Printed on acid-free paper

This book is dedicated to Miss Caragh Brien, my wonderful daughter.

Colin R. Martin

Foreword

The Editors are to be commended for bringing together what is arguably the best and most comprehensive text book on the complex interrelationships between the brain, behaviour, food selection and choice. There are more than 200 chapters describing not only how behaviour affects our food selection but also how what we eat affects how we behave. Content covers genetics, sensory factors, endocrine and neuro-endocrine processes, neurology, behaviour, psychology, physiology, the act of eating, food choice, selection, preferences, appetite, pregnancy, human development, children and adolescents, ageing, anorexia nervosa, bulimia nervosa, obesity, nutrient excess and toxicity, alcoholism, quality of life, body image and much more. The authors have helpfully included chapters on changing eating behaviour and attitudes. The International Handbook of Behavior, Food and Nutrition can truly be said to be research based, theoretical, factual, scientific, academic and practical.

The International Handbook of Behavior, Food and Nutrition is without doubt a quality text attractive to the wide range of practitioners and intelligent readers with an interest in these areas. These contributions are a testament not only to the skills of the authors, but the Editorial attributes of Professor Preedy, Watson and Martin. They have marshalled together a truly international team of experts. I especially like the structuring of the chapters. Each contribution has a mini-dictionary, "key facts" and "summary points" to facilitation the navigation across fields of interest.

This is a cross-disciplinary book of tremendous importance to the health of individuals and society at large and deserves wide dissemination.

The Editors and all the authors are to be congratulated.

Prof Betty Kershaw DBE FRCN
Emeritus Dean
The School of Nursing and Midwifery
The University of Sheffield
United Kingdom

Preface

In this book the Editors aims to disseminate important data pertaining to the modulatory effects of foods and nutritional substances on behavior and neurological pathways and visa versa. This ranges from the neuroendocrine control of feeding to the effects of disease on the brain. The importance of this book pertains to the fact that food is an essential component of cultural heritage but the effects of perturbations in the food-cognitive axis can be quite profound. The complex inter-relationship between neuropsychological processing, diet and behavioural outcome is explored within the context of the most contemporary psychobiological research in the area. This comprehensive psychobiologically and pathology-themed text examines the broad spectrum of diet, behavioural and neuropsychological interactions from normative function to occurrences of severe and enduring psychopathology. The Editors have taken a scientific and objective stand and included chapters that scrutinize the relationships between the brain, behaviour, food and nutrition in a scientific and rational way.

In very simple terms this books addresses limitations in other works that may individually look at the one-way-traffic of either food and behavior. This book examines via two-way-traffic at multiple levels. For example, it examines at both preclinical and clinical levels, genes and populations, and how (a) components in food will affect our sensory responses and (b) how our behavior and sensory responses affect what foods we eat, their pattern of consumption and so on. This book consists of over 200 chapters, and is conveniently divided into 5 main sections to represent the various specialty areas, namely:

General, normative aspects and overviews
Pathological and abnormal aspects
Specific conditions and diseases
Changing eating behaviour and attitudes
Selective methods

The Editors recognize the difficulty in assigning chapters to specific sections. For example in order to describe normative features, abnormal aspects of diet and behavior may also be described. Chapters on food choice may have coverage on the developing brain, behavior and neuroendocrinology. Thus, some chapters can potentially be assigned to several sections. However, this is resolved with the excellent indexing systems that Springer is renowned for. The chapters are well illustrated with numerous tables and figures.

This book represents a multidisciplinary "one-stop-shop" of information with suitable indexing of the various pathways and processes. The chapters are written by

national or international experts or specialists in their field. The Editors recognize that very often experts in one field may be novices in another. To bridge this knowledge-divide the authors have incorporated sections on "Applications to other areas health and disease", "Key Facts or Features" and "Summary Points" This reference book is for nutritionists, dietitians, food scientists, behavioral scientists, psychologists, doctors, nurses, physiologists, health workers and practitioners, college and university teachers and lecturers, undergraduates and graduates.

Ashby Road, Loughborough, Leicestershire, United Kingdom

R.H. Holloway, B.Sc. (Med), M.B.B.S., M.D., FRACP
Discipline of Medicine, University of Adelaide, Adelaide, Australia

Chang Hyung Hong
Department of Psychiatry and Ajou Institute of Aging, Ajou University School
of Medicine, San 5, Wonchun-dong, Youngtong-gu, Suwon-si, 443-749, Korea

Mary Hostler
Program Secretary, Cancer Research Center Hawaii, Prevention and
Control Program, University of Hawaii at Manoa, Honolulu, HI, USA

Jonathan O'B. Hourihane, M.B., D.M., MRCPI, FRCPCH
Clinical Investigations Unit, Department of Paediatrics and Child Health, Cork
University Hospital, University College Cork (UCC), Wilton, Cork, Ireland

Alexa Hoyland
Human Appetite Research Unit, Institute of Psychological Sciences, University
of Leeds, Leeds, UK

Wallace Huffman, Ph.D.
Department of Economics, Iowa State University, Ames, IA 50011, USA

Ethan E. Hull, Ph.D.
Children's Hospital of Pittsburgh, Pittsburgh, PA

Michael Huncharek, MD, MPH
Meta-Analysis Research Group, 10 Sasanqua Circle, Columbia, SC 29209, USA

Teresa Iannaccone
Department of Experimental Medicine, Section of Human Physiology, and Clinical Dietetic Service, Second University of Naples, Naples, Italy

Melinda J. Ickes, Ph.D.
Health Promotion & Education, University of Cincinnati, Cincinnati, OH, USA

Bruno P. Imbimbo, Ph.D.
Research and Development Department, Chiesi Farmaceutici, Parma, Italy
and
Department of Geriatrics, University of Foggia, Foggia, Italy

Syed A. Imran
Department of Physiology & Biophysics, Dalhousie University, Halifax, NS, Canada

Sheila M. Innis
Department of Paediatrics, Child and Family Research Institute, University of British Columbia, 950 West 28th Avenue, Vancouver, BC V5Z 4H4, Canada

Akio Inui
Department of Psychosomatic Internal Medicine, Kagoshima University Graduate School of Medical and Dental Sciences 8-35-1 Sakuragaoka, Kagoshima 890-8520, Japan

Shera C. Jackson, M.S., CLC
Department of Human Development and Family Studies, Texas Tech University, Lubbock, TX, USA

Sanjay Jaju, M.D. M.Phil.
Directorate of Research & Studies, DG Planning, Ministry of Health (HQ), Muscat, Sultanate of Oman

Anita Jansen
Department of Clinical Psychological Science, Maastricht University, P.O. Box 616, 6200 MD Maastricht, The Netherlands

Margaret Jastran
Division of Nutritional Sciences, Cornell University, Ithaca, NY, USA

Aminah Jatoi, M.D.
Department of Oncology, Mayo Clinic, 200 First Street SW, Rochester, Minnesota, USA

Vickii B. Jenvey
School of Psychology, Psychiatry, Monash University, Building 17, Clayton, Victoria 3800, Australia

Amanda Jepson
Department of Psychology, Cornell College, Mt. Vernon, IA, USA
and
Neuroscience Department, Centro Universitario de Ciencias de la Salud, University
of Guadalajara, Guadalajara, Jal, México

Amy R. Johnson
Department of Nutrition, University of North Carolina at Chapel Hill, Chapel Hill,
NC, USA

Fiona Jones
Department of Psychology, University of Bedfordshire, Luton, LU1 3JU, UK

Michelle P. Judge, Ph.D., RD
School of Nursing, University of Connecticut, 231 Glenbrook Rd, Unit 2026,
Mansfield, CT, USA

Alexei B. Kampov-Polevoy, M.D., Ph.D.
Department of Psychiatry, University of North Carolina at Chapel Hill, 237 Medical
School Wing B, Campus Box 7160, Chapel Hill, NC 27599-7160

Natalie Kanakam
Institute of Psychiatry, King's College London, London, UK
and
Department of Academic Psychiatry, Eating, Disorder Research Unit,
Guy's Hospital, London, UK

Masanori Katakura
Department of Environmental Physiology, Shimane University Faculty
of Medicine, Izumo, Shimane, Japan
and
Meta-Analysis Research Group, Columbia, SC, USA

Patrick G. Kehoe, Ph.D.
Dementia Research Group, Institute of Clinical Neurosciences, The John James
Building, Frenchay Hospital, University of Bristol, Bristol, UK

A.R. Kelles, Ph.D.
Department of Nutrition, New York Chiropractic College, Seneca Falls,
New York, USA

Eva Kemps
School of Psychology, Flinders University, GPO, Adelaide, SA 5001, Australia

Alexandra P.F. Key, Ph.D.
Vanderbilt Kennedy Center for Research on Human Development, 230 Appleton
Place, Peabody Box 74, Vanderbilt University, Nashville, TN 37203

Joan Khoo
Discipline of Medicine, Royal Adelaide Hospital, Adelaide, South Australia,
Australia

Hiroe Kikuchi
Educational Physiology Laboratory, Graduate School of Education, The University
of Tokyo, Tokyo, Japan

Atsushi Kimura
Sensory & Cognitive Food Science Laboratory, National Food Research Institute, Kannondai, Tsukuba, Ibaraki, Japan

Neil King
Human Movement Studies & Institute of Health and Biomedical Innovation, Queensland University of Technology, Brisbane, Queensland, Australia

Kelly L. Klump, Ph.D.
Department of Psychology, Michigan State University, East Lansing, MI, USA

Y. Kodra
National Centre for Rare Diseases, Istituto Superiore di Sanità, Roma, Italy

Anna Kokavec, Ph.D.
School of Psychological Science, La Trobe University, Bendigo, Australia, 3552

Hitoshi Komuro
Department of Neurosciences/NC30, Lerner Research Institute, The Cleveland Clinic Foundation, 9500 Euclid Avenue, Cleveland, OH 44195, USA

Yutaro Komuro
Department of Neurosciences/NC30, Lerner Research Institute, The Cleveland Clinic Foundation, Cleveland, OH, USA

Takashi Kondoh, Ph.D.
Institute of Life Sciences, Ajinomoto Co., Inc., Kawasaki, Japan
and
AJINOMOTO Integrative Research for Advanced Dieting, Graduate School of Agriculture, Kyoto University, Kyoto, Japan
and
Institute of Psychiatry, King's College London, London, UK
and
Department of Academic Psychiatry, Eating Disorders Research Unit, Guy's Hospital, London, UK

Karel Krafka
Department of Pediatric and Adolescent Surgery, General Hospital Klagenfurt, Klagenfurt, Austria

David Kugler
Department of Psychology, Cornell College, Mt. Vernon, IA, USA

Jyrki T. Kuikka
Imaging Center, Kuopio University Hospital, FIN-70211 Kuopio, Finland

Tatsuro Kumada
Department of Neurosciences/NC30, Lerner Research Institute, The Cleveland Clinic Foundation, Cleveland, OH, USA

Angela B. Kydd
School of Health Nursing and Midwifery, University of the West of Scotland, Hamilton Campus, Almada Street, Hamilton, Lanarkshire, ML3 0JB, UK

Christine Laborie
Neurostress (EA4347), Equipe Dénutritions Maternelles Périnatales,
Bâtiment SN4, Université des Sciences et Technologies de Lille, France

General and Normative Aspects: Evolutionary and Genetic

Chapter 1
Diet and Brain Evolution: Nutritional Implications of Large Human Brain Size

William R. Leonard, J. Josh Snodgrass, and Marcia L. Robertson

Abbreviations

AA	Arachidonic acid
DHA	Docosahexaenoic acid
DQ	Dietary quality
IGF-1	Insulin-like growth factor I
LC-PUFA	Long-chain polyunsaturated fatty acid
MYA	Million years ago
RMR	Resting metabolic rate
RQ	Respiratory quotient

1.1 Introduction

The evolution of the human nutritional requirements is now receiving ever-greater attention among scientists from a variety of different fields, including nutritional science, anthropology and exercise science (Crawford 1992; Leonard et al. 1992, Leonard and Robertson 1994; Aiello and Wheeler 1995; Cordain et al. 2005). We are increasingly coming to realize that many of the key features that distinguish humans from other primates have important implications for our distinctive nutritional needs (Leonard 2002). The most notable of these features is our relatively large brain sizes, which are ~3 times the size our nearest primate relatives, the great apes (Martin 1989; McHenry and Coffing 2000).

Because neural tissue has very high energy demands (~16 times that of muscle tissue; Kety 1957), our large brains exact a high metabolic cost. On average, adult humans spend some 350–400 kcal/day on brain metabolism (Holliday 1986). Yet, despite the fact that humans have much larger brains per body weight than other primates or terrestrial mammals, the resting energy demands for the human body are no more than for any other mammal of the same size (Leonard and Robertson 1994). As a consequence, humans expend a much larger share of their resting metabolic rate (RMR) to "feed their brains" than other primates or non-primate mammals (Leonard et al. 2003).

W.R. Leonard (✉)
Department of Anthropology, Northwestern University, 1810 Hinman Avenue, Evanston, IL 60208, USA
e-mail: w-leonard1@northwestern.edu

To support the high metabolic demands of our large brains, humans have diets of much higher quality – more dense in calories and nutrients – than other primates (Leonard and Robertson 1994). On average, we consume higher levels of dietary fat than other primates (Popovich et al. 1997), and much higher levels of key long-chain polyunsatured fatty acids (LC-PUFAs) that are critical to brain development (Cordain et al. 2001; Crawford et al. 1999). Moreover, humans also appear to be distinctive in their developmental changes in body composition. We have higher levels of body fatness than other primate species, and these differences are particularly evident in early in life.

This chapter draws on both analyses of living primate species and the human fossil record to explore the influence of brain evolution on human nutritional needs. We begin by examining comparative dietary data for modern human groups and other primate species to evaluate the influence that variation in relative brain size has on dietary patterns among modern primates. We then turn to an examination of the human fossil record to examine when and under what conditions in our evolutionary past key changes in brain size and diet likely took place. Finally, we explore how the evolution of large human brains was likely accommodated by distinctive aspects of human growth and development that promote increased levels of body fatness from early in life.

1.2 Comparative Perspectives on Primate Dietary Quality

The high energy costs of large human brains are evident in Fig. 1.1 which shows the allometric (scaling) relationship between brain weight (g) and RMR (kcal/day) for humans, 36 other primate species, and 22 non-primate mammalian species. The solid line denotes the best-fit regression for nonhuman
Fig. 1.1 Log-log plot of brain weight (*BW*;g) versus resting metabolic rate (*RMR*; kcal/day) for humans, 36 other primate species, and 22 non-primate mammalian species. The primate regression line is systematically and significantly elevated above the non-primate mammal regression. For a given RMR, primates have brain sizes that are three times those of other mammals, and humans have brains that are three times those of other primates

primate species, and the dashed line denotes the best-fit regression for the non-primate mammals. The data point for humans is denoted with a star.

The slopes of the primate and non-primate mammalian log-log regressions are comparable (0.93 vs 0.90, respectively), whereas the Y-intercept of the primate regression is significantly greater than that of the non-primate mammals (−0.38 vs −0.83; $P<0.001$). These differences imply that for a given RMR, primates have systematically larger brains than other mammals. Humans, in turn, are outliers on the primate regression, having markedly larger brains than expected for their RMRs. In caloric terms, this means that brain metabolism accounts for ~20–25% of RMR in adult humans, as compared to about 8–10% in other primate species, and roughly 3–5% for non-primate mammals.

To accommodate the metabolic demands of our large brains, humans consume diets that are more dense in energy and nutrients than other primates of similar size.

