases and moisture. They are used for caulking and sealing compounds and as a casting material. Shore hardness: 40 to 85. Temperature hardness: –50 to 121°C.

Polyurethane Rubbers. These have exceptional strength and tear and abrasion resistance (the best of all rubbers), low-temperature flexibility, and good resistance to fuels, hydrocarbons, ozone, and weather. Resistance to solutions of acids and alkalis, hot water, steam, glycol, and ketones is poor. They are used for wear-resistant applications such as floor coverings. Shore hardness: 35 to 100. Temperature hardness: –53 to 115°C.

Silicone Rubbers (SI). These have exceptionally high service-temperature ranges, but the mechanical properties and chemical resistance are poor. They cannot be used in applications which expose them to fuels, light mineral oils, or high-pressure steam. They are used for high- and low-temperature seals, high-temperature rotary seals, cable insulation, hydraulic seals, and aircraft door and canopy seals. Shore hardness: 30 to 90. Temperature hardness: –116 to 315°C (380°C for intermittent use).

Fluorosilicone Rubbers. These are similar to silicone rubbers but have better oil resistance and a lower temperature range. Shore hardness: 40 to 80. Temperature hardness: –64 to 204°C.

12.3 Adhesives

Richard L. Lehman

Introduction

Adhesives are substances capable of holding materials together in a useful manner by surface attachment. The principal attribute of adhesives is their ability to form strong bonds with surfaces of a wide range of materials and to retain bond strength under expected use conditions. Although most adhesives do not have excellent bulk properties and it is therefore important to keep adhesive films thin, some materials such as epoxies have bulk properties which qualify them as engineering materials and thus can be used in multifunctional applications.

Advantages and Limitations of Use

The principal advantages of adhesives are their ability to bond similar to dissimilar materials of different thickness; to enable the fabrication of complex shapes not feasible by other fastening means; to smooth external joint surfaces; to permit economic and rapid assembly; to distribute stresses uniformly over joined interfaces, to provide weight reduction in critical structures via the elimination of fasteners; to dampen vibrations; to prevent or reduce galvanic corrosion; and to provide thermal and electrical insulation.

The limitations of adhesives depend on the specific adhesive and application and may include the necessity of surface preparation, long curing times, service-temperature limitations, loss of properties during service, toxicity of flammability during assembly or use, and the tendency of many adhesives to creep under sustained load.

Classes of Adhesives

Thermoplastic adhesives are a general class of adhesives based upon long-chained polymeric structure, and are capable of being softened by the application of heat with subsequent hardening upon cooling (hot-melt adhesives). The softening process if reversible for numerous cycles, which facilitates assembly and disassembly of structures. Thermosetting adhesives are a general class of adhesives based upon cross-linked polymeric structures which develop strong bonds that cannot be reversibly broken once they are formed. Thus, the thermoset adhesives are incapable of being softened once solidified.

Thermoplastic and thermosetting adhesives are cured, a process often referred to as setting, by polymerization or solidification, by heat, catalysis, chemical reaction, free-radical activity, radiation, evaporation of solvent, or another process as governed by the chemical nature of the particular adhesive.

Elastomers are a special class of thermoplastic adhesive possessing the common quality of substantial flexibility or elasticity. Refer to Section 12.2 on polymers.

Anaerobic adhesives are a special class of thermoplastic adhesive, the polyacrylates, that set only in the absence of air (oxygen). The two basic types are (1) machinery — possessing shear strength only and (2) structural — possessing both tensile and shear strength.

Pressure-sensitive adhesives are permanently and aggressively tacky solids which form immediate bonds when two parts are brought together under pressure. They are available as films and tapes as well as hot-melt systems.

Performance of Adhesives

To obtain optimum mechanical performance of an adhesive, it is critical to select the proper compound for the target application. Table 12.3.1 illustrates compatibility of adhesives and five broad classes of common materials. Generally, for good adhesive bonds the chemistry of the adhesive must match or be

TABLE 12.3.2 High-Performance Engineering and Machine Part Adhesives

Thread locking	• Anaerobic acrylic
Hub mounting	• Anaerobic acrylic — compatible materials or flow migration unimportant
	• Modified acrylic — large gaps or migration must be avoided
	• Epoxy — maximum strength at high temperatures
Bearing mounting	• Anaerobic acrylic — compatible materials necessary and flow into bearing area to be prevented
	• Modified acrylic — for lowest cost
Structural joining	• Epoxies and modified epoxies — for maximum strength (highest cost)
	• Acrylics — anaerobic or modified cyanacrylates
Gasketing	• Silicones — primarily anaerobic

similar to the surface energy, polarity, and/or chemistry of the material being bonded. The elastic modulus of the adhesive should not be greater than the bonded material.

Adhesives are used in two classes of application, those requiring only shear strength and those requiring structural properties, often tensile and shear strength. Table 12.3.2 provides a quick reference for some typical applications. A much more detailed summary and classification of adhesives is given in Table 12.3.3.

Table 12.3.3 presents a sample of a number of adhesives (with practical information) that are available from various sources. The table is adapted from the rather extensive one found in J. Shields, *Adhesives Handbook*, CRC Press, Boca Raton, FL, 1970. For other extensive lists of trade sources, the reader is

TABLE 12.3.3 Properties and Applications of Adhesive Materials

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
			Animal		
Animal (hide)	Melted at 70–75°C; sets on cooling	<70	Paper, wood, textiles	Woodworking, carpet materials, paper, bookbinding	May be thinned with water
Animal (hide) + plasticizers	Applied as a melt at 60°C	<60	Paper, cellulosic materials	Bookbinding, stationery applications	Cures to permanent flexible film
Fish glue	1 hr at 20°C	<60	Wood, chipboard, paper	General-purpose for porous materials	Rapid setting; good flexibility, moderate resistance to water; high tack
Casein	Cold setting after 20 min standing period on mixing	<50	Timber with moisture content	Laminated timber arches and beams, plybox beams, and engineering timber work	Full bond strength developed after seasoning period of 48 hr
Casein + 60% latex	Cold setting after 20 min standing period on mixing	<60	Aluminum, wood, phenolic formaldehyde (rigid, leather, rubber)	Bonding of dissimilar materials to give flexible, water-resistant bond	Flexible
			Vegetable		
Dextrine	Air drying		Paper, cardboard, leather, wood, pottery	General-purpose glue for absorbent materials	Medium drying period of 2–3 hr
Dextrine–starch blend	Applied above 15°C air drying	<48	Cellulosic materials, cardboard, paper	Labeling, carton sealing, spiral-tube winding	Fast setting; may be diluted with water
Gum arabic	Cold setting	<50	Paper, cardboard	Stationery uses	Fast drying
			Mineral		
Silicate	8 hr at 20°C	10–430	Asbestos, magnesia	Lagging asbestos cloth on high-temperature insulation	Unsuitable where moisture; not recommended for glass or painted surfaces

TABLE 12.3.3 Properties and Applications of Adhesive Materials (continued)

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
Silicate with china-clay filler	Dried at 80°C before exposure to heat	–180–1500	Asbestos, ceramics, brickwork, glass, silver, aluminum, steel (mild)–steel	General purpose cement for bonding refractory materials and metals; furnace repairs and gastight jointing of pipe work; heat-insulating materials	Resistant to oil, gasoline, and weak acids
Sodium silicate	Dried at 20–80°C before exposure to heat	0–850	Aluminum (foil), paper, wood–wood	Fabrication of corrugated fiber board; wood bonding, metal foil to paper lamination	Suitable for glass-to-stone bonding
Aluminum phosphate + silica filler	Dried $^1/_2$ hr at 20°C, then $^1/_2$ hr at 70°C + $^1/_2$ hr at 100°C + 1 hr at 200°C + 1 hr at 250°C; repeat for two overcoatings and finally cure at 1 hr at 350°C	<750	Steels (low-alloy), iron, brass, titanium, copper, aluminum	Strain-gauge attachment to heat-resistant metals; heater-element bonding	Particularly suited to heat-resistant steels where surface oxidation of metal at high temperatures is less detrimental to adhesion
Bitumen/latex emulsion	Dried in air to a tacky state	0–66	Cork, polystyrene (foam), polyvinyl chloride, concrete, asbestos	Lightweight thermal-insulation boards, and preformed sections to porous and nonporous surfaces; building applications	Not recommended for constructions operated below 0°C
			Elastomers		
Natural rubber	Air dried 20 min at 20°C and heat-cured 5 min at 140°C	<60	Rubber (styrene butadiene), rubber (latex), aluminum, cardboard, leather, cotton	Vulcanizing cement for rubber bonding to textiles and rubbers	May be thinned with toluene
Natural rubber in hydrocarbon solvent	Air dried 10 min at 20°C and heat-cured for 20 min at 150°C	<100	Hair (keratin), bristle, polyamide fiber	Brush-setting cement for natural- and synthetic-fiber materials	Resistant to solvents employed in oil, paint and varnish industries, can be nailed without splitting
Rubber latex	Air drying within 15 min	<60	Canvas, paper, fabrics, cellulosic materials	Bonding textiles, papers packaging materials; carpet bonding	Resistant to heat; should be protected from frosts, oils

TABLE 12.3.3 Properties and Applications of Adhesive Materials (continued)

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
Chlorinated rubber in hydrocarbon solvents	Air dried 10 min at 20°C and contact bonded	–20–60	Polyvinyl chloride, acrylonitrile butadiene styrene, polystyrene, rubber, wood	General-purpose contact adhesive	Resistant to aging, water, oils, petroleum
Styrene–butadene rubber lattices	Air drying	–20–60	Polystyrene (foam), wood, hardboard, asbestos, brickwood	Bonding polystyrene foams to porous surface	—
Neoprene/nitrile rubbers in (?)	Dried 30 min in air and bonded under pressure; tacky	–20–60	Wood, linoleum, leather, paper, metals, nitrile rubbers, glass, fabrics	Cement for bonding synthetic rubbers to metals, woods, fabrics	May be thinned with ketones
Acrylonitrile rubber + phenolic resin	Primer air dried 60 min at 20°C, film cured 60 min at 175°C under pressure; pressure released on cooling at 50°C	–40–130	Aluminum (alloy)–aluminum to DTD 746	Metal bonding for structural applications at elevated temperatures	Subject to creep at 150°C for sustained loading
Polysulfide rubber in ketone solvent and catalyst	3 days at 25°C	–50–130, withstands higher temperatures for short periods	Metals	Sealant for fuel tanks and pressurized cabins in aircraft, where good weatherproof and waterproof properties are required	Resistant to gasoline, oil, hydraulic fluids, ester lubricants; moderate resistance to acids and alkalis
Silicone rubber	24 hr at 20°C (20% R.H.); full cure in 5 days	–65–260	Aluminum, titanium, steel (stainless), glass, cork, silicone rubber, cured rubber–aluminum, cured rubber–titanium, cured rubber–steel (stainless), aluminum–aluminum (2024 Alclad), cork–cork (phenolic bonded)	General-purpose bonding and scaling applications; adhesive/sealant for situations where material is expected to support considerable suspended weight; high-pressure exposure conditions	Resistant to weathering and moisture
Reclaim rubber	Contact bonded when tacky	<50	Fabric, leather, wood, glass, metals (primed)	General industrial adhesive for rubber, fabric, leather, porous materials	May be thinned with toluene
Polychloroprene	Air dried 10–20 min at 20°C	<60	Rubber, steel, wood, concrete	Bonding all types of rubber flooring to metals, woods, and masonry	Good heat resistance

© 1999 by CRC Press LLC

TABLE 12.3.3 Properties and Applications of Adhesive Materials (continued)

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
Modified polyurethane	3 hr at 18°C to 16 hr at –15°C	–80–110	Concrete, plaster, ceramics, glass, hardboards, wood, polyurethane (foam), phenol formaldehyde (foam), polystyrene (foam), copper, lead, steel, aluminum	Bonding to rigid and semirigid panels to irregular wall surfaces, wall cladding and floor laying; building industry applications	Foam remains flexible on aging even at elevated temperatures; will withstand a 12% movement
			Thermoplastic		
Nitrocellulose in ester solvent	Heat set 1 hr at 60°C after wet bonding	60	Paper, leather, textiles, silicon carbide, metals	Labeling, general bonding of inorganic materials including metals	Good resistance to mineral oils
Modified methyl cellulose	Dries in air	<50	Vinyl-coated paper, polystyrene foam	Heavy-duty adhesive; decorating paper and plastics	Contains fungicide to prevent biodeterioration
Ethylene vinyl acetate copolymer + resins	Film transfer at 70–80°C followed by bonding at 150–160°C	60, or 1 hr at 90	Cotton (duck)–cotton, resin rubber–leather, melamine laminate–plywood, steel (mild)–steel, acrylic (sheet) acrylic	Metals, laminated plastics, and textiles; fabrication of leather goods; lamination work	Good electrical insulation
Polyvinyl acetate	Rapid setting	<60	Paper, cardboard	Carton sealing in packaging industry	Resistant to water
Synthetic polymer blend	Applied as a melt at 177°C	<70	Paper, cardboard, polythene (coated materials)	Carton and paperbag sealing; packaging	—
Polychloroprene/resin blend in solvent	Air dried 10 min at 20°C and cured 4 days at 20°C to 7 hr at 75°C	<70	Chlorosulfonated polythene, polychloroprene fabrics, polyamide fabrics, leather, wood, textiles	Bonding synthetic rubbers and porous materials; primer for polyamide-coated fabrics such as nylon, terylene	—
Polychloroprene	Air dried 10–20 min at 20°C	—	Rubber, steel, wood, concrete	Bonding all types of rubber flooring to metals, woods, and masonry	Good heat resistance
Saturated polyester + isocyanate catalyst in ethyl acetate	Solvent evaporation and press cured at 40–80°C when tacky	—	Cellulose, cellulose acetate, polyolefins (treated film), polyvinyl chloride (rigid), paper, aluminum (foil), copper (foil)	Lamination of plastic films to themselves and metal foils for packaging industry, printed circuits	Resistant to heat, moisture, and many solvents

TABLE 12.3.3 Properties and Applications of Adhesive Materials (continued)

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
Cyanoacrylate (anaerobic)	15 sec to 10 min at 20°C substrate dependent	Melts at 165	Steel–steel, steel–aluminum, aluminum–aluminum, butyl rubber–phenolic	Rapid assembly of metal, glass, plastics, rubber components	Anaerobic adhesive. Curing action is based on the rapid polymerization of the monomer under the influence of basic catalysts; absorbed outer layer on most surfaces suffices to initiate polymerization and brings about bonding
Polyacrylate resin (anaerobic)	3 min at 120°C to 45 min at 65°C or 7 days at 20°C	–55–95	Aluminum–aluminum	Assembly requirements requiring high resistance to impact or shock loading; metals, glass and thermosetting plastics	Anaerobic adhesive
			Thermosetting		
Urea formaldehyde	9 hr at 10°C to 1 hr at 21°C after mixing powder with water (22%)	<90	Wood, phenolic laminate	Wood gluing and bonding on plastic laminates to wood; plywood, chipboard manufacture; boat building and timber engineering	Excess glue may be removed with soapy water
Phenolic formaldehyde + catalyst PX-12	Cold acting	<100	Wood	Timber and similar porous materials for outdoor-exposure conditions; shop fascia panels	Good resistance to weathering and biodeterioration
Resorcinol formaldehyde + catalyst RXS-8	Cured at 16–80°C under pressure	<100	Wood, asbestos, aluminum, phenolic laminate, polystyrene (foam), polyvinyl chloride, polyamide (rigid)	Constructional laminates for marine craft; building and timber applications; aluminum–plywood bonding; laminated plastics	Recommended for severe outdoor-exposure conditions
Epoxy resin + catalyst	24–48 hr at 20°C to 20 min at 120°C	100	Steel, glass, polyester–glass fiber composite, aluminum–aluminum	General-purpose structural adhesive	—

© 1999 by CRC Press LLC

TABLE 12.3.3 Properties and Applications of Adhesive Materials (continued)

Basic Type	Curing Cycle, Time at Temperature	Service Temperature Range, C	Adherends	Main Uses	Remarks
Epoxy resin + catalyst	8 hr at 24°C to 2 hr at 66°C to 45 min at 121°C	65	Steel, copper, zinc, silicon carbide, wood, masonry, polyester–glass fiber composite, aluminum–aluminum	Bonding of metals, glass, ceramics, and plastic composites	Cures to strong, durable bond
Epoxy + steel filler (80% w/w)	1–2 hr at 21°C	120	Iron, steel, aluminum, wood, concrete, ceramics, aluminum–aluminum	Industrial maintenance repairs; metallic tanks, pipes, valves, engine castings, castings	Good resistance to chemicals, oils, water
Epoxy + amine catalyst (ancamine LT)	2–7 days at 20°C for 33% w/w catalyst content	–5–60	Concrete stonework	Repair of concrete roads and stone surfaces	Excellent pigment-wetting properties; effective underwater and suited to applications under adverse wet or cold conditions
Epoxy resin (modified)	4–5 hr at 149°C to 20 min at 230°C to 7 min at 280°C	150	Aluminum, steel, ceramics	One-part structural adhesive for high-temperature applications	Good gap-filling properties for poorly fitting joints; resistant to weather, galvanic action
Epoxy	45 sec at 20°C	—	Gem stones, glass, steel, aluminum–aluminum	Rapid assembly of electronic components, instrument parts, printed circuits; stone setting in jewelry and as an alternative to soldering	—
Epoxy resin in solvent + catalyst	8 hr at 52°C to $^1/_2$ hr at 121°C	–270–371	Aluminum and magnesium alloys for elevated-temperature service	Strain gauges for cryogenic and elevated-temperature use; micromeasurement strain gauges	Cured material resists outgassing in high vacuum
Epoxy polyamide	8 hr at 20°C to 15 min at 100°C	100	Copper, lead, concrete, glass, wood, fiberglass, steel–steel aluminum–aluminum	Metals, ceramics, and plastics bonding; building and civil engineering applications	Resists water, acids, oils, greases

12.4 Wood

Daniel J. Strange

Definition

Wood is the structural component of a tree. It is composed of dead cells which were originally formed near the cambium (just beneath the bark). As the tree grows, the cambium moves outward, leaving the dead cells behind to serve as structure.

The two broad classifications for types of wood and softwoods and hardwoods. Softwoods come from conifers while hardwoods come from deciduous trees, and as the name implies softwoods are generally softer and hence weaker and with lower elastic modulus than hardwoods, although this generalization is not universally true.

The wood closest to the bark is called sapwood, and this layer extends about an inch into the tree. Although most of the cells in this layer are dead, this is the layer which transports moisture to the rest of the tree by capillary action. Beneath the sapwood layer is the heartwood, which is almost totally inactive except to provide structural support.

Composition

Wood is a fibrous cellular material with the cell walls composed primarily of cellulose, hemicellulose, and lignin. Cellulose is a linear polymer of glucose units and is the single most common organic chemical in nature. It accounts for roughly 40 to 50% of the wood by weight. Hemicellulose is a modified form of cellulose comprising approximately 30% of the cell wall whose structure can vary depending upon the exact type of wood. Lignin is a complex three-dimensional phenolic polymer which composes 20 to 30% of the structure of the wood. The rest of the weight of the wood is composed primarily of extraneous extractive substances which reside within the cellular structure and affect properties such as specific gravity, moisture absorption, and durability.

Variations in the compositions, structures, and volumes of these four components can have dramatic effects on the properties of the wood. These properties are relatively constant within a species, although growing conditions can have a significant influence.

Mechanical Properties

The properties of wood can vary substantially depending upon moisture content. “Green” wood, wood taken directly from a living tree with associated high moisture level, is significantly weaker (lower Young’s modulus, tensile strength, and compressive strength) than oven-dried wood. Typical ratios of dry to green wood strength properties vary from 1.2 to 1.8.

The failure modes of wood are more complex than one might expect. Because wood is essentially a composite material, it does not follow Hooke’s law at high stresses but instead exhibits viscoelastic behavior. Figure 12.4.1 shows typical stress–strain curves for wood in tension and compression. At very high stresses, creep can occur. Wood is strongest in tension parallel to the grain, on the order of 100 MPa for a typical softwood. Perpendicular to the grain this value drops to about 4 MPa. In compression the strength values are approximately half the tension values, due to the collapse of the cellular structure and buckling of the wood fibers.

There are three principal shear failure modes in wood, six if one distinguishes between the radial and tangential directions. These modes are shear perpendicular to grain, shear parallel to grain, and rolling shear. Rolling shear occurs when the failure plane is parallel to the grain but the sliding direction is perpendicular to the grain, hence the fibers “roll” over each other. Wood is strongest when the shear is perpendicular to the grain, and weakest in rolling shear.

© 1999 by CRC Press LLC

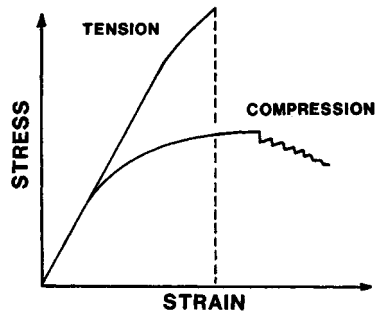

FIGURE 12.4.1 Stress–strain behavior of wood in tension and compression. Stress–strain curves for wood in tension and compression parallel to grain. Signs of stress and strain have been ignored so that both may be plotted together. Note particularly the difference in strength and in the extent of the nonlinear deformation prior to maximum stress.

Decay Resistance

Totally dry wood does not decay. Furthermore, wood kept completely submerged will not decay significantly. Wood decays most rapidly in warm, humid, low-altitude areas. Some species of wood are more decay resistant than others as a result of the presence of extractives. White oak, walnut, cherry, cedar, and yew are examples of highly decay-resistant woods. Pines, willows, elms, beeches, and spruces are examples of low decay-resistant woods.

Composites

By gluing wood plies, chips, fibers, or pulp together a composite material can be formed which has more isotropic and homogenous properties than regular timber. In addition, this technique creates a strong and durable product out of wood unsuitable for timber. In general, wood composites homogenize the extreme anisotropy of timber into a nearly isotropic material whose properties are an average of the properties in each direction of the original timber. Table 12.4.1 classifies the various wood composites based upon the constitutive particle and the binder.

The most common wood composite is paper. Paper is made from pulped and chemically treated cellulose fibers, which is then rolled into sheets, pressed, and dried. There is no glue involved, as the microfibrils of the cellulose interlock and form hydrogen bonds. Fiberboard is similar to paper, only thicker (by an arbitrary value, typically 0.012 in.) and with larger fiber bundles. *Hardboard* simply refers to a high-density fiberboard.

Wood chips and/or sawdust pressed and glued together is referred to as *particleboard*. Typically, the chips range in size from 10 to 300 mm long and are in the form of flakes or fibers. Particleboard is effectively isotropic, easily machineable, and inexpensive. It is often used in furniture and for floor underlayment. When larger wood chips are used the product is referred to as *flakeboard*.

Plywood is created by layering plies of radial-cut wood. Typically, the plies are oriented at 90° to each other, which results in a strong material when the stress in parallel or perpendicular to the grain of the face plies, but a lesser strength at any other angle. Some design strength specifications of plywood are given in Table 12.4.2. Plywood makes efficient use of timber due to its radial cut, minimizes the effects of imperfections, resists warping, and can be formed into large sheets. Plywood is also less expensive than clear lumber.

The reader is referred to Table C.14 in the Appendix for an overview of the physical properties and uses of American woods. The table also contains recommendations for appropriate applications. Table E.1 in the Appendix gives nominal sizes for lumber and timber, as well as allowable stresses in tension and compression and moduli of elasticity of various kinds of woods.

12.5 Portland Cement Concrete

Steven H. Kosmatka

Introduction

Portland cement concrete is a simple material in appearance with a very complex internal nature. In contrast to its internal complexity, versatility, durability, and economy of concrete have made it the most-used construction material in the world. This can be seen in the variety of structures it is used in, from highways and bridges to buildings and dams.

Concrete is a mixture of portland cement, water, and aggregates, with or without admixtures. The portland cement and water form a paste that hardens as a result of a chemical reaction between the cement and water. The paste acts as a glue, binding the aggregates (sand and gravel or crushed stone) into a solid rocklike mass. The quality of the paste and the aggregates dictate the engineering properties of this construction material. Paste qualities are directly related to the amount of water used in relation to the amount of cement. The less water that is used, the better the quality of the concrete. Reduced water content results in improved strength and durability and in reduced permeability and shrinkage. As the fine and coarse aggregates make up 60 to 75% of the total volume of the concrete (Figure 12.5.1), their selection is important. The aggregates must have adequate strength and resistance to exposure conditions and must be durable.

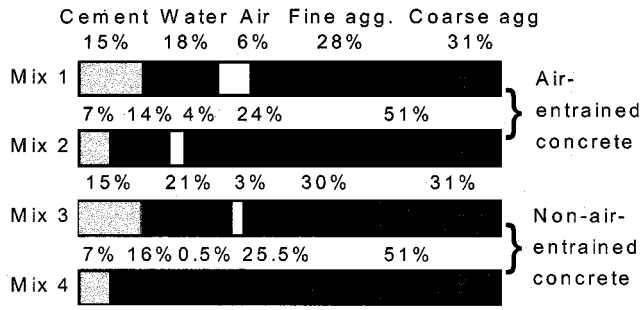

FIGURE 12.5.1 Range of proportions of materials used in concrete. (From *Design and Control of Concrete Mixtures*, EB001, Portland Cement Association, Skokie, IL, 1992. With permission.)

Fresh Concrete Properties

Freshly mixed concrete should be in a semifluid state capable of being molded by hand or mechanical means. All the particles of sand and coarse aggregate are encased and held in suspension. The ingredients should not segregate or separate during transport or handling. After the concrete hardens, it becomes a homogeneous mixture of all the components. Concrete of plastic consistency should not crumble, but flow sluggishly without segregation.

Concrete must be consolidated to form a homogeneous mass without the presence of large voids to achieve the desired strength and durability of the construction material. Internal and external vibration of concrete using vibrators allows stiff, slow-slump mixtures to be properly densified. The use of mechanical vibration provides an economical, practical method to quickly consolidate concrete without detrimentally affecting its properties.

Hardened Concrete Properties

Strength

Concrete gains strength by the reaction between cement and water — called hydration. Portland cement is primarily a calcium silicate cement. The calcium silicate combines with water and forms calcium

© 1999 by CRC Press LLC

silicate hydrate, which is responsible for the primary engineering properties of concrete, such as setting, hardening, strength, and dimensional stability. The compressive strength of concrete increases with age as long as an appropriate moisture content and temperature are available. This is illustrated in Figure 12.5.2. Compressive strength is usually specified at the age of 28 days; however, depending on the project, ages of 3 and 7 days can also be specified. For general-use concrete, a 28-day compressive strength between 20 and 40 MPa (3000 and 6000 psi) is used. 28 MPa (4000 psi) is most common. Higher-strength concrete, 50 to 140 MPa (7000 to 20,000 psi), is used in special applications to minimize structural dimensions, increase abrasion resistance and durability, and minimize creep (long-term deformation).

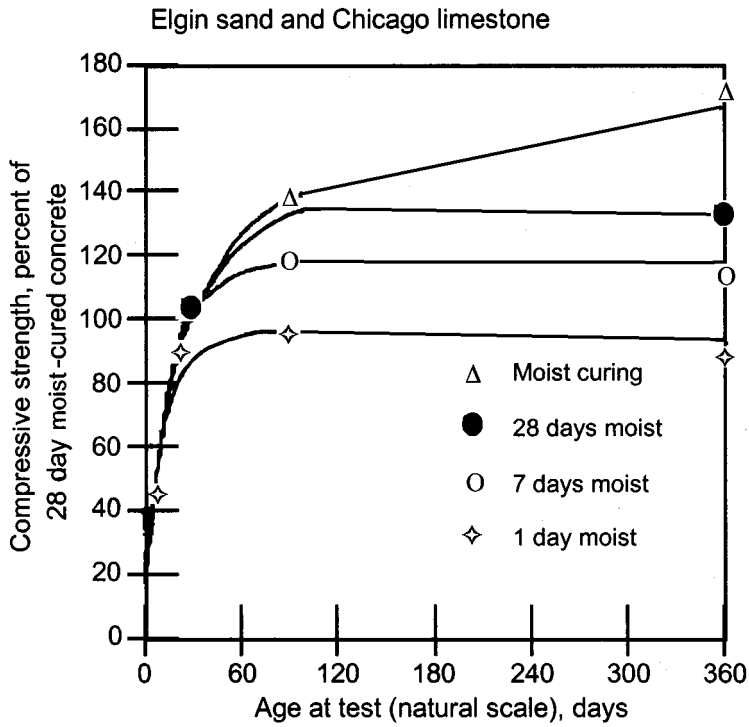

FIGURE 12.5.2 Concrete strength increases with age as long as moisture and a favorable temperature are present.

Increase in strength with age continues as long as any unhydrated cement is still present, the relative humidity in the concrete is approximately 80% or higher, and the concrete temperature is favorable. In order to maintain this increase in strength, concrete must be properly cured. Curing means that not only will a favorable temperature be present, but also moisture loss will not be permitted or extra water will be provided at the surface.