Figure 1.2 shows the association between dietary quality and body weight in living primates, including modern human foragers. The diet quality (DQ) index is derived from Sailer et al. (1985), and reflects the relative proportions (percentage by volume) of (1) structural plant parts (*s*; e.g., leaves, stems, bark), (2) reproductive plant parts (*r*; e.g., fruits, flowers), and (3) animal foods (*a*; including invertebrates):

$$DQ\ index = s + 2(r) + 35(a)$$

The index ranges from a minimum of 100 (a diet of all leaves and/or structural plant parts) to 350 (a diet of all animal material).
Fig. 1.2 Plot of diet quality (*DQ*) versus log-body mass for 33 primate species. DQ is inversely related to body mass (*r*=−0.59 [total sample]; −0.68 [nonhuman primates only]; *P*<0.001), indicating that smaller primates consume relatively higher quality diets. Humans have systematically higher quality diets than predicted for their size (Adapted from Leonard et al. 2003)

Table 1.1 Macronutrient composition of the diets of humans and modern apes

Species/group	Fat	Protein	CHO	References
Humans (*Homo sapiens*):				
United States (2000)	33	14	53	Briefel and Johnson (2004)
Modern foragers	28–58	19–35	22–40	Cordain et al. (2000)
Chimpanzees (*Pan troglodytes*)	6	21	73[a]	Richard (1985)
				Tutin and Fernandez (1992, 1993)
				Popovich et al. (1997)
Gorilla (*Gorilla gorilla*)	3	24	73[a]	Popovich et al. (1997)

Percent (%) of dietary energy intake derived from fat, protein, and carbohydrates (CHO) in selected human populations, chimpanzees (*Pan troglodytes*), and gorillas (*Gorilla gorilla*)

[a]Includes estimated energy derived from fermentation of dietary fiber

There is a strong inverse relationship between DQ and body mass across primates, with smaller primates relying on energy rich food such as insects, saps, and gums, whereas large-bodied primates rely on low-quality plant foods, such as foliage. Note that the diets of modern human foragers fall substantially above the regression line in Fig. 1.2, implying that humans have systematically higher DQs than expected for a primate of our size. In fact, the staple foods for all human societies are much more nutritionally dense than those of other large-bodied primates. Although there is considerable variation in the diets of modern human foraging groups, recent analyses by Cordain and colleagues (2000) have shown that modern human foragers derive fully 45–65% of their dietary energy intake from animal foods. In comparison, modern great apes obtain the bulk of their diet from low-quality plant foods. Gorillas derive over 80% of their diet from fibrous foods such as leaves and bark (Richard 1985). Even among common chimpanzees (*Pan troglodytes*), only about 5–10% of their calories are derived from animal foods, including insects (Stanford 1996). This higher quality diet means that we need to eat less volume of food to get the energy and nutrients we require.

Table 1.1 presents comparative data on macronutrient intakes of selected human groups, compared to those of chimpanzees and gorillas living in the wild. The dietary information for human populations were derived from the US NHANES data (Briefel and Johnson 2004) and from a recent review of the diets of contemporary hunter-gatherers (foragers) by Cordain et al. (2000). Data for chimpanzees and gorillas were derived from foraging studies in the wild (Tutin and Fernandez 1992, 1993; Richards 1985; Popovich et al. 1997) and compositional analysis of commonly consumed food items (Popovich et al. 1997). Contemporary foraging societies derive between 28% and 58% of their daily energy intakes from dietary fat. Those groups living in more northern climes (e.g., the Inuit) derive a larger share of their diet from animal foods, and thus have higher daily fat intakes. Conversely, tropical foraging populations generally have lower fat intakes because they obtain more of their diet from plant foods. In comparison, Americans and other populations of the industrialized world fall within the range seen for hunter-gatherers, deriving about a third of their daily energy intake from fat (Briefel and Johnson 2004).

In contrast to the levels seen in human populations, the great apes obtain only a small share of calories from dietary fat. Popovich and colleagues (1997) estimate that Western lowland gorillas derive approximately 3% of their energy from dietary fats. Chimpanzees appear to have higher fat intakes than gorillas (about 6% of dietary energy), but they are still well below the low end of the modern forager range. Thus, the higher consumption of meat and other animal foods among human hunter-gatherers is associated with diets that are higher in fat and more dense in energy.

The link between brain size and dietary quality is evident in Fig. 1.3, which shows relative brain size versus relative dietary quality for the 33 different primate species for which we have metabolic, brain size and dietary data. Relative brain size for each species is measured as the standardized residual (z-score) from the primate brain versus body mass regression, and relative DQ is measured
Fig. 1.3 Plot of relative brain size versus relative diet quality for 31 primate species (including humans). Primates with higher quality diets for their size have relatively larger brain size ($r=0.63$; $P<0.001$). Humans represent the positive extremes for both measures, having large brain to body size ratio and a substantially higher quality diet than expected for their size (Adapted from Leonard et al. 2003)

as the residual from the DQ versus body mass regression. There is a strong positive relationship ($r=0.63$; $P<0.001$) between the amount of energy allocated to the brain and the caloric density of the diet. Across all primates, larger brains require higher quality diets. Humans fall at the positive extremes for both parameters, having the largest relative brain size and the highest quality diet.

Thus, the high costs of the large, metabolically expensive human brain is partially offset by the consumption of a diet that is more dense in energy and fat than those of other primates of similar size. This relationship implies that the evolution of larger hominin brains would have necessitated the adoption of a sufficiently high-quality diet (including meat and energy-rich fruits) to support the increased metabolic demands of greater encephalization.

1.3 Evolutionary Trends in Diet, Brain Size, and Body Size

When we look at the human fossil record, we find that the first major burst of evolutionary change in hominin brain size occurs at about 2.0–1.7 million years ago, associated with the emergence and evolution of early members of the genus *Homo* (see Table 1.2). Prior to this, our earlier hominin ancestors, the australopithecines, showed only modest brain size evolution from an average of 400–510 cm³ over a 2 million year span from 4 to 2 million years ago. With the evolution of the genus *Homo*, there is rapid change, with brain sizes of, on average, ~600 cm³ in *Homo habilis* (at 2.4–1.6 mya) and 800–900 cm³ in early members of *H. erectus* (at 1.8–1.5 mya). Although the relative

Table 1.2 Brain size, body weight, and tooth size for selected prehistoric hominin species

| Species | Geological age (mya) | Brain size (cm³) | Body weight | | Postcanine tooth surface area (mm²) |
			Male (kg)	Female (kg)	
A. afarensis	3.9–3.0	438	45	29	460
A. africanus	3.0–2.4	452	41	30	516
A. boisei	2.3–1.4	521	49	34	756
A. robustus	1.9–1.4	530	40	32	588
Homo habilis (*sensu strictu*)	1.9–1.6	612	37	32	478
H. erectus (early)	1.8–1.5	863	66	54	377
Homo erectus (late)	0.5–0.3	980	60	55	390
H. sapiens	0.4–0.0	1,350	58	49	334

Geological ages (millions of years ago), brain size (cm³), estimated male and female body weights (kg), and postcanine tooth surface areas (mm²) for selected fossil hominin species (Data are derived from Leonard et al. 2003)

brain size of *H. erectus* has not yet reached the size of modern humans, it is outside of the range seen among other living primate species.

The evolution of *H. erectus* in Africa is widely viewed as a *major adaptive shift* in human evolution (Antón et al. 2002; Wolpoff 1999). Indeed, what is remarkable about the emergence of *H. erectus* in East Africa at 1.8 million years is that we find marked increases in both brain and body size, and the evolution of human-like body proportions at the same time that we see major reductions of posterior tooth size and craniofacial robusticity (McHenry and Coffing 2000; Ruff et al. 1997). These trends clearly suggest major energetic and dietary shifts: (a) the large body sizes necessitating greater daily energy needs; (b) bigger brains suggesting the need for a higher quality diet; and (c) the craniofacial changes suggesting that they were consuming a different mix of foods than their australopithecine ancestors.

The ultimate driving factors responsible for the rapid evolution of brain size, body size, and craniodental anatomy at this stage of human evolution appear to have been major environmental changes that promoted shifts in diet and foraging behavior. The environment in East Africa at the Plio-Peistocene boundary (2.0–1.8 mya) was becoming much drier, resulting in declines in forested areas and an expansion of open woodlands and grasslands (Bobe and Behrensmeyer 2002; Wynn 2004). Such changes in the African landscape likely made animal foods an increasingly attractive resource for our hominin ancestors (Behrensmeyer et al. 1997; Harris and Capaldo 1993; Plummer 2004).

The archeological record provides evidence that this occurred with *H. erectus*, as this species is associated with stone tools and the development of the first rudimentary hunting and gathering economy. Meat does appear to have been more common in the diet of *H. erectus* than it was in the australopithecines, with mammalian carcasses likely being acquired through both hunting and confrontational scavenging (Bunn 2006; Plummer 2004). In addition, the archeological evidence indicates that butchered animals were transported back to a central location (home base) where the resources were shared within foraging groups (Bunn 2006; Harris and Capaldo 1993; Potts 1998). Increasingly sophisticated stone tools (i.e., the Acheulean industry) emerged around 1.6–1.4 million years ago, improving the ability of these hominins to process animal and plant materials (Asfaw et al. 1992). These changes in diet and foraging behavior would not have turned our hominin ancestors into carnivores; however, the addition of even modest amounts of meat to the diet (10–20% of dietary energy) combined with the sharing of resources that is typical of hunter-gatherer groups would have significantly increased the quality and stability of the diet of *H. erectus*.

Beyond the energetic benefits associated with greater meat consumption, it appears that such a dietary shift would have also provided increased levels of key fatty acids that would have been

necessary for supporting the rapid hominin brain evolution (Cordain et al. 2001). Mammalian brain growth is dependent upon sufficient amounts of two long-chain polyunsaturated fatty acids (PUFAs): docosahexaenoic acid (DHA) and arachidonic acid (AA) (Cordain et al. 2001; Crawford et al. 1999). Species with relatively larger brain sizes have greater requirements for DHA and AA (Crawford et al. 1999). Since mammals have a limited capacity to synthesize these fatty acids, dietary sources of DHA and AA appear to be limiting nutrients that constrained the evolution of larger brain size in many mammalian lineages (Crawford 1992; Crawford et al. 1999).

Cordain and colleagues (2001) have shown that wild plant foods available on the African savanna (e.g., tubers, nuts) contain little or no AA and DHA, whereas muscle tissue and organ meat of wild African ruminants provide moderate to high levels of these fatty acids. As shown in Table 1.3, brain tissue is a rich source of both AA and DHA, whereas liver and muscle tissues are good sources of AA and moderate sources of DHA.

In addition to changes in diet composition, Wrangham and colleagues (1999; Wrangham 2009) have suggested that the development of cooking also helped to increase diet quality and promote brain evolution in early *Homo*. These authors argue that the controlled use of fire for cooking allowed early *Homo* to improve the nutritional density of their diet. They note that the cooking of savanna tubers and other plant foods would have served to both soften them and increase their energy content. In their raw form, the starch in roots and tubers is not absorbed in the small intestine and is passed through the body as non-digestible carbohydrate (Englyst and Englyst 2005). However, when heated, the starch granules swell and are disrupted from the cell walls. This process, known as gelatinization, makes the starch much more accessible to breakdown by digestive enzymes (García-Al.onso and Goñi 2000). Thus, cooking increases the nutritional quality of tubers by making more of the carbo-hydrate energy available for biological processes.

While it is clear that cooking is an innovation in hominin evolution that served to increase dietary digestibility and quality, there is very limited evidence for the controlled use of fire by hominins before 1.5 million years ago (Bellomo 1994; Pennisi 1999). The more widely held view is that the use of fire and cooking did not occur until later in human evolution, at 200–250,000 years ago (Weiner et al. 1998). In addition, compositional analyses of wild tubers consumed by contemporary hunting and gathering populations indicates that the energy content of these resources is markedly lower than that of animal foods, even after cooking (e.g., Schoeninger et al. 2001). In contrast to animal foods, tubers are also devoid of both DHA and AA (see Table 1.3). Consequently, there remain major questions about whether cooking and the heavy reliance on roots and tubers were important forces for promoting rapid brain evolution with the emergence of early *Homo*.

Overall, the available evidence seems to best support a mixed dietary strategy in early *Homo* that involved the consumption of larger amounts of animal foods than with the australopithecines. Greater

Table 1.3 Nutritional composition of selected wild plant and animal foods from Africa (Data are derived from Cordain et al. 2000)

Food item	Energy (kcal)	Fat (g)	Protein (g)	AA (mg)	DHA (mg)
African ruminant (brain)	126	9.3	9.8	533	861
African ruminant (liver)	159	7.1	22.6	192	41
African ruminant (muscle)	113	2.1	22.7	152	10
African ruminant (fat)	745	82.3	1.0	20-180	trace
African fish	119	4.5	18.8	270	549
Wild tuber/roots	96	0.5	2.0	0	0
Mixed wild plants	129	2.8	4.1	0	0

Energy (kcal), fat (g) protein (g), arachidonic acid (AA) and docosahexaenoic acid (DHA) contents of African ruminant, fish and wild plant foods per 100 g

consumption of animal foods would have increased total dietary fat consumption in early *Homo*, and markedly increased the levels of key fatty acids (AA and DHA) necessary for brain development. Together, the nutritional stability provided a critical foundation for fueling the energy demands of larger brain sizes.

1.4 Applications to Other Areas of Health

The high metabolic costs of our large brains also appear to have important implications for patterns of growth and development of human infants. During the human life course, the energy demands of our large brains are highest during infancy and early childhood, when brain to body weight ratios are largest and when brain growth is most rapid. Whereas brain metabolism accounts for 20–25% of resting needs in adults, in an infant of under 10 kg, it is using upward of 60% (Holliday 1986)! Table 1.4 shows changes in the percent of RMR allocated to the brain over the course of human growth and development.

To accommodate the extraordinary energy demands of the developing infant brain, human infants are born with high levels of body fat (Kuzawa 1998; Leonard et al. 2003). Human infants have the highest body fat levels of any mammalian species, and continue to gain fat during their early postnatal life (c.f., Dewey et al. 1993; Kuzawa 1998; Table 1.4). These high levels of adiposity in early life thus coincide with the periods of greatest metabolic demand of the brain.

For young children growing up in impoverished conditions in the developing world, getting sufficient energy and nutrients to sustain rapid rates of growth in both the brain and body can be challenging. This is particularly true during the weaning period, when children are exposed to both higher infectious disease loads and reduced dietary quality. To adapt to these stressors, human infants and toddlers show metabolic responses to preserve body fat reserves.

Research on children of the developing world suggests that chronic, mild-moderate undernutrition has a relatively small impact on a child's fatness. Instead of taking away the fat reserves, nutritional needs appear to be downregulated by substantially reducing rates of growth in height/ length – producing the common problem of infant/childhood "growth stunting" or growth failure that is ubiquitous among impoverished populations of the developing world (Martorell and Habitch 1986).

Figure 1.4 shows an example of this process based on growth data collected from young girls of the indigenous Tsimane' farming and foraging population of lowland Bolivia (from Foster et al. 2005).

Table 1.4 Changes in brain size, body weight, percent body fat, resting metabolic rate, and percent of energy allocated to the brain from birth to adulthood (All data are from Holliday (1986), except for percent body fat data for children 18 months and younger, which are from Dewey et al. (1993))

Age	Body weight (kg)	Brain weight (g)	Body fat (%)	RMR (kcal/day)	BrMet (%)
New born	3.5	475	16	161	87
3 months	5.5	650	22	300	64
18 months	11.0	1,045	25	590	53
5 years	19.0	1,235	15	830	44
10 years	31.0	1,350	15	1,160	34
Adult male	70.0	1,400	11	1,800	23
Adult female	50.0	1,360	20	1,480	27

Body weight (kg), brain weight (g), percent body fat (%), resting metabolic rate (RMR; kcal/day), and percent of RMR allocated to brain metabolism (BrMet; %) for humans from birth to adulthood
Fig. 1.4 Patterns of physical growth in stature (cm) and body fatness (as sum of triceps and subscapular skinfolds, mm) in girls of the Tsimane' of lowland Bolivia. Growth of Tsimane' girls is characterized by marked linear growth stunting, whereas body fatness compares more favorably to US norms (Data from Foster et al. 2005)

Table 1.5 Body size and metabolic measures for "stunted" and non-stunted children from São Paulo, Brazil (All values are presented as mean ± SEM)

Measure	Non-tunted (*n* = 30)	Stunted (*n* = 28)
Age (mo)	120 ± 3	122 ± 3
Stature (cm)	136 ± 3	126 ± 2[**]
Weight (kg)	32 ± 1	26 ± 1[**]
RMR (kcal/day)	1,179 ± 28	1,044 ± 22[**]
CHO oxidation (% of RMR)	66 ± 2	75 ± 2[*]
Fat oxidation (% of RMR)	34 ± 2	25 ± 2[*]

Age, stature (cm), weight (kg), resting metabolic rate (RMR; kcal/day), carbohydrate (CHO) and fat oxidation (% of RMR) in stunted and non-stunted children (8–11 years) from São Paulo, Brazil. Results are derived from Hoffman et al. (2000)

Differences between stunted and non-stunted groups are significant at: *$P < 0.01$; **$P < 0.001$

Note that early in life the stature of Tsimane' girls closely approximates the US median, but by age 3–4 it has dropped below the 5th centile, where it will track for the rest of life. In contrast, body fatness (as measured by the sum of the triceps and subscapular skinfolds) compares more favorably to US norms, tracking between the 15th and 50th US centiles. The problem of early childhood growth failure is the product of both increased infectious disease loads and reduced dietary quality.