The compressive strength of concrete is directly related to the water/cement ratio. A decrease in water/cement ratio results in higher strength. Concrete achieves about 70 to 75% of its 28-day strength in 7 days. Although concrete is very strong in compression, it is weak in tensile strength. Tensile strength is about 8 to 12% of the compressive strength. Flexural strength is 0.7 to 0.8 times (for English units 5 to 7.5 times) the square root of the compressive strength. Shear strength is about 20% of the compressive strength. Modulus of elasticity ranges from 14,000 to 41,000 MPa and can be estimated as 5000 times the square root of the compressive strength (2 to 6 million psi or 57,000 times the square root of the compressive strength in English units). Refer to Tables 12.5.1, 12.5.2, and 12.5.3.

TABLE 12.5.1 Typical Properties of Normal-Strength Portland Cement Concrete

Compressive strength	20–40 MPa (3000–6000 psi)
Flexural strength	3–5 MPa (400–700 psi)
Tensile strength	2–5 MPa (300–700 psi)
Modulus of elasticity	14,000–41,000 MPa (2–6 million psi)
Permeability	1×10^{-10} cm/sec
Coefficient of thermal expansion	10^{-5}/°C (5.5×10^{-6}/°F)
Drying shrinkage	$4–8 \times 10^{-4}$
Drying shrinkage of reinforced concrete	$2–3 \times 10^{-4}$
Poisson's ratio	0.20–0.21
Shear strain	6000–17,000 MPa (1–3 million psi)
Density	2240–2400 kg/m^3 (140–150 lb/ft^3)

Density

Normal-weight concrete has a density of 2240 to 2400 kg/m^3 (140 to 150 lb/ft^3). The density of concrete varies with the relative density of the aggregate, the amount of air present in the paste, and the amount of water and cement in the mixture.

Permeability

Concrete permeability is a function of the permeability of the paste and aggregate and the interface between them. Decreased permeability improves the resistance of concrete to saturation, sulfate attack, chemical attack, and chloride penetration. Paste permeability has the greatest influence on concrete permeability. Paste permeability is directly related to the water/cement ratio and the degree of hydration or length of moist curing. A low water cement ratio and an adequate moist-curing period result in concrete with low permeability (Figure 12.5.3). The water permeability of mature, good-quality concrete, is approximately 1×10^{-10} cm/sec.

Abrasion Resistance

Abrasion resistance is directly related to the compressive strength of the concrete. The type of aggregate and the surface finish also have a strong influence on abrasion resistance. A hard aggregate, such as a granite, would provide more abrasion resistance than a soft limestone aggregate.

Volume Change and Crack Control

Concrete changes slightly in volume for various reasons. Understanding the nature of these changes is useful in planning concrete work and preventing cracks from forming. If concrete is free to move, normal volume changes would have very little consequence; but since concrete in service is usually restrained by foundations, subgrades, reinforcement, or connecting elements, significant stresses can develop. As the concrete shrinks, tensile stresses develop that can exceed the tensile strength of the concrete, resulting in crack formation.

The primary factors affecting volume change are temperature and moisture changes. Concrete expands slightly as temperature rises and contracts as temperature falls. The average value for the coefficient of thermal expansion of concrete is about 1.0×10^{-5}/°C (5.5×10^{-6}/°F). This amounts to a length change of 5 mm for a 10-m length (0.66 in. for 100 ft) of concrete subjected to a rise or fall of 50°C (100°F). The thermal coefficient of expansion for steel is about 1.2×10^{-5} per degree Celsius (6.5×10^{-6}/°F), comparable to that of concrete. The coefficient for reinforced concrete can be assumed as 1.1×10^{-5}/°C (6×10^{-6}/°F).

Concrete expands slightly with a gain in moisture and contracts with a loss in moisture. The drying-shrinkage of concrete specimens ranges from 4 to 8×10^{-4} when exposed to air at a 50% relative humidity. Concrete with a unit shrinkage of 5.5×10^{-4} shortens about the same amount as a thermal contraction caused by a decrease in temperature of 55°C (100°F). The shrinkage of reinforced concrete is less than that for plain concrete because of restraint offered by the reinforcement. Reinforced concrete structures with normal amounts of reinforcement have a drying-shrinkage in the range of 2 to 3×10^{-4}.

The amount of shrinkage is directly related to the amount of water in the concrete. Higher water content results in higher shrinkage. Specimen size also has an effect. Larger specimens shrink less than small specimens.

Drying-shrinkage is an inherent and unavoidable property of concrete; therefore, properly positioned reinforcing steel is used to reduce crack widths or joints are used to predetermine or control the location of cracks. Shrinkage control joints should be spaced about 25 to 30 times the thickness of a concrete slab on ground.

Deformation and Creep

Concrete will deform a small amount when a load is placed on it. When concrete is loaded, the deformation caused by the load can be divided into two parts: a deformation that occurs immediately, such as elastic strain, and a time-dependent deformation that begins immediately but continues at a decreasing rate for as long as the concrete is loaded (Figure 12.5.4). This latter deformation is called creep. The amount of creep is dependent on the magnitude of the stress, the age and strength of the concrete when the stress is applied, and the length of time the concrete is stressed. Creep is of little concern for normal concrete pavements, bridges, and small buildings; however, creep should be considered in design for very tall buildings or very long bridges.

Concrete Ingredients

Portland Cements

Portland cements are hydraulic cements; that is, they set and harden by reacting with water. This reaction, called hydration, combines water and cement to form a stonelike mass. Portland cement was invented in 1824 by an English mason, Joseph Aspdin, who named his product portland cement because it produced a concrete that was of the same color as natural stone on the Isle of Portland in the English Channel.

Portland cement is produced by combining appropriate proportions of lime, iron, silica, and alumina and heating them. These raw ingredients are fed into a kiln that heats the ingredients to temperatures of 1450 to 1650°C (2600 to 3000°F) and changes the raw materials chemically into cement clinker. The clinker is cooled and then pulverized. During this operation a small amount of gypsum is added to control the setting of the cement. The finished pulverized product is portland cement. Portland cement is essentially a calcium silicate cement.

The American Society for Testing and Materials (ASTM) Standard C 150, Specification for Portland Cement, provides for the following types of portland cement:

Type I	General portland cement
Type II	Moderate-sulfate-resistant cement
Type III	High-early-strength cement
Type IV	Low–heat-of-hydration cement
Type V	High-sulfate-resistant cement

Types I, II, and III may also be designated as being air entraining. Type I portland cement is a general cement suitable for all uses where special properties of other cements are not required. It is commonly used in pavements, building, bridges, and precast concrete products.

Type II portland cement is used where precaution against moderate sulfate attack is important where sulfate concentrations in groundwater or soil are higher than normal, but not severe. Type II cement can also be specified to generate less heat than Type I cement. This moderate heat of hydration requirement is helpful when placing massive structures, such as piers, heavy abutments, and retaining walls. Type II cement may be specified when water-soluble sulfate in soil is between 0.1 and 0.2%, or when the sulfate content in water is between 150 and 1500 ppm. Types I and II are the most common cements available.

Type III portland cement provides strength at an early age. It is chemically similar to Type I cement except that the particles have been ground finer to increase the rate of hydration. It is commonly used in fast-track paving or when the concrete structure must be put into service as soon as possible, such as in bridge deck repair.

© 1999 by CRC Press LLC

Type IV portland cement is used where the rate and amount of heat generated from hydration must be minimized. This low heat of hydration cement is intended for large, massive structures, such as gravity dams. Type IV cement is rarely available.

Type V portland cement is used in concrete exposed to very severe sulfate exposures. Type V cement would be used when concrete is exposed to soil with a water-soluble sulfate content of 0.2% and higher or to water with over 1500 ppm of sulfate. The high sulfate resistance of Type V cement is attributed to its low tricalcium aluminate content.

Blended Hydraulic Cements

Blended hydraulic cements are produced by intimately blending two or more types of cementitious material. Primary blending materials are portland cement, ground granulated blast-furnace slag, fly ash, natural pozzolans, and silica fume. These cements are commonly used in the same manner as portland cements. Blended hydraulic cements conform to the requirements of ASTM C 595 or C 1157. ASTM C 5195 cements are as follows: Type IS — portland blast-furnace slag cement, Type IP and Type P — portland–pozzolan cement, Type S — slag cement, Type I (PM) — pozzolan-modified portland cement, and Type I (SM) — slag-modified portland cement. The most common blended cements available are Types IP and IS.

ASTM C 1157 blended hydraulic cements include the following: Type GU — blended hydraulic cement for general construction, Type HE — high-early-strength cement, Type MS — moderate-sulfate-resistant cement, Type HS — high-sulfate-resistant cement, Type MH — moderate-heat-of-hydration cement, and Type LH — low-heat-of-hydration cement.

Supplementary Cementing Materials (Mineral Admixtures)

Supplementary cementing materials, also called mineral admixtures, are sometimes added to concrete mixtures. They contribute to the properties of hardened concrete through hydraulic or pozzolanic activity. Typical examples are natural pozzolans, fly ash, ground granulated blast-furnace slag, and silica fume. These materials react chemically with calcium hydroxide released from the hydration of portland cement to form cement compounds.

Below is a summary of the specifications and classes of supplementary cementing materials:

1. Ground granulated iron blast-furnace slag—ASTM C 989

   Grade 80 — Slags with a low activity index
   Grade 100 — Slags with a moderate activity index
   Grade 120 — Slags with a high activity index
2. Fly ash and natural pozzolans — ASTM C 618
3. Class N — Raw or calcined natural pozzolans including diatomaceous earth, opaline cherts, shales, tuffs, volcanic ashes, and some calcined clays and shales
4. Class F — Fly ash with pozzolanic properties
5. Class C — Fly ash with pozzolanic and cementitious properties
6. Silica fume — ASTM C 1240

Mixing Water for Concrete

Almost any natural water that is drinkable can be used as mixing water for making concrete. However, some waters that are not fit for drinking may be suitable for concrete. Reference 1 provides guidance concerning the use of waters containing alkali carbonates, chlorides, sulfates, acids, oils, and other materials, and provides guidance as to allowable levels of contamination.

Aggregates for Concrete

The importance of using the right type and quality of aggregates cannot be overemphasized since the fine coarse aggregates occupy between 60 to 75% of the concrete volume and strongly influence the freshly mixed and hardened properties, mix proportions, and economy of the concrete. Fine aggregates consist of natural sand or crushed rock with particles smaller than 5 mm (0.2 in). Coarse aggregates

© 1999 by CRC Press LLC

consist of a combination of gravel or crushed aggregate with particles predominately larger than 5 mm (0.2 in.) and generally between 10 and 13 mm ($^3/_8$ and $^1/_2$ in.). The most common coarse aggregate size is 19 and 25 mm ($^3/_4$ and 1 in.) aggregate.

Normal weight aggregates should meet the requirements of ASTM C 33. This specification limits the amounts of harmful substances and states the requirements for aggregate characteristics, such as grading. The grading and maximum size of the aggregate affect the relative aggregate proportions as well as cement and water requirements, workability, pumpability, economy, shrinkage, and durability of the concrete.

Chemical Admixtures for Concrete

Admixtures are ingredients in concrete other than portland cement, water, and aggregates that are added to the mixture immediately before or during mixing. Common chemical admixtures include air-entraining, water-reducing, retarding, accelerating, and superplasticizing admixtures. The major reasons for using admixtures are to reduce the cost of concrete construction, achieve certain properties in concrete more effectively than by other means, or to ensure the quality of concrete during the states of mixing, transporting, placing, or curing in adverse weather conditions. Refer to Table 12.5.4.

Air-entraining admixtures are used purposely to entrain microscopic air bubbles in concrete. Air entrainment will dramatically improve the durability of concrete exposed to moisture during freezing and thawing. Air-entraining admixtures are commonly used to provide between 5 and 8% air content in concrete.

Water-reducing admixtures are used to reduce the quantity of mixing water required to produce concrete of a certain slump, reduce water/cement ratio, reduce cement content, or increase slump. Typical water-reducing admixtures reduce the water content by approximately 5 to 10%. High-range water reducers (superplasticizers) reduce the water content by approximately 12 to 30% and they can produce a highly fluid concrete.

Retarding admixtures are used to retard the rate of setting of concrete. An accelerating admixture is used to accelerate strength development of concrete at an early age.

Proportioning Normal Concrete Mixtures

The objective in proportioning concrete mixtures is to determine the most economical and practical combination of readily available materials to produce a concrete that will satisfy the performance requirements under particular conditions of use. To fulfill these objectives a properly proportioned concrete mix should possess these qualities: (1) acceptable workability of freshly mixed concrete, (2) durability, strength, and uniform appearance of hardened concrete, and (3) economy. Only with proper selection of materials and mixture characteristics can the above qualities be obtained in concrete production.

The key to designing a concrete mixture is to be fully aware of the relationship between the water/cement ratio and its effect on strength and durability. The specified compressive strength at 28 days and durability concerns dictate the water/cement ratio established for a concrete mixture. The water/cement ratio is simply the weight of water divided by the weight of cement. If pozzolans or slags are used, it would include their weights and would be referred to as the water/cementitious material ratio. The water/cement ratio can be established by a known relationship to strength or by durability requirements. For example, a concrete structure may require only 20 MPa (3000 psi) compressive strength, which would relate to a water/cement ratio of about 0.6; however, if the concrete is exposed to deicers, the maximum water/cement ratio should be 0.45 (Table 12.5.5). For corrosion protection or reinforced concrete exposed to deicers, the maximum water/cement ratio should be 0.40. When designing concrete mixtures, remember that where durability is concerned, water/cement ratio should be as low as practical. Entrained air must be used in all concrete that will be exposed to freezing and thawing and

TABLE 12.5.4 Concrete Admixtures by Classification

Type of Admixture	Desired Effect	Material
Accelerators (ASTM C 494, Type C)	Accelerate setting and early-strength development	Calcium chloride (ASTM D 98) Triethanolamine, sodium thiocyanate, calcium formate, calcium nitrite, calcium nitrate
Air detrainers	Decrease air content	Tributyl phosphate, dibutyl phthalate, octyl alcohol, water-insoluble esters of carbonic and boric acid, silicones
Air-entrained admixtures (ASTM C 260)	Improve durability in environments of freeze-thaw, deicers, sulfate, and alkali reactivity Improve workability	Salts of wood resins (Vinsol resin) Some synethic detergents Salts of sulfonated lignin Salts of petroleum acids Salts of proteinaceous material Fatty and resinous acids and their salts Alkylbenzene sulfonates Salts of sulfonated hydrocarbons
Alkali-reactivity reducers	Reduce alkali-reactivity expansion	Natural pozzolans, fly ash, silica fume, blast-furnace slag, salts of lithium and barium
Bonding admixtures	Increase bond strength	Rubber, polyvinyl chloride, polyvinyl acetate, acrylics, butadiene-styrene copolymers
Coloring agents	Colored concrete	Modified carbon black, iron oxide, phthalocyanine, umber, chromium oxide, titanium oxide, cobalt blue (ASTM C 979)
Corrosion inhibitors	Reduce steel corrosion activity in a chloride environment	Calcium nitrite, sodium nitrite, sodium benzoate, certain phosphates or fluorosilicates, fluoroaluminates
Dampproofing admixtures	Retard moisture penetration into dry concrete	Soaps of calcium or ammonium stearate or eleate Butyl stearate Petroleum products
Finely divided mineral admixtures		
Cementitious	Hydraulic properties Partial cement replacement	Ground granulated blast-furnace slag (ASTM C 989) Natural cement Hydraulic hydrated lime (ASTM C 141)
Pozzolans	Pozzolanic activity Improve workability, plasticity, sulfate resistance; reduce alkali reactivity, permeability, heat of hydration Partial cement replacement Filler	Diatomaceous earth, opaline cherts, clays, shales, volcanic tufts, pumicites (ASTM C 618, Class N); fly ash (ASTM C 618, Classes F and C), silica fume
Pozzolanic and cementitious	Same as cementitious and pozzolan categories	High calcium fly ash (ASTM C 618, Class C) Ground granulated blast-furnace slag (ASTM C 989)
Nominally inert	Improve workability Filler	Marble, dolomite, quartz, granite
Fungicides, germicides, and insecticides	Inhibit or control bacterial and fungal growth	Polyhalogenated phenols Dieldrin emulsions Copper compounds
Gas formers	Cause expansion before setting	Aluminum powder Resin soap and vegetables or animal glue Saponin Hydrolized protein
Grouting agents	Adjust grout properties for specific applications	See Air-entraining admixtures, Accelerators, Retarders, Workability agents
Permeability reducers	Decrease permeability	Silica fume (ASTM C 1240) Fly ash (ASTM C 618) Ground slag (ASTM C 989) Natural pozzolans (ASTM C 618)

TABLE 12.5.4 Concrete Admixtures by Classification (continued)

Type of Admixture	Desired Effect	Material
		Water reducers
		Latex
Pumping aids	Imnprove pumpability	Organic and synthetic polymers
		Organic flocculents
		Organic emulsions of paraffin, coal tar, asphalt, acrylics
		Bentonite and pyrogenic silicas
		Natural pozzolans (ASTM C 618, Class N)
		Fly ash (ASTM C 618, Classes F and C)
		Hydrated lime (ASTM C 141)
Retarders (ASTM C 494, Type B)	Retard setting time	Lignin
		Borax
		Sugars
		Tartaric acid and salts
Superplasticizers[a] (ASTM C 1017, Type 1)	Flowing concrete	Sulfonated melamine formaldehyde condensates
	Reduce water/cement ratio	Sulfonated napthalene formaldehyde condensates
		Ligonsulfonates
Superplasticizer[a] and retarder (ASTM C 1017, Type 2)	Flowing concrete with retarded set Reduce water	See Superplasticizers and also Water reducers
Water reducer (ASTM C 494, Type A)	Reduce water demand at least 5%	Lignosulfonates
		Hydroxylated carboxylic acids
		Carbohydrates
		(Also tend to retard set so accelerator is often added)
Water reducer and accelerator (ASTM C 494, Type E)	Reduce water (minimum 5%) and accelerate set	See Water reducer, Type A (Accelerator is added)
Water reducer and retarder (ASTM C 494, Type D)	Reduce water (minimum 5%) and retard	See Water reducer, Type A
Water reducer — high range (ASTM C 494, Type F)	Reduce water demand (miniumum 12%)	See Superplasticizers
Water reducer — high range — and retarder (ASTM C 494, Type G)	Reduce water demand (miniumum 12%) and retard set	See Superplasticizers and also Water reducers
Workability agents	Improve workability	Air-entraining admixtures
		Finely divided admixtures, except silica fume
		Water reducers

[a] Superplasticizers are also referred to as high-range water reducers or plasticizers. These admixtures often meet both ASTM C 494 and C 1017 specifications simultaneously.

the presence of deicing chemicals. A typical air content for concrete would range from 5 to 8%. Reference 1 provides step-by-step procedures for proportioning concrete. Refer to Tables 12.5.6, 12.5.7, and 12.5.8.

Mixing, Transporting, and Placing Concrete

All concrete should be mixed thoroughly until it is uniform in appearance with all ingredients evenly distributed. If concrete has been adequately mixed, samples taken from different portions of a batch will have essentially the same unit weight, air content, slump, and strength. Concrete is sometimes mixed at a job site at a stationary mixer or paving mixer, and other times it is mixed in central mixers at ready-mix plants (ASTM C 94). Once concrete is transported to a job site it is then conveyed by a variety of methods including belt conveyors, buckets, shoots, cranes, pumps, wheelbarrows, and other equipment.

TABLE 12.5.5 Relationships Between Water Cement Ratio and Compressive Strength of Concrete

Compressive Strength at 28 days, MPa (psi)	Water-Portland Cement Ratio, by Mass	
	Non-Air-Entrained Concrete	Air-Entrained Concrete
40 (5800)	0.42	—
35 (5100)	0.47	0.39
30 (4400)	0.54	0.45
25 (3600)	0.61	0.52
20 (2900)	0.69	0.60
15 (2200)	0.79	0.70

Note: Strength is based on 150 × 300-mm cylinders moist cured 28 days at 23 ± 2°C. Relationship assumes maximum size of aggregate about 25 mm.
Adapted from *Design and Control of Concrete Mixtures,* EBDD1, Portland Cement Association, Skokie, IL, 1992. With permission.

Concrete should be conveyed in a manner in which the concrete is not allowed to dry out, be delayed, or allowed to segregate before it is placed.

Curing

All concrete must be properly cured. Curing is the maintenance of a satisfactory moisture content and temperature in concrete during some definite time period immediately following placing and finishing so that the desired properties of strength and durability may develop. Concrete should be moist cured for 7 days at a temperature between 10 and 27°C (50 and 80°F). Common methods of curing include ponding, spraying, or fogging; use of wet covers, impervious paper, plastic sheets, and membrane-forming curing compounds; or a combination of these.

Durability

Freeze-Thaw and Deicer Scaling Resistance

As water freezes in wet concrete, it expands 9%, producing hydraulic pressures in the cement paste and aggregate. Accumulated effects of successive freeze-thaw cycles and disruption of the paste and aggregate eventually cause significant expansion and extensive deterioration of the concrete. The deterioration is visible in the form of cracking, scaling, and crumbling.

The resistance of hardened concrete to freezing and thawing in a moist condition, with or without the presence of deicers, is significantly improved by the use of entrained air. Air entrainment prevents frost damage and scaling and is required for all concretes exposed to freezing and thawing or deicer chemicals. An air content of between 5 and 8% should be specified. Air-entrained concrete should be composed of durable materials and have a low water/cement ratio (maximum 0.45), a minimum cement content of 335 kg/m^3 (564 lb/yd^3) or move, proper finishing after bleed water has evaporated from the surface, adequate drainage, a minimum of 7-days moist curing at or above 10°C (50°F), a minimum compressive strength of 28 MPa (4000 psi), and a minimum 30-day drying period after moist curing. Sealers may also be applied to provide additional protection against the effects of freezing and thawing and deicers. However, a sealer should not be necessary for properly proportioned and placed concrete.

Sulfate-Resistant Concrete

Excessive amounts of sulfates in soil or water can, over 5 to 30 years, attack and destroy concrete that is not properly designed. Sulfates attack concrete by reacting with hydrated compounds in the hardened cement paste. Due to crystallization growth, these expansive reactions can induce sufficient pressure to

disrupt the cement paste, resulting in cracking and disintegration of the concrete. The first defense against sulfate attack is to use a low water/cement ratio (0.45 or preferably less), and to select a Type II or V cement (see the section on cement).

Corrosion Protection

Concrete protects embedded steel from corrosion through its highly alkaline nature. The high-pH environment (usually greater than 12.5) causes a passive and noncorroding protective oxide film to form on steel. However, carbonation or the presence of chloride ions from deicers or seawater can destroy or penetrate the film, causing rusting of the reinforcing steel. In addition to using a water/cement ratio of 0.40 or less, the following protective strategies can be used individually or in combination to reduce the risk of corrosion:

1. Cover thickness of 90 mm (3.5 in.) or more of concrete over top, reinforcing steel of compression zones. [*Note:* Excessive cover in tension zones exacerbates surface crack width.]
2. Low-slump dense concrete overlay
3. Latex-modified concrete overlay
4. Interlayer membrane/asphaltic concrete systems
5. Epoxy-coated reinforcing steel
6. Corrosion-inhibiting admixtures in concrete
7. Sealers with or without overlay
8. Silica-fume or other pozzolans that significantly reduce concrete permeability
9. Low water/cement ratio (<0.35) superplasticized concrete
10. Cathodic protection
11. Polymer concrete overlay

12. Galvanized reinforcing steel
13. Polymer impregnation
14. Lateral and longitudinal prestressing for crack control
15. Blended cements containing silica fume or other pozzolans to reduce permeability

Alkali–Silica Reaction

Most aggregates are chemically stable in hydraulic cement concrete, without deleterious interaction with other concrete ingredients. However, this is not the case for aggregates containing certain siliceous substances that react with soluble alkalis in concrete. Alkali–silica reactivity (ASR) is an expansive reaction between reactive forms of silica in aggregate and alkali hydroxides in concrete. Very reactive aggregates can induce cracks within a year, whereas slowly reactive aggregates can take over 20 years to induce noticeable cracks. ASR is best controlled through the use of fly ash, slag, silica fume, natural pozzolans, or blended hydraulic cement. With proper care in analyzing aggregates and selecting appropriate concrete ingredients, ASR can be effectively minimized using available materials. Reference 2 provides guidance on ASR.

12.6 Composites

Introduction

Victor A. Greenhut

A composite material is a macroscopic, physical combination of two or more materials in which one material usually provides reinforcement. Composites have been developed where no single, quasi-continuous material will provide the required properties. In most composites one phase (material) is continuous and is termed the *matrix*, while the second, usually discontinuous phase, is termed the *reinforcement*, in some cases *filler* is applied when the reinforcement is not a quasi-continuous fiber. Matrix-filler nomenclature is one method of categorization. This yields the categories *metal matrix* (MMC), *polymer (plastic) matrix* (PMC), and *ceramic matrix* (CMC) composites — the major subdivisions of this section. Other categories are given the shape and configuration of the reinforcing phase. The reinforcement is usually a ceramic and/or glass. If it is similar in all dimensions, it is a *particulate-reinforced* composite; if needle-shaped single crystals, it is *whisker-reinforced*; if cut continuous filament, *chopped fiber-reinforced*; and if continuous fiber, *fiber composite*. For fiber composites configuration gives a further category. If fibers are aligned in one direction, it is a *uniaxial fiber composite*; if arranged in layers, it is a *laminar composite*; if a three-dimensional arrangement, it is a *3D weave composite*. Laminates and 3D weaves can be further divided by the weave used for the fiber.

Composites are not new materials. Perhaps the first important engineering structural composite was the Biblical straw-reinforced, sun-dried mud brick — adobe. Laminated structures such as bows have been used since prehistoric times. In the early 1900s doped fabric was employed in early aircraft surfaces. Reinforced phenolics were developed in the 1930s and glass-reinforced plastics in the 1940s. More recently, emphasis turned to reinforcements, with graphitic and boron-based fibers developed in the 1960s. High-performance aramids, such as Kevlar™, were developed in the 1970s. This and the previous decade have seen new developments in both fiber and matrix with lightweight aerospace MMCs and high-temperature CMCs showing major advances.

This section will concentrate on advanced composites in which major structural performance is achieved, but it should be noted that the largest tonnage and dollar value of composites is driven by the cost of materials. Polymers are reinforced with glass particulate or chipped fiber because it lowers the price per pound of a plastic, hence the term *filler* for reinforcement material. The structural properties are also improved, as PMCs show increased stiffness (resistance to bending) and strength (resistance to failure). These and other properties will receive the emphasis in this section. In MMCs high hardness, maintenance of hardness at elevated temperature, and precise tolerance are often lead properties, although stiffness and strength are important. The metal matrix confers some ductility so that the catastrophic failure of a solely ceramic material is avoided. In CMCs the reinforcement is chiefly incorporated to prevent catastrophic failure to introduce a more predictable failure stress (increased reliability), and to a lesser extent to increase strength. Particulate-reinforced plastics and fiberglass (glass fiber–reinforced plastic) have become commonplace engineering materials, as have ceramic-reinforced metal matrices (cemented carbides and cermets). Reinforcement with graphite and other advanced technology fibers has emerged for aerospace applications, biomedical use, and high-performance/high-cost consumer products such as sporting goods. Fiber-reinforced MMCs and ceramic–ceramic composites have developed greatly, but are still quite limited in application to very advanced technologies which can bear relatively high costs.

An important consideration for composite production is the bond between the matrix and the reinforcement. For MMCs and PMCs load must be transferred (Figure 12.6.1) to the relatively high-strength, high-elastic-modulus ceramic or glass in order to maximize the mechanical performance. For best transfer there must be no relative sliding or interface failure, so the strain at the matrix-to-reinforcement area can be maximum and equal ($\varepsilon_{matrix} = \varepsilon_{reinforcement} = \varepsilon_{m,c}$). This means that the reinforcement bears the major portion of the load, σ_c, while the weaker matrix bears a lower load, σ_m, because it has lower modulus.

© 1999 by CRC Press LLC

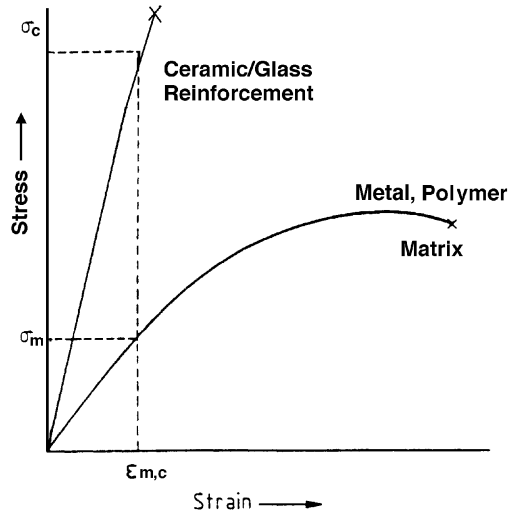

FIGURE 12.6.1 In a composite with good bonding between high-modulus ceramic and low-modulus metal or polymer matrix the interfacial strain must be the same. Thus, the high-strength ceramic fiber bears most of the load (stress).

To accomplish load transfer the bond interface must be engineered because metal and polymers do not show intrinsic bonding to ceramic reinforcement. A *coupling agent*, often a xylene, is applied to the ceramic or glass to promote bonding to a polymer. For metals, a metal matrix often has to be selected because it will wet and bond to the selected ceramic when molten or sintering during fabrication. Commonly, a controlled "forming gas" atmosphere must be used to produce MMCs composites so that a strong metal-to-ceramic bond is made.

The situation is somewhat different for ceramic–ceramic composites. These materials usually bond strongly to each other during fabrication. However, unlike the PMCs and MMc a less perfect bond is required. This is because local failure is required between matrix and reinforcement to introduce toughness or noncatastrophic fracture. This will be discussed further in the section on CMCs.

Polymer Matrix Composites

Weiping Wang, R. Allan Ridilla, and Mathew B. Buczek

Introduction

PMCs are used extensively as commodity and specialty engineering materials and constitute the largest class of composite materials on a dollar basis. The enormous success of PMCs arises from the wide range of properties which can be obtained and the low cost of low-end materials, such as fiberglass-reinforced polyester. Furthermore, the combination of high-strength/high-stiffness fibers in commodity polymer matrices offers an outstanding example of the composite principle — taking the best properties of both materials. The result is a strong, tough, stiff material which, depending on the matrix and reinforcement type, provides value in applications as diverse as consumer products, construction, and aerospace.

A distinction must be made between reinforced plastics and advanced composites. The term *reinforced plastics* generally refers to plastic materials fabricated with a relatively low percentage of discontinuous, randomly oriented fibers, with rather moderate properties, and used in commodity applications. *Advanced composites*, on the other hand, refers to a class of materials where a high percentage of continuous, highly oriented fibers are combined with a suitable polymeric matrix to produce articles of high specific strength and specific stiffness. At present, composites are widely used in the aerospace and sporting

goods industries for their superior performance. Figure 12.6.2 illustrates the evolution of applications for carbon fibers.

Polymers are also often "filled" with particulate reinforcements to increase certain properties, such as deflection temperature under load (DTUL). Although these materials are formally composites, they are usually regarded as filled polymers and not composites and thus will not be discussed explicitly in this section. Refer to the polymer section of this chapter.

Architecture

Each of the constituent materials in advanced composites must act synergistically to provide aggregate properties that are superior to the materials individually. The functional effectiveness of composites is principally due to the anisotropy of the materials and the laminate concept, where materials are bonded together in multiple layers. This allows the properties to be tailored to the applied load so that the structure can be theoretically more efficient than if isotropic materials were used. The reinforcements come in a variety of forms. Unidirectional tapes with all fibers along a common axis, woven fabrics constructed with fibers along both axes in the x–y plane, and 3-D architectures with reinforcements in more than two axial directions are just a few of the building blocks of composite structures.

The concept of laminate is illustrated in Figure 12.6.3. On the left is the unidirectional composite where all reinforcements are aligned in one direction. This construction provides excellent properties in the fiber direction but is limited to the properties of the resin in the transverse directions. The cross-plied construction on the right creates a structure that has common properties in the x- and y-direction but is limited to the characteristics of the resin in the z-direction. A large number of variations exist, allowing the designer to tailor the properties of the structure by varying the type of fibers and fiber orientations. Shown in Figure 12.6.4 are typical values of specific tensile strength (strength-to-density ratio) and specific tensile modulus (modulus-to-density ratio) for 65% volume fraction, cross-plied quasi-isotropic composites. Also included in the plot for comparison are properties of mild steel, titanium (Ti-6A1-4V), and aluminum (2024-T6). The actual properties of a composite will vary significantly due to flaws created during processing.

In selecting polymer composite materials for design, one should consider both the potential advantages and concerns typical to composites as illustrated in Table 12.6.1. Clearly, the advantages of materials should be put into use to achieve higher levels of performance in many kinds of products. On the other

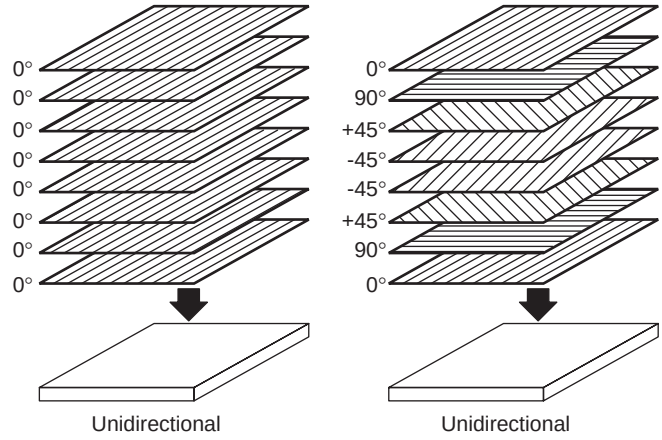

FIGURE 12.6.3 The basic concept of composite laminate.

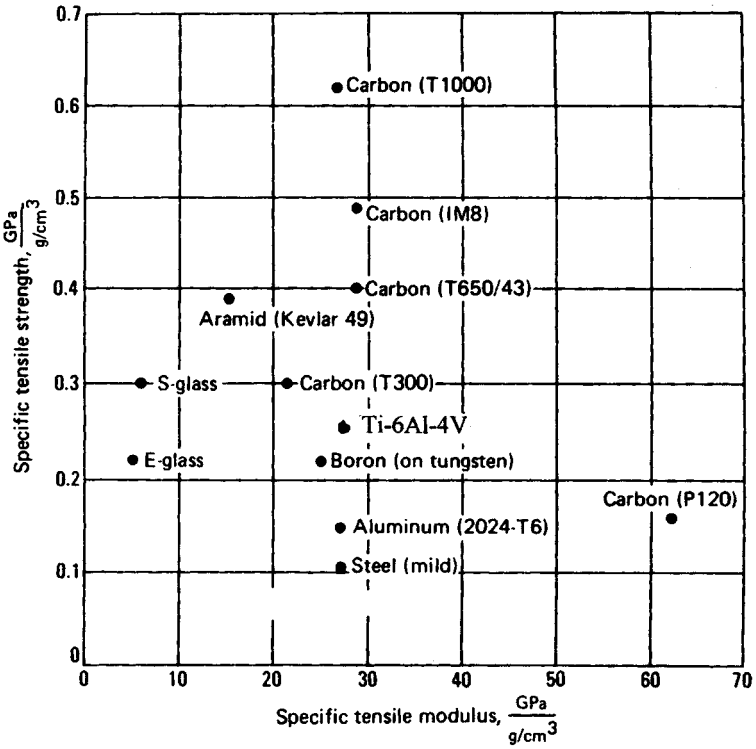

FIGURE 12.6.4 A comparative plot of specific tensile strength (strength-to-density) and specific tensile modulus (modulus-to-density) of composite material.

hand, potential issues in higher raw material cost and lower production volume and yield should also be weighed.

Fiber

Introduction. The most common reinforcement in polymer composites are fibers. Fibrous reinforcements come from compounds of light elements, (e.g., B, C, Si, O). These compounds typically contain

© 1999 by CRC Press LLC

TABLE 12.6.1 Advantages and Limitations of Polymer Matrix Composites

Potential Advantages	Potential Limitations
High strength-to-density ratio	Low–volume production methods
High stiffness-to-density ratio	High raw material cost
Excellent corrosion resistance	Poor impact resistance
Good fatigue resistance	Poor high-temperature performance
Low thermal expansion	Delamination/out-of-plane loading

stable covalent bonds which impart greater strength and stiffness compared with metallic or ionic bonds. The compounds are processed to the final unable form of a fiber or filament with a highly aligned and directional microstructure so that the strength and stiffness properties are optimized along the fiber axis. Glass, graphite/carbon, aramid, and boron are among most notable fibers currently used in polymer composites.

Glass Fiber. Glass fiber reinforcements represent the largest volume used in the composites industry. These fibers are characterized by their low cost, clear to white color, good mechanical and electrical properties, high moisture and chemical resistance, and excellent dimensional stability with operational service to 550°C. Manufacturing of the fibers begins with molten glass which is drawn through a furnace into a fibrous form of final diameter of about 10 μm and then quenched to secure the final amorphous microstructure prior to applying final coatings or sizing. Common types of commercially available glass fiber are E-glass and S-glass, both of which are low alkali boro-alumino-silicate glasses. E-glass fiber, the workhorse of glass fiber applications, is the lower-cost fiber and is used in both structural and electrical applications. S-glass provides higher tensile properties and increased temperature resistance needed for aerospace and aircraft applications with a price premium. Representative properties for the glass fibers are shown in Table 12.6.2.

TABLE 12.6.2 Fibers Used in Polymer Composites — Mechanical Properties

	E-Glass	S-Glass	AS4 PAN-Based Carbon	IM7 PAN-Based Carbon	P120 Pitch-Based Graphite	Kevlar-49	Boron

Carbon Fiber. Graphite/carbon fibers are the reinforcement of industrial choice for advanced composite applications where stiffness and performance are critical. Typical attributes of these fibers are excellent tensile strength and elastic modulus, ease of handling, black color, and a wide range of properties and cost. Graphite fibers are initially formed as from polymer precursor compounds such as polyacrylonitrile (PAN) or rayon and pitch, an amorphous, aromatic by-product of petroleum distillation. PAN-based graphite fiber, the predominant commercial fiber, starts with the liquid PAN polymer, which is spun into a fiber and stretched to align the microstructure. It is then stabilized and the microstructure is aligned at 400 to 500°F in an oxidizing atmosphere under tension. Next, carbonization occurs in an inert atmosphere at 1800 to 2300°F to remove most noncarbon elements. Finally, the graphitization step is performed on the carbon fiber by applying tension to the fiber in an inert atmosphere at 3600 to 6500°F. The result is a highly aligned, highly graphitic fiber with preferred graphite orientation along the fiber axis. The temperature and tension fabrication parameters of the graphitization step, along with the purity of the initial PAN polymer, are the variables which are modified to differentiate “low-end” (low strength,

© 1999 by CRC Press LLC

modulus, cost) from the "high-end" fiber (high strength, modulus, cost) and all of the grades in between. Typical properties of several commercial grades of carbon/graphite fiber are listed in Table 12.6.2.

Aramid Fibers. The aramid fiber derives its properties from long, rodlike aromatic polyamides. These fibers are characterized by low density, white yellow color, extremely high tensile properties, poor compressive strength, and high toughness, and they are difficult to cut mechanically. The manufacturing process for these fibers involves complex polymerization steps as the liquid polymer in acid is extruded or spun into a fiber form, water washed, dried, and finally heat treated under tension. The result is a highly aligned radial system of axially pleated lamellae in the microstructure. Aramid fibers have proved extremely useful in tension-critical application where the intrinsic compressive weaknesses of the fiber cannot be exploited. Commercially known as Kevlar, the most notable applications for aramid fibers are bulletproof vests (without matrix), and various high-pressure composite vessels. Typical properties for Kevlar 49 are listed in Table 12.6.2.

Boron Fibers. Boron reinforcements are referred to as filaments rather than fibers since they are made by the chemical vapor deposition of boron onto a fine tungsten wire. This fabrication process produces a large-diameter, stiff, and expensive reinforcement that is somewhat difficult to handle and produce into subsequent product forms such as fabrics and contoured structures. Although boron filaments possess the combination of high strength and high specific modulus that glass could not achieve, its use has been reduced to a minuscule level. Carbon/graphite fiber varieties have supplanted boron where high specific modulus is a requirement. A small volume of boron filaments still remain in a handful of military aircraft as well as in some recreational products such as golf club shafts. Typical properties of boron filaments are shown in Table 12.6.2.

Polymer Matrix Materials

Introduction. While fibers provide much of the strength and stiffness in advanced composites, equally important is the matrix resin. The matrix holds the fiber network together, to protect the structure from environmental attack and to support the fibers so that loads can be transferred throughout the structure through a shear mechanism. Polymeric matrices can either be thermoset or thermoplastic resins.

Thermosets cannot be reformed or thermally reworked after polymerization (curing). They are subdivided into categories based on their chemical reactions. The first are addition-type polymers, generally considered easier to process, where two (or more) reactants combine to form the final cured product. The second is the condensation type, in which the reactants combine to form products in addition to water and other volatile constituents. These systems are more difficult to process due to the required management of the volatile to minimize process defects such as porosity.

Thermoplastic materials, on the other hand, are polymers which can be softened and melted with the application of heat. Although they can be recycled, thermoplastic matrices have found more-limited applications in the advanced composite applications since they are particularly susceptible to attack by fluids and to creep at high stresses, and are relatively difficult to handle in laminate or structural form prior to final consolidation. The remainder of this discussion will focus on thermoset matrices which account for more than 90% of present-day advanced composite applications. Three principal organic matrix materials will be discussed: polyesters, epoxies, and polyimides.

Polyester Matrix. Low-cost polyester resins constitute the highest volume usage for the general composite industry. There are many resins, formulations, curatives, and other additive constituents that provide a wide array of properties and performance characteristics, such as mechanical strength, toughness, and heat resistance. The vast majority of applications utilize glass since its interfacial adhesion to these resins has been optimized by the development of silane surface treatments. These resins when combined with glass have found wide application in the chemical processing construction, and marine industries where cured properties and low cost are tailor-made for design requirements. Applications with carbon/graphite and aramid fibers are far less frequent since adhesion to these fibers is generally

© 1999 by CRC Press LLC

poor and cure shrinkage on these resins is quite high. Additionally, structures requiring the high performance of carbon/graphite can often justify the use of more-expensive epoxy resins.

Epoxy Matrix. Epoxy resins are the prevalent polymer used with advanced composites. Their extensive use is primarily due to their superior mechanical properties, excellent adhesion, good processibility utilizing addition-type reactions, low cure shrinkage and low cost. When choosing epoxy resins two elements are crucial: the base resin and the curing agent or hardener. Since there are many base resins and curing agents, the following general relationships are given to provide a practical framework when utilizing epoxy compounds:

- *Chemistry*: Aromatic compounds are more thermally stable, stronger, and more resistant to fluids than are aliphatics.
- *Cross-link density*: Higher-temperature cures and longer cure times will increase cross-link density and therefore strength/modulus, service temperature, and chemical resistance.
- *Curing agents*: Amine-cured systems have better chemical resistance and superior thermal stability, but are more brittle than anhydride-cured systems.

Epoxies are categorized by the cure temperature. The "250 F epoxies" are those that cure at 250°F and are suitable for service up to 250°F. The "350 F epoxies" are those with higher processing and service temperatures. One of the design concerns with epoxies is moisture absorption. The effects of moisture often require design stresses to be reduced in applications where moisture is a concern. Modern epoxy formulations include lower cost, higher toughness, and other properties which continue to make epoxies attractive to the end user.

Polyimide resins span the temperature spectrum from 350 to 600°F. There are three general types of polyimides:

1. *Addition-reaction* polyimides such as bismaleimides (BMI)
2. *Condensation-reaction* polyimides such as commercial Monsanto Skybond resin
3. *Combination* condensation/addition-reaction polyimides such as PMR-15

BMIs are similar to epoxies in that they undergo addition reactions, are easy to process, and share many of the handling characteristics that make epoxies desirable. These materials are the composite resins of choice for temperatures in the range of 350 to 450°F to bridge the temperature gap between epoxies and other polyimides. They are more expensive and tend to be more brittle than epoxies. Condensation polyimides are used for composite applications from 450 to 520°F. These materials are difficult to process and tend to be quire brittle so their application is limited to adhesive bonding with some structural composite hardware. Combination-reaction polyimides have the highest thermal and oxidative stability and are used at service temperatures to 600°F. These resins are considerably more complicated because of their reaction mechanisms and the handling difficulties of the chemicals. Their application is principally restricted to aerospace composite structures where the performance needs to justify the difficult processing and high cost.

Processing

Continuous-fiber composites are manufactured in two steps, preform fabrication and consolidation/curing. The material comes in either the dry-fiber (without resin) form or with resin included called *prepreg*. Dry fibers are used in filament winding, pultrusion, weaving, braiding. In the case of filament winding and pultrusion, resin is introduced at the same time fibers are during the time of winding and pultrusion. Resin can also be introduced to the fiber later by resin-transfer molding (RTM). Prepreg, at a higher material cost, eliminates the step of resin addition and provides the adhesion to hold the material together. Layup of prepreg, a time-consuming process, is a common method used in the aerospace industry where complex contoured surfaces are present.

Consolidation and curing consist of compacting the material to remove entrapped air, volatile, and excess resins while developing the structural properties by increasing the polymer chain length and

© 1999 by CRC Press LLC

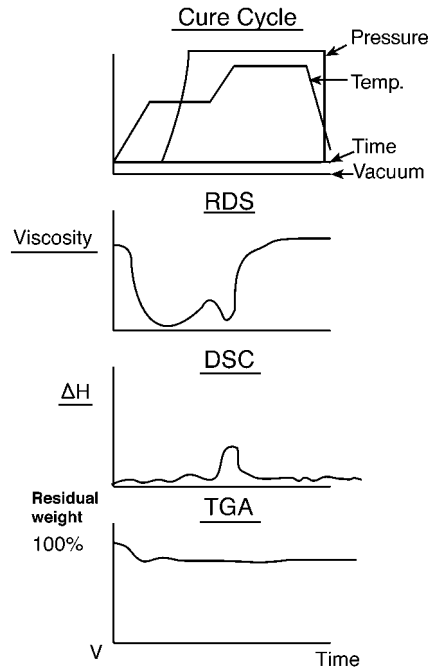

FIGURE 12.6.5 A typical curing cycle of epoxy composite with corresponding Rheometric Dynamic Spectroscopy (RDS), Differential Scanning Calorimetry (DSC), and Thermogravimetric Analysis (TGA) curves.

cross-linking. Thermosetting polymer matrices must be cured *in situ* with the fibers to form composites. The goals of a successful cure are good consolidation with low porosity and high conversion of initial monomeric constituents to polymer (degree of cure).

The cure cycle of an epoxy resin composite is shown in Figure 12.6.5. At the start of the cure cycle, the material is normally under vacuum to remove residual volatile. The temperature is then ramped to the point where the polymer is melted. The ramp rates on heating must be slow enough as not to cause unnecessary thermal gradients and to avoid dangerous exotherm (runaway reactions) but not so slow as to cause excessive process time or premature cross-linking. Normal ramp rates are generally in the 1 to 5°F/min range. An isothermal hold of about 30 to 60 min is performed at the point where the resin reaches its minimum in viscosity, during which pressure is applied and the polymer allowed to flow, thus consolidating the laminate. Following consolidation, the temperature is increased to the point where cross-linking occurs (350°F for this example). An additional hold of about 30 to 90 min is performed at this temperature to allow for the material to complete cross-linking. This event is shown as the end of the exothermic peak in the DSC curve as well as the asymptotic high-viscosity region.

Epoxies cure via addition reactions where no volatile is generated during the cross-linking process. However, many other matrix materials (e.g., phenolics and many polyimides) cure via condensation reactions.

Mechanical Properties

Mechanical properties of polymer composites depend substantially on the processing and fabrication methods used, as well as on the fiber orientation. Thus, standard materials do not exist and it is difficult to generalize regarding properties. The three most significant factors in determining properties are the type of fiber, the volume fraction fiber, and the orientation of the fiber. High-strength high-modulus graphitic carbon fibers will, of course, produce stronger, stiffer composites than those produced from fiberglass. Similarly, 60 vol % fiber composites will be stronger and stiffer than 30 vol %, and uniaxially aligned fiber composites will have maximum properties along the alignment axis, but will be highly

© 1999 by CRC Press LLC

anisotropic and will have poor properties in off-axis orientations. Cross-ply and laminated structures are standard approaches to reducing anisotropy.

Composite stiffness, E_c, can be approximated for polymer composites by application of the rule of mixtures:

$$E_c = E_f V_f + E_m\left(1 - V_f\right)$$

where E is the modulus of elasticity and V is the volume fraction fibers. Subscripts c, f, and m refer to composite, fiber, and matrix, respectively. Similar expressions approximate other properties. Properties of commonly used commodity composite materials are given in Tables 12.6.3 to 12.6.5. Advanced engineering polymer composites have specialized properties which depend on the parameters discussed previously. Expected properties of such advanced polymer composites can only be approximated once the component and material variables are determined during the design stage. The recommended approach is to work with a composite fabricator during the design phase to establish the expected mechanical properties.

TABLE 12.6.3 Typical Properties of Glass Fiber–Reinforced Polymers

Property	Base Resin

Notes: Most nylon resins listed in this table are used for injection molding, and test values are determined from standard injection-molded specimens. In these cases a single typical value is listed. Exceptions are MoS_2-filled nylon and direct-polymerized (castable) nylon, which are sold principally in semifinished stock shapes. Ranges of values listed are based on tests on various forms and sizes produced under varying processing conditions.

Because single values apply only to standard molded specimens, and properties vary in finished parts of different sizes and forms produced by various processes, these values should be used for comparison and preliminary design considerations only. For final design purposes the manufacturer should be consulted for test experience with the form being considered. Listed values should not be used for specification purposes.

Metal Matrix Composites

Introduction

The term *metal matrix composites* is usually reserved for fiber-reinforced materials, although technically it applies to particulate-reinforced systems also. The general term for particulate-, whisker-, and chopped-fiber-reinforced systems is *cermet*. A majority of commonly used systems are based upon particulate reinforcements.

Cermets and Cemented Carbides — Particulate-Reinforced MMCs

The term *cemented carbide* is applied to particulate composites based upon tungsten carbide in a cobalt matrix. This distinction is largely historical, not technical. The tungsten carbide–cobalt-based materials were first developed in Germany, while development of other cermets (including noncarbide-, oxide-, and nitride-based systems) occurred in the United States during and immediately after World War II. Thus, a distinguishing nomenclature was developed both because "carbide" was no longer completely appropriate with oxide systems available and for geopolitical reasons. This nomenclature confusion between the most common cermets, the cemented carbides, and other materials still survives. The structure consists of a continuous metal alloy functioning as cement which holds together particles of carbide, oxide, or nitride ceramic. These materials provide strength, high hardness, wear (abrasion) resistance, low sliding friction, and precise tolerance even at quite high temperatures. Cermets and cemented carbides derive their usefulness when the compressive strength, hardness, and thermal resistance of the ceramic reinforcement is coupled with the ductility, toughness, adhesion, and lubricity provided by the metal. Common applications include metal and rock cutting and grinding tools, high-temperature containers, and pouring spouts, rocket nozzles, turbine parts, flame nozzles, friction and glide parts, seals, magnetron tube cathodes, flame nozzles, and ballpoint pen tips.

A cermet is usually fabricated by mixing the ceramic and metal powders together with a binder incorporated. This often requires high-energy mixing because of density differences with tooling made of the same cermet to avoid contamination. Subsequently, the part is formed, commonly by unidirectional or isostatic pressing, to final shape (accounting for shrinkage) with a wear-resistant die and with the formed object then liquid phase sintered in a controlled-atmosphere furnace. The chemistry is often quite complex in order to control the structure and the interfacial bond between metal and ceramic. Molybdenum promotes wetting of titanium carbide by molten nickel. Tantalum and titanium carbides are usually added to tungsten carbide–cobalt cemented carbides. Some cermets are prepared by slip casting, liquid metal infiltration, hot pressing, or solid-state sintering of parts. In some cases the material is "deficient" in metal to provide porosity for the passage of ink (pen tips) or incorporation of lubricant.

As indicated in the introduction to this section, a good bond between ceramic grain and metal "cement" is required for proper load transfer and to provide a homogeneous structure for good load bearing and uniform deformation. This normally requires a good wetting between liquid metal and ceramic grains. This is affected by minor alloying additions to the metal and the firing atmosphere.

The distribution, stability, and composition of phases have profound effects on properties. The production of WC–6 $^{w}/_{o}$ Co is a good example of the need for strict compositional control. The tertiary-phase diagram shows that the composition range from 6.00 to 6.12 $^{w}/_{o}$ must be adhered to in order to prevent formation of phases other than WC and Co — a composition range of less than 0.12 $^{w}/_{o}$! Embrittlement by graphite occurs at higher carbon content and by eta phase (η–WC_{1-x}) at lower carbon levels. Precise formulation and furnace atmosphere control is required, usually assisted by using a graphite-lined furnace. About 0.1% outside the acceptable composition range there is a drop of about 25% from the optimum strength.

It is important to engineer the microstructure of cermets in order to optimize properties. A uniform dispersion of round oxide, carbide, or nitride grains in the matrix of metal binder is desired. Inhomogeneity and sharp grain corners can act as failure origins. Round grains result from powder preparation and/or partial dissolution of sharp contours in the molten metal. As the amount of binder increases (Figure 12.6.6), the indentation hardness of the composite decreases, because metal, compared with

© 1999 by CRC Press LLC

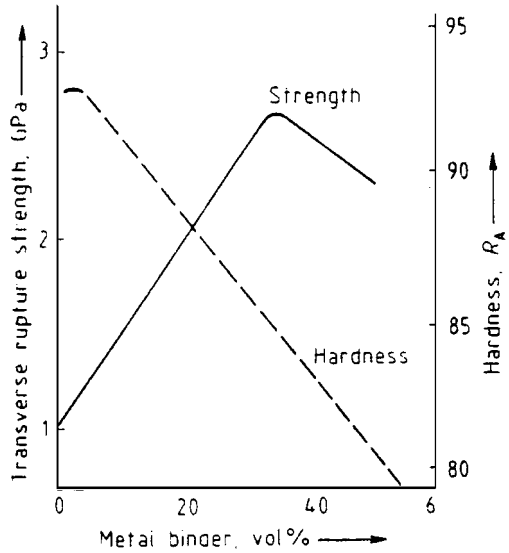

FIGURE 12.6.6 Effect of increased binder on strength and hardness of a TiC-Ni-Mo cermet with a 1 μm average carbide particle size.

ceramic, has a lower elastic modulus and will deform more easily. Fracture strength increases with binder because the metal phase confers fracture toughness. Generally, as ceramic grain size decreases, hardness and resistance to deformation increase for a fixed relative amount of ceramic. However, if the surface area increases sufficiently because of small grain size, there may not be sufficient metal to wet all the grain.

With these diverse factors a simplified way of looking at microstructural features and adjusting them for optimum performance is the mean free path, the average distance between neighboring ceramic grains (the average thickness of the binder phase). The mean free path depends on the size and shape of the grains and the amount of metal matrix available. Hardness, elevated-temperature hardness, strength, and toughness depend on the mean free path because it is the zone for absorption of crack energy and the medium for load transfer from grain-to-grain. Figure 12.6.7 shows that hardness varies with mean free path for a variety of cobalt contents and tungsten carbide grain sizes in cemented carbide. The curve does not continue below 0.1 μm because the metal binder becomes discontinuous.

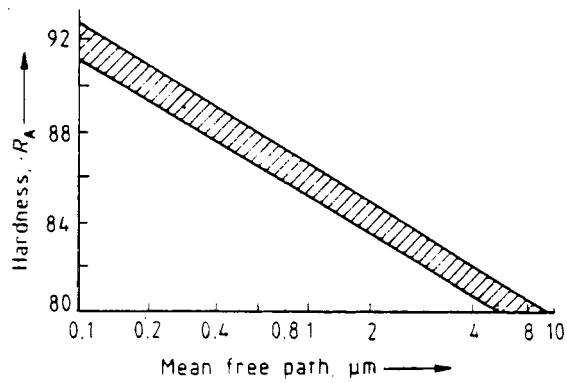

FIGURE 12.6.7 Effect of mean free path on hardness for a cemented carbide.

[b] Stress for 100-hr rupture life, 450°C.
[c] Stress for 100-hr rupture life, 1100°C.
[d] Stress for 10^{-4} in./in./hr creep rate.
[e] Modulus of elasticity, E = stress/strain.

B. Strength Ratios at High Temperatures

	Dispersed Particles		Strength by Test	
Matrix Metal	**Material**	**% by Volume (Range)**	**Range of Test Temperatures, °F**	**Strength Ratio, (Referred to Matrix at Same Temperature)**
Aluminum	Al_2O_3	10–15	400–800	2–4[a]
Copper	Al_2O_3	3–10	800–1100	5–10
Iron	Al_2O_3	8–10	1100–1300	5–10
Nickel	ThO_2	3	1600–2100	Strength higher than that of many super alloys
Platinum	ThO_2	12	2000–2400	8–11
Uranium	Al_2O_3	4–7	900–1100	2–3

[a] The tensile strength of the final product is two to four times the strength of the aluminum.

Table 12.6.6 presents data for selected metal matrix systems with particulate reinforcement, including strength values at elevated temperatures. A section of Table 12.6.7 provides stiffness values for cobalt and nickel strengthened with sintered carbides.

Fiber-Reinforced MMCs

Fiber-reinforced MMCs may still be classed as an emerging materials area. A number of applications have been practiced driven by the need for a lightweight, high-stiffness material and/or for elevated-temperature resistance in structures. These applications are typically for aerospace and similar advanced applications which can use a premium material. The limited scope of current practical application and the limitations placed on technology disclosure by the Export Control Act and International Traffic-in-Arms Regulations make this section brief.