Research on impoverished children in Brazil provides insights into the mechanisms for preserving body fatness under conditions of growth stunting. Hoffman and colleagues (2000) found that children who were growth stunted had significantly lower rates of fat oxidation than those of their "non-stunted" group. Table 1.5 presents a summary of the results of this study. The authors measured RMR on a sample of 28 stunted and 30 non-stunted (control) children between the ages of 8 and 11 years from the slums of Sao Paulo, Brazil. They used the respiratory quotient (RQ) assess levels of fat and carbohydrate oxidation form.

As shown in Table 1.5, the stunted children have significantly lower RMRs and lower levels of fat oxidation compared to their non-stunted counterparts. Under fasting conditions, the stunted children derived only 25% of the resting energy needs from fat, as compared to 34% in the non-stunted group. These researchers hypothesize that the impaired fat oxidation of the stunted children is associated with reductions in insulin-like growth factor I (IGF-I) that is commonly observed with poor childhood growth (Sawaya et al. 2004; Hoffman et al. 2000). IGF-I has been shown to increase lipolysis

(Hussain et al. 1994); hence, significant reductions in IGF-1 during growth can be expected to result in decreased fat oxidation.

Overall, key aspects of human growth and development of body composition are shaped by the very high metabolic demands of brain metabolism early in life. Human infants are born altricially (relatively underdeveloped for their age), and unlike other primates, continue rapid brain growth into early postnatal life (Martin 1989; Rosenberg 1992). To provide energy reserves for the high metabolic demands of large, rapidly growing brains, human infants are born with high body fat levels, and continue to gain fat during the first year of postnatal life. Further, under conditions of chronic nutritional stress, human infants show the capacity preserve brain metabolism by (1) "downregulating" linear growth, (2) reducing fat oxidation, and (3) increasing fat storage. These adaptive responses are evidenced in the preservation of body fatness among "growth stunted" children, and in the tendency of stunted children to gain weight and body fatness later in life (see Frisancho 2003).

1.5 Conclusions

The evolution of large human brain size has had important implications for the nutritional biology of our species. Humans expend a much larger share of their resting energy budget on brain metabolism than other primates or non-primate mammals. Comparative analyses of primate dietary patterns indicate that the high costs of large human brains are supported, in part, by diets that are relatively rich in energy and fat. Relative to other large bodied apes, modern humans derive a much larger share of their dietary energy from fat. Among living primates, the relative proportion of metabolic energy allocated to the brain is positively correlated with dietary quality. Humans fall at the positive end of this relationship, having both a very high quality diet and a large brain.

High levels of encephalization in humans also appear to have important consequences for early childhood growth and development. Human infants have much higher levels of body fatness than the infants of other mammals. These greater levels of adiposity help to accommodate the high metabolic demands of rapid brain growth by providing a ready supply of stored energy. Under conditions of nutritional stress, human infants and toddlers preserve body fat reserves for brain metabolism by reducing rates of linear growth. This process of "'linear growth stunting" is also associated with reduced rates of fat oxidation and increased rates of fat storage. Thus, humans appear to show important adaptations in fat metabolism to accommodate the high energy demands of the brain early in life.

The human fossil record indicates that major changes in both brain size and diet occurred in association with the emergence of early members of the genus *Homo* between 2.0 and 1.7 million years ago in Africa. With the evolution of early *H. erectus* at 1.8 million years ago, we find evidence of an important adaptive shift – the evolution of the first hunting and gathering economy, characterized by greater consumption of animal foods, transport of food resources to "home bases," and sharing of food within social groups. *H. erectus* was human-like in body size and proportions, and had a brain size beyond that seen in nonhuman primates, approaching the range of modern humans. In addition, the reduced size of the face and grinding teeth of *H. erectus*, coupled with its more sophisticated tool technology suggest that these hominins were consuming a higher quality and more stable diet that would have helped to fuel the increases in brain size. Consequently, while dietary change was not the prime force responsible for the evolution of large human brain size, improvements in dietary quality and increased consumption of dietary fat appear to have been a necessary condition for promoting encephalization in the human lineage. Further research is needed to better understand the nature of the dietary changes that took place with the emergence of early human ancestors.

1.6 Table of Key Points on Diet and Human Brain Evolution

The energy demands of brain tissue are ~16 times those of skeletal muscle.

Human adults spend 20–25% of their resting energy budget on brain metabolism, as compared to 8–10% in other primates, and 3–5% in non-primate mammals

Humans fuel the high energy costs of our brains by consuming diets that are much richer in energy and fat than other primates. Human hunter-gatherers derive about half of their daily energy intake from animal foods, much more than chimpanzees, who obtain less than 10%

Over the last 4–5 million years of human evolution, brain size has more than tripled, going from ~400 cc in our australopithecine ancestors to 1,300–1,500 cc in modern humans.

The rate of human brain evolution has been highly variable over the last 4 million years. From 4 to 2 million years ago, brain evolution was relatively slow. With the evolution of the genus *Homo* at ~2 million years ago, brain sizes evolved quite rapidly, in association with changes in foraging and dietary patterns.

Human infants have distinct nutritional needs and growth patterns that are shaped, in part, by the extraordinary energy costs of large, rapidly growing brains.

Human infants have higher levels of body fatness than those of any other mammal. This high level of adiposity helps to accommodate the energy demands of the brain.

Under conditions of chronic, mild-moderate nutritional stress, human infants substantially reduce rates of growth in length/stature, while preserving levels of body fatness. This pattern of growth stunting – characterized by "low height-for-age" – is commonly observed among impoverished populations of the developing world.

Definitions

Altricial: Being relatively "underdeveloped" for one's chronological age.

Australopithecus: Genus of early hominins that existed in Africa between 4 and 1.2 million years ago.

Acheulean: Stone tool industry of the early and middle Pleistocene characterized by hand axes and cleavers. First evident 1.4–1.6 million years ago, associated with early *Homo*.

Encephalization: Brain size in relation to body size. In general, primates are more encephalized than other mammals.

Hominin: Living humans and our fossil ancestors that lived after the last common ancestor between humans and apes.

Scaling (allometry): The change in size on biological measure with respect to another (often body size).

1.7 Summary Points on Diet and Human Brain Evolution

- Humans expend a much larger share of their resting energy budget on brain metabolism than other species. Adult humans spend 20–25% of the RMR on the brain, as compared to 8–10% in other primates, and 3–5% in non-primate mammals.
- To support the high energy costs of brain metabolism, humans consume diets that are easier to digest and much more dense in energy and fat than other primate species.
- The first major increase in brain size in the human lineage occurred with the evolution of the genus *Homo* at 2.0–1.7 million years ago. During this time, we also have evidence from the fossil and archaeological record for greater consumption of animal foods. This increased dietary quality was likely important for supporting brain evolution.

- The addition of animal foods to the diet of early *Homo* would also have increased the availability of key long-chain polyunsaturated fatty acids that are essential for brain growth and development: DHA and AA.
- For human infants, the energy costs of brain metabolism are extraordinarily high (<60% of RMR) due to high brain to body weight ratios and rapid brain growth. These costs are supported, in part, by very high levels of body fatness. At 15–16% fat, humans have the fattest infants of any mammal.
- Under conditions of chronic nutritional and disease stress, human infants "downregulate" growth in length/stature, while preserving body fatness. This pattern of "linear growth stunting" is widely observed among impoverished populations of the developing world, and appears to be associated with reduced fat oxidation and increased fat storage.
- Ongoing research is attempting to better characterize the dietary patterns of our earliest human ancestors through chemical analyses of hominin bones and analyses of microscopic wear patterns of hominin teeth.

Chapter 2
Epigenetics, Phenotype, Diet, and Behavior

Patrick O. McGowan, Michael J. Meaney, and Moshe Szyf

Abbreviations

CBP	CREB binding protein
DNMT	DNA methyltransferase
HAT	Histone acetyltransferase
HDAC	Histone deacetylase
HDACi	HDAC inhibitor ()
HMT	Histone methyltransferase ()
LG	Licking/Grooming
MBD2	Methylated domain DNA-binding Protein 2
NGFI-A	Nerve growth factor-inducible protein A
SAM	*S*-adenosyl methionine
TSA	Trichostatin A

2.1 Introduction

Different cell types execute distinctive programs of gene expression, which are highly responsive to developmental, physiological, pathological, and environmental cues. The combinations of mechanisms that confer long-term programming to genes and could bring about a change in gene function without changing gene sequence are termed here as epigenetic changes. We therefore propose here a definition of epigenetics, which includes any long-term change in gene function that does not involve a change in gene sequence or structure. This definition stands in contrast to other classical definitions of epigenetics that emphasize heritability. Epigenetic changes occurring in the germ line would result in heritable and trans-generational transmission of alterations in gene function in the classical sense of epigenetics. In addition, epigenetics changes in dividing cells are heritable from cell to daughter cells but are not inherited through the germ line or in postmitotic cells such as neurons and are therefore

Table 2.1 Key facts about the epigenome

1. Almost all cells in the body have the same genetic information, but the cell's epigenetic state determines what genes it expresses, and thus its specific cell type identity (e.g., blood cell, brain cell, etc.)
2. DNA methylation is believed to mark silent genes, and thus aberrant methylation could have similar consequences as genetic mutations.
3. There are also extensive epigenetic marks on chromatin that define whether genes are active or silent
4. The epigenetic status of DNA and chromatin is thought to regulate gene activity by targeting specific molecules to specific sites in the genome
5. There is thought to be a bilateral relationship between DNA methylation and epigenetic marks on chromatin
6. DNA methylation is an extremely stable chemical modification of the DNA, with important diagnostic potential for human disease
7. Both chromatin modifications and DNA methylation are potentially reversible in response to particular environmental conditions
8. The dietary, social, behavioral, and physiological environment can modify the epigenome, with long-term consequences for gene expression, cell signaling, and thus phenotype

This table delineates the role of the epigenome in cellular function and its response to signals from the environment

not heritable. Such changes could be environmentally driven, may occur in response to triggers at different points in life and are potentially reversible, whereas genetic differences are germ line transmitted, fixed, and irreversible.

Many of the phenotypic variations seen in human populations might be caused by differences in long-term programming of gene function rather than the sequence per se, and any future study of the basis for interindividual phenotypic diversity should consider epigenetic variations in addition to genetic sequence polymorphisms (Meaney and Szyf 2005). In effect, epigenetic silencing and genetic silencing could have similar phenotypic consequences. Therefore, epigenetic mapping is potentially as important as genetic mapping in our quest to understand phenotypic differences in human behavior.

Thus, identifying epigenetic changes that are associated with behavioral pathologies have important implications for human health, because they are potentially reversible and amenable to therapeutic intervention (Szyf 2001). Drugs that target epigenetic mechanisms are currently being tested in clinical trials in psychiatric disorders (Simonini et al. 2006). Once we understand the rules through which different environmental exposures modify the epigenetic processes, we might also be able to design behavioral strategies to prevent and revert deleterious environmentally driven epigenetic alterations. The dynamic nature of epigenetic regulation in difference from the static nature of the gene sequence provides a mechanism for reprogramming gene function in response to changes in life style trajectories, including diet. Thus, epigenetics could provide an explanation for well-documented gene x environment interactions. In this chapter, we will describe the path, which we have taken to delineate the basic mechanisms involved in epigenetic programming by maternal care in rats as a paradigm for unraveling the epigenetic basis of phenotypic differences in behavior in humans. We will also discuss our studies of epigenetic differences associated with early life adversity in humans and potential dietary contributions to epigenetic regulation (Table 2.1).

2.2 The Epigenome

2.2.1 Chromatin and the Histone Code

The epigenome consists of the chromatin, a protein-based structure around which the DNA is wrapped, as well as a covalent modification of the DNA itself by the methylation of cytosine rings found at CG dinucleotides (Razin 1998). The epigenome determines the accessibility of the

transcription machinery – which transcribes the genes into messenger RNA – to the DNA. Inaccessible genes are therefore silent whereas accessible genes are transcribed. Densely packaged chromatin can be visualized microscopically and is termed heterochromatin while open accessible chromatin is termed euchromatin. Recently, another new level of epigenetic regulation by small noncoding RNAs termed microRNA has been discovered (Bergmann and Lane 2003), which could potentially play an important role in behavioral pathologies in humans (Vo et al. 2005).

The basic building block of chromatin is the nucleosome, which is made up of an octamer of histone proteins. The N-terminal tails of these histones are extensively modified by methylation, phosphorylation, acetylation, and ubiquitination. The state of modification of these tails plays an important role in defining the accessibility of the DNA wrapped around the nucleosome core. It was proposed that the amino terminal tails of H3 and H4 histones that are positively charged form tight interactions with the negatively charged DNA backbone, thus blocking the interaction of transcription factors with the DNA. Modifications of the tails neutralize the charge on the tails, thus relaxing the tight grip of the histone tails. Different histone variants, which replace the standard isoforms also play a regulatory role and serve to mark active genes in some instances (Henikoff et al. 2004). The specific pattern of histone modifications was proposed to form a "histone code," that delineates the parts of the genome to be expressed at a given point in time in a given cell type (Jenuwein and Allis 2001).

2.2.2 Histone-Modifying Enzymes and Chromatin Remodeling

The most investigated histone-modifying enzymes are histone acetyltransferases (HAT), which acetylate histone H3 at the K9 residue as well as other residues and H4 tails at a number of residues, and histone deacetylases (HDAC), which deacetylate histone tails (Kuo and Allis 1998). Histone acetylation is believed to be a predominant signal for an active chromatin configuration (Perry and Chalkley 1982; Lee et al. 1993). Deacetylated histones signal inactive chromatin and chromatin associated with inactive genes. Histone tail acetylation is believed to enhance the accessibility of a gene to the transcription machinery whereas deacetylated tails are highly charged and believed to be tightly associated with the DNA backbone and thus limiting accessibility of genes to transcription factors (Kuo and Allis 1998).

Some specific histone methylation events are associated with gene silencing and some with gene activation (Lachner et al. 2001). Particular factors recognize histone modifications and further stabilize an inactive state. Recently described histone demethylases remove the methylation mark causing either activation or repression of gene expression (Shi et al. 2004; Tsukada et al. 2006). Chromatin remodeling complexes, which are ATP dependent, alter the position of nucleosomes around the transcription initiation site and define its accessibility to the transcription machinery. It is becoming clear now that there is an interrelationship between chromatin modification and chromatin remodeling (Bultman et al. 2005).

A basic principle in epigenetic regulation is targeting. Histone-modifying enzymes are generally not gene specific. Specific transcription factors and transcription repressors recruit histone-modifying enzymes to specific genes and thus define the gene-specific profile of histone modification (Jenuwein and Allis 2001). Transcription factors and repressor recognize specific *cis*-acing sequences in genes, bind to these sequences and attract the specific chromatin-modifying enzymes to these genes through protein–protein interactions. Signal transduction pathways, which are activated by cell-surface receptors, could serve as conduits for epigenetic change, linking the environmental trigger at cell surface receptors with gene-specific chromatin alterations and reprogramming of gene activity.

2.2.3 DNA Methylation and Gene Expression Silencing

The DNA molecule itself can be chemically modified by methyl residues at the 5′ position of the cytosine rings in the dinucleotide sequence CG in vertebrates (Razin 1998), thus offering a mode of direct interaction between the environment such as diet and the genome itself (Fig. 2.1). What distinguishes DNA methylation in vertebrate genomes is the fact that not all CGs are methylated in any given cell type (Razin 1998). Distinct CGs are methylated in different cell types, generating cell type–specific patterns of methylation. Thus, the DNA methylation pattern confers upon the genome its cell type identity (Razin 1998). Since DNA methylation is part of the chemical structure of the DNA itself, it is more stable than other epigenetic marks and thus it has extremely important diagnostic potential in humans (Beck et al. 1999).

Recent data supports the idea that similar to chromatin modification, DNA methylation is also potentially reversible (Ramchandani et al. 1999b) even in predominantly post mitotic tissues such as the brain (Weaver et al. 2004a). The DNA methylation pattern is not copied by the DNA replication machinery, but by independent enzymatic machinery, (Razin and Cedar 1977) the DNA methyltransferase(s) (DNMT) (Figs. 2.2 and 2.3). DNA methylation patterns in vertebrates are distinguished by their correlation with chromatin structure. Active regions of the chromatin, which enable gene expression, are associated with hypomethylated DNA whereas hypermethylated DNA is packaged in inactive chromatin (Razin and Cedar 1977; Razin 1998).