High-strength/high-elastic-modulus fibers such as boron, silicon carbide, graphite, aluminum oxide, and tungsten metal are typically incorporated in light metal matrices such as aluminum, magnesium, and titanium. The specific modulus (elastic modulus divided by density) has been shown to be two to four times that of high-strength structural metals. The specific strength may be substantially higher than the metal. These properties are maintained to many hundreds of degrees above ambient, while those of many advanced structural metals deteriorate both in immediate heating and long-term creep. Some systems have been shown to have considerable fatigue resistance, showing several times the stress for equivalent cycle lifetimes. These properties are important for structural shapes in which light weight and elevated-temperature resistance can afford a premium. Some applications have been struts and tubes

[c] Percentage of tensile strength at room temperature retained when tested at 300°C.
[d] Tensile strength, room temperature.
[e] Modulus of elasticity, E, measured in compression; hardness, 90 R-A; compressive strength, about 600,000 psi.
[f] Modulus of elasticity, E measured in compression; hardness about 85 R-A.
Compiled from various sources.

for space structures, bicycle frames, turbine parts, propellers, and engine components. The fiber may be incorporated unidirectionally, as a woven 2D laminate or a 3D structure. Fabrication methods include diffusion bonding, pultrusion (hot isostatic drawing), hot rolling, molten metal infiltration, and casting.

Table 12.6.7 gives metal matrix strengthening values for fiber reinforcements added in volume percentages from 8 to 60%.

Ceramic Matrix Composites

Richard L. Lehman and Daniel J. Strange

CMCs are ceramic matrix materials, either oxide, carbide, nitride, boride, or similar material, reinforced with particulates, whiskers, or continuous fibers. The reinforcing phase may be of any material, but most interest is directed toward ceramic reinforcement media. The following sections address fiber- and whisker-reinforced ceramic composites, the materials which offer the greatest potential for ameliorating the brittleness of ceramics and for developing exceptional mechanical and structural properties.

Ceramic Matrix Fiber Composites

Introduction. Ceramic matrix fiber composites (CMFCs) are the focus of substantial research but of limited commercial application as of this writing. The research enthusiasm is stimulated by the potential of high strength and toughness, mechanical and chemical durability, hardness, and oxidation resistance, all at elevated temperatures in the range 1000 to 1400°C. The limited commercialization, which is principally in military and aerospace applications, stems from the substantial cost of the fabricated materials, often in the range of thousands of dollars per kilogram. Fiber and matrix materials and properties used in CMFCs are presented in Table 12.6.8.

Mechanical Behavior. The primary goal of reinforcing a ceramic material with ceramic fibers is to increase the fracture toughness of otherwise brittle ceramic materials. In a monolithic ceramic, a flaw will propagate through the material under tension due to stress concentration at the crack tip. CMCs are designed with $E_f/E_m > 1$ so that the reinforcing fiber absorbs stresses which tend to open and propagate cracks. Thus, the stress at the crack tip is reduced. Fiber debonding at the crack front, sliding, crack deflection, and other mechanisms also contribute to toughness. Often this is referred to as "rising R-curve" behavior, indicating that the strength of the ceramic at a crack tip increases with increasing crack length, stopping or slowing further crack growth. The most significant feature of CMFCs is the extensive fiber pullout, which occurs during failure. The fiber pullout results from low interfacial shear strengths, τ, which is designed into the composite by modifying interfacial properties and by using fibers with a *low* Weibull modulus. Loading is characterized by an initial elastic region followed by progressive failure of the matrix. The behavior is illustrated in Figure 12.6.8. During this matrix failure region, monotonically increasing loads are supported by the fibers. Ultimately, the fibers begin to fail according to bundle theory and the remaining load support is provided by the frictional resistance to fiber pullout, a highly significant effect which absorbs large amount of energy and contributes a high strain-to-failure performance previously unknown in ceramics. This "graceful" failure allows for a less catastrophic failure than normally encountered in ceramics and is of great significance in the design of such materials as turbine blades where the consequences of catastrophic failure are severe.

Continuous and Chopped Fiber Composites. The use of a continuous fiber reinforcement can have several advantages over the use of chopped fibers. There is a larger strain to pullout due to the increased fiber length, and the continuous fibers do not have stress-concentrating "flaws" as do the exposed ends of chopped fibers. Also, the prearrangement of the fibers allows very careful control of the properties in each direction, and the properties parallel to the fiber orientation will more closely mirror those of the fibers themselves than of the matrix. However, this type of composite is much more difficult to fabricate because of the problems of fiber weaving and forming, resistance to matrix infiltration, and

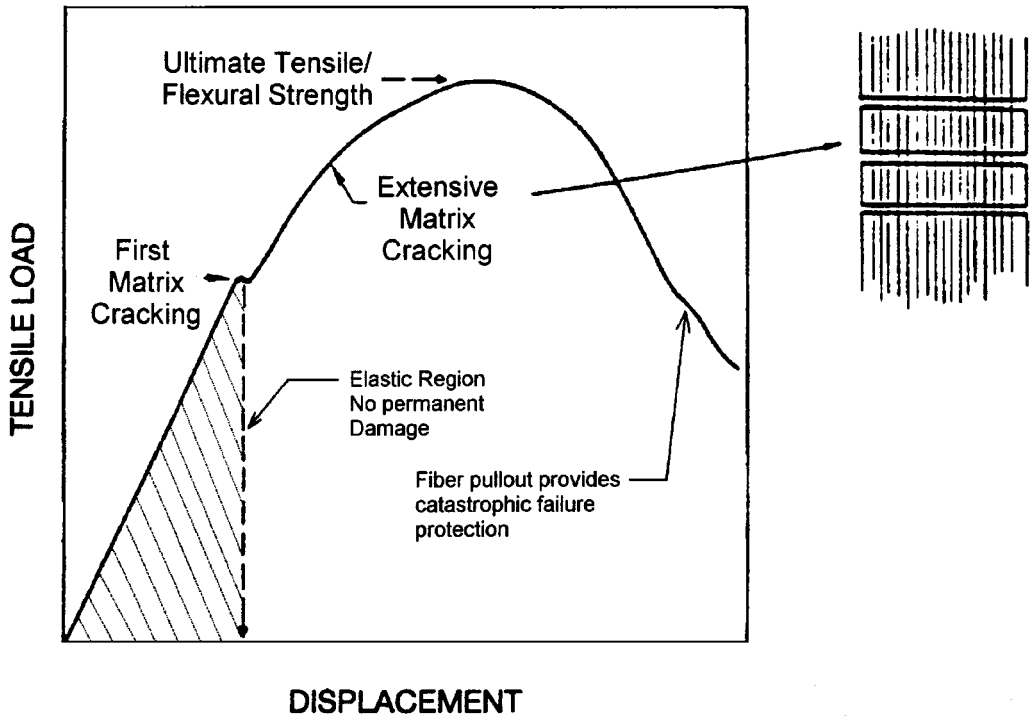

FIGURE 12.6.8 Load deflection behavior of CMFCs illustrating regions of fracture behavior.

resistance to densification, which necessitates expensive densification techniques, such as hot pressing, chemical vapor infiltration, polymer pyrolysis, directed metal oxidation, or sol–gel infiltration.

Glass Matrix CMFCs. A broad class of CMFCs has been developed and commercialized based on glassy matrix materials. The incentive for using a glassy matrix is the ease with which the matrix can be densified at low temperatures by vitreous sintering as opposed to the high-temperature solid-state sintering required for crystalline matrices. The low-temperature processing, in addition to being lower cost, preserves the high-strength properties of the fibers, which can easily be degraded at high temperatures. Unfortunately, the useful temperature of a glass-based CMC is limited to the T_g of the matrix, or slightly above, which prohibits traditional glass matrix CMCs from being used in extreme temperature applications (above approximately 1000°C). Newer glass and glass–ceramic compositions in the CaO-Al_2O_3-SiO_2 system are pushing this limit to the region of 1300°C. Two commercial glass matrix composites are Compglas™ and Blackglas™, both glass and glass/ceramic matrix materials reinforced with SiC fibers.

Polycrystalline matrix CMCs achieve higher temperature stability than the glass matrix composites, allow a wider choice of matrix materials, and generally have fewer problems with matrix reactivity. Typical crystalline matrix materials are the SiC, Si_3N_4, Al_2O_3, ZrO_2, and mixed silicates. Unfortunately, it is extremely difficult to sinter a CMC with a polycrystalline matrix to full density because of the interference of the fibers. This is particularly true with the nonoxide matrix materials. Pressureless sintering is ineffective for these materials, which necessitates the use of hot pressing or other exotic forming processes which raise material costs considerably.

Ceramic Matrix Whisker Composites (CMWCs)

Whisker reinforcement of ceramic matrices, while not as exotic, can dramatically increase toughness while preserving relatively inexpensive forming techniques. Figure 12.6.9 illustrates the "rising R-curve" behavior of alumina with the addition of SiC whiskers, while Figure 12.6.10 shows the increase in

© 1999 by CRC Press LLC

fracture strength. The composites can generally be fully densified with hot pressing or hot isostatic pressing (HIP). Unfortunately, the toughness values achieved to date with whisker reinforcement are not as high as those for continuous-fiber reinforcement, although the lower cost of whisker composites has stimulated industrial applications. Cutting tool inserts, which must withstand high stresses at elevated temperatures (1200°C), are fabricated commercially from SiC-whisker-reinforced Al_2O_3 (SiC/Al_2O_3). These composite inserts have been a commercial product for a decade and are an excellent example of cost-effective CMCs, i.e., high-value-added material applied to a small part exposed to extreme conditions. Health concerns regarding highly durable ceramic whiskers produced from SiC or Si_3N_4 have severely limited development and commercialization of these composites in the United States and Europe.

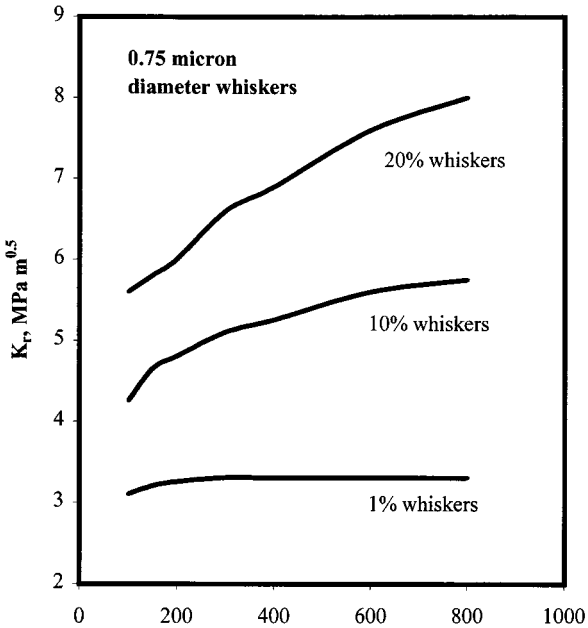

FIGURE 12.6.9 Fracture toughness and R-curve behavior of ceramic matrix whisker composites.

Carbon–Carbon Composites

Introduction

Carbon–carbon composites were originally developed for rocket nose cones in the 1960s because of their high specific strength, fracture toughness, thermal shock, and erosion resistance. Today, carbon–carbon composites are used in a broader range of applications, including brake components, fasteners, heaters, crucibles, and other assorted high-strength/high-temperature products.

High-Temperature Oxidation

Perhaps the greatest obstacle to the use of carbon–carbon composites as an engineering material, aside from high cost, is low oxidation resistance above 500°C. Although carbon–carbon maintains its mechanical properties to very high temperatures (>2000°C), it must be protected from oxidizing atmospheres at these temperatures or it will quickly degrade. Generally this is accomplished with SiC coatings with varying degrees of success. For most high-temperature oxidizing applications, carbon–carbon composite components are simply replaced when erosion reaches specified limits.

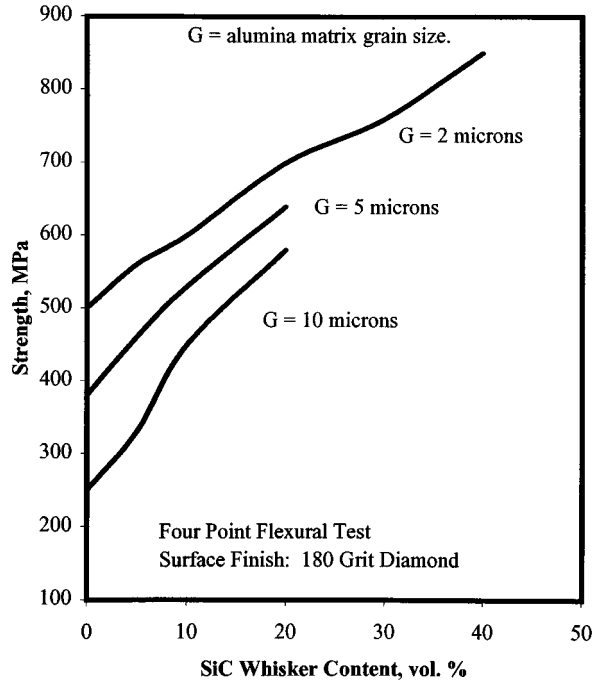

FIGURE 12.6.10 Strength behavior of SiC whisker-reinforced alumina matrix ceramic composite.

Fabrication

Most carbon–carbon composites are fabricated by polymer pyrolysis, the process of soaking carbon fiber yarns in a solution of a suitable polymer, then winding or laminating the fibers into the desired shape. Coal tar–based pitches, phenolics, and polyimides are also used as precursors.

The resulting green composite is then pressed, cured, and heated to 800 to 1200°C in an inert atmosphere, carbonizing the precursor. Some structures are heated to 2500°C to graphitize the matrix. The matrix after carbonization will contain a high porosity, typically 30%. This porosity is reduced by infiltrating the matrix with the precursor again and repeating the carbonization cycle. The densification cycle is repeated until the desired density is reached.

Carbon–carbon composites can be formed in random, unidirectional, 2D, 2.5D, and 3D weaves. Unidirectional weaves provide the highest strength along the fiber axis, but much lower strength in other directions. Unidirectional weaves are generally only used in laboratory investigations, as they have little technical value. 2D weaves (fabrics) are by far the most common due to the relative ease of manufacture and good mechanical properties in the plane of the fabric. 2.5D and 3D weaves allow the weaving of very complex structures with good properties in any desired direction, yet the weaving costs can be prohibitive and unnecessary for most industrial applications.

Mechanical Properties

Properties of some carbon–carbon composite materials are given in Table 12.6.9. The properties can vary considerably, however, depending upon factors such as the weave, tow diameter, precursor, pressing pressure, heat-treatment temperature, and number of densification cycles.

Under cyclical loading, carbon–carbon withstands 70 to 80% of its ultimate tensile strength. Carbon–carbon composites also have large strains to failure, exhibiting pseudoplastic behavior. This is unusual for a high-temperature ceramic material and is one of its prime attractions. The responsibility for this behavior lies with the low fiber–matrix interfacial bond strength and matrix microcracking. Unlike most high-temperature materials, the mechanical properties of carbon–carbon do not degrade at

high temperatures. In fact, in inert atmospheres the strength of carbon–carbon composites increases by 40 to 50% up to a temperature of 1600°C.

Thermal conduction, electrical conduction, and thermal expansion are all much greater along the direction of the weave than perpendicular to it. Interestingly, thermal expansion is negative in 2D weaves perpendicular to the fibers. It is therefore possible to use the fiber architecture to achieve near zero thermal expansion in some directions.

12.7 Ceramics and Glass

Richard L. Lehman, Daniel J. Strange, and William F. Fischer, III

Traditional Ceramics

Traditional ceramics encompass many materials, not simply pottery, dinnerware, tile, and sanitaryware, but also technical whitewares, structural clay products, refractories, glazes, and enamels. The product and processing technology of these materials has advanced substantially in recent years which has improved products, reduced costs, and expanded application. Refer to Table 12.7.1 for properties of selected ceramics in this group.

TABLE 12.7.1 (Part I) Physical Properties of Selected Ceramics

Whitewares

Whitewares are principally comprised of traditional ceramic bodies that are white, cream, ivory, or light gray in appearance. Most whiteware materials are formulated from clay, flint, and feldspar (triaxial compositions) although other additives may be incorporated. The engineering properties of whitewares are strongly affected by porosity, a characteristic that reduces frost resistance and cleanability but is essential for certain aesthetic effects.

Vitreous. Vitreous whiteware bodies are translucent and have no open porosity, while earthenware and wall tile, for example, have substantial porosity, and semivitreous bodies bridge the gap in both porosity and translucency. The firing temperature is largely responsible for the differences in properties of the bodies by affecting the degree of vitrification. The general categories of products within the whiteware group are given in Table 12.7.2.

Earthenware. Earthenware materials are defined as a nonvitreous clay-based ceramic ware of medium porosity (4 to 20%). They can be glazed or unglazed in their finished form. There are four primary subclasses of earthenware, natural clay, fine, semivitreous, and talc earthenware. Natural clay earthenware is derived from a single, unbeneficiated clay, whereas fine earthenware possesses beneficiated clays, as well as nonplastic materials, to comprise a triaxial body. Semivitreous earthenware is also a triaxial body, but it is fired to a higher temperature to form a more glassy phase, thereby creating a body with

the lowest porosity of the earthenware group, usually between 4 and 9%. The final earthenware body is talc earthenware, produced principally from raw talc, with porosity ranging up to 20%. Earthenware bodies range in color from white for the talc and triaxial bodies, to tan and brown for many artware bodies, to a rusty red for terra-cotta.

Stoneware. Stoneware bodies can be either vitreous or semivitreous. They are primarily composed of nonrefractory fireclays or a combination of triaxial materials that matches the forming, firing, and finished properties of a natural stoneware body, bodies made from a single, naturally occurring, largely unbeneficiated clay-bearing material. Fine stonewares incorporate beneficiated clays, as well as nonplastics. Jasper stonewares are composed primarily from barium-containing compounds, while basalt stonewares contain large amounts of iron oxide.

Vitreous stoneware bodies are made from blends of a variety of beneficiated materials that are fired to higher temperatures to achieve low porosity levels (0 to 5%) necessary for many applications. Stoneware bodies are usually quite durable and resistant to chipping. However, translucency is less than that of china and the colors are not as white because of the presence of iron and other impurities.

China and Porcelain. China and porcelain are nearly synonymous terms which refer to fully vitreous (no porosity) clay, flint, feldspar compositions which are typically glazed, fired to high temperatures, and exhibit strength, hardness, and chemical durability. The term *china* is used to describe exceptionally fine materials prepared from low-impurity raw materials and used in artware and dinnerware. In modern times there has been a trend toward highly vitreous and highly translucent china compositions. Porcelain is used to describe mostly technical ceramics of the triaxial composition which are used as electrical insulators, sanitaryware, and chemical ware.

Subclassifications of china exist, such as vitreous china, hotel china, cookware, technical ceramics, fine chinas, and porcelains. Body formulations are usually based on the triaxial body, clays, flint/silica and fluxing agents, most usually feldspathic materials. However, there are a large number of bodies that are composed of a large fraction of other materials. Inclusive of these are alumina, bone ash, cordierite,

© 1999 by CRC Press LLC

other fluxes, and/or lithium compounds. Vitreous china is a category of traditional ceramics referring to the various sanitaryware plumbing fixtures and accompaniments. Hotel chinas, as the name implies, are generally used in commercial food establishments. Both bodies are glazed in a single firing operation in which both the body and glaze mature at the same time.

Technical whitewares account for a wide variety of vitreous ceramics used in the chemical, dental, refractory, mechanical, electrical, and structural areas. The compositions of most of these materials are similar to that used in the hotel chinas, with the possible substitution of alumina and zircon for some or all of the silica. These materials can be either glazed or unglazed with water absorption less than 0.5%.

Fine china bodies, including bone china, are highly vitrified and translucent materials that are usually fired in two or more separate operations. The first, higher-temperature firing matures the body and a second, lower-temperature firing matures the newly applied glaze. The separate firing conditions allow for the use of high-gloss glazes. Subsequent firings are used to apply decals and metallic decorations.

Porcelain ceramics are mostly used in technical applications. The typical body is triaxial (Table 12.7.2), although some or all of the silica can be replaced with alumina to increase the mechanical properties. Aside from triaxial porcelains, compositions in the $MgO \cdot Al_2O_3 \cdot SiO_2$ composition range are popular for electronic applications due to the absence of mobile alkali ions.

Refractories

Introduction. Refractory ceramic materials are by nature inert, high-melting-point compounds that are resistant to corrosion throughout the temperature range of use. Refractories must also withstand thermal cycling, thermal shock, mechanical fatigue, and a range of chemical attack from the elevated-temperature environments typical of most applications. Refractory materials are used in the processing of metals (75% of all refractories), glass, cement, and in the processing of nearly all ceramics.

Temperature Tolerance. A quality refractory must be stable at the intended use temperature. Refractoriness is a measure of the highest use temperature the material can withstand and is limited by the softening or melting point of the constituent oxides. Most refractories are a mixture of phases, and, as such, do not display a distinct melting point, but have a range of temperatures where the material starts to soften or melt. Most frequently, a refractory is categorized by an upper use temperature, but sometimes the refractoriness is quantified by the PCE or pyrometric cone equivalent. The PCE is a measure of the heat content that the refractory can withstand before beginning to soften, which is determined by the slumping of pyrometric cones during thermal cycle testing. This value may correspond to different temperatures under different environments or atmospheres and is thus a good indicator of maximum-use conditions. Refractory suppliers can provide PCEs for specific products. Another measure of a refractory quality is the failure under load temperature. The temperature where a refractory sags or deforms is part of all refractory specifications and is related to the amount and composition of the glassy phase within the material.

Dimensional Stability and Spalling. Dimensional stability and resistance to spalling are important performance criteria for most refractories. Spalling is the cracking or flaking of the refractory which usually results from thermal cycling, thermal gradients within the refractory, or compression effects due to differing thermal expansion of the different system materials. Spalling reduces the effectiveness and lifetime of the refractory. The dimensional stability of the refractory is also important. Since the refractory is subjected to both heating and cooling cycles, as well as thermal gradients in use, the expansion of the material is very important when choosing a refractory. Large changes in the size of a refractory set up stresses that can reduce the effectiveness of the refractory and may result in its failure.

Porosity. Refractory porosity is closely controlled in manufacturing since it leads to a reduction in the mechanical strength of the material and allows for the penetration and chemical attack of liquids or gases to the internal surface of the refractory. However, on the positive side, the presence of internal pores reduces the thermal conductivity of the material and increases fracture toughness, K_{IC}.

© 1999 by CRC Press LLC

Fireclay Refractories. Fireclay refractories are composed of hydrated aluminosilicates with silica content of up to 75% or more with alumina and other minor contents of less than 40%, although alumina-fortified fireclay refractories are made with considerably higher alumina contents. Properties vary greatly over this wide range of compositions — generally, the higher the alumina content, the higher the performance. Fireclay refractories based on kaolin have a high refractoriness and high load resistance. Resistance to chemical attack and thermal conductivity decrease with increasing porosity, whereas spalling resistance increases. Increased alumina content raises the resistance of the material to attack in molten environments. Fireclay refractories are the most widely used refractory and find application in many industries.

Alumina Refractories. High-alumina refractories contain 80 to 99% or more aluminum oxide. As with fireclay materials, the higher the alumina content, the higher the refractoriness and the higher the load-bearing capacity. The chemical resistance of alumina refractories is greater than that of the fireclay refractories. Alumina brick is used to replace fireclay brick in more severe applications in the steel industry. Alumina bricks with phosphate bonding are used in the production of aluminum because of their refractoriness and the resistance of the phosphate bonding to chemical attack by the molten aluminum. Mullite ($3Al_2O_3 \cdot 2SiO_2$) refractories are similar to alumuna refractories in performance, but are cheaper and more resistant to thermal shock at the expense of some temperature capability.

Silica. Silica brick refractories, used in the glassmaking industry, range in composition from almost pure silica to mixtures containing lime, iron oxide, and alumina, depending on the degree of beneficiation of the raw materials. These refractories show a high degree of volume stability below 650°C (1200°F) and a lower degree of spalling than the fireclay bricks, largely because of the low thermal expansion of the silica.

Basic Refractories. Basic refractories are constituted from magnesite (MgO), calcia (CaO), and chrome (Cr_2O_3) and are used widely in metallurgical industries where basic slags predominate. They are not suitable in acid, or high-silica, environments. Refractories in this group, such as pure magnesite, dolomite (CaO-MgO), and chrome magnesite materials, have high refractoriness, volume stability, and are very resistant to chemical attack. Magnesite refractories have between 80 and 95% MgO content, a level at which the refractoriness and resistance to chemical attack is extremely high. Chromite refractories also have excellent chemical resistance in basic environments, with moderate resistance in acidic environments. The chrome content in these refractories ranges between 30 and 45%. Chrome–magnesite refractories are composed of over 60% MgO. Compositions and properties of selected basic and high-duty refractories are given in Table 12.7.3.

Glazes and Enamels

A glaze is a continuous glassy layer that is bonded to the surface of a ceramic. The glaze is typically hard, impervious to moisture, and easily cleaned. An enamel is similar in properties to a glaze, but the substrate is metallic. The surface finish of either can be altered from glossy to matte by varying the composition or the firing conditions. A glaze is usually composed of an aqueous suspension of ceramic particles that is applied to the surface of a material, dried, and fired. During firing, the materials within the glaze react and melt, forming a thin glassy layer on the surface of the ceramic material. Some materials are prefired and then the glaze is applied, or, as is becoming more common, the glaze can be fired along with the body. The maturing temperature of most glazes is on the order of 500 to 1500°C, or 930 to 2730°F. Glazes can be either clear, transparent, or opaque. Some glazes are formulated to form crystals within the glaze for a variety of optical effects, such as opalescence.

There are three main types of glazes used. The first of these are the raw glazes. Raw glazes can be further broken down into leaded, leadless, zinc-containing, slip, and porcelain glazes. Lead promotes the processing of the glaze via low viscosity and surface tension and imparts a high refractive index to the finished glaze. However, due to the health hazards associated with free lead, there has been a movement toward lead-free glazes in certain applications. Lead-free glazes require an increase in the

Silica	100% SiO_2	1200	2190	0.8	1.4	1.8
Mullite	72% Al_2O_3, 28% SiO_2	1850	3360	5.3	3.8	3.4

firing temperature of approximately 150°C, from 1030 to around 1190°C. Porcelain glazes mature at temperatures in the same regime as the underlying body from which they get their name. Zinc-containing glazes are similar to porcelain glazes except that they mature at lower temperatures. Slip glazes are used in artware glazing and high-tension electrical insulators. Fritted glazes are in the form of prereacted glass which has been ground to form a powder. Special glazes offer special optical properties in the finished surface. Salt glazes are formed by injecting salts into the firing kiln, with the resulting glaze having a complex pattern of crystalline and glassy phases. Crystalline glazes are often zinc based and produce crystals within the glaze, again for artistic value. Luster glazes form a metallic coating on the glaze.

Structural Clay Products

Ceramic materials are used in a wide variety of applications in the construction industry, ranging from concrete and cement for buildings and highways, to structural clay materials for use in piping and roofing. For a discussion of concrete materials refer to Section 12.5.

Structural clay products have been used for millennia. Original uses included tile and clay brick for building construction, as well as pipes in water supply and sewer applications. These materials are still used today because of their high compressive strength and imperviousness to water. Structural ceramics are coarse-grained materials with the one exception of ceramic tile. Typical raw material compositions for these bodies are 35 to 55% clay, 25 to 45% filler, usually silica, and 25 to 55% fluxing material. Colors range from white for the kaolinitic clay products, to a buff for the fireclay materials, to red for the illitic materials. Properties vary widely between the different materials. Most concern is placed on the water absorption, which relates to freeze/thaw durability and compressive strength.

Advanced Ceramics

Classes of Advanced Ceramics

Advanced ceramic materials are materials which have been engineered to possess exceptional levels of mechanical, optical, thermal, or other property. Most often the materials possess high strength, high stiffness, or are chemically inert. Typical materials contain oxides, nitrides, or carbides which may be monolithic structures or reinforced with various particulate and/or fibrous materials. Refer to Section

© 1999 by CRC Press LLC

12.6 for a detailed discussion of composites. The reinforcement phase usually, but not necessarily, differs from the matrix material. Phases used in designing engineered ceramics are listed in Table 12.7.4 with specific property characteristics as indicated. Advanced ceramic materials are currently much more varied and less standardized than metals, and materials from different manufacturers, or even from different production lots, will have varied properties.

TABLE 12.7.4 Selected Properties of Crystalline Phases Used in Engineered Ceramics

Crystalline Phases	Formula	Melting Temperature (C)	Thermal Expansion α (ppm/°C)	Dielectric Constant κ
Magnesia	MgO	2852	14	5.5
Magnesia spinel	$MgO \cdot Al_2O_3$	2135	8	8.0

Structural Ceramics

Required Properties. Structural applications involve the use of ceramic materials in load-bearing situations. Material properties required for these conditions include strength over a wide temperature range, often as high as 1400°C, stiffness, creep resistance, resistance to corrosion and oxidation, and, ideally, damage tolerance or toughness. The major difficulty in the use of ceramics for structural applications is their low fracture toughness compared with metals. Conversely, ceramics excel at high-temperature behavior, have low density/weight ratios, high stiffness, and chemical inertness. At the present level of technology, there is a trade-off between high strength and high toughness. To get a high-strength material usually requires a fine-grain-sized ceramic, while a tough ceramic material often has elongated grains or reinforcement phases that are usually quite large.

Applications. Existing and potential applications include automotive, biomedical, power generation, heat exchangers, wear materials, aerospace and military applications, cutting tools, and various other technologies. Table 12.7.5 provides the mechanical properties of selected advanced ceramics. The property values listed are guidelines; exact properties are difficult to specify since the exact properties depend largely on processing. Material selection is governed by the environmental conditions of each application.

Electronic and Magnetic Ceramics

Electronic and magnetic ceramic materials have a variety of useful functions. Alumina, alumina titanate, and aluminum nitride are used as substrate materials, zirconia is used in oxygen sensors, lead zirconate

titanate (PZT) and lead magnesium niobate are common actuator and transducer materials, and barium titanate and related materials are used in capacitors. Ceramic materials are used not only in military and aerospace applications, but also in consumer electronics, computers, automotive and transportation systems, and power generation systems. Electronic/magnetic ceramics are useful as a result of a variety of properties. Refer to Table 12.7.1 for dielectric property data of selected compositions.

Optical Ceramics

Zirconia and transparent alumina, or sapphire, are often used as high-temperature windows, due to their high melting points, chemical inertness, and high transparency. They are also used as watch crystals, due to their high scratch resistance. Mirrors made from silicon carbide are being evaluated because of the higher strength-to-weight ratio compared with glass materials and the relatively low coefficient of thermal expansion of SiC. Laser crystals are a group of materials which are often based on doped crystals — yttrium aluminum garnet (YAG) is representative, Infrared (IR) transparent windows and shields are used principally in military and aerospace applications to protect IR sensors from damage. Missile nose cones, or randomes, must possess high mechanical strength and be resistant to mechanical erosion and thermal shock. Typical materials include aluminum oxynitride, spinel, zinc sulfide, calcium fluoride, yttria, and sapphire. Refer to Table 12.7.6 for IR absorption ranges of important ceramic materials.

Effect of Finishing and Machining on Properties

Final finishing of many advanced ceramics is required to obtain the optimum mechanical properties or to meet design tolerances. Since sharp corners act as stress concentrators and are not associated with good design, they are usually machined to a several-millimeter radius if they occur in the as-manufactured product. Other operations include surface grinding, polishing, or lapping operations. Ceramics are very hard materials, which makes final matching machining extremely time-consuming and expensive. Every effort should be made to fabricate components to close to net shape tolerances, or to machine the piece as much as possible prior to final firing.

Traditional Glasses

Definition and Introduction

Traditionally, glass is defined as an inorganic product of fusion which has cooled to a rigid state without crystallizing. This broad definition says nothing about the chemistry of the glass but rather refers to the traditional concept of cooling liquid melts below the melting point to form substances which are rigid elastic mechanical solids but which have not crystallized. The historical model for this process is the melting of soda–lime silicate glass by fusing the raw materials at high temperature and cooling quickly to form the well-known window and container glass still in wide use today. Although this definition is still generally valid, processes exist today in which glass is made without fusion. Chemical and physical vapor deposition, and sol–gel processes are examples. Many organic and metallic materials form glasses and are in commercial use today, thus rendering the “inorganic” part of the historical definition inappropriate.

A more applicable definition of glass is an X-ray diffraction amorphous material which exhibits a glass transition. A glass transition is the temperature point at which the amorphous solid exhibits a continuous change in thermodynamic quantities such as heat capacity and expansion coefficient. Because the structure of the glass is frozen before it reaches equilibrium, a glass is metastable with respect to its corresponding crystalline phase. Unlike the crystalline phase, the glass can have a range of physical properties depending upon the rate of cooling (thermal history) and these properties are universally isotropic.

Although glass can be made from an enormous range of polymers, oxides, metals, and inorganic and organic salts, the principle glasses of interest to a mechanical engineer will be glasses with oxide network formers such as SiO_2, B_2O_3, P_2O_5. These oxides, among others, are known as glass formers. They are capable of forming the three-dimensional network essential to the existence of the glassy state. Other

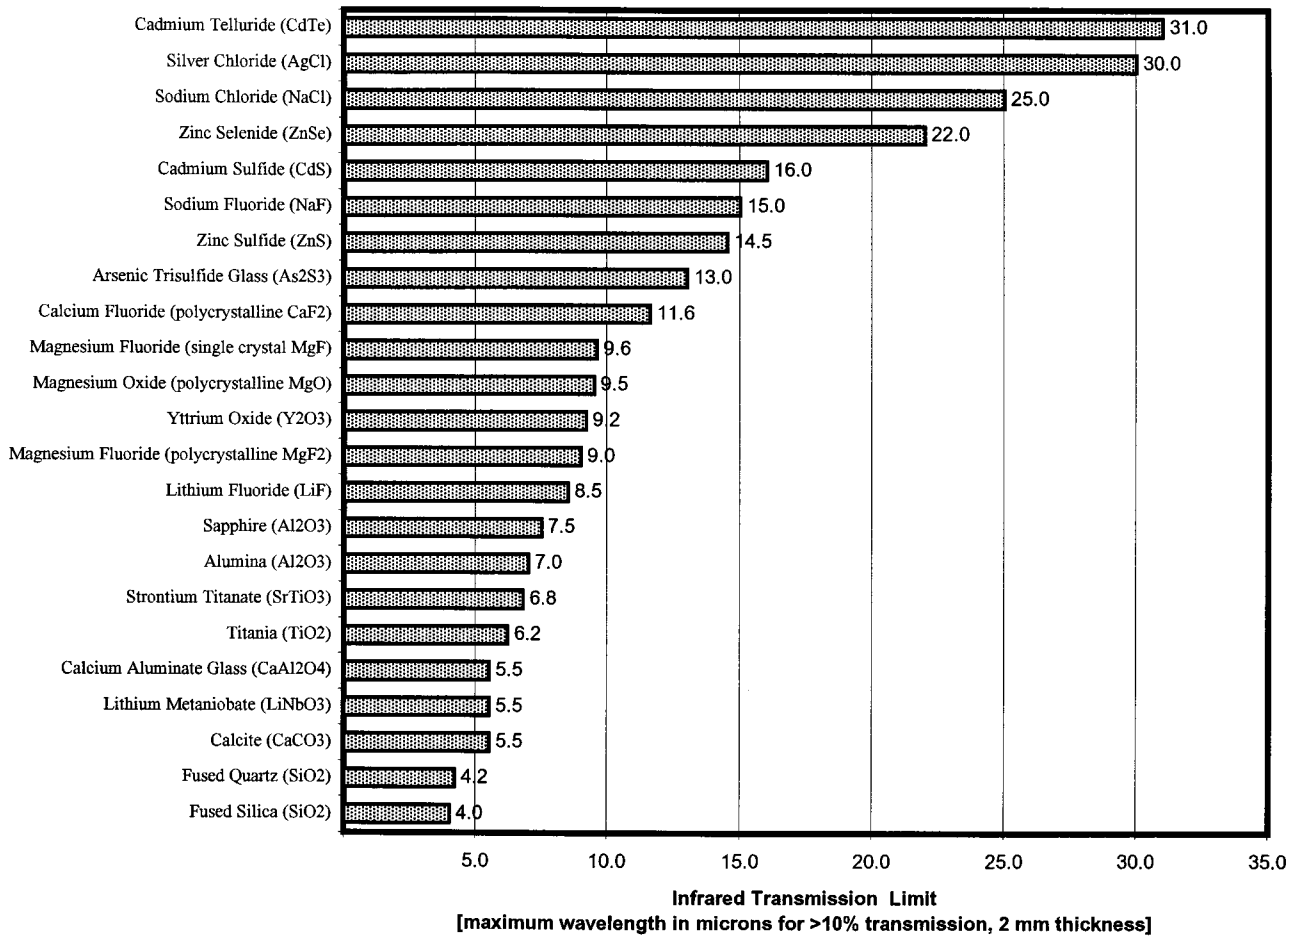
TABLE 12.7.6 IR Transmission Limits for Selected Materials



© 1999 by CRC Press LLC

oxides, such as alkalis, alkaline earths, and various transition elements simply serve to modify the basic network to produce varying properties.

The most common glass in use today is the very old soda–lime–silicate glass composition based on the weight composition: 74% SiO_2, 16% Na_2O, and 10% CaO. In this composition the silica is the network former, the sodium breaks up the silicate network to permit melting and fabrication at reasonable temperatures, and the calcia provides ionic bonding within the network to provide chemical durability. This composition is used today, with minor variations, for early all container, window, and tableware glass articles.

Composition/Properties

Traditional glasses are silicate glasses, i.e., glass which contain SiO_2 as the principal network-forming oxide. Table 12.7.7 give compositions for a representative range of commercial glasses, and Table 12.7.8 lists properties for flat glass. All glasses in Table 12.7.7 contain at least 50% SiO_2 and many are quite close to the traditional 74/16/10 composition mentioned above. The types and amount of modifier oxides are determined by the properties required in use. A more specific list of technical glass compositions from Corning, Inc., and identified by Corning glass codes, is given in Table 12.7.9. Principal glass types are discussed in the following sections.

Pure Silica Glass. Pure silica glass (fused silica) has excellent thermal, mechanical, chemical, and optical properties. Thermal expansion is $5.5 \times 10^{-7}°C^{-1}$, use temperature is above 1000°C, and it has excellent visible and ultraviolet (UV) transmission. However, the melting point is greater than 2000°C, which makes manufacture extremely difficult and expensive. Therefore, fused silica is used primarily for such demanding applications as optical fibers, semiconductor process equipment, UV lamps, optics, and space shuttle windows. If 7 wt% titanium dioxide (TiO_2) is added, the thermal expansion coefficient is reduced to zero in normal temperature ranges. This glass (ULE, or ultra low expansion) is used in applications which require exceptional dimensional stability. Telescope mirrors are an example.

High-Silica Glass. The high melting temperatures needed to produce pure SiO_2 glass can be avoided by first melting a special sodium borosilicate glass which can be formed into the desired shape. This glass (Vycor®) phase separates and after acid leaching results in a high (>96%) silica glass with nearly the same properties as pure vitreous silica.

Soda Silica. In order to lower the melting point, a flux is added. The most common flux is sodium oxide (Na_2O), which makes a low-melting glass that is soluble in water and is called water glass. Dissolved glass is used to seal or bond materials such as low-speed grinding wheels.

Soda–Lime–Silica. This is the most common glass and accounts for more than 90% of all the glasses made today. In this glass, lime (CaO) has been added to improve the durability of simple soda–silica glass. Small amounts of other oxides such as alumina (Al_2O_3), magnesium oxide (MgO), and potassium oxide (K_2O) are also added to further enhance the desired properties. The lime is usually obtained from limestone, and the sodium monoxide is obtained from any number of sodium compounds, notably sodium bicarbonate or common baking soda.

Aluminosilicate Glass. Aluminosilicate glass is produced by adding up to 20% Al_2O_3 to soda–lime glass. Aluminosilicate glasses are resistant to thermal shock and high temperatures, and they are not as difficult to produce as silica glass. They find wide use in electronics and in high-temperature laboratory equipment.

Borosilicate Glass. In borosilicate glass much of the soda and lime of ordinary glass is replaced by boric oxide. The result is a glass that has a low thermal expansion and is thus resistant to heat and to sudden changes in temperature. The first borosilicate glass was developed by the Corning Glass Works under the trade name Pyrex. Borosilicate glasses are used in laboratory glassware, as well as in home ovenware. Because of their low thermal expansion they are suitable for applications requiring dimensional stability.

Lead Silicates. Lead silicate glass has a higher index of refraction and also a higher dispersion than soda–lime–silicate glass and thus finds use in optical applications. The high gloss resulting from high Fresnel reflection makes lead glasses of 24 to 35% PbO popular for consumer products in the form of artware and lead crystal glass. Lead glasses of different compositions are used widely in electronic applications since low-melting sealing glasses can be formed with little or no alkali, a constituent which promotes high electrical loss.

Strength of Glass

Theoretical Strength. Glass below the glass transition temperature (T_g) is a brittle solid, with failure originating at flaws (scratches, defects, minute compositional differences) which act as stress concentrators. Without flaws of any kind the strength of glass approaches theoretical levels of about 17 GPa (2.5×10^6 psi). Unfortunately, unless glass is processed under the utmost pristine conditions and then immediately coated to prevent surface abrasion by dust or other environmental agents, the glass will contain flaws which decrease the strength by several orders of magnitude from theoretical levels. Synthetic silica glass optical fibers, prepared under meticulous conditions and tested at 77 K, are among the few glass materials which exhibit nearly theoretical strength.

Nominal and Design Strength. The exact failure stress for a specific piece of glass will depend upon the configuration and size of the defect at the crack origin. Since these defects vary in size over a wide range, the standard deviation in the strength of glass will also be large. The glass design engineer must allow large safety factors, often 20 to 50%, to account for the statistical variation. For most types of glass a nominal strength of 70 MPa and a design stress of 7 MPa are typical. Table 12.7.10 summarizes strength and variability in the strength of glasses.

Strengthening and Tempering. Glass can be substantially strengthened, or tempered, either by rapid cooling or by ion-exchange of the surface to develop compressive stresses. Fast, uniform cooling of glass plates heated to the softening point will introduce surface compressive stresses on the glass (with corresponding tensile stress in the center) which become permanently frozen into place upon cooling to room temperature. These compressive stresses, typically 70 to 200 MPa, will resist externally applied tensile stresses and help to prevent crack propagation. Tempering will increase the strength of glass by as much as three to six times. Tempered glass will shatter violently when it fails as a result of the sudden release of stored elastic energy, although the broken pieces will not be sharp. Generally, only simple shapes can safely be thermally tempered.

Ion-exchange tempering also improves the strength of the glass by introducing surface compression. In the ion-exchange process large ions are "stuffed" into the interstices in the glass structure previously occupied by smaller ions. This is done by immersing the glass in a molten bath of the alkali salt (typically KNO_3 for a sodium-containing glass) at an elevated temperature. The larger ions will introduce a compressive strain as they force their way into the glass network. The strains obtainable are much higher

than those from thermal tempering, generating stresses as high as 700 MPa, although the surface compressive layer is quite shallow and subject to penetration. Ion-exchanged glasses can be more than 10 to 20 times as strong as normal glass and are used, for example, in aircraft windshields to resist bird impacts.

Behavior at Elevated Temperatures

Glasses do not have a clearly defined melting temperature. Instead, there is a temperature range where the viscosity of the glass changes smoothly from solid (greater than 10^{14} Pa · sec) to liquid (less than 10 Pa · sec). It is useful to define some points on the viscosity–temperature curve to create a clearer

picture of the viscosity behavior of a glass. The strain point is defined as the temperature at which a glass will release 95% of its stresses within a period of 6 hr. This occurs at a viscosity of approximately $10^{13.5}$ Pa · sec. The annealing point occurs at 10^{12} Pa · sec a viscosity at which 95% of stresses will be released in 15 min. At $10^{6.6}$ Pa · sec, the softening point, the glass will deform under its own weight. The working point is defined as 10^3 Pa · sec, and is a typical minimum viscosity for machine working during forming. Refer to Table C.12 in the Appendix, Properties of Silicate Glasses. Many properties of glasses are presented in this comprehensive table, including maximum application temperatures (upper working temperature) and viscosity data for most common glasses. Generally, the extreme upper working temperature corresponds to the strain point of the glass. Normal service conditions are typically 50 to 60% of the strain point on the Kelvin temperature scale. Under normal service conditions glass is a brittle, mechanical solid, it possesses no mechanical characteristics of a liquid, and it will not flow. Specific heat and thermal conductivity data are presented in Table 12.7.11. Below the glass transition, glass is not a supercooled liquid, it is a glass. Old windows are not thicker at the bottom because of viscous flow.

Chemical Durability

Although glass is often considered an extraordinarily inert material, even the most durable glasses undergo some environmental degradation and many glasses are rapidly attacked by strong acid or basic solutions. Corrosive aqueous environments can cause the ions in the glass to be extracted by a leaching process. Chemical durability behavior is difficult to generalize and trial-and-error testing is usually required for each application. The most severe attack is experienced at extreme high and low pH values; neutral pH solutions rarely attack glass at significant rates. Glasses high in SiO_2, Al_2O_3, and CaO are generally most durable. Glasses high in alkali, such as Na_2O or K_2O, are less durable. B_2O_3 and PbO are intermediate.

A notable form of chemical degradation which occurs under simple, apparently benign, conditions is weathering. Standard soda–lime–silicate window glass can be permanently damaged in a short time (~30 days) if held under high humidity with a means to retain adsorbed moisture on the surface. Such a means

can be a dirt film or perhaps a sheet of newspaper. The moisture ion-exchanges with sodium ions in the glass, which form a high-pH surface film which accelerates the attack on the glass. Pitting and adherent surface deposits can quickly form, making the glass unusable.

For container applications requiring extremely high purity, it is common to use a durable glass such as a borosilicate or to increase the chemical resistance of the glass using surface treatments of SO_2, SnO_2, or TiO_2.

Optical Properties

Traditional glasses are principally used because they are transparent in the visible region of the spectrum; windows, containers, and precision optics are examples. Although pure silica is highly transmissive overt the entire visible spectrum, impurities impart coloration which detract from the performance of some glasses but which can also be used to produce beautiful and useful colored glasses. Table 12.7.12 lists impurity ions and their resulting colors. Iron is the most common impurity, imparting a blue-green-yellow tint depending on the oxidation state. It is possible to neutralize but not bleach impurity colors by "decolorization," the addition of complementary coloring oxides to produce an overall neutral gray absorption. Traditional glasses do not transmit well in the UV or IR range, with the exception of certain specialty glasses. Pure silica is the best example, enabling high transmission levels (>10%, 2 mm thickness) from 160 nm to 4 μm.

The refractive index of common silicate glasses are in the range of 1.5 to 1.7 and specific values are given in Table C.12 in the Appendix, *Properties of Silicate Glasses*.

Specialty Glasses

Non-Silica-Oxide Glasses

Glasses made from B_2O_3 and P_2O_3 glass formers rather than SiO_2 possess some special thermal, optical, and chemical properties which make them of interest in certain narrow engineering fields. Borate glasses, often in combination with PbO, are useful solder and sealing glasses for electronic applications; phosphate glasses have special optical properties and are also used as water-soluble chemicals in industry. Tellurite glasses have high refractive indexes and, hence, are used in some demanding refractive optic applications. Glasses based on Bi_2O_3, Sb_2O_3, TeO_2, or V_2O_5 have very low melting points, suggesting their use as low-temperature electrical seals. Boro-aluminates have very high electrical resistivities. Alkaline earth aluminates have excellent IR transmitting properties and make excellent high-temperature

TABLE 12.7.12 Coloring Additives to Glass

Color	Additive
Red	Colloidal Au or Cu, Cd-Se (S, Te)
Pink	$MnO_2 \cdot CeO_2$, Se^{2-}
Orange	CdS (Se)
Amber	FeS_x, $Fe_2O_3 \cdot TiO_2$
Yellow	UO_2, $CeO_2 \cdot TiO_2$, CdS
Green	Cr_2O_3, Fe_2O_3, CuO, U_2O_3
Blue	CoO, FeO, CuO
Violet	NiO, Mn_2O_3
Gray	$Co_3O_4 \cdot NiO$
Black	$Mn_2O_3 \cdot Cr_2O_3$, PbS, FeS, $CoSe_x$
UV absorption	CeO_2, TiO_2, Fe_2O_3, V_2O_5, CrO_3
IR absorption	FeO, CuO
Decolorization, i.e., mask Fe_2O_3 color	MnO, Se^{2-}, NiO, Co_3O_4
Opacification, i.e., white opals	CaF_2, NaF, ZnS, $Ca_2(PO_4)_3$
Solarization	Cerium, arsenic

lamp seals. Despite their unique properties, non-silica-oxide glasses are costly and make up only a very small percentage of the glass produced annually.

Chalcogenide Glasses

A class of excellent IR-transmitting glasses, the chalcogenides, are obtained by combining group VI elements with group V and IV elements. Glasses in this group also exhibit photoconductivity and semiconductivity. Applications for these glasses consist of IR-transmitting optical waveguides (to 20 μm), high-performance IR optical applications, and specialty applications which utilize their photoconductivity properties. Most notable of these applications is the photosensitive coating applied to photocopy drums. Purity issues have limited applications in optical fibers as of this writing.

Heavy Metal Fluoride Glasses

Heavy metal fluoride glasses (HMFG) are an important new (1975) composition group because of their extremely low theoretical optical attenuation (10^{-3} dB/km at 3.5 μm), which makes them candidates for repeaterless transoceanic communication links. Unfortunately, this magnitude of transmission has not been obtained in practice because of problems with high oxygen impurities and crystallization. Furthermore, HMFGs are readily attacked by water, and current development efforts are aimed at improving chemical durability. At present, HMFGs are limited to short transmission distance IR optical applications.

Amorphous Metals

Certain metal compositions can be fabricated as glasses by subjecting streams of the molten metal to extremely rapid quenching rates (10^5 to 10^8°C/sec). The resulting glasses possess intriguing properties. Strengths approach theoretical limits, and electrical resistivities are greater than their crystalline counterparts yet decrease with temperature. Most importantly, they have extremely low B–H hysteresis curves. For this reason they are used commercially as power transformer core laminations.

Amorphous Semiconductors

Many elements and compounds which exhibit semiconducting properties in the crystalline state are also semiconductors in the amorphous state. Si, Ge, P, As, $CdGe_xAs_2$ (x = 0 to 1.2), $Si_{1-x}H_x$ (x = 0.1 to 0.2) are important examples. These materials are use in fabrication of inexpensive vapor deposition fabrication of photovoltaic cells.

© 1999 by CRC Press LLC

Glass Ceramics

A useful group of materials is made by batching, melting, and forming a product as a glass followed by heat treatment to nucleate and grow crystalline phases from the glass to produce a ceramic with up to 99% crystalline phase content. The microstructure contains crystals of about 1 μm size, a glassy matrix, and no porosity. The processing route is a principal advantage since high-speed glass-forming methods can be used, no porosity exists, the formed shape can be inspected as a transparent glass, and rejects at the forming stage can be recycled.

Glass ceramics are typically stronger than most ceramics as a result of zero porosity, and they are tougher than glass because of the deflection of crack fronts around the crystals. High-temperature properties are generally not good due to the glassy phase and the nature of the process, thus limiting most glass ceramics to low- and intermediate-temperature applications (<1000°C). A wide range of products has been made from glass ceramics, from home cookware to industrial bearings and aerospace radomes.

13.1 Introduction

Jay Lee and Robert Shafrik

Manufacturing is the means by which the technical and industrial capability of a nation is harnessed to transform innovative designs into well-made products that meet customer needs. This activity occurs through the action of an integrated network that links many different participants with the goals of developing, making, and selling useful things.

Manufacturing is the conversion of raw materials into desired end products. The word derives from two Latin roots meaning *hand* and *make*. Manufacturing, in the broad sense, begins during the design phase when judgments are made concerning part geometry, tolerances, material choices, and so on. Manufacturing operations start with manufacturing planning activities and with the acquisition of required resources, such as process equipment and raw materials. The manufacturing function extends throughout a number of activities of design and production to the distribution of the end product and, as necessary, life cycle support. Modern manufacturing operations can be viewed as having six principal components: materials being processed, process equipment (machines), manufacturing methods, equipment calibration and maintenance, skilled workers and technicians, and enabling resources.

There are three distinct categories of manufacturing:

- *Discrete item manufacturing*, which encompasses the many different processes that bestow physical shape and structure to materials as they are fashioned into products. These processes can be grouped into families, known as unit manufacturing processes, which are used throughout manufacturing.
- *Continuous materials processing*, which is characterized by a continuous production of materials for use in other manufacturing processes or products. Typical processes include base metals production, chemical processing, and web handing. Continuous materials processing will not be further discussed in this chapter.
- *Micro- and nano-fabrication*, which refers to the creation of small physical structures with a characteristic scale size of microns (millionths of a meter) or less. This category of manufacturing is essential to the semiconductor and mechatronics industry. It is emerging as very important for the next-generation manufacturing processes.

Manufacturing is a significant component of the U.S. economy. In 1995, 19% of the U.S. gross domestic product resulted from production of durable and nondurable goods; approximately 65% of total U.S. exports were manufactured goods; the manufacturing sector accounted for 95% of industrial research and development spending; and manufacturing industries employed a work force of over 19 million people in 360,000 companies. In the modern economy, success as a global manufacturer requires the development and application of manufacturing processes capable of economically producing high-quality products in an environmentally acceptable manner.

Modern Manufacturing

Manufacturing technologies address the capabilities to design and to create products, and to manage that overall process. Product quality and reliability, responsiveness to customer demands, increased labor productivity, and efficient use of capital were the primary areas that leading manufacturing companies throughout the world emphasized during the past decade to respond to the challenge of global competitiveness. As a consequence of these trends, leading manufacturing organizations are flexible in management and labor practices, develop and produce virtually defect-free products quickly (supported with global customer service) in response to opportunities, and employ a smaller work force possessing multidisciplinary skills. These companies have an optimal balance of automated and manual operations.

To meet these challenges, the manufacturing practices must be continually evaluated and strategically employed. In addition, manufacturing firms must cope with design processes (e.g., using customers' requirements and expectations to develop engineering specifications, and then designing components),

© 1999 by CRC Press LLC

production processes (e.g., moving materials, converting materials properties or shapes, assembling products or components, verifying processes results), and business practices (e.g., turning a customer order into a list of required parts, cost accounting, and documentation of procedures). Information technology will play an indispensable role in supporting and enabling the complex practices of manufacturing by providing the mechanisms to facilitate and manage the complexity of manufacturing processes and achieving the integration of manufacturing activities within and among manufacturing enterprises. A skilled, educated work force is also a critical component of a state-of-the-art manufacturing capability. Training and education are essential, not just for new graduates, but for the existing work force.

Manufacturing is evolving from an art or a trade into a science. The authors believe that we must understand manufacturing as a technical discipline. Such knowledge is needed to most effectively apply capabilities, quickly incorporate new developments, and identify the best available solutions to solve problems. The structure of the science of manufacturing is very similar across product lines since the same fundamental functions are performed and the same basic managerial controls are exercised.

© 1999 by CRC Press LLC

13.2 Unit Manufacturing and Assembly Processes

Robert E. Schafrik

There are a bewildering number of manufacturing processes able to impart physical shape and structure to a workpiece. However, if these processes are broken down into their basic elements and then examined for commonality, only a few fundamental processes remain. These are the building blocks, or unit processes, from which even the most complicated manufacturing system is constructed. This section describes these unit processes in sufficient detail that a technically trained person, such as a design engineer serving as a member of an integrated product and process design team comprised of members from other specialties, could become generally knowledgeable regarding the essential aspects of manufacturing processes. Also, the information presented in this section will aid such an individual in pursuing further information from more specialized manufacturing handbooks, publications, and equipment/tool catalogs.

Considering the effect that a manufacturing process has on workpiece configuration and structure, the following five general types of unit manufacturing process can be identified (Altan et al., 1983; NRC, 1995):

Material removal processes — Geometry is generated by changing the mass of the incoming material in a controlled and well-defined manner, e.g., milling, turning, electrodischarge machining, and polishing.

Deformation processes — The shape of a solid workpiece is altered by plastic deformation without changing its mass or composition, e.g., rolling, forging, and stamping.

Primary shaping processes — A well-defined geometry is established by bulk forming material that initially had no shape, e.g., casting, injection molding, die casting, and consolidation of powders.

Structure-change processes — The microstructure, properties, or appearance of the workpiece are altered without changing the original shape of the workpiece, e.g., heat treatment and surface hardening.

Joining and assembly processes — Smaller objects are put together to achieve a desired geometry, structure, and/or property. There are two general types: (1) consolidation processes which use mechanical, chemical, or thermal energy to bond the objects (e.g., welding and diffusion bonding) and (2) strictly mechanical joining (e.g., riveting, shrink fitting, and conventional assembly).

Unit Process Selection

Each component being manufactured has a well-defined geometry and a set of requirements that it must meet. These typically include

- Shape and size
- Bill-of-material
- Accuracy and tolerances
- Appearance and surface finish
- Physical (including mechanical) properties
- Production quantity
- Cost of manufacture

In order to satisfy these criteria, more than one solution is usually possible and trade-off analyses should be conducted to compare the different approaches that could be used to produce a particular part.