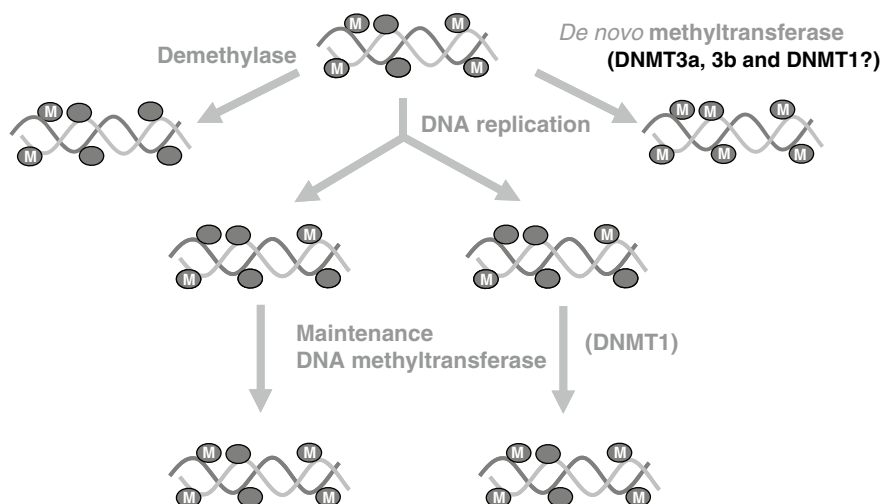
DNA methylation in critical regulatory regions serves as a signal to silence gene expression. There are two main mechanisms by which cytosine methylation suppresses gene expression (Fig. 2.3). The first mechanism involves direct interference of the methyl residue with the binding of a transcription factor to its recognition element in the gene. The interaction of transcription factors with genes is required for activation of the gene; lack of binding of a transcription factor would result in the silencing of gene expression. This form of inhibition of transcription by methylation requires that the methylation events occur within the recognition sequence of a transcription factor. A second mechanism is indirect. A certain density of DNA methylation moieties in the region of the gene attracts the binding of methylated-DNA-binding proteins such as MeCP2 (Nan et al. 1997). MeCP2 recruits other proteins such as SIN3A and histone-modifying enzymes, which lead to formation of a "closed" chromatin configuration and silencing of gene expression (Nan et al. 1997). Thus, aberrant methylation will silence a gene resulting in loss of function, which will have a similar consequence to a loss of function by genetic mechanism such as mutation, deletion, or rearrangement (Fig. 2.4).
Fig. 2.1 The reversible DNA methylation reaction. DNA methyltransferases (DNMT) catalyze the transfer of methyl groups from the methyl donor *S*-adenosylmethionine to DNA releasing *S*-adenosylhomocysteine. Demethylases release the methyl group from methylated DNA. This is the first mechanism by which the environment can directly interact with the DNA, as levels of *S*-adenosylmethionine are regulated by diet


Fig. 2.2 DNA methylation reactions. Early after fertilization many of the methylation marks are removed by demethylases. (methyl groups are indicated by M, potential methylatable sites are indicated by an open circle). De novo DNA methyltransferases (DNMT) add methyl groups. Once a pattern is generated it is inherited by maintenance DNMTs that copy the methylation pattern
Fig. 2.3 Two mechanisms of silencing gene expression by DNA methylation. An expressed gene (transcription indicated by horizontal arrow) is usually associated with acetylated histones and is unmethylated. An event of methylation would lead to methylation by two different mechanisms. The methyl group (CH_3) interferes with the binding of a transcription factor, which is required for gene expression resulting in blocking of transcription. The second mechanism shown in the bottom right is indirect. Methylated DNA attracts methylated-DNA-binding proteins, which in turn recruit corepressors, histone methyltransferases that methylate histones, and histone deacetylases (HDAC), which remove the acetyl groups from histone tails. Methylated histones recruit heterochromatin proteins, which contribute to a closed chromatin configuration and silencing of the gene
Fig. 2.4 Demethylation is directed by the state of chromatin structure. Histone acetylation (Ac) triggered by a pharmacological inhibitor of histone deacetylase facilitates the interaction of demethylases with methylated DNA allowing for demethylation

2.2.4 The Roles of the DNA Methylation Machinery and the Reversibility of DNA Methylation Patterns

The DNA methylation machinery in vertebrates has two main roles. First, it has to establish new cell-type-specific DNA methylation patterns during development and possibly during adulthood in response to new signals. Second, it has to maintain these patterns during downstream cell divisions and after DNA repair. The different enzymes and proteins of the DNA methylation machinery must address these different tasks. The methylation of DNA occurs immediately after replication by a transfer of a methyl moiety from the donor *S*-adenosyl-l-methionine (AdoMet) in a reaction catalyzed by DNA methyltransferases (DNMT) (Fig. 2.2). In effect, this reaction consists of the first mechanism by which the environment can directly interact with the genome, as levels of AdoMet are regulated by diet. Three distinct phylogenic DNA methyltransferases were identified in mammals. DNMT1 shows preference for hemimethylated DNA in vitro, which is consistent with its role as a maintenance DNMT (Fig. 2.2), whereas DNMT3a and DNMT3b methylate unmethylated and methylated DNA at an equal rate which is consistent with a de novo DNMT role (Okano et al. 1998).

We have proposed that the DNA methylation pattern is a balance of methylation and demethylation reactions that are responsive to physiological and environmental signals and thus forms a platform for gene–environment interactions (Ramchandani et al. 1999a) (Fig. 2.1). There are now convincing examples of active, replication-independent DNA demethylation during development as well as in somatic tissues (Lucarelli et al. 2001; Kersh et al. 2006). One example we will explain in detail is that of the glucocorticoid receptor gene promoter in adult rat brains upon treatment with the HDAC inhibitor TSA (Weaver et al. 2004a). This finding has implications for humans, because drugs and dietary constituents known to be HDAC inhibitors are currently in widespread use.

We also propose that the direction of the DNA methylation reaction is defined by the state of chromatin. The gene specificity of the state of chromatin is defined by sequence-specific *trans*-acting

factors that recruit chromatin-modifying enzymes to specific genes. Chromatin configuration then gates the accessibility of genes to either DNA methylation or demethylation machineries (Cervoni and Szyf 2001; D'Alessio and Szyf 2006) (Fig. 2.4). We propose the following model: Factors that target specific chromatin modification events to genes define the direction of the DNA methylation equilibrium by either recruiting DNA methylation enzymes or by facilitating demethylation. We will illustrate how this might be working using gene expression programming by maternal care as a paradigm for behavioral programming of DNA methylation.

2.3 Mechanisms of Epigenetic Programming by Maternal Care and Diet

2.3.1 Maternal Care Epigenetically Programs Stress Responses in the Offspring

In the rat, the adult offspring of mothers that exhibit increased levels of pup licking/grooming and arched-back nursing (i.e., high-LG mothers) over the first week of life show increased hippocampal GR expression, enhanced glucocorticoid feedback sensitivity, decreased hypothalamic corticotrophin releasing factor (CRF) expression, and more modest HPA stress responses compared to animals reared by low-LG mothers (Liu et al. 1997; Francis et al. 1999). Cross-fostering studies suggest direct effects of maternal care on both gene expression and stress responses (Liu et al. 1997; Francis et al. 1999). We have previously published evidence to support the hypothesis that epigenetic mechanisms mediate the maternal effect on stress response. Increased maternal LG is associated with demethylation that includes a nerve-growth-factor-inducible protein A (NGFI-A) transcription factor response element located within the exon 1_7 GR promoter (Weaver et al. 2004a) (Fig. 2.5). The difference in the methylation status of this CpG site between the offspring of high- and low-LG mothers emerges over the first week of life, is reversed with cross-fostering, persists into adulthood, and is associated with altered histone acetylation and NGFI-A binding to the GR promoter (Weaver et al. 2004a). Thus maternal care affects the chromatin, DNA methylation, and transcription factor binding to the GR exon 1_7 promoter, illustrating the basic principles of epigenetic regulation discussed above. We have also shown that maternal care early in life affected the expression of hundreds of genes in the adult hippocampus (Weaver et al. 2006), thus illustrating the profound effect of the social environment early in life on gene expression programming throughout life.

2.3.2 Epigenetic Programming by Maternal Care is Reversible in the Adult Animal

Although epigenetic programming by maternal care is highly stable and results in long-term changes in gene expression, it is nevertheless reversible. The possibility that certain adverse gene expression programming of behaviorally relevant genes could be reversed by either epigenetic drugs or perhaps even by behavioral intervention has obvious implications. To test this hypothesis we used the well-documented histone deacetylase (HDAC) inhibitor TSA (Yoshida et al. 1990). Since the state of histone acetylation is a balance of histone deacetylation and histone acetylation reactions, inhibition of HDAC activity would tilt the equilibrium toward acetylation and as a consequence bring
Fig. 2.5 The methylation of the hippocampal glucocorticoid receptor $GR1_7$ promoter blocks the binding of the transcription factor binding NGFI-A. The epigenetic programming of the GR exon 1_7 promoter expression by maternal care is reversible later in life by either the HDAC inhibitor TSA or by the methyl donor SAM

about increased acetylation of histones leading to open chromatin configuration. We have previously proposed as discussed above that chromatin states and DNA methylation states are linked so that opening up of chromatin by increasing histone acetylation would tilt the balance of the DNA methylation equilibrium toward demethylation (Fig. 2.5) (Cervoni et al. 2001; Cervoni and Szyf 2001). Treating adult offspring of low-LG maternal care with TSA reversed the epigenetic marks on the GR exon 1_7 promoter; histone acetylation increased, the gene was demethylated, and there was increased occupancy of the promoter with the transcription factor NGFI-A, resulting in increased GR exon 1_7 promoter expression. The epigenetic reversal was accompanied with a behavioral change so that the stress response of the TSA-treated adult offspring of low LG was indistinguishable from the offspring of high LG (Weaver et al. 2004b). This was the first illustration of reversal of early life behavioral programming by pharmacological modulation of the epigenome during adulthood. TSA is not a DNA methylation inhibitor but nevertheless TSA treatment resulted in demethylation as we predicted. We propose that increased histone acetylation triggered by the HDAC inhibitor facilitated the interaction of a resident demethylase with the GR exon 1_7 promoter (Fig. 2.6). These data illustrate the tight association between the DNA methylation and histone acetylation equilibriums in the adult brain and the potential reversibility of the DNA methylation pattern in the nondividing adult neuron.

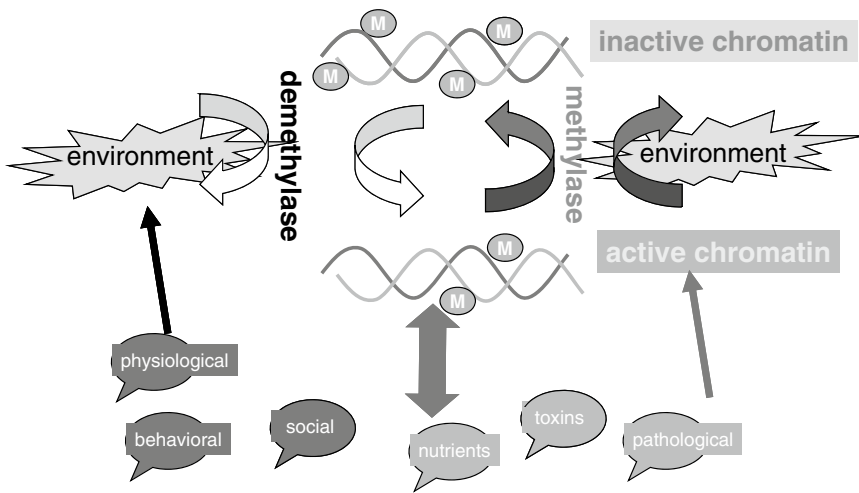
If the DNA methylation state remains in equilibrium of methylation–demethylation in adult neurons throughout life, it should be possible also to reverse the DNA methylation in the opposite direction by increasing DNA methylation, including manipulations of methyl donors. We have previously demonstrated that the methyl donor *S*-adenosyl methionine (SAM), and amino acid present in the diet, inhibit the demethylation reaction (Detich et al. 2003). Thus, changing SAM levels would alter the DNA methylation equilibrium by either increasing the rate of the DNA methylation reaction or by inhibiting the demethylation reaction or both (Fig. 2.6). Injection of methionine to the brain led to hypermethylation and reduced expression of the GR exon 1_7 expression in the adult hippocampus of offspring of high LG and reversal of its stress response to a pattern that was indistinguishable from offspring of low LG (Weaver et al. 2005). Thus, maternal epigenetic programming could be reversed later in life in both directions.


Fig. 2.6 Hypothesis: The steady state methylation pattern is a dynamic equilibrium between methylase and demethylase activities, defined by the state of chromatin. Different environmental exposures could tilt the balance of chromatin state and the DNA methylation state

These studies in rodents offer a model of epigenetic regulation of gene expression in the context of brain, behavior, and nutrition. The data show the regulation of epigenetic mechanisms in the brain (hippocampal glucocorticoid function) by a behavioral mechanism (early life environment) that is susceptible to modulation by l-methionine (a dietary amino acid). The data imply that in animals with a strong parental investment during early development, such as humans, early environment may have a profound effect on later behavioral trajectories. Thus, in humans, it may be expected that analogous mechanisms may exist to those in the animal studies reviewed above, while others may have special relevance in the context of human society.

2.4 Epigenetic Contributions to Mental Health in Humans

2.4.1 Influence of DNA Methylation on Mental Health

Genetic defects in genes encoding the DNA methylation and chromatin machinery exhibit profound effects on mental health in humans. A classic example is RETT syndrome, a progressive neurodevelopmental disorder and one of the most common causes of mental retardation in females, which is caused by mutations in the methylated-DNA-binding protein MeCP2 (Amir et al. 1999). Mutations in MeCP2 and reduced MeCp2 expression were also associated with autism (Nagarajan et al. 2006; Ben Zeev Ghidoni 2007; Herman et al. 2007; Lasalle 2007). ATRX a severe, X-linked form of syndromal mental retardation associated with alpha thalassaemia (ATR-X syndrome) is caused by a mutation in a gene, which encodes a member of the SNF2 subgroup of a superfamily of proteins with similar ATPase and helicase domains, which are involved in chromatin remodeling (Picketts et al. 1996). The ATRX mutation is associated with DNA methylation aberrations (Gibbons et al. 2000). Although these genetic lesions in the methylation machinery were present through development and

are thus fundamentally different from methylation changes after birth, these data nevertheless support the hypothesis that DNA methylation defects could lead to mental pathologies as well. Thus, it is possible that environmental exposuresthat would affect the activity of the methylation machinery would also lead to behavioral and mental pathologies.

There are some data indicating aberrant methylation in late onset mental pathologies, although it is unclear whether these changes in DNA methylation originated during embryogenesis or later in life as a response to an environmental exposure. The gene encoding *REELIN*, a protein involved in neuronal development and synaptogenesis, which is implicated in long-term memory, was found to be hypermethylated in brains of schizophrenia patients. The methylation of *REELIN* was correlated with its reduced expression and increased DNMT1 expression in GABAergic neurons in the prefrontal cortex (Chen et al. 2002; Costa et al. 2002, 2003; Grayson et al. 2005; Veldic et al. 2007).

We have found in our own work that promoters of the genes encoding rRNA are heavily methylated in hippocampi from subjects who committed suicide relative to controls (McGowan et al. 2008). Methylation of rRNA defines the fraction of rRNA molecules that is active in a cell, and the output of rRNA transcription defines to a large extent the protein synthesis capacity of a cell. Protein synthesis is critical for learning and memory. Thus, a reduced capacity for protein synthesis required for learning and memory in the brains of suicide victims could be epigenetically determined. This might be involved in the pathology leading to suicide. Thus, evidence is emerging that aberrant DNA methylation is involved in psychopathologies, and our study was the first published report of aberrant methylation associated with suicide. In our study, however, we found that the sequence of rRNA was identical in all subjects, and there was no difference in methylation between suicide victims and controls in the cerebellum, a brain region not normally associated with psychopathology. These data imply that epigenetic effects that influence psychopathology likely target particular neural pathways. Standardized forensic psychiatry methods had been used to ascertain that all of the suicide victims in our study had a history of severe abuse or neglect during childhood, which is common among suicide victims. Thus, the data suggest that severe adversity during early childhood may have been a contributing factor to the observed epigenetic pathology. It was unclear whether the observed abnormalities were a result of early adversity or whether they had emerged during adulthood as a result of the mental disorders associated with suicide. We undertook another study to address this question, and to examine whether epigenetic alterations analogous to those observed in rodents with differences in maternal care exist in humans.

As in the previous study, we examined the glucocorticoid receptor gene promoter in the hippocampus of human suicide victims and controls (McGowan et al. 2009). All of the suicide victims, and none of the controls, had a history of childhood abuse or severe neglect. A third group comprised suicide victims with a history that was negative for childhood abuse or neglect. We found that, as in the animal model described above, the glucocorticoid receptor was epigenetically regulated in the brain, and associated with altered glucocorticoid receptor gene expression. In humans, hypermethylation of the glucocorticoid receptor gene was found among suicide victims with a history of abuse in childhood, but not among controls or suicide victims with a negative history of childhood abuse. The data are consistent with other data from the literature suggesting that suicide has a developmental origin. They suggest that epigenetic processes might mediate the effects of the social environment during childhood on hippocampal gene expression and that stable epigenetic marks such as DNA methylation might then persist into adulthood and influence the vulnerability for psychopathology through effects on intermediate levels of function, such as HPA activity. However, it remains unclear whether the epigenetic aberrations documented in brain pathologies were present in the germ line, whether they were introduced during embryogenesis, or whether they were truly changes occurring during early childhood.

2.4.2 Chromatin Modification and Its Role in Mental Health

The fact that histone methylation is reversible provides a wide platform for pharmacological and therapeutic manipulations of the state of histone methylation in both directions. Both histone demethylases and histone methyltransferase are excellent candidates for new drug discovery. Understanding the intricate details of their genomic targets will allow the design of targeted and specific therapeutics.

The epigenetic effects of current clinically used monoamine oxidase inhibitors provide leads to further development of therapies targeting the epigenome. For example, H3K4Me2 is a hallmark of active genes and the target of the histone demethylase LSD1, which demethylates H3-K4Me2. Interestingly, certain nonselective monoamine oxidase inhibitors used as antidepressants such as Tranylcypromine that were clinically used for some time and believed to be acting on monoamine oxidases also appear to inhibit LSD1 demethylase (Lee et al. 2006). It is tempting to speculate that the inhibition of LSD1 is part of the mechanism of action of these antidepressants through activation of critical genes suppressed by the H3-K4me2 demethylating activity of LSD1 in the brain (Shi et al. 2004) or by repressing genes activated by the H3-K9Me2 demethylation activity of LSD1 (Metzger et al. 2005). Thus, it is possible that LSD1 inhibition is involved in the mechanism of action of antidepressive agents. It is tempting to speculate that selective inhibitors of LSD1 might be effective as antidepressants. This is an idea that might be pursued in the future.

Valproic acid, a long established antiepileptic and mood stabilizer, is also an HDACi (Phiel et al. 2001), suggesting a possible role for HDACi in treating mental disorders such as schizophrenia and bipolar disorder. Valproic acid has some effect in alleviating psychotic agitation as an adjunct to antipsychotics in schizophrenia (Bowden 2007; Yoshimura et al. 2007). HDACi were shown to improve memory and induce dendritic sprouting in a transgenic mouse model of neurodegeneration, suggesting that HDACi might be of use in treating neurodegeneration and memory loss as well (Fischer et al. 2007). Although biological and behavioral effects of HDACi in the brain are somewhat characterized, the specific gene targets of HDACi in the brain and their function in mental pathologies are not well delineated. Nevertheless, the limited clinical and animal data suggest a potentially important role for HDACi in treatment of mental disorders. Experiments with a novel HDACi from the benzamide class *N*-(2-aminophenyl)-4-[*N*-(pyridin-3-yl-methoxycarbonyl)aminomethyl]benzamide derivative (MS-275) in mice resulted in brain region specific induction of acetylation in the frontal cortex at two genes involved with schizophrenia pathogenesis, *REELIN* and *GAD*(*67*) (Simonini et al. 2006). Valproic acid was shown to induce the expression of *REELIN*, which was silenced by methionine treatment in mice (Dong et al. 2007). These studies raise the possibility that treatment of schizophrenics with HDACi might cause activation of expression of critical genes such as *REELIN* and could reverse the course of this disease (Sharma et al. 2006). Several clinical trials have tested valproate as an adjunctive therapy to antipsychotics in schizophrenia. There are indications that valproate might improve violent episodes in a subset of schizophrenia patients (Basan and Leucht 2004) and might have an effect on euphoric mania in combination with antipsychotics (Bowden 2007), as well as, features of manic symptomatology in bipolar disorders (Bowden 2007). It should be noted that many of these trials were of small size and that further clinical trials are needed with valproate and with more potent and selective HDACi to methodically test the therapeutic potential of HDACi in mental pathologies.

One question that needs to be addressed is whether the observed defects in histone acetylation in mental disease are a consequence of aberrant deregulation of the overall levels of certain HDAC isotypes or HATs, or whether it involves the aberrant targeting of HDAC to a selection of promoters.

The fact that inhibition of a general enzyme such as HDAC results in exquisite positive changes in the brain implies some specificity, even for a general inhibitor of a specific class of HDACs as discussed above. How could such specificity be achieved by treatment with nonselective HDACi? It will be important to delineate the response of the transcriptomes of different brain regions to HDACi and to map the genes that are critically involved in the molecular pathology of the disease. It will also be important to characterize the critical isoforms of HDAC for regulation of these genes. The advent of isotypic-specific HDACi might enhance the efficacy and potency of the treatment and reduce its toxicity.

2.5 Applications to Other Areas of Health and Disease: Role of Dietary Epigenetics in Behavior and Mental Health

The experiments described above involving infusion of methionine into the lateral ventricles of the brain raise the possibility that diet can affect the phenotype being studied. Because intracellular levels of methionine can be affected by both dietary intake and polymorphisms of enzymes involved in methionine metabolism, such as methylenetetrahydrofolate-reductase (Friso et al. 2002), it is tempting to consider the possibility that diet could modify epigenetic programming in the brain not only during early development but also in adult life in humans.

Rodent models have been useful in elucidating the mechanisms involved in epigenetic alterations related to diet during development. Several studies have shown that additional dietary factors, including zinc and alcohol, can influence the availability of methyl groups for SAM formation, and thereby influence CpG methylation (Ross 2003; Davis and Uthus 2004; Pogribny et al. 2006; Ross and Milner 2007). Maternal methyl supplements affect epigenetic variation and DNA methylation and positively affect the health and longevity of the offspring (Wolff et al. 1998; Cooney et al. 2002; Waterland and Jirtle 2003). We hypothesize that reversal of epigenetic states in the brain, such as the remethylation of the exon 1_7 GR promoter, could be triggered not only by pharmacological agents but also by stable variations in environmental conditions.

Other studies have shown that certain dietary components may act as an HDACi, including diallyl disulfide, sulforaphane, and butyrate. For example, broccoli, which contains high levels of sulforaphane, has been associated with H3 and H4 acetylation in peripheral blood mononuclear cells in mice 3–6 h after consumption (Dashwood and Ho 2007). The long-term consequences of such epigenetic effects on human health remain to be studied, however HDACis are an active area of research as anti-inflamatory and neuroprotective agents in autoimmune diseases such as lupus and multiple sclerosis (Gray and Dangond 2006), and sodium butyrate has been shown to have antidepressant effects in mice (Schroeder et al. 2007). Thus, it is conceivable that dietary compounds that influence histone acetylation may affect signaling mechanisms that regulate neural function. In light of the aforementioned link between histone modifications and DNA methylation, future studies are needed to address the possibility that sustained exposure to such compounds may affect DNA methylation at susceptible loci, with implications for mental health in humans. Dietary components could act through cellular signaling pathways, leading from cell surface receptors down to *trans*-acting factors that deliver chromatin-modifying enzymes to specific sequences. The dynamic epigenome has obviously adaptive and physiological roles in the crosstalk between our environment and our inherited genome, but could at the same time serve as a target for dietary components (Figs. 2.6 and 2.7). Thus, unraveling the conduits between our diet and our genomes should have an important impact on our health.

Summary Points

- We propose that the DNA methylation and chromatin structure are found in a dynamic balance through life, which is maintained and defined by sequence-specific factors that deliver histone modification and DNA modification enzymes to genes.
- We propose that the direction of the DNA methylation reaction is defined by the state of chromatin and, as such, factors that target specific chromatin modification events to genes define the direction of the DNA methylation equilibrium by either recruiting DNA methylation enzymes or by facilitating demethylation.
- Epigenetic programming in the brain of rodents by maternal care during the first week of life is a highly stable yet reversible process that results in long-term changes in gene expression.
- In our studies, we found that aberrant DNA methylation of the ribosomal RNA promoter as well as the glucocorticoid receptor promoter lead to decreased transcription of each gene, and that this effect was associated with a history of early childhood abuse or neglect in humans.
- Many of the phenotypic variations seen in human populations might be caused by differences in long-term programming of gene function rather than the sequence per se, and any future study of the basis for interindividual phenotypic diversity should consider epigenetic variations in addition to genetic sequence polymorphisms.
- The fact that histone methylation, histone acetylation, and DNA methylation are potentially reversible processes provides a wide platform for research into pharmacological and therapeutic manipulations with known epigenetic effects from drugs used to treat mental illness such as valproate to dietary supplements such as l-methionine.

Key Terms

Epigenetics: DNA and chromatin modifications that persist from one cell division to the next, despite a lack of change in the underlying DNA sequence.

Epigenome: The overall epigenetic state of a cell that serves as an interface between the environment and the genome.

DNA methylation/demethylation: A biochemical modification of the DNA involving the transfer of a methyl group (CH_3), typically to the 5′ position of the cytosine ring in the dinucleotide combination CG in mammals. In plants and other species DNA methyation may affect other nucleotide pairs.

Histone code: The specific pattern of histone protein modifications that delineate the parts of the genome to be expressed at a given point in time in a given cell type.

Chromatin: Histone proteins associated with the cell's DNA that regulate its accessibility to gene transcription machinery. Chromatin comes in two forms: Heterochromatin, where the DNA is tightly coiled and therefore inaccessible to the transcriptional machinery and euchromatin, where the DNA is more loosely associated with histone proteins.

Phenotype: Any observable characteristic of an organism, including its behavior. An organism's phenotype is a product of its genetics and its environment.

Methyltransferase: Enzymes involved in the transfer of a methyl donor from *S*-Adenosyl Methionine to histone proteins (histone methyltransferases) or DNA (DNA methyltransferases). Epigenetic regulation by histone methyltransferases tends to inhibit transcription.

Histone deacetylase inhibitor (HDACi): A class of chemicals that inhibits the acetylation of histones, leading to a chromatin structure that is more accessible to the transcriptional machinery. A variety of therapeutic chemicals (e.g., valproic acid) and dietary constituents (e.g., sulforaphane) have known HDACi properties.

Psychopathology: The manifestation of mental illness in the form of phenotype, including abnormal behavior and physiology.

Chapter 3
The Michigan State University Twin Registry (MSUTR): Genetic, Environmental, and Neurobiological Influences on Food and Diet-Related Behavior

Sarah E. Racine, Kristen M. Culbert, S. Alexandra Burt, and Kelly L. Klump

Abbreviations

MSUTR   Michigan State University Twin Registry
MZ   Monozygotic
DZ   Dizygotic
MTFS   Minnesota Twin Family Study
BMI   Body mass index

Key Terms

Phenotype: an observed trait or behavior
Prevalence: an estimate of how common a disorder or phenotype is in a given population
Etiology: the cause or origin of a disorder or phenotype
Heritability: the amount of total variation in a population on a given trait that is due to genetic factors
Moderation: a case when the strength or direction of a causal relationship is influenced by a third variable
Masculinization: the development of male typical physiology, morphology, and patterns of behavior

---

3.1 Introduction

The Michigan State University Twin Registry (MSUTR) is a population-based twin registry that recruits twins from across lower Michigan (Klump and Burt 2006). The MSUTR was created to understand changes in genetic, environmental, and neurobiological influences on internalizing and externalizing psychopathology across development as well as sex differences in these effects, and thus consists of male and female twins across a range of ages, including childhood, adolescence,

East Lansing, MI, USA
e-mail: klump@msu.edu

and adulthood. Eating disorders (i.e., anorexia nervosa, bulimia nervosa, and disordered eating attitudes and behaviors) are the main internalizing phenotype of interest for the MSUTR. Research thus far suggests that there are likely two critical periods for the development of disordered eating: puberty and the prenatal period.

Notably, the predominant influences during these two periods appear to differ, such that genetic effects on disordered eating are most important during puberty (Klump et al. 2007b), whereas "environmental" effects (more specifically, the hormonal environment) are critical during the prenatal period (Culbert et al. 2008). In both cases, gonadal hormones are likely to account for these genetic/environmental effects and may also operate to influence sex differences in prevalence (i.e., Ten females to every one male; American Psychiatric Association 2000). Ongoing data collection will continue to aid in understanding how gonadal hormones may influence individual and sex differences in risk for eating pathology.

This chapter will review twin studies from the MSUTR and other twin registries in order to illustrate differences in genetic and environmental effects on disordered eating across development. First, twin studies of eating disorders in adulthood will be briefly reviewed to demonstrate that genetic and non-shared environmental effects predominate during this time. Second, findings from a series of developmental twin studies from the Minnesota Twin Family Study (MTFS) and the MSUTR will be discussed in depth. These findings suggest that there are stark differences in the genetic and environmental influences on disordered eating across puberty, and that ovarian hormones may be critical for the "activation" of genetic effects. Finally, the prenatal period and in utero testosterone exposure will be presented as potentially influential for individual and sex differences in risk for disordered eating.

3.2 Twin Study Method

Twin studies provide a novel design for examining the etiology of phenotypes or behavior. Twins allow us to separate the effect of genes from that of the environment, as both contribute to the similarity of family members reared together. The twin method takes advantage of the fact that monozygotic (MZ) twins share 100% of their genes, whereas dizygotic (DZ) twins share, on average, 50% of their segregating genetic material. Comparing the degree of similarity among MZ and DZ twin pairs accordingly informs us of the relative importance of genetic and environmental influences on a given phenotype. Using statistical modeling, the total variance in a phenotype within a given population is partitioned into additive genetic (i.e., the additive effects of multiple genes), shared environmental (i.e., factors that make members of a twin pair similar to one another), and non-shared environmental influences (i.e., factors that make members of a twin pair different from one another) (Plomin et al. 2001).

3.3 Twin Studies of Disordered Eating

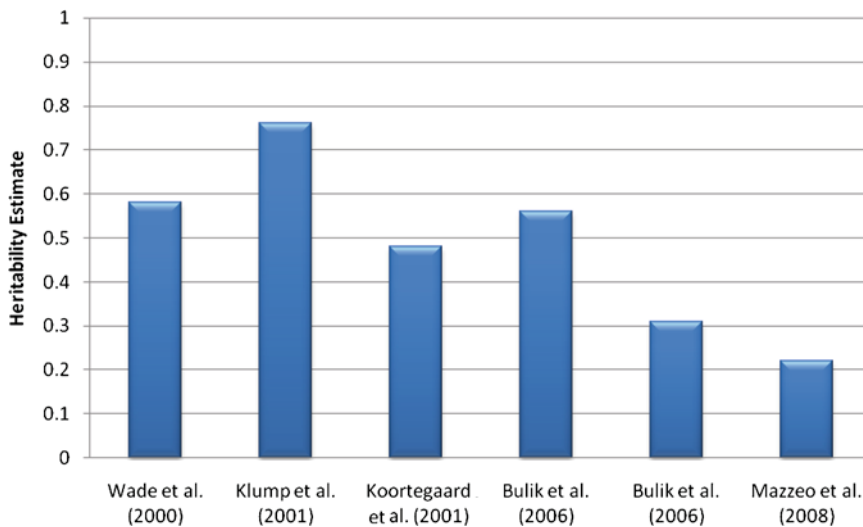
Twin studies of eating disorders and disordered eating date back to the 1980s and have informed us of the genetic and environmental architecture of eating pathology. Heritability estimates for anorexia nervosa and bulimia nervosa have generally been greater than 50% in adulthood (see Figs. 3.1 and 3.2). Similar heritability estimates have been reported for a range of disordered eating attitudes and behaviors, such as weight preoccupation, body dissatisfaction, dietary restraint,


Fig. 3.1 Heritability estimates for anorexia nervosa in adulthood. Twin studies of anorexia nervosa in adulthood indicate that anorexia nervosa is significantly heritable, with heritability estimates ranging from 22% to 76% (Copyright not required)
Fig. 3.2 Heritability estimates for bulimia nervosa in adulthood. Twin studies of bulimia nervosa in adulthood indicate that bulimia nervosa is significantly heritable, with heritability estimates ranging from 28% to 83% (Copyright not required)

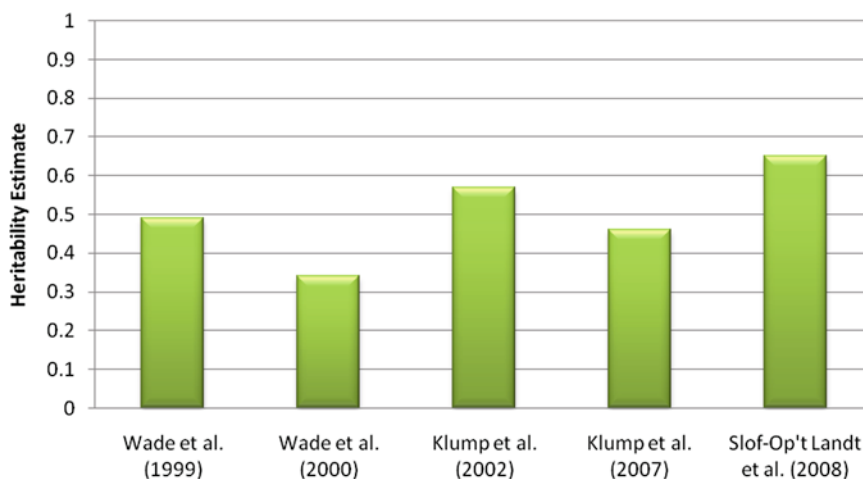
binge eating, and compensatory behaviors (See Fig. 3.3), thereby indicating that the symptoms that commonly precede the development of anorexia and bulimia nervosa are also highly heritable. With the exception of a few studies (e.g., Kendler et al. 1995; Reichborn-Kjennerud et al. 2004), little to no shared environmental influence has been reported for eating pathology in adulthood (Klump et al. 2009). In general, the remaining variance in disordered eating and eating disorders is accounted for by non-shared environmental influences. These could include factors such as differential parental treatment (e.g., parent(s) are more critical of one twin), different peer group


Fig. 3.3 Heritability estimates for overall disordered eating in adulthood. Twin studies of overall disordered eating, measured continuously, in adulthood indicate that disordered eating is significantly heritable, with heritability estimates ranging from 34% to 65% (Copyright not required)

characteristics (e.g., deviant vs. conforming peer groups), and different life experiences (e.g., experience of abuse/trauma), although these possibilities have not been extensively investigated (Klump et al. 2002).