Control and Automation of Unit Processes

Every unit process must be controlled or directed in some way. The need for improved accuracy, speed, and manufacturing productivity has spurred the incorporation of automation into unit processes regarding both the translation of part design details into machine instructions, and the operation of the unit process

© 1999 by CRC Press LLC

itself and as a subsystem of the overall production environment. The section of this chapter on computer-aided design/computer-aided manufacturing (CAD/CAM) discusses the technology involved in creating and storing CAD files and their use in CAM. The expectations of precision are continuing to change, as indicated in Figure 13.2.1. This drive for ever-tighter tolerances is helping spur interest in continual improvements in design and manufacturing processses.

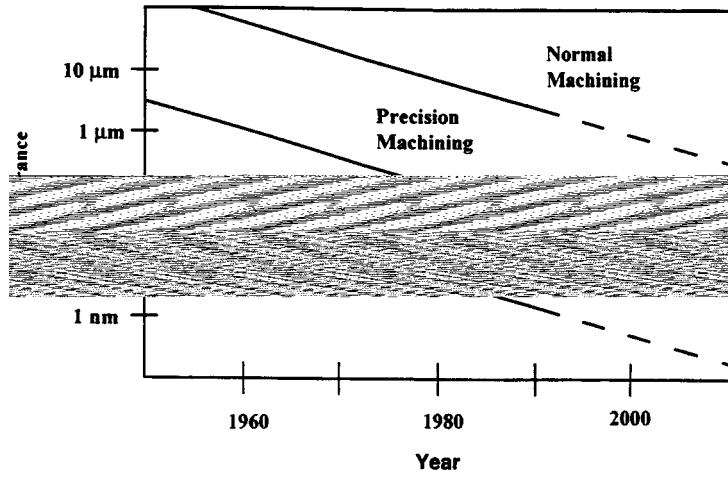

FIGURE 13.2.1 Precision machining domains. (From NRC, *Unit Manufacturing Processes*, National Academy Press, Washington, D.C., 1995, 169. With permission.)

Modern machine tool controls are emphasizing two areas: adaptive control and communication. For *adaptive control* the controller must adapt its control gains so that the overall system remains at or near the optimal condition in spite of varying process dynamics. Expanded *communication* links the data collected by a unit process controller to other segments of the manufacturing operation. Data regarding production time and quantity of parts produced can be stored in an accessible database for use by inventory control and quality monitoring. This same database can then be used by production schedulers to avoid problems and costs associated with redundant databases.

At the factory level, machining operations employing two or more numerically controlled (NC) machine tools may use a separate mainframe computer that controls several machine tools or an entire shop. The system is often referred to as *distributed numerical control* (DNC).

Today many factories are implementing *flexible manufacturing systems* (FMS), an evolution of DNC. An FMS consists of several NC unit processes (not necessarily only machine tools) which are interconnected by an automated materials handling system and which employ industrial robots for a variety of tasks requiring flexibility, such as loading/unloading the unit process queues. A single computer serves as master controller for the system, and each process may utilize a computer to direct the lower-order tasks. Advantages of FMS include:

- A wide range of parts can be produced with a high degree of automation
- Overall production lead times are shortened and inventory levels reduced
- Productivity of production employees is increased
- Production cost is reduced
- The system can easily adapt to changes in products and production levels

Unit Processes

In the following discussion, a number of unit processes are discussed, organized by the effect that they have on workpiece configuration and structure. Many of the examples deal with processing of metals

© 1999 by CRC Press LLC

since that is the most likely material which users of this handbook will encounter. However, other materials are readily processed with the unit processes described in this chapter, albeit with suitable modifications or variations.

Mechanical assembly and material handling are also discussed in this section. On average, mechanical assembly accounts for half of the manufacturing time, and processes have been developed to improve the automation and flexibility of this very difficult task. Material handling provides the integrating link between the different processes — material-handling systems ensure that the required material arrives at the proper place at the right time for the various unit processes and assembly operations.

The section ends with a case study that demonstrates how understanding of the different unit processes can be used to make engineering decisions.

Material Removal Processes

These processes, also known as machining, remove material by mechanical, electrical, laser, or chemical means to generate the desired shape and/or surface characteristic. Workpiece materials span the spectrum of metals, ceramics, polymers, and composites, but metals, and particularly iron and steel alloys, are by far the most common. Machining can also improve the tolerances and finish of workpieces previously shaped by other processes, such as forging. Machining is an essential element of many manufacturing systems (ASM, 1989b; Bakerjian, 1992).

Machining is important in manufacturing because

- It is precise. Machining is capable of creating geometric configurations, tolerances, and surface finishes that are often unobtainable by other methods. For example, generally achievable surface roughness for sand casting is 400 to 800 μin. (10 to 20 μm), for forging 200 to 400 μin. (5 to 10 μm), and for die casting 80 to 200 μin. (2 to 5 μm). Ultraprecision machining (i.e., super-finishing, lapping, diamond turning) can produce a surface finish of 0.4 μin (0.01 μm) or better. The achievable dimensional accuracy in casting is 1 to 3% (ratio of tolerance to dimension) depending on the thermal expansion coefficient and in metal forming it is 0.05 to 0.30% depending on the elastic stiffness, but in machining the achievable tolerance can be 0.001%.
- It is flexible. The shape of the final machined product is programmed and therefore many different parts can be made on the same machine tool and just about any arbitrary shape can be machined. In machining, the product contour is created by the path, rather than the shape, of the cutter. By contrast, casting, molding, and forming processes require dedicated tools for each product geometry, thus restricting their flexibility.
- It can be economical. Small lots and large quantities of parts can be relatively inexpensively produced if matched to the proper machining process.

The dominating physical mechanism at the tool/workpiece interface in conventional machining is either plastic deformation or controlled fracture of the workpiece. Mechanical forces are imposed on the workpiece by the application of a tool with sharp edges and higher hardness than the workpiece. However, many new materials are either harder than conventional cutting tools or cannot withstand the high cutting forces involved in traditional machining. Nontraditional manufacturing (NTM) processes can produce precision components of these hard and high-strength materials. NTM processes remove material through thermal, chemical, electrochemical, and mechanical (with high impact velocity) interactions.

Machinability is defined in terms of total tool life, power requirements, and resultant workpiece surface finish. To date, no fundamental relationship incorporates these three factors and thus machinability must be empirically determined by testing.

Process Selection

Machine tools can be grouped into two broad categories:

- Those that generate surfaces of rotation
- Those that generate flat or contoured surfaces by linear motion

Selection of equipment and machining procedures depends largely on these considerations:

© 1999 by CRC Press LLC

- Size of workpiece
- Configuration of workpiece
- Equipment capacity (speed, feed, horsepower range)
- Dimensional accuracy
- Number of operations
- Required surface condition and product quality

For example, Figure 13.2.2 graphically indicates the various tolerance levels that can be typically achieved for common machining unit processes as a function of the size of the workpiece. Such data can help in identifying candidate unit processes that are capable of meeting product requirements.

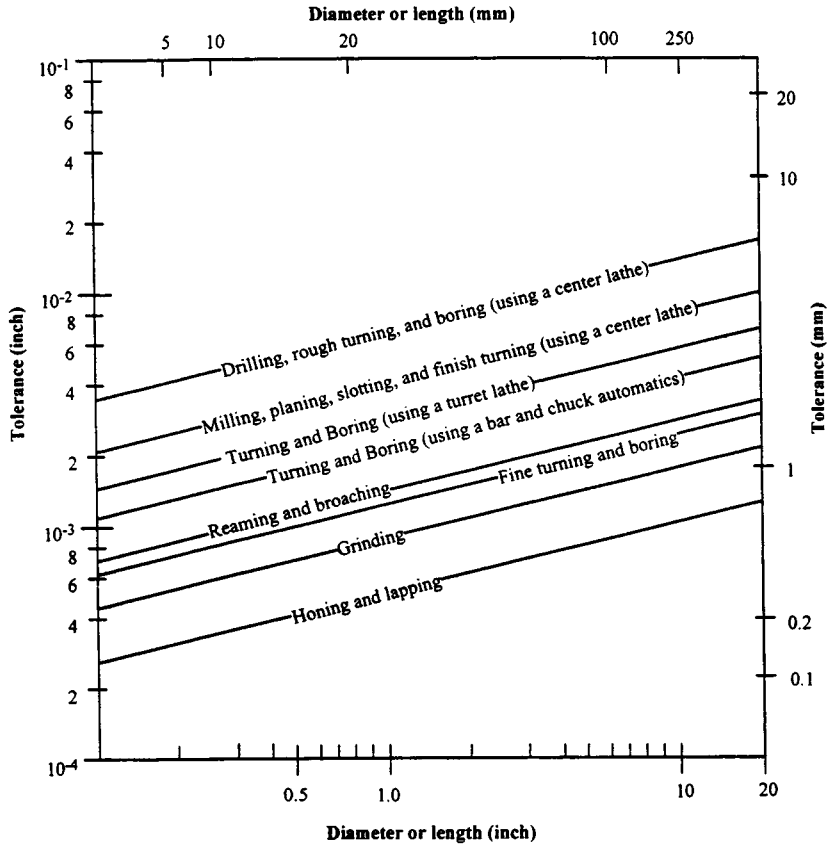

FIGURE 13.2.2 Tolerance vs. dimensional data for machining processes. (From NRC, *Unit Manufacturing Processes*, National Academy Press, Washington, D.C., 1995, 168. With permission.)

Traditional Machining

Steven Y. Liang

Traditional machining processes remove material from a workpiece through plastic deformation. The process requires direct mechanical contact between the tool and workpiece and uses relative motion between the tool and the workpiece to develop the shear forces necessary to form machining chips. The tool must be harder than the workpiece to avoid excessive tool wear. The unit processes described here are a representative sample of the types most likely to be encountered. The reference list at the end of

© 1999 by CRC Press LLC

the section should be consulted for more detailed information on the unit processes discussed below, plus those that are not included here.

Process Kinematics in Traditional Machining. In all traditional machining processes, the surface is created by providing suitable relative motion between the cutting tool and the workpiece. There are two basic components of relative motion: primary motion and feed motion. Primary motion is the main motion provided by a machine tool to cause relative motion between the tool and workpiece. The feed motion, or the secondary motion, is a motion that, when added to the primary motion, leads to a repeated or continuous chip removal. It usually absorbs a small proportion of the total power required to perform a machining operation. The two motion components often take place simultaneously in orthogonal directions.

The functional definitions of turning, milling, drilling, and grinding are not distinctively different, but machining process specialists have developed terminology peculiar to a given combination of functions or machine configurations. Commonly used metal-cutting machine tools, however, can be divided into three groups depending upon the basic type of cutter used: single-point tools, multipoint tools, or abrasive grits.

Dynamic Stability and Chatter. One of the important considerations in selecting a machine tool is its vibrational stability. In metal cutting, there is a possibility for the cutter to move in and out of the workpiece at frequency and amplitude that cause excessive variations of the cutting force, resulting in poor surface quality and reduced life of the cutting tool (Welboum, 1970).

Forced vibrations during cutting are associated with periodic forces resulting from the unbalance of rotating parts, from errors of accuracy in some driving components, or simply from the intermittent engagement of workpiece with multipoint cutters. *Self-excited vibrations* occur under conditions generally associated with an increase in machining rate. These vibrations are often referred to as chatter. All types of chatter are caused by a *feedback loop* within the machine tool structure between the cutting process and the machine frame and drive system. The transfer function of the machine tool, in terms of the stiffness and damping characteristics, plays a critical role in the stability of the overall feedback system. The static stiffness of most machine tools, as measured between the cutting tool and the workpiece, tends to be around 10^5 lb-ft/in. A stiffness of 10^6 lb-ft/in. is exceptionally good, while stiffness of 10^4 lb-ft/in. is poor but perhaps acceptable for low-cost production utilizing small machine tools.

Basic Machine Tool Components. Advances in machine-tool design and fabrication philosophy are quickly eliminating the differences between machine types. Fifty years ago, most machine tools performed a single function such as drilling or turning, and operated strictly stand-alone. The addition of automatic turrets, tool-changers, and computerized numerical control (CNC) systems allowed lathes to become *turning centers* and milling machines to become *machining centers*. These multiprocess centers can perform a range of standard machining functions: turning, milling, boring, drilling, and grinding (Green, 1992).

The machine tool *frame* supports all the active and passive components of the tool — spindles, table, and controls. Factors governing the choice of frame materials are: resistance to deformation (hardness), resistance to impact and fracture (toughness), limited expansion under heat (coefficient of thermal expansion), high absorption of vibrations (damping), resistance to shop-floor environment (corrosion resistance), and low cost.

Guide ways carry the workpiece table or spindles. Each type of way consists of a *slide* moving along a track in the frame. The slide carries the workpiece table or a spindle. The oldest and simplest way is the *box way.* As a result of its large contact area, it has high stiffness, good damping characteristics, and high resistance to cutting forces and shock loads. Box slides can experience stick-slip motion as a result of the difference between dynamic and static friction coefficients in the ways. This condition introduces positioning and feed motion errors. A *linear way* also consists of a rail and a slide, but it uses a rolling-element bearing, eliminating stick-slip. Linear ways are lighter in weight and operate with less friction,

© 1999 by CRC Press LLC

so they can be positioned faster with less energy. However, they are less robust because of the limited surface contact area.

Slides are moved by hydraulics, rack-and-pinion systems, or screws. *Hydraulic pistons* are the least costly, most powerful, most difficult to maintain, and the least accurate option. Heat buildup often significantly reduces accuracy in these systems. Motor-driven *rack-and-pinion* actuators are easy to maintain and are used for large motion ranges, but they are not very accurate and require a lot of power to operate. Motor-driven screws are the most common actuation method. The screws can either be lead screws or ballscrews, with the former being less expensive and the latter more accurate. The *recirculating ballscrew* has very tight backlash; thus, it is ideal for CNC machine tools since their tool trajectories are essentially continuous. A disadvantage of the ballscrew systems is the effective stiffness due to limited contact area between the balls and the thread. (*Note:* a case study at the end of this section discusses the manufacture of precision ballscrews.)

Electric motors are the prime movers for most machine tool functions. They are made in a variety of types to serve three general machine tool needs: spindle power, slide drives, and auxiliary power. Most of them use three-phase AC power supplied at 220 or 440 V. The design challenge with machine tools and motors has been achieving high torque throughout a range of speed settings. In recent years, the operational speed of the spindle has risen significantly. For example, conventional speeds 5 years ago were approximately 1600 rpm. Today, electric motors can turn at 12,000 rpm and higher. Higher speeds cause vibration, which makes use of a mechanical transmission difficult. By virtue of improvement in motor design and control technology, it is now possible to quickly adjust motor speed and torque. Mechanical systems involving more than a three-speed transmission are becoming unnecessary for most high-speed and low-torque machines. Spindle motors are rated by horsepower, which generally ranges from 5 to 150 hp (3.7 to 112 kW) with the average approximately 50 hp (37 kW). Positioning motors are usually designated by torque, which generally ranges from 0.5 to 85 lb-ft (0.2 to 115 Nm).

The *spindle* delivers torque to the cutting tool, so its precision is essential to machine tool operation. The key factors influencing precision are bearing type and placement, lubrication, and cooling.

Cutting Tool Materials. The selection of cutting tool materials is one of the key factors in determining the effectiveness of the machining process (ASM, 1989b). During cutting, the tool usually experiences high temperatures, high stresses, rubbing friction, sudden impact, and vibrations. Therefore, the two important issues in the selection of cutting tool materials are hardness and toughness. *Hardness* is defined as the endurance to plastic deformation and wear; hardness at elevated temperatures is especially important. *Toughness* is a measure of resistance to impact and vibrations, which occur frequently in interrupted cutting operations such as milling and boring. Hardness and toughness do not generally increase together, and thus the selection of cutting tool often involves a trade-off between these two characteristics.

Cutting tool materials are continuously being improved. Carbon steels of 0.9 to 1.3% carbon and tool steels with alloying elements such as molybdenum and chromium lose hardness at temperatures above 400°F (200°C) and have largely been replaced by *high-speed steels* (HSS). HSS typically contains 18% tungsten or 8% molybdenum and smaller amounts of cobalt and chromium. HSSs retain hardness up to 1100°F (600°C) and can operate at approximately double the cutting speed with equal life. Both tool steels and HSS are tough and resistive to fracture; therefore, they are ideal for processes involving interrupted engagements and machine tools with low stiffness that are subject to vibration and chatter.

Powder metallurgy (P/M) high-speed tool steels are a recent improvement over the conventionally cast HSSs. Powder metallurgy processing produces a very fine microstructure that has a uniform distribution of hard particles. These steels are tougher and have better cutting performance than HSS. Milling cutters are becoming a significant application for these cutting tool materials.

Cast cobalt alloys, popularly known as Stellite tools, were introduced in 1915. These alloys have 38 to 53% cobalt, 30 to 33% chromium, and 10 to 20% tungsten. Though comparable in room temperature hardness to HSS tools, cast cobalt alloy tools retain their hardness to a much higher temperature, and they can be used at 25% higher cutting speeds than HSS tools.

© 1999 by CRC Press LLC

Cemented carbides offered a four- or fivefold increase in cutting speeds over conventional HSS. They are much harder, but more brittle and less tough. The first widely used cemented carbide was tungsten carbide (WC) cemented in a ductile cobalt binder. Most carbide tools in use now are a variation of the basic WC-Co material. For instance, WC may be present as single crystals or a solid solution mixture of WC-TiC or WC-TiC-TaC. These solid solution mixtures have a greater chemical stability in the cutting of steel. In general, cemented carbides are good for continuous roughing on rigid machines, but should avoid shallow cuts, interrupted cuts, and less rigid machines because of likely chipping.

A thin layer of TiC, TiN, or Al_2O_3 can be applied to HSS or carbide substrate to improve resistance to abrasion, temperature, friction, and chemical attacks. The *coated tools* were introduced in the early 1970s and have gained wide acceptance since. Coated tools have two or three times the wear resistance of the best uncoated tools and offer a 50 to 100% increase in speed for equivalent tool life.

Ceramic tools used for machining are based on alumina (Al_2O_3) or silicon nitride (Si_3N_4). They can be used for high-speed finishing operations and for machining of difficult-to-machine advanced materials, such as superalloys (Komanduri and Samanta, 1989). The alumina-based materials contain particles of titanium carbide, zirconia, or silicon carbide whiskers to improve hardness and/or toughness. These materials are a major improvement over the older ceramic tools. Silicon nitride–based materials have excellent high-temperature mechanical properties and resistance to oxidation. These materials also have high thermal shock resistance, and thus can be used with cutting fluids to produce better surface finishes than the alumina tools.

These tools can be operated at two to three times the cutting speeds of tungsten carbide, usually require no coolant, and have about the same tool life at higher speeds as tungsten carbide does at lower speeds. However, ceramics lack toughness; therefore, interrupted cuts and intermittent application of coolants can lead to premature tool failure due to poor mechanical and thermal shock resistance.

Cermets are titanium carbide (TiC) or titanium carbonitride particles embedded in a nickel or nickel/molybdenum binder. These materials, produced by the powder metallurgy process, can be considered as a type of cemented carbide. They are somewhat more wear resistant, and thus can be used for higher cutting speeds. They also can be used for machining of ferrous materials without requiring a protective coating.

Cubic boron nitride (CBN) is the hardest material at present available except for diamond. Its cost is somewhat higher than either carbide or ceramic tools but it can cut about five times as fast as carbide and can hold hardness up to 200°C. It is chemically very stable and can be used to machine ferrous materials.

Industrial *diamonds* are now available in the form of polycrystalline compacts for the machining of metals and plastics with greatly reduced cutting force, high hardness, good thermal conductivity, small cutting-edge radius, and low friction. Recently, diamond-coated tools are becoming available that promise longer-life cutting edges. Shortcomings with diamond tools are brittleness, cost, and the tendency to interact chemically with workpiece materials that form carbides, such as carbon steel, titanium, and nickel.

Wear of Cutting Tool Materials. Cutting tools are subjected to large forces under conditions of high temperature and stress. There are many mechanisms that cause wear.

- Adhesion. The tool and chip can weld together; wear occurs as the welded joint fractures and removes part of the tool material, such as along a tool cutting edge.
- Abrasion. Small particles on the wear surface can be deformed and broken away by mechanical action due to the high localized contact stresses; these particles then abrade the cutting tool. Typically, this is the most common wear mode.
- Brittle fracture. Catastrophic failure of the tool can occur if the tool is overloaded by an excessive depth of cut and/or feed rate.
- Diffusion. Solid-state diffusion can occur between the tool and the workpiece at high temperatures and contact pressures, typically at an area on the tool tip that corresponds to the location of

© 1999 by CRC Press LLC

maximum temperature, e.g., cemented carbide tools used to machine steel. High-speed machining results in higher chip temperatures, making this an increasingly important wear mode.

- Edge chipping.
- Electrochemical. In the presence of a cutting fluid, an electrochemical reaction can occur between the tool and the workpiece, resulting in the loss of a small amount of tool material in every chip.
- Fatigue.
- Plastic deformation.

Single-Point Cutting Tool Geometry. Figure 13.2.3 depicts the location of various angles of interest on a single-point cutting tool. The most significant angle is the *cutting-edge* angle, which directly affects the shear angle in the chip formation process, and therefore greatly influences tool force, power requirements, and temperature of the tool/workpiece interface (ASM, 1989a). The larger the positive value of the cutting-edge angle, the lower the force, but the greater the load on the cutting tool. For machining higher-strength materials, negative rake angles are used. *Back rake* usually controls the direction of chip flow and is of less importance than the side rake. Zero back rake makes the tool spiral more tightly, whereas a positive back rake stretches the spiral into a longer helix. *Side rake* angle controls the thickness of the tool behind the cutting edge. A thick tool associated with a small rake angle provides maximum strength, but the small angle produces higher cutting forces than a larger angle; the large angle requires less motor horsepower.

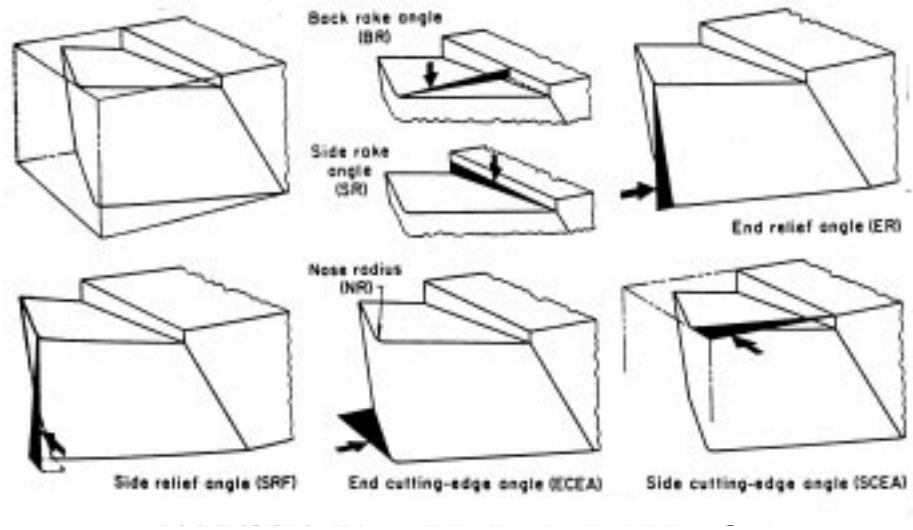

FIGURE 13.2.3 Standard nomenclature for single-point cutting tool angles. (From *ASM Handbook, Machining*, Vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 141. With permission.)

The *end relief angle* provides clearance between the tool and the finished surface of the work. Wear reduces the angle. If the angle is too small, the tool rubs on the surface of the workpiece and mars the finish. If the angle is too large, the tool may dig into the workpiece and chatter, or show weakness and fail through chipping. The *side relief angle* provides clearance between the cut surface of the work and the flank of the tool. Tool wear reduces the effective portion of the angle closest to the workpiece. If this angle is too small, the cutter rubs and heats. If the angle is too large, the cutting edge is weak and the tool may dig into the workpiece. The *end cutting-edge angle* provides clearance between the cutter and the finished surface of the work. An angle too close to zero may cause chatter with heavy feeds, but for a smooth finish the angle on light finishing cuts should be small.

Machinability. Optimum speed and feed for machining depend on workpiece material, tool material, characteristics of the cut, cutting tool configuration, rigidity of setup, tolerance, and cutting fluid. Consequently, it is not possible to recommend universally applicable speeds and feeds.

Drilling and Reaming

Description and Applications. *Drilling* is the most widely used process for making circular holes of moderate accuracy. It is often a preliminary step to other processes such as tapping, boring, or reaming. *Reaming* is used to improve the accuracy of a hole while increasing its diameter. Holes to be reamed are drilled undersize.

Key System Components. Drills are classified by the material from which they are made, method of manufacture, length, shape, number and type of helix or flute, shank, point characteristics, and size series (Table 13.2.1). Selection of drill depends on several factors (ASM, 1989b):

TABLE 13.2.1 Common Drill Types

Drill Type	Description	Application
Core	Has large clearance for chips	Roughing cuts; enlarging holes
General-purpose (jobber)	Conventional two-flute design; right-hand (standard) or left-hand helix. Available with flute modification to break up long chips	General-purpose use, wide range of sizes
Gun	Drill body has a tube for cutting fluid; drill has two cutting edges on one side and counter-balancing wear pads on the other side	Drill high-production quantities of holes without a subsequent finishing operation
High helix	Wide flutes and narrow lands to provide a large bearing surface	Soft materials, deep holes, high feed rates
Low helix	Deep flutes facilitate chip removal	Soft materials, shallow holes
Oil hole	Has holes through the drill body for pressurized fluid	Hard materials, deep holes, high feed rate
Screw-machine	Short length, short flutes, extremely rigid	Hard materials; nonflat surfaces
Step	Two or more drill diameters along the drill axis	Produce multiple-diameter holes, such as for drilling/countersinking
Straight flute	Flutes parallel to the drill axis minimize torquing of the workpiece	Soft materials; thin sheets

- Hardness and composition of the workpiece, with hardness being more important
- Rigidity of the tooling
- Hole dimensions
- Type of drilling machine
- Drill application — originating or enlarging holes
- Tolerances
- Cost

The most widely used drill is the general-purpose twist drill, which has many variations. The flutes on a twist drill are helical and are not designed for cutting but for removing chips from the hole. Typical twist drills are shown in Figure 13.2.4.

Machining forces during *reaming* operations are less than those of drilling, and hence reamers require less toughness than drills and often are more fragile. The reaming operation requires maximum rigidity in the machine, reamer, and workpiece.

Most *reamers* have two or more flutes, either parallel to the tool axis or in a helix, which provide teeth for cutting and grooves for chip removal. The selection of the number of flutes is critical: a reamer with too many flutes may become clogged with chips, while a reamer with too few flutes is likely to chatter (Table 13.2.2).

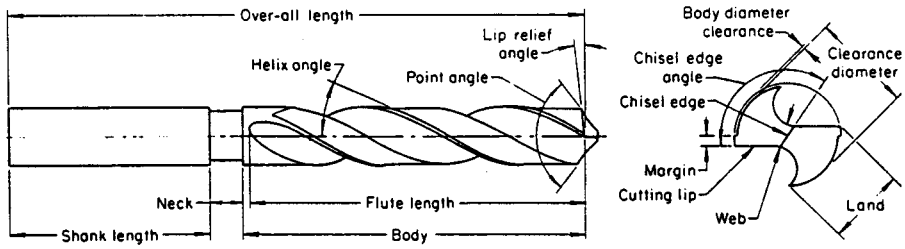

FIGURE 13.2.4 Design features of a typical straight-shank twist drill. (From *ASM Handbook, Machining*, Vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 218. With permission.)

TABLE 13.2.2 Common Reamer Types

Reamer Type	Description	Application
Adjustable	Tool holder allows adjustment of the reamer diameter to compensate for tool wear, etc.	High-rate production
End-cutting	Cutting edges are at right angles to the tool axis	Finish blind holes, correct deviations in through-holes
Floating blade	Replaceable and adjustable cutting edges to maintain tight tolerances	High-speed production (workpiece rotated, tool stationary)
Gun	Hollow shank with a cutting edge (e.g., carbide) fastened to the end and cutting fluid fed through the stem	High-speed production (workpiece rotated, tool stationary)
Shell	Two-piece assemblies, mounted on arbors, can be adjusted to compensate for wear	Used for finishing operations (workpiece rotated, tool stationary)
Spiral flute	Flutes in a helix pattern, otherwise same as straight-flute reamer	Difficult to ream materials, and holes with irregularities
Straight flute	Flutes parallel to the tool axis, typically pointed with a 45° chamfer	General-purpose, solid reamer

Machining Parameters. The optimal speed and feed for drilling depend on workpiece material, tool material, depth of hole, design of drill, rigidity of setup, tolerance, and cutting fluid. For *reaming* operations, hardness of the workpiece has the greatest effect on machinability. Other significant factors include hole diameter, hole configuration (e.g., hole having keyways or other irregularities), hole length, amount of stack removed, type of fixturing, accuracy and finish requirements, size of production run, and cost. Most reamers are more easily damaged than drills; therefore, the practice is to ream a hole at no more than two thirds of the speed at which it was drilled.