3.4 Developmental Twin Studies of Disordered Eating

Although numerous twin studies have been conducted on disordered eating in adulthood, until recently, little was known about developmental changes in genetic and environmental influences on disordered eating. The first study to empirically examine this question was conducted by Klump et al. (2000) using a large cross-sectional twin sample from the MTFS. The genetic and environmental influences on disordered eating attitudes and behaviors (i.e., overall levels of disordered eating as well as weight preoccupation) differed in an interesting way by age, independent of body mass index (BMI). Specifically, in 11-year-old twins, genetic effects were negligible, as the majority of the variance in disordered eating was accounted for by shared and non-shared environmental factors. In contrast, genetic effects were substantial in 17-year-old twins, with the remaining variance accounted for by non-shared environmental influences. These findings significantly contributed to the literature, as this was the first study to highlight developmental differences in genetic and environmental effects on disordered eating.

Importantly, Klump et al. (2007a) extended these initial cross-sectional results by using longitudinal data to investigate developmental changes in genetic and environmental influences across MTFS twins assessed at ages 11, 14, and 18. Similar to findings from Klump et al. (2000), genetic effects increased with age. Again, minimal genetic influences were found at age 11, yet significant genetic influences were found at age 14 and remained constant through age 18. Thus, this study was able to narrow the time frame for the "activation" of genetic influences on disordered eating by suggesting that the critical period occurs between ages 11 and 14. Taken together, this line of research suggests clear developmental differences in the etiological influences on disordered eating.

Notably, a developmental study that examined unique and common etiological influences on eating, depressive, and anxiety symptoms reported slightly different results. Similar to Klump et al. (2000, 2007a), Silberg and Bulik (2005) found that genes accounted for more variance in eating pathology in adolescent (14–17 years) compared to preadolescent (8–13 years) twins. However, this study also reported that a unique set of genetic factors contributed to the variance in eating disorder symptoms in the 8–13-year-old group. It is possible that differences in the measures used to assess disordered eating could have contributed to these conflicting results. In addition, the preadolescent group in Silberg and Bulik (2005) included twins whose ages overlapped with both the 11 (10–12 years) and 14 (13–15 years) year-old groups from Klump et al. (2007a). Thus, differences in age categorizations could also account for differences in the pattern of results.

3.5 Puberty as a Critical Time Period

Given that our findings suggest that the onset of substantial genetic influences on disordered eating likely occurs between 11 and 14 years, the next line of research aimed to examine the mechanisms responsible for developmental changes in the relative influence of genes and environment. One crucial milestone that occurs between 11 and 14 years for most females is puberty (Herman-Giddens et al. 1997). Puberty is a significant event in a girl's life and is associated with a cascade of biological as well as psychosocial transitions. Research suggests that rates of disordered eating and eating disorders increase across the pubertal period (Killen et al. 1992). Thus, puberty is clearly associated with increases in the incidence of disordered eating and may similarly account for increases in genetic influences on this phenotype.

Indeed, developmental twin studies from the MTFS and MSUTR have suggested that pubertal development moderates the heritability of disordered eating, even after controlling for age. Specifically, there were little to no genetic influences on disordered eating in prepubertal 11-year-old twins from the MTFS, but genetic effects accounted for approximately 50% of the variance in 11-year-old twins who were in mid to late puberty (Klump et al. 2003). Interestingly, 11-year-old twins who had begun puberty closely resembled adult twins in the magnitude of genetic effects; indeed, the best-fitting biometric model constrained genetic influences to be equal in pubertal 11-year-old twins and adult twins. These findings suggest that puberty accounts entirely for changes in genetic effects on disordered eating that occur with age (Klump et al. 2007a).

A series of studies have now replicated these results. Using data from the MTFS, Klump et al. (2007b) demonstrated that genetic influences on disordered eating increase linearly with increasing pubertal development (see Fig. 3.4). These findings were replicated in an independent sample of twins from the MSUTR (Culbert et al. 2009). Again, nominal genetic influences on disordered eating were present in prepubertal young adolescent twins, but substantial and equal genetic influences were found in twins during puberty and into young adulthood. Importantly, this study indicated that the shift in etiological influences may be missed if late markers of pubertal development are used. For example, when menarcheal status is used to categorize pubertal development (see Rowe et al., 2002), no differences in genetic effects are observed in pre-menarche versus post-menarche groups (Culbert et al. 2009; Rowe et al. 2002). By contrast, when categorizations are made using mid-puberty, differences in genetic effects are observed (Culbert et al. 2009; Klump et al. 2003). These findings continue to highlight puberty as the critical period for developmental changes in the genetic and environmental influences on disordered eating.
Fig. 3.4 Contributions of genes, shared environment, and non-shared environment to disordered eating across pubertal development. Using gene–environment interaction models, we have shown that the heritability of disordered eating increases from 0% to 44% across pubertal development. In contrast, shared environmental influences sharply decline during this time. Abbreviations include *a* additive genetic effects, *c* shared environment, *e* non-shared environment (From Klump et al. 2007b. Reprinted with the permission of Cambridge University Press, © 2007 Cambridge University Press)

3.6 Ovarian Hormones: Activation of Genetic Influences?

Research examining the mechanisms underlying puberty's effect on the genetic diathesis of disordered eating is still in its infancy. There are numerous possible factors (e.g., hormones, body weight, mood, peer influences) that change at puberty and could influence the increasing genetic influences on disordered eating. While the MSUTR includes assessment of these multiple factors, our research thus far has focused on the role of ovarian hormones. Animal studies suggest that ovarian hormones have direct effects on food intake and body weight (Kemnitz et al. 1989; Wade 1972), and ovarian hormones are important regulators of gene transcription within neurotransmitter systems implicated in eating disorders (Ostlund et al. 2003; Klump and Culbert 2007). Because ovarian hormones appear to have direct genomic effects on behavior, they represent a plausible pubertal mechanism that could influence heritability estimates for disordered eating.

Indeed, data from the MSUTR have supported our hypotheses regarding the role of ovarian hormones in the onset of genetic influences on disordered eating at puberty. One study includes direct assessments of steroid hormone concentrations in 10–15-year-old same-sex female twins. Analyses are ongoing, but initial data suggest that estradiol levels moderate genetic effects on disordered eating, even after controlling for BMI and age (Klump et al. 2010). Specifically, the heritability of disordered eating was greater in twins with high estradiol versus low estradiol levels during puberty. Thus, estrogen's onset at puberty may partially account for the increase in genetic influences on disordered eating with increasing pubertal development.

Moreover, data from the MSUTR suggest that ovarian hormone concentrations show longitudinal associations with disordered eating (Klump et al. 2008). Same-sex female twins were asked to collect daily saliva samples of estradiol and progesterone and daily assessments of binge eating for 65 days. Findings suggested that natural fluctuations in ovarian hormones across the menstrual cycle precede and predict corresponding changes in binge eating, independent of fluctuations in negative affect (see Fig. 3.5). Identical findings have also been reported in women with bulimia nervosa
Fig. 3.5 Levels of binge eating, estradiol, and progesterone across the menstrual cycle. Data from female twins across the menstrual cycle have demonstrated that changes in estradiol are negatively correlated with fluctuations in binge eating, whereas changes in progesterone are positively correlated with fluctuations in binge eating (From Klump et al. 2008. Reprinted with the permission of Cambridge University Press, © 2008 Cambridge University Press)

(Edler et al. 2007). Importantly, the MSUTR is currently collecting a larger twin sample to investigate the genetic origins of the associations between ovarian hormones and disordered eating across the menstrual cycle.

3.7 The Prenatal Period as a Critical Time Period

While puberty and ovarian hormones appear to be critical for understanding the emergence of genetic effects on disordered eating, the prenatal period may be important for understanding environmental effects, particularly those that contribute to sex differences in eating disorder prevalence. Animal studies indicate that intrauterine hormones, particularly testosterone, permanently masculinize (i.e., make more male-like) the central nervous system and patterns of behaviors (e.g., increased aggression and food intake). Given the robust sex difference in eating pathology and the effects of prenatal testosterone on sexually dimorphic behaviors, the MSUTR has focused on examining whether variation in testosterone exposure during prenatal development permanently alters levels of disordered eating.

Since prenatal exposure to testosterone cannot be readily examined or manipulated in humans, the MSUTR has used finger-length (2D:4D) ratios and opposite-sex twins as proxies for prenatal testosterone exposure. Specifically, finger length ratios correlate inversely with prenatal testosterone levels (Lutchmaya et al. 2004) and are sexually dimorphic (i.e., lower in males relative to females) (Manning et al. 1998). Data from the MSUTR found significant associations between masculinized/lower 2D:4D finger length ratios and lower levels of disordered eating in adult women (Klump et al. 2006). These findings suggested that prenatal testosterone exposure may exert masculinizing effects on disordered eating in women, and thus, serve as a protective factor against eating disorder development.

Nonetheless, given the inclusion of only females, findings from Klump et al. (2006) could not speak to whether prenatal testosterone influences sex differences in disordered eating. Consequently, the MSUTR used opposite-sex twins to investigate whether prenatal testosterone exposure explains sex differences in eating pathology. Females from opposite-sex twin pairs

develop in utero with a male co-twin and are thus thought to be exposed to increased levels of prenatal testosterone (Ryan and Vandenbergh 2002). Indeed, adult opposite-sex female twins displayed lower levels of disordered eating compared to same-sex female twins from the MSUTR (Culbert et al. 2008). The magnitude of masculinization appeared to depend on the level of testosterone exposure, as same-sex male twins were most masculinized on eating pathology, followed by opposite-sex male twins, opposite-sex female twins, and same-sex female twins. Importantly, these effects were not accounted for by the masculinization of anxiety symptoms or by socialization of being raised with a male sibling. Together, these findings underscore the likely role of prenatal testosterone in explaining lower levels of disordered eating in opposite-sex female twins (Culbert et al. 2008).

However, results from two other twin registries suggested more modest effects than those described above. No significant differences in disordered eating were found between females from opposite-sex versus same-sex twin pairs (Baker et al. 2009; Raevuori et al. 2008), although trends (p's 0.06–0.10) were observed for lower rates of intentional weight loss and anorexia nervosa in opposite-sex female twins (Raevuori et al. 2008). Additional replications are needed, but findings thus far suggest that elevated prenatal testosterone exposure may exert small masculinizing/protective effects on disordered eating and provide a biological mechanism underlying the sex disparity in eating disorder prevalence.

3.8 Combined Influences of Puberty and the Prenatal Period

If elevated exposure to prenatal testosterone does exert masculinizing effects, it will be important to understand the mechanisms underlying such effects. One possible mechanism, currently under investigation within the MSUTR, is that prenatal testosterone alters sex-specific sensitivity to gonadal hormones during puberty. Animal studies have demonstrated that lower exposure to testosterone early in life permits the brain to respond to the female-typical effects of ovarian hormones on food intake at puberty (Gentry and Wade 1976; Madrid et al. 1993). Since ovarian hormones directly influence disordered eating (Edler et al. 2007; Klump et al. 2008), lower rates of disordered eating in opposite-sex female twins may result from decreased sensitivity to the activating effects of ovarian hormones on disordered eating during puberty. Understanding the combined role of prenatal and pubertal effects of gonadal hormones may provide further insight into the etiology of eating pathology and individual and sex differences in risk.

3.9 Applications to Other Areas of Health and Disease

In addition to a focus on disordered eating, the MSUTR assesses a wide range of other phenotypes. This is important given that developmental changes in genetic and environmental influences have been reported for phenotypes in addition to disordered eating, such as anxiety and depressive symptoms, externalizing behaviors, and intelligence (Bergen et al. 2007). Continued exploration of mechanisms underlying these shifts will be important for future research.

The MSUTR is poised to contribute to this future research. The MSUTR is unique in its developmentally informed approach and collection of molecular genetic and neurobiological data. Currently,

the MSUTR is implementing a large-scale, population-based recruitment of approximately 30,000 twins born in Michigan who are between the ages of 3–17-years-old. Once complete, the MSUTR will be one of the largest and most diverse twin registries in the United States. Importantly, all families are asked to complete a comprehensive health questionnaire that assesses a range of internalizing and externalizing psychopathology in the twins (e.g., depression, anxiety, inattention, hyperactivity, conduct problems), twin pubertal development, and family history of numerous medical and psychiatric illnesses (see Table 3.1). Therefore, twin analyses can be conducted to examine differences in the etiology of these phenotypes across a wide range of age groups. Moreover, a database of twins interested in participating in future research will be compiled and will allow researchers the option to select twins with a particular disorder or a specific family history for follow-up studies. The MSUTR will be an invaluable resource for examining developmentally relevant mechanisms underlying potential changes in etiology for a wide range of psychiatric and medical phenotypes.

Table 3.1 Psychiatric and medical illnesses assessed in the Michigan State University Twin Registry (MSUTR) via the family health checklist

Psychiatric conditions	Medical conditions
Eating disorders	Allergies
Anorexia nervosa	Asthma
Binge eating disorder	Blindness
Bulimia nervosa	Cancer
EDNOS	Cerebral palsy
Mood disorders	Cystic fibrosis
Bipolar disorder	Diabetes
Major depressive disorder	Head injury
Anxiety disorders	Hearing problems
Agoraphobia	Heart problems
OCD	Overweight/obesity
Panic disorder	Polycystic ovary syndrome
PTSD	Sleeping problems
Separation anxiety disorder	Smoking
Externalizing disorders	Snoring
ADHD	Stroke
Alcohol abuse	"Other" chronic illnesses
Conduct disorder	
Drug abuse	
Oppositional defiant disorder	
Developmental disorders

Asperger's disorder	
Personality disorders	
Antisocial personality disorder	
Borderline personality disorder	
Other	
Schizophrenia	
Learning disabilities	
Reading problems	

This table provides a comprehensive list of conditions assessed in the MSUTR. Research examining differences in the genetic and environmental influences on these conditions across development is possible using data from the MSUTR (Copyright not required)

Table 3.2 Key features and findings of the Michigan State University Twin Registry (MSUTR)

Key features
- Focus on developmental differences in genetic, environmental, and neurobiological influences
- Focus on sex differences in psychopathology
- Main internalizing phenotype of the MSUTR: disordered eating
- Direct assessment of some key genetic and environmental variables
- Candidate genes
- Hormone concentrations
- Parent–child interactions

Key findings
- Substantial increases in genetic influences on disordered eating during puberty
- Ovarian hormone activation at puberty may account for these effects
- Prenatal testosterone exposure masculinizes the brain and leads to lower levels of disordered eating that may underlie sex differences in eating pathology

This table summarizes the unique features of the MSUTR and the most important empirical findings thus far with regard to biological influences on disordered eating across development (Copyright not required)

3.10 Conclusions

The MSUTR is a new twin registry that is interested in examining critical developmental periods for genetic and environmental influences on disordered eating. Research from the MSUTR suggests that puberty is likely a critical period for the development of disordered eating. Specifically, genetic influences on eating pathology appear to increase across the pubertal period, and one hypothesis is that ovarian hormones moderate genetic risk for disordered eating during this time. In addition, the prenatal period may also be relevant for individual and sex differences in eating pathology, such that prenatal exposure to testosterone may be protective against development of disordered eating. These hypotheses must continue to be investigated, as research into the role of gonadal hormones on disordered eating is early in its development.

Summary Points

- One main focus of the MSUTR is to examine genetic, environmental, and neurobiological influences on disordered eating across development.
- Twin studies of eating disorders and disordered eating in adulthood consistently implicate genetic factors and non-shared environmental factors in the etiology of eating pathology.
- Disordered eating during preadolescence does not show significant genetic effects; shared and non-shared environmental influences predominate during this developmental stage.
- The pubertal period appears to be a critical time for the activation of genetic influences on disordered eating.
- One possibility is that the onset of ovarian hormones at puberty is responsible for the onset of genetic effects for disordered eating.
- The prenatal period is also important for disordered eating development, as environmental exposure to prenatal testosterone may masculinize the brain and lead to lower levels of disordered eating.
- Thus, gonadal hormones appear to be relevant for the development of disordered eating and may act primarily through genetic mechanisms during puberty and environmental mechanisms prenatally.

General and Normative Aspects: Sensory

Chapter 4
Cerebral Activity to Visual Presentation of Food

Jyrki T. Kuikka

Keywords Attention • Block design • Eating disorder • fMRI • Food • Statistical parametric mapping

Abbreviations

ACC	Anterior cingulate cortex
BMI	Body mass index
BOLD	Blood oxygen level-dependent. Changes in BOLD contrast originate from changes in the amount of deoxyhemoglobin present in tissue. These changes are measured by means of an MR scanner.
CBF	Cerebral blood flow
CBV	Cerebral blood volume
$CMRO_2$	Cerebral metabolic rate of oxygen
EEG	Electroencephalography
FDR	False discovery rate. FDR is a thresholding method to correct the amount of false positive areas (voxels) in the region of interest.
fMRI	Functional magnetic resonance imaging
FWHM	Full width half maximum. FWHM is a measure of the spatial resolution.
MEG	Magnetoencephalography. MEG is closely related to EEG in which the magnetic signals are generated by electric current with neurons. MEG offers millisecond temporal resolution but the spatial localization may be ambiguous
MNI	Montreal Neurological Institute
PCC	Posterior cingulate cortex
PET	Positron emission tomography
ROI	Region of interest
SPECT	Single-photon emission tomography
SPM	Statistical parametric mapping. A statistical method to increase reliability and reproducibility of fMRI image findings
T	Tesla. Tesla is the unit of the strength of magnetic field

4.1 Introduction

Food intake is fundamental for survival, and efficient brain processing of information related to this vital function is essential. Potential food sources are perceived through multiple sensory systems and are evaluated based on associative learning (Kringelbach 2004). Food-related disorders, especially obesity, have become common and worldwide problems today. World Health Organization has named obesity as one of the most important preventable health problems in the world today. Research on the central mechanisms regulating food intake can provide new insight to the understanding of mechanisms regulating eating and thereby contribute to the prevention and treatment of eating related disorders.

Positron emission tomography (PET) (Del Pagiri et al. 2002) and single-photon emission computer tomography (SPECT) (Karhunen et al. 1997) can be used for assessing blood flow changes and molecular level connectivity within the brain and body related to obesity and regulation of food intake but their temporal and spatial resolution for activation studies is poorer than that of fMRI (Ogawa et al. 1990; Belliveau et al. 1991; Kuikka et al. 1996; Frank and Kaye 2005; Riera et al. 2008). Moreover, repeated studies increase rapidly subject's radiation exposure. Next, we discuss fMRI studies only.

During recent years, there has been a growing interest to investigate the mechanisms related to regulation of food intake in humans (Kilgore and Yurgelun-Todd 2006; Cornier et al. 2007; Kaurijoki et al. 2008; Stoeckesl et al. 2008; Schienle et al. 2009). These studies have identified several cortical and limbic brain regions with apparent food-related functions in humans. Visual food stimuli have been shown to activate the prefrontal, orbitofrontal, and temporal cortices, cingulate, insula, striatum, and amygdala in the healthy human brain (Morris and Dolan 2001; Killgore et al. 2003; Uher et al. 2004; Kaurijoki et al. 2008; Stice et al. 2008; Siep et al. 2009).

However, it is not in all cases known whether the cerebral activations, observed so far, are specific for processing of food-related information, or whether they are also related, for example, to the complexity of the visual stimuli used in the experiments. Moreover, food is a motivational stimulus and closely related to emotions (Kringelbach 2004). The observed activations might thus have also been associated with emotional processing.

4.2 Functional Magnetic Resonance Imaging (fMRI)

4.2.1 Blood Oxygen Level-Dependent Imaging

Functional magnetic resonance imaging (fMRI) has advanced to be the major tool for the assessment of brain function such as blood flow and blood volume changes using the venous blood oxygenation level-dependent (BOLD) magnetic resonance contrast (Ogawa et al. 1990; Norris 2006) (Table 4.1). Since its initial introduction in 1990 for fMRI about 87,000 studies have been published during the first 20 years to record brain activation in both humans and animals.

Changes in BOLD contrast originate from changes in the amount of deoxyhemoglobin, which act as an endogenous paramagnetic contrast agent (Pauling and Coruell 1936; Ogawa et al. 1990). BOLD signal is generally measured by means of T2*-weighted MRI sequence (Norris 2006). The amount of deoxyhemoglobin present depends on three physiological parameters:

1. The local rate of metabolic consumption of oxygen ($rCMRO_2$)
2. The regional cerebral blood volume (rCBV)
3. The regional cerebral blood flow (rCBF)

Table 4.1 Key features of blood oxygenation level-dependent (BOLD) functional magnetic resonance imaging (fMRI)

1. The subject performs a task in the MR scanner while BOLD images of the whole brain are acquired every 1–3 s and hundreds of images are accumulated
2. A complete fMRI scan lasts around 2–10 min depending on the paradigm
3. fMRI has a spatial resolution as low as 1 mm
4. The images show small changes in the brightness (signal intensity) levels of certain brain areas during the task
5. These brightness changes are compared to another moment when that task is not executed or another condition
6. A subtraction principle is applied between the images of two conditions and any BOLD signal difference above the statistical level chosen represents the brain region involved in the performance of that task
Fig. 4.1 Time course of the blood oxygenation level-dependent (BOLD) response to a haemodynamic short duration stimulus. The BOLD effect peaks 3–4 s after the stimulus and signal takes almost a minute to return to baseline

An increase in neural activity will lead to an increase in all three of these parameters (Fig. 4.1). The current hypothesis is that activation-induced blood flow changes are driven by synaptic input to a brain region. The increase in rCBF is to satisfy an increased demand for oxygen, and that the increase in rCBV is driven by the increase in rCBF. However, we must realize that observed fMRI signal intensity changes are only indirect consequences of synaptic inputs to the regions of interest (ROIs).

Popularity of BOLD studies is based on both wide availability of MRI scanners and safety of the studies in healthy subjects since they can be performed without harmful side effects and without radiation exposure, making repeated studies of the same subjects readily feasible (Norris 2006). The spatial resolution of BOLD fMRI is limited to about 3 mm. The sensitivity of BOLD fMRI depends on main magnetic field strength being order of 1–5% when measured in a scanner of 1.5 T and 2–10% in a scanner of 3.0 T. The temporal resolution is in second scale (1–3 s), as a comparison electroencephalography (EEG) and magnetoencephalography (MEG) enable one to study the living cortical areas within a millisecond (ms) scale but with much poorer spatial resolution (in cm-scale) than fMRI (in mm-scale).

4.2.2 Motion and Movement

A major potential confound for all imaging studies is the object's motion due to the subject's involuntary movement, eyes motion as well as respiratory and cardiac changes during the scan. Motion can introduce a number of artifacts and image blurring of varying degrees and severity. Most current methods rely on realignment to correct for motion, which is capable of correcting interscan motion at the subvoxel level (Norris 2006). There are several freely available programs for motion correction (Statistical parametric mapping, SPM; prospective acquisition correction, PACE; automatic image registration, AIR) (Norris 2006).

Artifacts, image blurring, and pitfalls can arise at any step in the activation fMRI study and can be grouped into issues related to the study design, the subjects, the fMRI protocol, and the statistical analysis (Amaro and Barker 2006).

4.3 Procedure

4.3.1 Subject's Preparation for fMRI

All subjects have to have normal or corrected-to-normal vision (with contact lenses) and no magnetic material in their body. Depending on the aim of the study, the background information, e.g., weight, body mass index (BMI), handiness, eating history, psychiatric diagnosis (including claustrophobia, panic disorder), neurological illnesses, and medication of the subjects should be known. The subjects are usually prohibited from consuming any food, cigarettes, coffee, tea, and cola drinks at least for 2 h before the fMRI session. Whenever possible, all scans should be conducted at about the same time of the day for the all subjects. Avoid all shortcomings between and among the study groups. The size of the study groups depends on many things but for the statistical analysis each group should have at least 12 subjects. The study protocol and scanning process should be carefully explained to the subjects or even trained before the study.

4.3.2 Tasks and Paradigms

It is not known whether the cerebral activations, observed so far, are specific for processing of food-related information, or whether they are also related, for example, to the complexity of the visual stimuli used in the experiments. Moreover, food is a motivational stimulus and closely related to emotions (Kringelbach 2004). The observed activations might thus have also been associated with emotional processing. Therefore, to investigate cerebral responses to visual food stimuli relative to responses evoked by nonfood, stimuli have to be matched with respect to their visual complexity. In addition, the subjects could be presented emotionally different pictures to examine whether the responses evoked by the food stimuli were specific to food or were influenced by the emotional content of the stimuli.

The experiment typically consists of the presentation of several visual activation conditions such as: food, nonfood, and emotionally different conditions (e.g., neutral, pleasant, and unpleasant) (Fig. 4.2). A low-level baseline, a blank gray screen, should be included in the experiment in case direct comparisons of different conditions would not yield specific activations. All pictures
Fig. 4.2 Examples of food and nonfood picture pairs. *Top*: cold smoked salmon versus a rose, centre: slices of ham versus playing cards and bottom: an apple versus a tennis ball. The photograph of each object was presented on a gray background and nonfood items were matched for color, luminance, and visual complexity with the food items (Reprinted from Kaurijoki et al. (2008). With permission of Wiley-Blackwell)

Table 4.2   Key features of food and nonfood pictures

1.   The most important topic here is that the food and nonfood images are similar in texture, color, background, and visual complexity.

should present familiar and well-known items on a neutral, e.g., gray background (Table 4.2). The motivational salience of the pictures, e.g., the caloric content of food pictures, can also be manipulated.

The neutral, pleasant, and unpleasant pictures can be selected, for example, from the International Affective Picture System (IAPS) (Lang et al. 2001). To confirm that the pictures have the expected emotional valence, volunteers of the same age and gender as the study subjects should evaluate these pictures. The food and nonfood pictures should also be pre-evaluated by the volunteers to confirm that the pictures are recognized accordingly. To minimize activation related to eye-movements, the subjects are instructed to visually fixate a central cross on the screen.

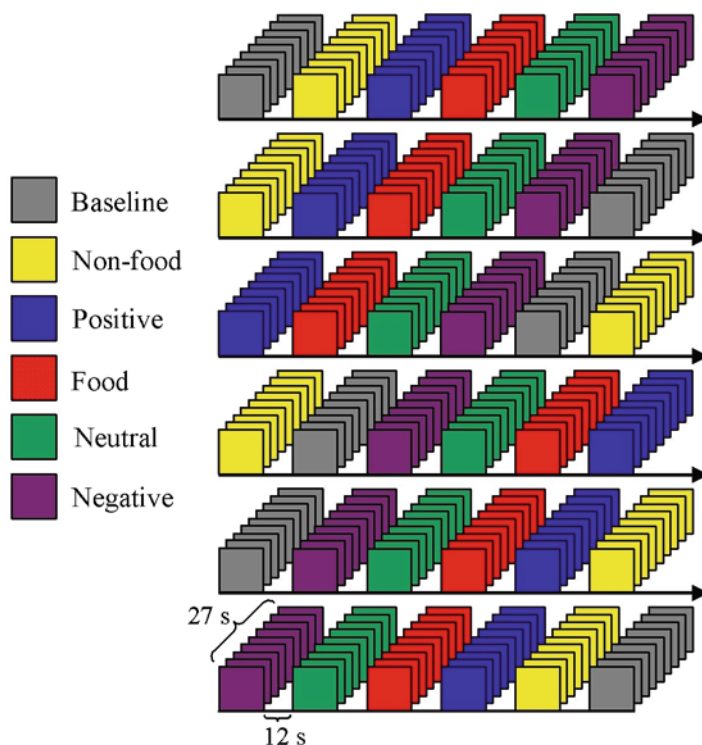
4.3.3 Block Design

In our study (Kaurijoki et al. 2008), a two-conditions block design (Friston et al. 1999) was used (Table 4.3) in which each condition (food, nonfood, neutral, pleasant, unpleasant, and control) was shown in six blocks of nine pictures in the central visual field (horizontal visual angle 9.7°, vertical 7.7°). Each condition consisted thus of 54 pictures and each picture was shown only once (Fig. 4.3). Each image was shown for 1 s, followed by a blank gray screen for 2 s. The order of the blocks was counterbalanced. The interval between the blocks was 12 s to allow recovery of the cerebral blood flow from the effects of the previous block. Using Presentation 0.05 software (Neurobehavioral Systems, Inc., San Francisco, CA, USA), the stimuli are displayed on a rear-projection screen placed at the foot of the MR scanner bed. Subjects view this screen from within the bore of the magnet in a mirror placed on the head coil. The computer that controls the stimulus display is triggered by the scanning sequence.

Before the experiment, subjects were informed that various types of pictures would be shown during the scan. The pictures were, however, not specified in more detail. In addition, subjects were shown two examples of the visual stimuli not used in the experiment, as well as a baseline and target

Table 4.3 Key features of two conditions block design

1. The block design is the most efficient paradigm for studying activated areas, for blocks of stimulation allows more time to the BOLD signal to build up
2. The use of this block design has lead to much criticism related to the neuropsychological drawbacks but its increased statistical power still makes it a most valuable technique
3. BOLD-based fMRI can never match the temporal resolution (ms) of EEG or MEG

Fig. 4.3 An example of a block design to show pictures during functional magnetic resonance imaging (fMRI) scan. The order of the blocks is counterbalanced. Each stimulus condition is shown in six blocks of nine pictures, so that each condition consists of 54 images (Unpublished data of Kaurijoki et al. (2008))


picture. The target which was shown six times over the whole experiment was a neutral picture from the IAPS, and was included into the experiment for monitoring that subjects were awake during the scan. The presentation of the target picture was randomized and located between the blocks so that one block of each condition is followed by the target picture. Subjects were instructed to attend to all stimuli, avoid head movements, focus on the fixation cross in each picture, and press a button when detecting the target picture.

4.3.4 Assessment of Affect

Positive and negative effects have different effects on activation of specific brain areas while undergoing fMRI study. Therefore, post-scanning ratings of the pictures used in stimuli should be done to measure the subject's experience of the emotional content of the picture. This could be performed, e.g., memory and intensity rating test by showing the fMRI stimuli pictures one by one on a computer monitor and to ask the subjects to judge the emotional valence of each picture by, e.g., on a 7-point scale (1 = very pleasant, 2 = pleasant, 3 = slightly pleasant, 4 = neutral, 5 = slightly unpleasant, 6 = unpleasant, 7 = very unpleasant) (Kaurijoki et al. 2008). If also new previously unshown pictures are presented, the test can also be used as an indirect measurement of the subjects' ability to recognize the objects. Subjects judge then whether or not they have seen the presented picture during the scan, e.g., by reporting if their judgment is based on a distinct recollection of having seen the picture, a less certain feeling of familiarity, or on a distinct certainty of not having seen the picture.

4.4 Data Analysis

In our study (Kaurijoki et al. 2008) data was analyzed using Statistical Parametric Mapping software (SPM; Wellcome Department of Cognitive Neurology, London, UK; http://www.fil.ion.ucl. ac.uk) running on MATLAB (The Mathworks, Inc., Natick, MA, USA). Movement-related artifacts were removed by realigning the scans to the middle scan of the time series and resliced using sinc interpolation. Differences in acquisition time of slices were corrected to make the data on each slice correspond to the same point in time. Functional images were then co-registered to structural T1-images. In order to spatially normalize images, thus facilitating intersubject averaging, the data from different subjects have to be transformed into a standard anatomic space. Therefore, the functional images were normalized using the MNI template supplied with SPM to the standard stereotactic space. Finally, to conform to the Gaussian field theory, and to increase the signal-to-noise ratio data were smoothed with an isotropic Gaussian kernel with full width at half maximum (FWHM) of 8 mm.