Capabilities and Process Limitations. Most drilled holes are $^1/_8$ to 1 in. (3.2 to 40 mm) in diameter. However, drills are available for holes as small as 0.001 in. (0.03 mm) (microdrilling), and special drills are available as large as 6 in. (150 mm) in diameter. The range of length-to-diameter (L/D) of holes that can be successfully drilled depends on the method of driving the drill and the straightness requirements. In the simplest form of drilling in which a rotating twist drill is fed into a fixed workpiece, best results are obtained when L/D is <3. But by using special tools, equipment, and techniques, straight holes can be drilled with L/D = 8 or somewhat greater. Nonconventional machining processes can also generate high-aspect-ratio holes in a wide variety of materials.

Reaming and boring are related operations. Hole diameter and length, amount of material to be removed, and required tolerance all influence which process would be most efficient for a given application (ASM, 1989b). Most holes reamed are within the size range of $^1/_8$ to 1 inch (3.2 to 40 mm), although larger and smaller holes have been successfully reamed. For most applications with standard reamers, the length of a hole that can be reamed to required accuracy ranges from slightly longer to much shorter than the cutting edges of the reamer, but there are many exceptions to this general rule-of-thumb. Tolerances of 0.001 to 0.003 in. (0.03 to 0.08 mm) with respect to the diameter are readily

© 1999 by CRC Press LLC

achievable in production reaming operations. Surface finish for annealed steels can be held within the range of 100 to 125 μin. (2.50 to 3.20 μm), but a surface as smooth as 40 μin. (1 μm) can be obtained under appropriate processing conditions (ASM, 1989b).

Turning and Boring

Description and Applications. *Turning* produces external cylindrical surfaces by removing material from a rotating workpiece, usually with a single-point cutting tool in a lathe. *Boring* is this same process applied for enlarging or finishing internal surfaces of revolution.

Key System Components. The basic equipment for turning is an *engine lathe* that consists of a bed, a headstock, a carriage slide, a cross slide, a tool holder mounted on the cross slide, and a source of power for rotating the workpiece (Table 13.2.3). Engine lathes are often modified to perform additional types of machining operations through the use of attachments. Most turning machines can also perform boring operations, but boring machines may not be able to perform turning operations. Sizes of lathes range from fractional horsepower to greater than 200 hp.

TABLE 13.2.3 Typical Lathes Used for Turning

Lathe	Description	Applications
Bench lathe	An engine lathe that can be placed on a workbench	Small workpieces and prototype parts
Engine lathe	Has a leadscrew that moves the slide uniformly along the bed; available with chucking or centering headstock	Chucking type allows centering and clamping for rotation, e.g., holding castings or forgings Centering type secures workpiece between pointed centers, e.g., for turning long workpieces, such as shafts
Gap-frame lathe	Modified engine lathe for turning larger diameter parts	Workpieces requiring off-center mounting or irregular protuberances
Numerically controlled lathe	Uses a computer program to control the lathe to generate the desired shape	Produces consistent parts in a CAD/CAM environment
Tracer-controlled lathe	A duplicating lathe that uses a stylus moving over a template to control the cutting tool	Manufacture of prototype parts and low-rate production

TABLE 13.2.4 Typical Machines Used for Boring

Boring Machine	Description	Applications
Bar (screw) machine	Modified turret lathe to handle bars and tubes	Parts made from bars or tubes
Engine lathe	Versatile machine; essentially same machine as used for turning	Bores one hole at a time in a single part; limitations regarding workpiece size and configuration
Horizontal boring mill	Workpiece remains stationary and tool rotates	Wide variety of parts; cost-effective for a relatively high production volume
Precision boring machine	Vertical and horizontal models	Parts requiring extreme tolerances
Special-purpose machines	Boring machine modified for specialized application	Single-purpose applications with high production rates
Turret lathe	Has rotating turret on a lathe, tooled for multiple machining operations	More versatile than engine lathe; supports high production rates
Vertical boring mill	Same basic components as a lathe	Very large, heavy, or eccentric workpieces
Vertical turret lathe	Same features as vertical boring mill; may also have a second vertical head	Flexible machine, useful in CAD/CAM environment; simultaneous multiple machining operations possible

© 1999 by CRC Press LLC

Machines used for boring are noted for their rigidity, adaptability, and ability to maintain a high degree of accuracy (Table 13.2.4). For extremely large workpieces, weighing thousands of pounds, the boring cutting tool is rotated and the workpiece is fixed.

Machine Tool and Machining Parameters. In turning and boring operations, a single-point tool is traversed longitudinally along the axisymmetric workpiece axis parallel to the spindle. A tangential force is generated when the cutting tool engages the rotating work. This force is generally independent of the cutting speed and directly proportional to the depth of cut for a particular material, tool shape (particularly side rake angle), and feed rate. That force, when multiplied by the surface speed of the workpiece, estimates the net horsepower required to remove material. The extent to which workpiece material affects required machining power is illustrated in Figure 13.2.5. Moving the tool longitudinally requires much less power (ASM, 1989b).

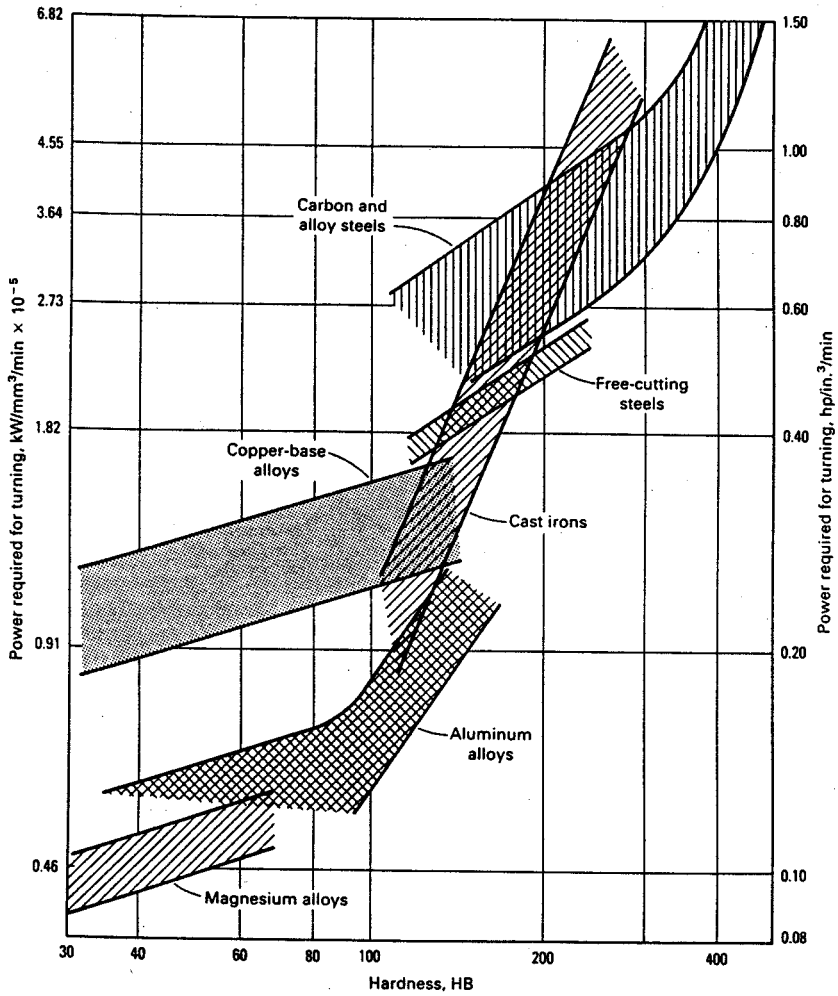

FIGURE 13.2.5 Effect of workpiece composition and hardness on power required for turning. (From *ASM Handbook, Machining*, Vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 136. With permission.)

To minimize the number of cuts required, the depth of cut should be as great as possible, which is limited by the strength of the part and the fixturing, and the power output of the machine tool. The feed rate is a function of the finish desired and the strength and rigidity of the part and machine tool.

© 1999 by CRC Press LLC

Capabilities and Limitations. Components that range in size from those used in watches up to large steel propeller shafts more than 80 ft (24 m) long are regularly turned. Aluminum parts over 10 ft (3 m) in diameter have been turned. In practice, the weight of the workpiece per unit of volume determines the size of the workpiece that is practical to turn. Large, heavy parts can be turned in a vertical boring machine. Irregular-shaped parts, such as crankshafts, may require the use of counter-weighting to achieve dynamic balance for vibration-free turning.

For both turning and boring, the rotation speed, feed, and depth of cut determine the rate of material removal and resulting surface quality. Feed rate for most applications falls between 0.005 and 0.020 in./rev (0.13 and 0.51 mm/rev). Finishing cuts have a significantly lower feed rate (e.g., 0.001 in./rev, 0.03 mm/rev), and roughing cuts are made at a significantly higher feed rate (e.g., 0.25 in./rev, 6.35 mm/rev). Boring is not limited by the L/D ratio of a hole — this ratio can be as great as 50 if the tool bar and workpiece are adequately supported.

There are many potential sources of tolerance error in turning and boring operations. The more common errors are summarized in Tables 13.2.5 and 13.2.6.

TABLE 13.2.5 Factors Affecting Dimensional Accuracy in Turning

Quantity	Basic Cause of Inaccuracy	Corrective Actions
Diametrical roundness	Lathe spindle runout	Preload angular bearings to eliminate side and end movement
Diameter variation (taper)	Parallelism of spindle to longitudinal travel	Establish true parallelism between the axis of rotation of the workpiece and the longitudinal travel of the cutting tool
Face flatness	Lack of true normality of cross slide to axis of rotation	Precision align cross slide to axis of rotation
Length dimensions parallel to the axis of rotation	Improper positioning of longitudinal slide	Adjust positioning of longitudinal slide
Diameter accuracy	Inadequate gauging	Employ proper measurement technique

TABLE 13.2.6 Factors Affecting Dimensional Accuracy in Boring

Quantity	Basic Cause of Inaccuracy	Corrective Actions
Diameter accuracy	Inadequate gauging, or heat generated by the machining action	Employ proper measurement techniques; use cutting fluid to control temperature
Taper of the cylindrical bore	Deflection of the boring bar	Reduce the boring bar unsupported length; use a higher-stiffness material for the boring bar
Roundness, as determined by the variation in radius about a fixed axis	Finish cut is not concentric with the previous cut; or out-of-balance workpiece or holder	Begin with a semifinish cut, followed by a finish cut; carefully balance the initial setup
Concentricity of one surface with another	Too great a clamping force on the workpiece	Redesign clamping fixture, or use a precision boring machine
Squareness and parallelism of holes in relation to other features of the work	Dimensional changes in machine components	Maintain constant ambient temperature; maintain cutting fluid at constant temperature; or stabilize oil temperature

Planing and Shaping

Description and Applications. *Planing* is a widely used process for producing flat, straight surfaces on large workpieces. A variety of contour operations and slots can be generated by use of special attachments. It is often possible to machine a few parts quicker by planing than by any other method. *Shaping* is a process for machining flat and contour surfaces, including grooves and slots.

Principle of Operation. *Planers* develop cutting action from straight-line reciprocating motion between one or more single-point tools and the workpiece; the work is reciprocated longitudinally while the tools

© 1999 by CRC Press LLC

are fed sideways into the work. Planer tables are reciprocated by either mechanical or hydraulic drives, with mechanical drives predominating.

Shapers use a single-point tool that is supported by a ram which reciprocates the tool in a linear motion against the workpiece. The workpiece rests on a flat bed and the cutting tool is driven toward it in small increments by ram strokes. Shapers are available with mechanical and hydraulic drives, with mechanical drives predominating.

Machine Tool and Machining Parameters. Planing and shaping are rugged machining operations during which the workpiece is subjected to significant cutting forces. These operations require high clamping forces to secure the workpiece to the machine bed.

In general, it is advisable to plane steel with as heavy a feed and as high a speed as possible to promote good chip-formation conditions so that chip breakers are not needed. Carbide cutters allow cutting speed to be increased from 225 to 300 surface feet per minute (sfm) (70 to 90 m/min). For best results, uniform cutting speed and feed are maintained throughout the entire stoke (ASM, 1989b).

In general, speeds are related to workpiece material characteristics and associated machinability. Feeds are influenced by the workpiece machinability, but also by ram speed, depth of cut, and required dimensional accuracy and surface finish. Common practice in shaping is to make roughing cuts at as high a feed and slow a speed as practical, and make finishing cuts at a low feed rate and high speed (ASM, 1989b). For low carbon steel, a typical speed for a roughing cut is 50 sfm (15 m/min), while for a finishing cut it is 80 sfm (25 m/min) using a conventional cutting tool. Similarly for aluminum, a roughing cut of 150 sfm (45 m/min) is typically followed by a finishing cut of 200 sfm (60 m/min).

There is a practical lower bound on minimum feed rate. Feed rates that are too low will cause the tool to chatter; feed rates less than 0.005 in. (0.125 mm) are seldom used in shaping. Similarly, shallow cuts (less than 0.015 in., 0.38 mm) will cause chatter during shaping.

Key System Components. Planers are available in a wide range of sizes (Table 13.2.7). Tools are available in a variety of configurations for undercutting, slotting, and straight planing of either horizontal or vertical surfaces (ASM, 1989b).

TABLE 13.2.7 Types of Planers

Planer Type	Description	Application
Double housing	Two vertical uprights support the crossrail which in turn supports the tools	Rigid machine; restricts the width of workpiece
Open side	A single upright column supports a cantilevered crossrail; less rigid than the double-housing type	Accommodates wide workpieces which can overhang one side of the table without interfering with the planer operation

Shapers are available in a large variety of sizes (Table 13.2.8), ranging from small models with a maximum stroke length of less than 6 in. (150 mm) to large machines with a maximum stroke of 36 in. (914 mm). On each machine, the length of stroke can be varied from its maximum to slightly less than 1 in. (25 mm) for the largest machine, and to $^1/_8$ in. (3.2 mm) for the smallest machine.

TABLE 13.2.8 Types of Shapers

Shaper Type	Description	Application
Horizontal	The ram drives the tool in the horizontal direction; uses plane or universal table (rotates on three axes)	Gears, splined shafts, racks, and so on; not used for rate production
Vertical	The ram operates vertically, cutting on the downstroke	Slots, grooves, keyways; matching die sets, molds, fixtures; not used for rate production

© 1999 by CRC Press LLC

Capabilities and Process Limitations. Planing is a precision process in which flatness can be held within 0.0005 in. (0.013 mm) total indicated runout (TIR) on workpieces up to 4 ft^2 (0.4 m^2). Although planing is most widely used for machining large areas, it is also used for machining smaller parts, although 12 in. is about the minimum distance for a planing stoke. Size of the workpiece that can be planed is limited by the capacity of the planing equipment.

Shaping is a versatile process in which setup time is short and relatively inexpensive tools can be used. Under good conditions, a shaper can machine a square surface of 18 in. on a side (0.2 m^2) to a flatness within 0.001 in. (0.025 mm); under optimum conditions this can be improved to 0.0005 in. (0.013 mm). The size of the workpiece that can be shaped is limited by the length of the stoke, which is usually about 36 in. (914 mm). Shaping should be considered for machining flat surfaces in these instances:

- Required flatness cannot be achieved by another method
- Production quantity is insufficient to justify the tooling costs of milling or broaching

Planing and shaping are interrupted cutting processes, and are comparatively inefficient means of metal removal; for example, shaping costs five times that of milling, exclusive of the tooling and setup costs.

Milling

Description and Applications. Milling is a versatile, efficient process for metal removal. It is used to generate planar and contour surfaces through the action of rotating multiple-tooth cutters. Surfaces having almost any orientation can be machined because both the workpiece and cutter can move in more than one direction at the same time.

Principle of Operation. Cutters with multiple cutting edges rotate in a spindle. The machining process is interrupted as the teeth of the milling cutter alternately engage and disengage from the workpiece.

Key System Components. Most milling is done in machines designed for milling (Table 13.2.9). Milling can also be done by any machine tool that can rigidly hold and rotate a cutter while feeding a workpiece into the cutter. Milling machines are usually classified in terms of their appearance: knee-and-column, bed-type, planar-type, and special purpose. The knee-and-column configuration is the simplest milling machine design. The workpiece is fixed to a bed on the knee and the tool spindle is mounted on a column, as depicted in Figure 13.2.6. For very large workpieces, gantry or bridge-type milling machines are used. Machines having two columns can provide greater stability to the cutting spindle(s). Special-purpose machines are modifications of the three basic models.

The usual power range for knee-and-column machines is 1 to 50 hp (0.75 to 37 kW). Bed-type machines are available in a wide range of sizes, up to 300 hp (225 kW). Planar-type machines are available from 30 to 100 hp (22 to 75 kW).

There is a wide variety of milling cutters, using the full range of cutting tool materials; there are three basic constructions (ASM, 1989b):

- Solid — Made from a single piece of HSS or carbide; cutters can be tipped with a harder material; teeth can designed for specific cutting conditions; low initial cost.
- Inserted blade — Usually made from HSS, carbide, or cast alloy; individual blades can be replaced as they wear out, saving replacement cost; ideal for close-tolerance finishing.
- Indexable insert — Cutter inserts are made from carbide, coated carbide, ceramic, or ultrahard material such as diamond; each insert has one or more cutting edges; as inserts wear, they are repositioned to expose new cutting surface or indexed to bring another cutting insert on line. These inserts, widely used in computer-controlled machines due to their performance and flexibility, can produce a rougher surface than the other tool constructions and require somewhat higher cutting forces to remove metal.

TABLE 13.2.9 Types of Milling Machines

Milling Machine	Description	Application
Knee-and-column	Six basic components: • Base — the primary support • Column — houses spindle and drive • Overarm — provides support for the arbor-mounted cutting tools • Knee — supports the table, saddle, and workpiece; provides vertical movement • Saddle — provides 1° of horizontal motion • Table — directly supports the workpiece and provides a second degree of horizontal motion	Widely used for low production milling; provides three-axis movement; primary drawback is lack of rigidity due to the number of joints
Bed-type	Table and saddle mounted on a bed in fixed vertical position; vertical motion obtained by movement of the spindle carrier; available with horizontal or vertical spindle	Very rigid machine; permits deep machining cuts and close dimensional control
Planar-type (adjustable rail)	Can accommodate almost any type of spindle for driving cutters and boring bars; utilizes several milling heads	Use for mass-production milling; can perform simultaneous milling and boring operations
Special purpose	Many possible configurations involving major modifications or combinations of the basic types of milling machines; adapted for automated control	Optimized for high-volume production; includes profilers and machining centers; these machines are capable of performing multiple simultaneous machining operations

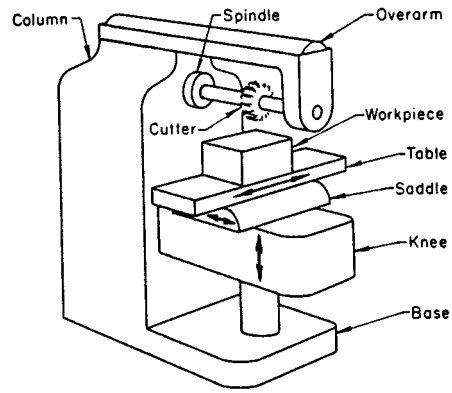

FIGURE 13.2.6 Principal components of a plain knee-and-column milling machine with a horizontal spindle. (From *ASM Handbook, Machining*, Vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 304. With permission.)

Milling cutters are also described by the location of the cutting edges, as described in Table 13.2.10. Several cutters are depicted in Figure 13.2.7.

Machine Tool and Machining Parameters. The angular relationships of the cutting edge greatly influence cutting efficiency, analogous to single-point cutting tools. A milling cutter should have enough teeth to ensure uninterrupted contact with the workpiece, yet not so many so as to provide too little space between the teeth to make chip removal difficult.

Milling speed varies greatly depending on workpiece material composition, speed, feed, tool material, tool design, and cutting fluid. Speeds as low as 20 sfm (6.1 m/min) are employed for milling low machinability alloys, while speeds as high as 20,000 sfm (6100 m/min) have been reported for milling aluminum (ASM, 1989b). If the setup is sufficiently rigid, carbide or carbide-tipped cutters can be operated three to ten times faster than HSS cutters; top speed is usually constrained by onset of tool chatter.

TABLE 13.2.10 Types of Milling Cutters

Milling Cutters	Description	Application
Peripheral mills	Cutting is primarily done by teeth on the periphery of the cutting tool; mounted on an arbor having its axis parallel to the machined surface	Removing metal from simple flat surfaces; milling contoured surfaces and surfaces having two or more angles or complex forms
Face mills	Machining action is accomplished by the bevel cutting edge located along the circumference of the mill; driven by a spindle on an axis perpendicular to the surfaced being milled	Can be more efficient at removing material than peripheral milling; very rigid tool setup possible; can achieve tight tolerances
End mills	Incorporate cutting edges on both the face and the periphery; can be used for face cuts and periphery cuts	Allow multiple operations without changing cutters; cutters can have difficulty in maintaining dimensional accuracy due to long unsupported length
Special mills	Can be almost any design	Optimized for a particular task

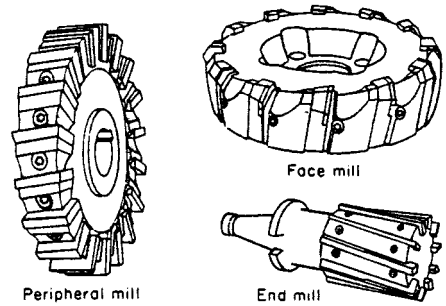

FIGURE 13.2.7 Three typical milling cutters. (From *ASM Handbook, Machining*, Vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 311. With permission.)

For highest efficiency in removing metal while minimizing chatter conditions, the feed per tooth should be as high as possible. The optimum feed rate is influenced by a number of factors (ASM, 1989b): type of cutter, number of teeth on the cutter, cutter material, workpiece machinability, depth of cut, width of cut, speed, rigidity of the setup, and machine power. The surface finish obtainable by milling can be quite good. A finish of 125 μin. (3.2 μm) can be readily achieved under normal circumstances with HSS mills, and finishes of 63 μin. (1.6 μm) are common if carbide tools are used. With careful selection of cutters and stringent control of process conditions, a finish of 10 min (0.25 mm) can be produced.

Process Limitations. The initial cost of a milling machine is considerably greater than that of a planar or a shaper that can machine workpieces of similar size to similar finishes. Milling tools usually cost up to 50 times as much as tools for planers and shapers, and the setup time is usually longer. However, milling is far more efficient in removing material, and milling machines are commonly highly automated. Therefore, milling is preferred for production operations.

Grinding is often preferred to milling when the amount of metal to be removed is small and the dimensional accuracy and surface finish are critical. Milling and grinding are frequently used in combination.

Broaching

Description and Applications. Broaching is a precision machining process. It is very efficient since both roughing cuts and finishing cuts are made during a single pass of the broach tool to produce a smooth surface, and further finishing is usually not necessary. Consequently, close tolerances can be readily achieved at a reasonable cost for high rates of production.

© 1999 by CRC Press LLC

Broaches are expensive multitoothed cutting tools. Thus, the process is usually employed for low or high production when broaching is the only practical method to produce the required dimensional tolerance and surface quality. An example of the latter case is the dovetail slots in jet engine turbine disks.

Principle of Operation. Broaching is a machining process similar to planing. A broach is essentially a tapered bar into which teeth are cut, with the finishing teeth engaging last on the end with the larger diameter. A single broach has teeth for rough cutting, semifinishing, and finishing. Broaching involves pushing or pulling a broach in a single pass through a hole or across a surface. As the broach moves along the workpiece, cutting is gradual as each successive tooth engages the workpiece, removing a small amount of material. Overall machining forces are much greater than that of other machining methods, and consequently broaching is considered to be the most severe of all machining operations.

Key System Components. Broaching machines are categorized as horizontal or vertical, depending on the direction of broach travel. Industry usage is almost evenly divided between these two categories. The selection of machine type depends heavily on the configuration of the workpiece and available space in the factory, considering both floor space and vertical clearance requirements.

Broaches can be categorized by the method through which they are actuated (push or pull), by type of cut (internal or external), and by the construction of the broach body. Figure 13.2.8 depicts typical internal and external broaching operations. Table 13.2.11 describes broaches according to their construction.

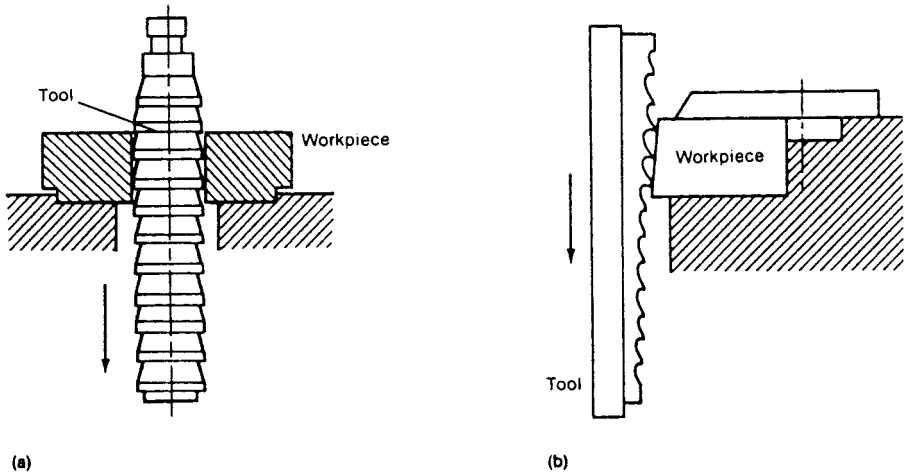

FIGURE 13.2.8 Internal (a) and external (b) broaching. (From *ASM Handbook, Machining*, vol. 16, 9th ed., ASM International, Metals Park, OH, 1989, 195. With permission.)

TABLE 13.2.11 Types of Broaches

Broaches	Description	Application
Solid	One-piece broach produced from tapered bar stock; repair of broken teeth is difficult	Parts which require high dimensional accuracy and concentricity
Shell	Multipiece broach consisting of a main body, an arbor section over which a removable shell fits, and a removable shell containing the cutting edges; worn or damaged sections can be replaced	Internal and selected external broaching; sacrifices some accuracy and concentricity as the tool is not as stiff as a solid broach
Insert-type	Effectively a tool holder with inserts to perform the actual cutting; inserts are typically made from HSS or carbides; worn or damaged inserts can be readily replaced	Broaching large, flat surfaces

© 1999 by CRC Press LLC

Machine Tool and Machining Parameters. Length and depth of cut have the most influence on determining the required broaching tool length. For internal cutting operations, as the cut length increases, more chip storage capacity must be provided between the cutting edges for the same amount of tooth advance. Cutting fluids are useful in preventing the work metal from adhering to the broach, and thus result in higher-quality surface finishes and increased broach life.

The primary consideration in the selection of optimum broaching speed is the trade-off between speed and wear rate. In general, steels are broached at 10 to 30 sfm (3 to 9 m/min); the harder the steel, the slower the broach speed (ASM, 1989b).

Capabilities and Process Limitations. Broaching can maintain tight tolerances during long production runs since metal-cutting operations are distributed among the different roughing and finishing teeth. Also, broach teeth can be repeatedly sharpened, allowing cutting efficiency and accuracy to be maintained.

Broaching is an extremely fast, precise machining operation. It is applicable to many workpiece materials over a wide range of machinability, can be accomplished in seconds, is readily automated, and can easily be done manually. For example, for low-carbon steels, tolerances of 0.002 in. (0.05 mm) can be readily attained with a surface finish of 60 μin. (1.55 μm); if desired, tighter tolerances and surface finishes of 30 μin. (0.8 μm) are possible without much additional effort. For difficult-to-machine superalloys, tolerances of 0.001 in. (0.025 mm) and surface finishes of 30 μin. (0.8 μm) are commonly achieved in production (ASM, 1989b).

Broaching is rarely used for removing large amounts of material since the power required would be excessive. It is almost always more effective to use another machining method to remove the bulk of material and use broaching for finishing.

Since a broach moves forward in a straight line, all surface elements along the broach line must be parallel to the direction of travel. Consequently, the entire surface of a tapered hole cannot be broached. Also, cutting is done sequentially with the finishing teeth engaging last. Therefore, a blind hole can be broached only if a sufficiently long recess is provided to permit full travel of the broach.

The direction of travel of the broach cannot realistically be changed during a broaching stroke, except for rotating the tool. Thus, surfaces having compound curves cannot be broached in a single operation. On external surfaces, it is impossible to broach to a shoulder that is perpendicular to the direction of broach movement.

Grinding

Trevor D. Howes, John Webster, and Ioan Marinescu

Description and Applications. Grinding, or abrasive machining, refers to processes for removing material in the form of small chips by the mechanical action of irregularly shaped abrasive grains that are held in place by a bonding material on a moving wheel or abrasive belt (Green, 1992). In surface-finishing operations (e.g., lapping and honing) these grains are suspended in a slurry and then are embedded in a roll-on or reference surface to form the cutting tool. Although the methods of abrasion may vary, grinding and surface-finishing processes are used in manufacturing when the accuracy of workpiece dimensions and surface requirements are stringent and the material is too hard for conventional machining.

Grinding is also used in cutoff work and cleaning of rough surfaces, and some methods offer high material-removal rates suitable for shaping, an area in which milling traditionally has been used.

Grinding is applied mainly in metalworking because abrasive grains are harder than any metal and can shape the toughest of alloys. In addition, grinding wheels are available for machining plastics, glass, ceramics, and stone. Conventional precision metal and ceramic components and ultraprecision electronic and optical components are produced using grinding.

Mechanics of Grinding. Three types of energy are involved in grinding (Andrew et al., 1985). *Rubbing energy* is expended when the grains (cutting edges) of the grinding wheel wear down. As they wear,

© 1999 by CRC Press LLC

they cut less and produce increasing friction, which consumes power but removes less material. *Plowing energy* is used when the abrasive does not remove all of the material but rather plows some of it aside plastically, leaving a groove behind. *Chip-formation energy* is consumed in removing material from the workpiece as the sharp abrasive grain cuts away the material (or chip) and pushes it ahead until the chip leaves the wheel.

The grinding wheel experiences *attritious wear* as the abrasive grains develop wear flats from rubbing on the workpiece, or when grains break free from the bond material. Attritious wear gives rise to rubbing energy resulting from friction, and thus can lead to thermal damage as power consumption increases without an increase in material removal rate. The wheel can wear through *fracture*, predominating at relatively high in-feed rates. In this case, pieces of the abrasive grain break free and expose a new, sharp surface.

Materials can be classified as either easy to grind or difficult to grind. For *easy-to-grind materials*, most of the power consumption becomes invested in chip formation; thus, rubbing and plowing energy are minimal. *Difficult-to-grind materials* involve considerable rubbing and plowing energy since the force required to remove chips is comparatively high.

Types of Grinding. In *surface grinding*, the grinding wheel traverses back and forth across the workpiece. Grinding can take place by using either the periphery or side face of the wheel. The table holding the part may also reciprocate. Surface grinding is done most commonly on flat surfaces and surfaces with shapes formed of parallel lines, e.g., slots.

Creep-feed grinding is a form of surface grinding in which the wheel feeds into the workpiece at a low rate (0.4 to 40 in./min, 10 to 1000 mm/min) while grinding at a large depth of cut (0.04 to 0.4 in., 1 to 10 mm, or deeper). A large amount of material can be removed with one pass of the wheel, compared with conventional surface grinding in which the wheel makes many quick passes over the workpiece at slight depths of cut. This process is limited by the large amount of heat generated at the grinding arc which can result in thermal damage (grinding "burn"). Application of coolant is critical in creep-feed operations. CBN wheels, with their good heat transfer property, can also reduce the severity of burn (King and Hahn, 1986).

Cylindrical grinding produces round workpieces, such as bearing rings, although some machines can also grind tapered parts. The workpiece is mounted to a spindle and rotates as the wheel grinds it. The workpiece spindle has it own drive motor so that the speed of rotation can be selected. Both inner surfaces (internal cylindrical grinding) and outer (external cylindrical grinding) can be worked, although usually the same machine cannot do both.

There are three variants for *external grinding*:

- *Plain grinding* — the wheel carriage is brought to the workpiece on its spindle and in-feeds until the desired dimensions are reached
- *Traverse grinding* — the rotating workpiece is mounted on a table that reciprocates under the wheel; the grinding wheel is stationary except for its downward feed into the workpiece
- *Plunge grinding* — the table with the rotating workpiece is locked while the wheel moves into the workpiece until the desired dimensions are attained

Centerless grinding is a form of cylindrical grinding. In this method workpieces are not held in a centering chuck but instead rotate freely between a support, regulating wheel, and the grinding wheel. The force of the rotating grinding wheel holds the workpiece against the support. The supports are usually stationary and so a flow of lubricant is required to reduce friction between workpiece and support. An example of centerless grinding is shown in Figure 13.2.9.

Abrasive belt machines use a flexible fabric coated with an abrasive stretched between two rollers, one of which is driven by a motor. Usually, the abrasive coating is aluminum oxide for steels and bronzes and silicon carbide for hard or brittle materials. In the metal industries, common use of such machines is for dry grinding of metal burrs and flash and polishing of surfaces. However, some fabrics permit use

© 1999 by CRC Press LLC

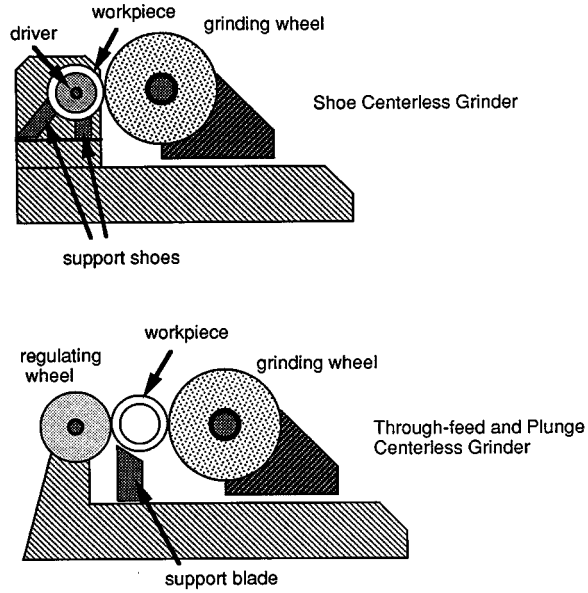

FIGURE 13.2.9 Through-feed and plunge centerless grinding. (Courtesy of T. D. Howes, John Webster, and I. Marinescu.)

of grinding fluids to enhance chip removal and provide cooling and lubrication, which results in better cutting action and longer belt life.

Honing, lapping, and polishing use abrasives to improve the accuracy of the form of a workpiece or the surface finish beyond the capabilities of grinding.

- *Honing* is a low-surface-speed operation, usually performed on an internal, cylindrical surface but possible also on external ones. Stock is removed by the shearing action of abrasive grains: a simultaneous rotary and reciprocating motion of fixed abrasive in the form of a stone or stick. Finishes range from under 1 to 50 μin. (0.025 to 1.3 μm). The development of CBN has revolutionized the honing process because this material easily outperforms conventional abrasives such as aluminum oxide, lasting up to 100 times longer.
- *Superfinishing*, like honing, uses fixed abrasives in the form of a stone. Unlike honing, which has a helical motion inside a bore, superfinishing uses high-speed, axial reciprocation combined with slow rotation of the outside diameter of the cylindrical component being processed. The geometry produced by a previous operation generally is not improved.
- *Lapping* is a fine-finishing, abrasive machining process used to obtain superior finish and dimensional accuracy. Lapping is unlike other finishing processes because some of the abrasive is loose rather than bonded. In general, lapping occurs when abrasive grains in a liquid vehicle (called a slurry) are guided across a workpiece by means of a rotating plate.
- *Polishing* uses free abrasive, as in lapping, but requires a soft support unlike the relatively hard support used in lapping. The total depth of cut during polishing can be as little as nanometers where chemical interactions will play a stronger role than mechanical or physical interactions. When the depth of cut is greater than 1 μin. (0.025 μm), the interactions are usually of a mechanical nature. Many industrial components, especially electronic and optical, required highly polished surfaces.

Key System Components. A *grinding wheel* consists of thousands of small, hard grains of abrasive material held on the surface in a matrix of bond material (Table 13.2.12). The bond material is matched to the characteristics of the grain to retain the grain sufficiently to maximize its use before shedding it.

© 1999 by CRC Press LLC

TABLE 13.2.12 Common Grinding Wheel Abrasives

Abrasive	Characteristic	Grinding Application
Aluminum oxide	Friable	Steel: soft or hardened, plain or alloyed
Seeded gel aluminum oxide	More friable and expensive than aluminum oxide	Steel: soft or hardened, plain or alloyed; use at higher stock removal rates
CBN	Tough; increased life at higher speeds; high accuracy and finish	Hardened steels; tough superalloys
Synthetic diamond	Hardest of all abrasives; can be friable; seldom need dressing/truing	Grinding hardened tool steels, cemented carbides, ceramics, and glass; cutting and slicing of silicon and germanium wafers
Silicon carbide	Friable	Cast iron; nonferrous metals; nonmetallics

The structure of the wheel formed by specific types of grains and bonds determines its characteristics. The grains are spaced apart depending on the cutting required. Widely spaced grains (open structure) cut aggressively, which is useful for hard materials or high rates of material removal, but which tends to produce coarse finishes. Closely packed grains (dense structure) make fine and precise cuts for finish grinding.

Grain spacing is also important for temporary storage of chips of material removed from the workpiece. An open structure is best for storing chips between the grains, which are then released after wheel rotation moves the grains away from the workpiece. An open structure also permits more coolant to enter the spaces to dissipate heat.

The bonding material is important to grinding performance. This material is weaker than the cutting grains so that ideally, during grinding, the grain is shed from the wheel surface when it becomes dull, exposing new sharp grains. For instance, wheels with friable abrasives that fracture to expose new, sharp grains must retain the grains longer to maximize the use of the abrasive; these wheels use stronger bonding materials. The four types of bond material are vitrified, resinoid, rubber, and metal. Table 13.2.13 shows their properties and uses.

TABLE 13.2.13 Characteristics of Grinding Wheel Bonds

Bond Type	Characteristic	Application
Rubber	Relatively flexible	Wet cut-off wheels; high-finish work; regulating wheels for centerless grinding
Resinoid (thermoplastic)	Relatively flexible	Rough grinding; portable grinders
Vitrified (glasslike)	Endure high temperatures; resist chemical effects of coolants; sensitive to impacts	Most widely used of all bonding materials
Metal	Electrodeposited nickel or sintered metal powder often used to bond CBN and diamond abrasives; has long wheel life; electrically conductive	Aggressive cutting operations such as creep-feed and deep grinding; electrically conductive grinding (e.g., electrochemical methods)

Grinding wheels must be resharpened on occasion. *Dressing*, not always required, sharpens the grains before grinding. *Truing* operations ensure the wheel conforms to the required cutting shape and will rotate concentrically to its spindle.

Because grinding wheels have relatively high mass and high operating speed, they must be *precisely balanced*. Imbalance causes vibrations that reduce the quality of the workpiece, hasten the wear of the spindle and bearings of the machine, affect other devices mounted on the grinder, and possibly transmit vibration from the grinder through the shop floor to other machines. Mounting of the wheel on the spindle and subsequent wheel wear can degrade the balance of the rotating system. Wheels are balanced by moving counterweights on balancing flanges. Some machines have an automatic balancer that shifts internal counterbalance masses.

© 1999 by CRC Press LLC

Coolants are usually sprayed on the grinding zone to cool the wheel and workpiece, lubricate the surface to reduce grinding power, and flush away the chips. Excessive heat can damage both the wheel and workpiece by inducing undesirable physical changes in materials, such as metallurgical phase changes or residual stresses, or softening of the bond material in the grinding wheel. Coolant application is especially important in creep-feed grinding where the wheel-to-workpiece contact arc is long, heat generation is high, and the chips produced and abrasive lost from the wheel must be flushed away.

Selecting the type of *coolant system* depends on many factors, including the grinding wheel speed, material removal rate, depth of cut, and wheel/workpiece materials. The type of fluids used in this system requires consideration of both physical and environmental issues. Use of oil fluids can favor the formation of preferred residual stress patterns and better surface finish, and these oils can be recycled for long periods. However, oils present health risks, potential for groundwater contamination, and fire risks (especially with high-sparking superalloys). Water-based fluids offer far fewer environmental problems. Disadvantages of water-based fluids lie in their limited life expectancy of 3 to 12 months. Also, the relatively low viscosity of a water-based fluid at high velocity promotes a dispersed jet which reduces cooling capacity.

Capabilities and Process Limitations. Surface grinding can be a cheaper, faster, and more precise method than milling and planing operations. For profiled shapes, the grinding wheel can be dressed with less cost and inconvenience than changing milling setups for different parts. Grinding can be used as a high-stock-removal process; for example, creep-feed grinding has a depth of cut more typical of milling operations (0.1 in., 2.54 mm, and deeper). Creep-feed grinding is used for machining materials that are too difficult to work by other machining methods.

High-speed grinding can be extremely efficient. CBN abrasive allows high rates of material removal because CBN transfers heat away from the grinding zone due to its relatively high thermal conductivity, and CBN does not react with steel.

Considerable effort has been expended on modeling and testing the thermal limitations of grinding (Malkin, 1989). Nearly all models depend on a fundamental model which depends on sliding contact theory. All models confirm the following guidelines for grinding with conventional abrasives when burn is a limitation: decrease wheel speed, increase workpiece speed, use softer-grade wheels.

Grinding operations can be limited by two types of vibration:

- *Forced vibration.* Typical causes are out-of-balance wheels, nonuniform wheels, couplings, belts, noise from hydraulic systems, bearing noise, and forces transmitted from the floor to the grinding machine.
- *Self-excited vibration.* Typical causes are wheel wear, workpiece surface error regeneration, wheel loading, and wear flats. Typical solutions include softer grinding wheels, flexible (for dampening) wheel structures, and stiffer machine structures.

Nontraditional Machining

K. P. Rajurkar and W. M. Wang

The processes described below are representative of the types most likely to be encountered. The references listed at the end of the section contain detailed information on these processes, plus those that are not described here.

Electrical Discharge Machining (EDM)

Description and Applications. The EDM process machines hard materials into complicated shapes with accurate dimensions. EDM requires an electrically conductive workpiece. Process performance is unaffected by the hardness, toughness, and strength of the material. However, process performance is a function of the melting temperature and thermal conductivity. EDM is currently widely used in aerospace, machinery, and die and mold industries.

There are two types of EDM processes:

- Die-sinking EDM uses a preshaped tool electrode to generate an inverted image of the tool on the workpiece; commonly used to generate complex-shaped cavities and to drill holes in different geometric shapes and sizes on hard and high-strength materials.
- Wire EDM (WEDM) uses a metal wire as the tool electrode; it can generate two- or three-dimensional shapes on the workpiece for making punch dies and other mechanical parts.

Principle of Operation. EDM removes workpiece materials by harnessing thermal energy produced by pulsed spark discharges across a gap between tool and workpiece. A spark discharge generates a very small plasma channel having a high energy density and a very high temperature (up to 10,000°C) that melts and evaporates a small amount of workpiece material. The spark discharges always occur at the highest electrical potential point that moves randomly over the machining gap during machining. With continuous discrete spark discharges, the workpiece material is uniformly removed around the tool electrode. The gap size in EDM is in the range of 400 μin. to 0.02 in. (0.01 to 0.5 mm), and is determined by the pulse peak voltage, the peak discharge current, and the type of dielectric fluid.

EDM Power System. The discharge energy during EDM is provided by a direct current pulse power generator. The EDM power system can be classified into RC, LC, RLC, and transistorized types. The transistorized EDM power systems provide square waveform pulses with the pulse on-time usually ranging from 1 to 2000 msec, peak voltage ranging from 40 to 400V, and peak discharge current ranging from 0.5 to 500 A. With the RC, LC, or RLC type power system, the discharge energy comes from a capacitor that is connected in parallel with the machining gap. As a result of the low impedance of plasma channel, the discharge duration is very short (less than 5 msec), and the discharge current is very high, up to 1000 A. The peak voltage is in the same range of transistorized power systems.

The transistorized power systems are usually used in die-sinking EDM operations because of their lower tool wear. Capacitive power systems are used for small hole drilling, machining of advanced materials, and micro-EDM because of higher material removal rate and better process stability. WEDM

© 1999 by CRC Press LLC

power generator usually is a transistor-controlled capacitive power system that reduces the wire rupture risk. In this power system, the discharge frequency can be controlled by adjusting the on-time and off-time of the transistors that control the charging pulse for the capacitor connected in parallel with the machining gap.

Key System Components. The machining gap between tool and workpiece during EDM must be submerged in an electrically nonconductive *dielectric fluid*. In die-sinking EDM, kerosene is often used as a dielectric fluid because it provides lower tool wear, higher accuracy, and better surface quality. Deionized water is always used as a dielectric fluid in WEDM to provide a larger gap size and lower wire temperature in order to reduce the wire rupture risk. This fluid also serves to flush debris from the gap and thus helps maintain surface quality.

Copper and graphite are commonly used as die-sinking *EDM tool materials* because of the high electrical conductivity and high melting temperature and the ease of being fabricated into complicated shapes. The wire electrode for WEDM is usually made of copper, brass, or molybdenum in a diameter ranging from 0.01 to 0.5 mm. Stratified copper wire coated with zinc brass with diameter of 0.25 mm is often used.

In the traditional die-*sinking EDM process*, the tool is fabricated into a required shape and mounted on a ram that moves vertically. The spark discharges can only occur under a particular gap size that determines the strength of electric field to break down the dielectric. A servo control mechanism is equipped to monitor the gap voltage and to drive the machine ram moving up or down to obtain a dischargeable gap size and maintain continuous sparking. Because the average gap voltage is approximately proportional to the gap size, the servo system controls the ram position to keep the average gap voltage as close as possible to a preset voltage, known as the servo reference voltage.

In a WED machine, the wire electrode is held vertically by two wire guides located separately above and beneath the workpiece, with the wire traveling longitudinally during machining. The workpiece is usually mounted on an *x-y* table. The trajectory of the relative movement between wire and workpiece in the *x-y* coordinate space is controlled by a CNC servo system according to a preprogrammed cutting passage. The CNC servo system also adjusts the machining gap size in real time, similar to the die-sinking EDM operation. The dielectric fluid is sprayed from above and beneath the workpiece into the machining gap with two nozzles.

The power generators in WED machines usually are transistor-controlled RC or RLC systems that provide higher machining rate and larger gap size to reduce wire rupture risks. In some WED machines, the machining gap is submerged into the dielectric fluid to avoid wire vibration to obtain a better accuracy. The upper wire guide is also controlled by the CNC system in many WED machines. During machining, the upper wire guide and the *x-y* table simultaneously move along their own preprogrammed trajectories to produce a taper and/or twist surface on the workpiece.

Machining Parameters. The polarity of tool and workpiece in EDM is determined in accordance with the machining parameters. When the discharge duration is less than 20 μsec, more material is removed on the anode than that on the cathode. However, if the discharge duration is longer than 30 μsec, the material-removal rate on the cathode is higher than that on the anode. Therefore, with a transistorized power system, if the pulse on-time is longer than 30 μsec, the tool is connected as anode and the workpiece is connected as cathode. When the on-time is less than about 20 μsec, the polarity must be reversed. With an RC, LC, or RLC power system, since the discharge duration is always shorter than 20 μsec, the reversed polarity is used.

With transistorized EDM power systems, the machining rate and surface finish are primarily influenced by the peak current. The machining rate increases with the peak current. The relationship between the machining rate and pulse on-time is nonlinear, and an optimal pulse on-time exists. Reducing peak current improves the surface finish, but decreases the machining rate.

Capabilities and Process Limitations. Die-sinking ED machines with transistorized power systems under good gap-flushing conditions can attain a material-removal rate as high as 12 mm^3/min/amp (for

a steel workpiece). The wire cut EDM process can cut ferrous materials at a rate over 100 mm^2/min. A surface roughness value of 0.01 in. (0.2 mm) can be obtained with a very low discharge current. The tool wear ratio can be controlled within 1% during rough machining and semifinishing with the transistorized power generator. Dimensional tolerance of ±118 μin. (3 μm) and taper accuracy of 20 to 40 μin. (0.5 to 1 μm/mm) with both die-sinking and WEDM can be obtained.

EDM can machine materials having electrical conductivity of 10^{-2} W^{-1} cm^{-1} or higher. An average current density more than 4 A/cm^2 tends to cause substantial tool wear and unstable machining, and may lead to dielectric fire. This factor largely limits the productivity of EDM. During machining a deep cavity using die-sinking EDM under difficult flush condition, arc discharges occur, and the resultant thermal damage on workpiece substantially limits the productivity and the machined surface quality. Dielectric properties also impose additional constraints.

Electrical Chemical Machining (ECM)

Description and Applications. The ECM process uses the electrochemical anodic dissolution effect to remove workpiece material. Like die-sinking EDM, the tool electrode of ECM is preshaped according to the requirements of the workpiece. During machining, the inverted shape of the tool is gradually generated on the workpiece. ECM machines complex contours, irregular shapes, slots, and small, deep, and/or noncircular holes. Typical applications of ECM include machining nickel-based superalloy turbine blade dovetails, slots in superalloy turbine disks, engine castings, gun barrel rifles, and forging dies. ECM is also used for deburring, surface etching, and marking.

Principle of Operation. Electrolyte fluid is forced through the gap between tool and workpiece during ECM. A low-voltage and high-current DC power system supplies the machining energy to the gap. The tool electrode of ECM must be connected as cathode and the workpiece must be connected as anode. The electrochemical anodic dissolution phenomenon dissolves workpiece surface material into metal ions. The electrolyte fluid flushes the metal ions and removes heat energy generated by the deplating actions. The gap size in ECM is in the range of 0.004 to 0.04 in. (0.1 to 1 mm). ECM process performance is independent of the strength, hardness, and thermal behavior of workpiece and tool materials.

Key System Components. Copper, brass, stainless steel, and titanium are commonly used as *ECM tool electrode materials* due to their good electrical conductivity, resistance to chemical erosion, and ease of being machined into desired shapes. The geometric dimensions of the machined surface generated by ECM depend on the shape of tool and the gap size distribution.

The structure of an EC machine varies with the specific applications. An ECM must have a tool feed system to maintain the machining gap, a power system to supply the power energy, and a fluid-circulating system to supply the electrolyte and to flush the machining gap. The power system used in ECM is a DC power source with the voltage ranging from 8 to 30 V and a high current in the range of 50 to 50,000 A, depending on the specific design of the power system.

The *electrolyte* is the medium enabling the reaction of electrochemical dissolution occurring on the anode. The electrolyte can be classified into categories of aqueous and nonaqueous, organic and nonorganic, alkaline and neutral, mixed and nonmixed, and passivating and nonpassivating, and acidic. The electrolyte is selected according to the type of workpiece material, the desired accuracy, surface finish requirements, and the machining rate. Neutral salts are used in most cases. Acid electrolytes are used only for small hole drilling when the reaction products must be dissolved in the electrolyte.

Machining Parameters. ECM performance is mainly influenced by electrical parameters, electrolyte, and geometry of tool and workpiece. The electrical parameters include machining current, current density, and voltage. ECM systems with 50 to 50,000 A and 5 to 30 V DC are available, and the current density can be in the range of 10 to 500 A/cm^2. Key electrolyte parameters consist of flow rate, pressure, temperature, and concentration. Important parameters of tool and workpiece geometry are contour gradient, radii, flow path, and flow cross section. When the tool feed rate equals the machining rate, an equilibrium gap size is obtained; this is critical to maintaining shaping accuracy.

The electrolyte selection also plays an important role in ECM dimension control. In this regard, the sodium nitrate solution is preferable because the metal-removal rate at smaller gap size locations is higher than at other places. Therefore, the characteristics of current efficiency in ECM influence the uniformity of the gap size distribution. ECM accuracy has recently been shown to improve with pulsed voltage (instead of continuous voltage) and an appropriate set of pulse parameters (on-time, off-time, etc.).

Capabilities and Process Limitations. ECM is capable of machining any electrically conductive metallic material, and the process is generally unaffected by the hardness, strength, and thermal behaviors of materials. This process can be used to machine parts with low rigidity such as parts with thin walls. Machining rates of 2 to 2.5 cm^3/min/1000 A current, surface roughness of 4 to 50 μin. (0.1 to 1.2 μm), and accuracy of 400 μin. to 0.01 in. (10 to 300 μm) can be achieved with ECM. The available ECM equipment can machine a 0.04 to 80 in. (1 to 2000 mm) long workpiece. The typical energy consumption is 300 to 600 J/mm^3.

The machining rate and surface finish with ECM are much higher than that with EDM due to higher allowable current density and the molecular level of material removal. The machining accuracy, however, is substantially lower than EDM and is much more difficult to control.

The gap size distribution is influenced by many factors including the type of electrolyte, electrolyte flow rate and flow pattern, electrolyte temperature, current density of machining, etc. Therefore, the gap size distribution is not uniform in most cases and is difficult to determine analytically. The shape of machined surface by ECM will not be a perfect mirror image of the tool electrode. In order to achieve an acceptable accuracy, the tool shape must be modified by using trial-and-error method in test machining before machining of actual workpieces.

ECM cannot machine materials with electrical conductivity less than 10^3 W^{-1} cm^{-1}. ECM cannot produce very sharp corners (less than 800 μin., 0.02 mm, radius). The machining rate is limited by the electrolytic pressure (less than 5 MPa) and boiling point as well as the applied current (less than 50,000 A). The gap size which determines the final shape and accuracy is limited to 800 μin. to 0.004 in. (0.02 to 0.1 mm).

ECM generates a large amount of sludge and spent electrolyte. This waste requires significant processing before it can be safely disposed of.

Water and Abrasive Jet Machining

Description and Application. Water jet machining (WJM) and *abrasive water jet machining* (AWJM) are used in many applications. In the WJM process, relatively soft workpiece materials are cut by a high-velocity water jet; e.g., food, wood, paper, plastic, cloth, rubber, etc. The AWJM process uses the fine abrasive particles mixed in the water jet to machine harder workpiece materials. The AWJM is used for drilling, contour cutting, milling, and deburring operations on metal workpieces, as well as for producing cavities with controlled depths using multipass and non-through-cutting methods. The cutting path of the WJM and AWJM can be controlled by a CNC system according to a preprogrammed program.

Principle of Operation and Machine Structures. During WJM, the workpiece material is removed by the mechanical energy generated by the impact of a high-velocity water jet. In a water jet machine, a high-pressure pumping system increases the pressure of water in the pipe system, and the pressurized water is sprayed from a nozzle with a small diameter to generate a high-velocity water jet.

In the AWJM process, pressurized water is sprayed from an orifice in the nozzle body into a mixing chamber to generate a negative pressure that absorbs the abrasive particles (supplied by an abrasive feed hose) into the water jet. The water jet/abrasive grain mixture is then sprayed through a tungsten carbide nozzle. The abrasive grains in the high-velocity water jet provide small cutting edges that remove material. The relative distance between water jet nozzle and workpiece is controlled by a two- or three-dimensional CNC system. This process can be used to generate a complicated shape.

Process Parameters and Limitations. The key parameters are the water and/or abrasive flow velocity, abrasive grain size, and mixing tube (nozzle) length and diameter. The typical water flow velocity is in the range of 2000 to 3000 ft/sec (600 to 900 m/sec) as determined by the water pressure. The water pressure in WJM and AWJM is very high, up to 2.7×10^6 psi (400 MPa), and the nozzle diameter is in the range of 0.003 to 0.08 in. (0.8 to 2 mm). The abrasive flow rate is governed by the water flow rate and the mixing density, and can be controlled up to 10 g/sec. Abrasive particles are usually in the range of 60 to 150 mesh size. Increasing water jet flow velocity increases cutting depth. The taper error of cutting is determined by the traverse rate that describes the ratio between the material removal and the cutting depth and width. This parameter is influenced by the water and abrasive velocity and cutting speed. Proper selection of AWJ parameters is essential for the elimination of burrs, delaminations, and cracks.

Limitations of the process include stray cutting and surface waviness, high equipment costs, hazard from the rebounding abrasive, high noise levels, and short nozzle lifetimes due to wear and abrasion.

Ultrasonic Machining

Description and Applications. *Ultrasonic machining* (USM) is a process that uses the high velocity and alternating impact of abrasive particles on the workpiece to remove material. The abrasive particles are mixed in a slurry that fills the machining gap between the tool and workpiece. The alternating movement of abrasive particles is driven by the vibration of the frontal surface of tool at an ultrasonic frequency. The ultrasonic machining process can machine hard and brittle materials.

USM is often used for machining of cavities and drilling of holes on hard and brittle materials including hardened steels, glasses, ceramics, etc. Rotary ultrasonic machining (RUM) is a new application that uses a diamond grinding wheel as the tool for drilling, milling, and threading operations. During RUM, the tool is rotating at a high speed up to 5000 rpm and vibrating axially at ultrasonic frequency. This process is able to drill holes with diameter from 0.02 to 1.6 in. (0.5 to 40 mm) at depths up to 12 in. (300 mm). The material removal rate of 6 mm^3/sec can be obtained with the RUM process. The tolerance of ±300 μin. (±0.007 mm) can be easily achieved with both conventional and rotary ultrasonic processes.

Principle of Operation. In the USM process, the machining gap between tool and workpiece is filled with an abrasive slurry composed of an oil mixed with abrasive particles, with the frontal surface of the tool vibrating at ultrasonic frequency to provide the machining energy. The inverted shape of the tool is gradually generated on the workpiece. Material removal by the USM process is very complex. When the machining gap is small, the material may be removed as the frontal surface of the tool moves toward the workpiece, hitting an abrasive particle that impacts the workpiece surface. Material can also be removed by the impact of the abrasive particles when the machining gap is relatively large. In this case, the abrasive particles are accelerated by the pressure of slurry due to the ultrasonic vibration of the frontal surface of the tool. Also, ultrasonic-induced alternating pressure and cavitation in the slurry assist material removal.