The hemodynamic response was modeled with a fixed-response box-car function with additional temporal derivates. Low-frequency confounds were excluded from the model with a high-pass filter of twice the experimental run's length. Variations in global signal intensity were not removed. The six realignment parameters for each run were included in the model as covariates, to account for undesired effects of head movement.

In the analysis at single subject level, the following linear contrasts were specified and t-contrasts were calculated: (1) food > nonfood and (2) nonfood > food. In the group level analysis, the relevant contrasts of parameter estimates from the single subjects were entered into a one-sided *t*-test to analyze the mean of group observations using a random-effects approach. A correction of multiple

comparisons was based on the false discovery rate (FDR) (Genovese et al. 2002) at the significance level of $P \leq 0.01$.

Clusters smaller than ten contiguous voxels ($10 \times 2 \times 2 \times 2$ mm $= 80$ mm³) in the combined group image were excluded from the analysis. The SPM (Bellgowan et al. 2003) maps were displayed on an average template brain in the standardized coordinate space [x, y, z in space of Montreal Neurological Institute (MNI) template] within SPM. Active brain regions were specified using the Talairach and Tournoux (1988) after adjustment (www.mrc-cbu.cam.ac.uk/Imaging/mnispace.html) for differences between MNI and Talairach coordinates. Posthoc analysis was performed using a region-of-interest (ROI) approach.

4.5 Cerebral Activity to Visual Presentation of Food in Humans

4.5.1 Food > Nonfood Visual Stimuli and Visualization of Genotypes

The neuroanatomical sites affected by food versus nonfood stimuli depends on several aspects such as genetic, eating behavior, hunger, satiety, study design, etc., and so far results are often spread and partly controversial.

Some examples of recent studies about the cerebral activity to the visual presentation of food in humans are summarized next (Table 4.4).

The main interest in the study of Kaurijoki et al. (2008) was the cerebral reactivity to pictures of food versus nonfood and their links to certain well-known, potentially food-related genetic polymorphisms. Therefore, only the food-related comparisons between the various conditions are presented. In addition, to rule out the possible contribution of differences in the visual complexity among the different conditions, the same comparisons are also presented for the visually matched nonfood stimuli. As a result, the comparison between the food and nonfood stimuli conditions (food>nonfood; Fig. 4.4) showed a significant activation in the left posterior cingulate (PCC), left anterior cingulate (ACC) cortices, and left supramarginal gyrus. No significantly activated areas were found in the comparison of nonfood>food.

The individual analysis of the results of this study also suggests a possible genetically driven variation in the cerebral activity to visual presentation of food (Kaurijoki et al. 2008). In the comparison between food and nonfood conditions, the genotype groups of the serotonin transporter regulatory region polymorphism (5-HTTLPR) showed different mean signal intensities of the left PCC activity ($P < 0.01$). This region probably mediates interactions of food-related emotional and memory processes. Subjects homozygous for the long allele (L/L-genotype) exhibited greater left PCC activity in comparison to food>nonfood compared with short allele (L/S and S/S-genotype; Fig. 4.5). These preliminary data suggest that vulnerability for overeating and obesity may even be enhanced by the presence of L/L genotype.

Table 4.4 Key features of data analysis

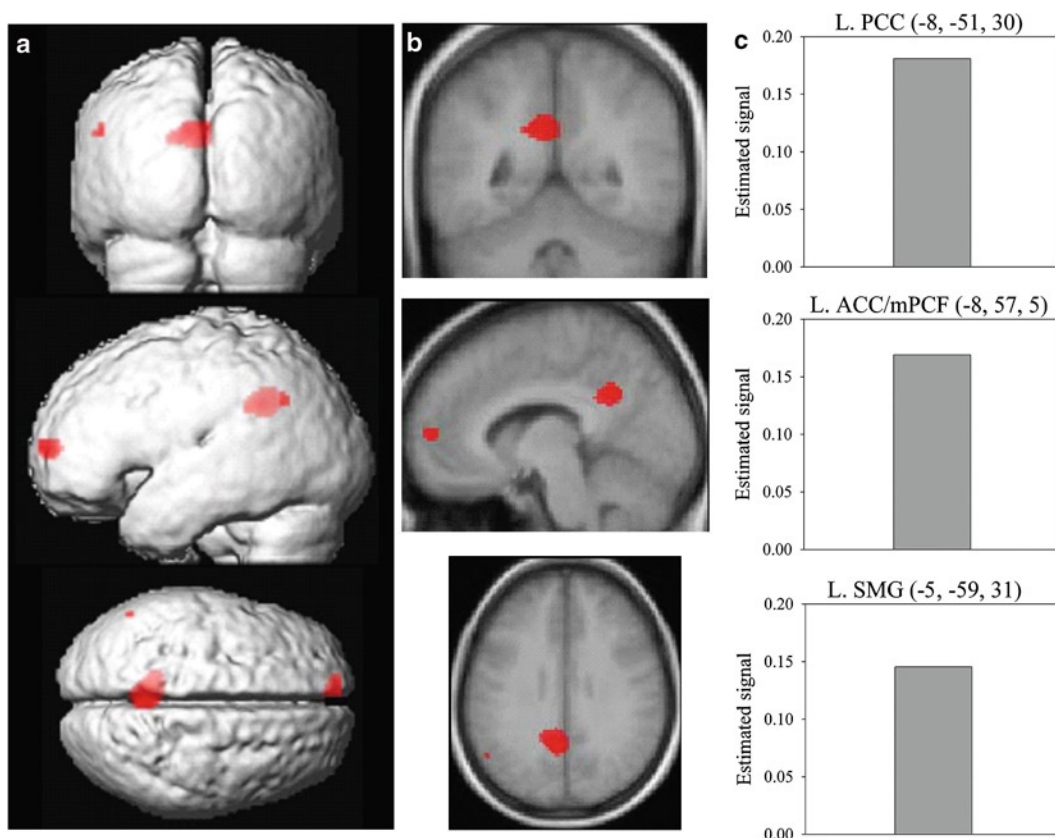
1. A major component of the noise in fMRI studies is physiological in origin
2. Group studies should be smoothed with a filter of about 10 mm in width to allow for intersubject variations in the anatomy
3. Both a region of interest (ROI) and a whole-brain voxel-based analysis with individual ratings of appetite, arousal, etc. should be included
4. Activated regions are generally presented in Talairach x-, y-, and z-coordinates


Fig. 4.4 Brain regions activated during the food when compared with nonfood pictures. (**a**) Render images of the coronal view (*top*), left hemisphere (*center*), and transaxial view (*bottom*), and (**b**) coronal, sagittal, and transaxial slices showing the location of increased activation superimposed on a mean anatomical image of the 28 subjects. (**c**) Parameter estimates for the local maxima of the left posterior cingulate (PCC) and left anterior cingulate cortices/ medial prefrontal cortices (ACC/mPCF) and the left supramarginal gyrus (SMG) activations in the food > nonfood comparison (Reprinted from Kaurijoki et al. (2008). With permission of Wiley-Blackwell)

4.5.2 High- and Low-calorie Food > Nonfood Visual Stimuli

Killgore and Yurgulun-Todd (2006) examined whether affect ratings predicted regional cerebral responses to high- and low-calorie food pictures among normal-weight adult women. Positive and negative affect had different effects on appetite-related regions depending on the calorie content of the food images. When viewing high-calorie images, positive affect was associated with increased activity in satiety-related regions (lateral orbitofrontal cortex), but when viewing low-calorie food, affect was associated with increased activity in hunger-related regions (medial orbitofrontal cortex and insular cortex).

4.5.3 Food > Nonfood Visual Stimuli While Fasting > 12 h

St-Onge et al. (2005) employed fMRI to isolate cortical sites involved in the appreciation of food and nonfood pictures in healthy, normal-weight, and fasting individuals. Food, and nonfood images were presented to subjects both visually and tactilely. Brain regions that were significantly activated to a

Fig. 4.5 Association between genotype and brain activation. Effects of serotonin transporter promoter regulatory region polymorphism (5-HTTLPR) variation on the response for the fMRI signal intensity change food > nonfood in the left posterior cingulate cortex (PCC). The subjects with two copies of the long allele variant have the strongest activation (Reprinted from Kaurijoki et al. (2008). With permission of Wiley-Blackwell)
greater extent during the presentation of foods compared with nonfood items included the anterior cingulate cortex, superior temporal gyrus, parahippocampal gyrus, hippocampus, and the insula. This study as well as many others, suffer that in a group analysis alone, all findings are not necessarily observed in all subjects.

4.5.4 Cerebral Activity in Hunger and Satiety

Führer et al. (2008) explored brain activity during hunger versus satiety using visual simulation. During the hunger condition, significantly enhanced brain activity was found in the left striatum and extrastriatal cortex, the inferior parietal lobe, and the orbitofrontal cortex. Stimulation with food images was associated with increased activity in insula, the left striatum, and extrastriatal cortex, and the anterior midprefrontal cortex. A significant interaction in activation pattern between the states of hunger and satiety and stimulation with food and nonfood images was found for the left anterior cingulate cortex, the superior occipital sulcus, and in the vicinity of the right amygdala.

They emphasized that central nervous system activation is not only altered with hunger and satiety but that food and nonfood images have also specific effects on regional cerebral activity if exposure takes place in different states of satiety (Führer et al. 2008; Chechlacz et al. 2009).

4.6 Applications to Other Areas of Health and Disease

The primary field of fMRI applications remains the cognitive neurosciences, but several applications are also found in surgical treatment planning (Vlieger et al. 2004), vascular diseases (Sharma et al. 2009) and preclinical studies (Marota et al. 2000).

4.7 Conclusions

The imaging methods (fMRI, MEG, PET, and SPECT) for evaluating cerebral activity to visual presentation of food have been in use for a decade. The versatility of fMRI makes it a powerful tool and BOLD imaging has proven to have the capacity to objectively measure the response changes, despite the fact that the underlying mechanisms are still not fully understood. The increased sensitivity and specificity of higher-field (≥ 3 T) MRI systems will improve our understanding of the underlying mechanisms related to the regulation of food intake and that way also on the pathophysiology of eating disorders. Further studies on regional activation and connectivity, coupled with psychological observations of the particular affective processes involved, will improve our understanding of food-related disorders.

Summary Points

- The block design is the most efficient paradigm for studying activated areas. Blocks of stimulation allow more time to the BOLD signal to build up and thus statistical certainty between the task minus another condition increases.
- In healthy subjects, a stronger focus locates on the left hemisphere (such as anterior cingulate cortex, insula, medial prefrontal cortex, orbitofrontal cortex, and posterior cingulate cortex).
- The subjects with eating disorder exhibit greater activation in response to food pictures in a large number and usually bilateral regions than controls.
- The present results suggest the possible genetically driven variation in the response of the certain brain regions to visual presentation of food.
- However, the results are still very preliminary and heterogeneous due to the several confounding factors such as subjects' selection, their nutritional and hormonal status, study protocol, statistical settings, etc.

GPCR	G-protein coupled reaction
Kg	Kilogram
LCPUFA	Long chain polyunsaturated fatty acid
Mg	Milligrams
SCO	Single-cell oil
VEP	Visual evoked potential

5.1 Introduction

The visual system comprises a complex signaling system involving the retina, thalamus and primary visual cortex. In addition, other cortical regions are involved in the cognitive integration of visual information. Researchers have assessed the impact of long-chain polyunsaturated fatty acids (LCPUFA) on infant visual development by evaluating two main aspects of the infant's visual system; retinal development using electroretinogram (ERG) and visual processing at the level of the primary visual cortex. Cortical measures of grated visual acuity include sweep visual evoked potential (VEP) and behavioral assessments such as the forced-choice preferential looking (FPL). Of the grated acuity measures, VEP measures cortical response directly and has less inherent variability. However, behavioral acuity measures provide the most direct measure of what an infant actually perceives and normative data are well established for these procedures (Neuringer 2000).

e-mail: Michelle.Judge@uconn.edu

Compared to other cells in the body, the retinal photoreceptors are known to have the highest content of the LCPUFA docosahexaenoic acid (DHA, 22:6 n-3) (Neuringer 2000). The gray matter in the visual cortex and multiple other cortical regions also have high levels of DHA. In rhesus monkeys, a diet deficient in LCPUFA during pregnancy impeded the accumulation of DHA in these tissues in the offspring. A 50% reduction of DHA in retinal tissue and 25% reduction in cerebral cortex DHA were reported for the offspring of rhesus monkeys fed a diet deficient in α-linonenic acid (18:3, n-3) during pregnancy compared to controls (Neuringer et al. 1986). Linolenic acid is the precursor to along the biosynthetic pathway. Neuringer and colleagues also demonstrated that these deficient animals had lower visual acuity measured using preferential looking and a prolonged recovery time of the dark-adapted ERG after a saturating flash.

Behavioral methods for assessment of visual acuity have repeatedly shown that human infants have better visual function with the provision of DHA during the postnatal period (Birch et al. 1993a; Makrides et al. 1993, 1995; Carlson et al. 1996; Jorgensen et al. 1996; Hoffman et al. 2003). To date, there is one report (Judge et al. 2007) of improved infant visual acuity (assessed using the Acuity Card Procedure, ACP) related to maternal dietary DHA intake during pregnancy. Malcolm et al. used VEP (Malcolm et al. 2003a) and ERG (Malcolm et al. 2003b) to assess visual acuity related to maternal DHA supplementation, but no relationship was apparent. There was no significant treatment effect for ERG in the first postnatal week (Malcolm et al. 2003a) or VEP at 2.5 or 6.5 months of age (Malcolm et al. 2003b).

Pregnant women in the USA and Canada have DHA intakes below the current recommended amount of 200 mg/day for optimal fetal development (Koletzko et al. 2008; Lewis et al. 1995; Innis and Elias 2003; Loosemore et al. 2004; Denomme et al. 2005). As the developing fetus has extremely limited capacity for deriving DHA from the 18 carbon precursor, the fetus is clearly at risk for DHA deficiency when maternal DHA intake is low. Given this risk for deficiency, marine, egg-phospholipid, and single-cell oils (SCO) have been developed and explored for maternal and infant supplementation. Increased efforts toward community-based educational programs targeting women of child-bearing age with the goal of increasing DHA intake are recommended. Interruptions in visual development can delay the achievement of other developmental milestones with important long-term implications. This chapter will outline the contemporary research related to infant visual development, contrast assessment methodologies of visual acuity, and explore dietary factors that are fundamental to neurodevelopment.

5.2 Neuroanatomy of the Visual System

The cerebral cortex is comprised of two distinct tissue layers, gray and white matter. The cortex surrounds the entire perimeter of the brain and comprises approximately 80% of the volume of the human brain (Kolb and Whishaw 2003). Neuronal cell bodies are found primarily in the gray matter. The white matter of the brain is comprised primarily of the myelinated nerve axons. Different areas of the cortex are responsible for receiving and processing stimuli. The four functional areas of the cerebral cortex include: motor, sensory, visual and auditory. The primary functional areas of the cerebral cortex receive initial sensory information and the secondary and tertiary areas are responsible for association and processing. Visual information goes to the primary visual cortex and processing related to assessment of shape, color and categorization occur in secondary and tertiary visual areas. These secondary and tertiary areas, include, motor, sensory and auditory cortical areas; all communicate with central brain structures for further processing.

5.3 The Visual System

Vision and behavioral responses to visual stimuli rely on a complex system of communication between the retina, thalamus and multiple regions of the cerebral cortex. Visual processing is initiated when the photoreceptors of the retina receive a visual stimulus that triggers signal transduction. The impulse travels down the optic tract where signal transductions are sent to the opposite cerebral hemisphere after crossing at the optic chiasm (Fig. 5.1). After passing the optic chiasm, the optic tract sends the signal to the lateral geniculate nucleus of the thalamus, which relays visual signaling to the primary visual cortex. When visual information is sent to the primary visual cortex it is disseminated to various cortical areas by two main pathways, the dorsal and ventral streams, for higher cortical processing. The dorsal stream projections are sent to the parietal lobe to process information pertaining to location and movement (Zigmond et al. 1999). The ventral stream projects to the temporal lobe where more integrative processing occurs, e.g., object and facial recognition (Fig. 5.2). The process of facial recognition relating to memory is conducted primarily by the limbic system which involves the entorhinal cortex, hippocampus and amygdala.

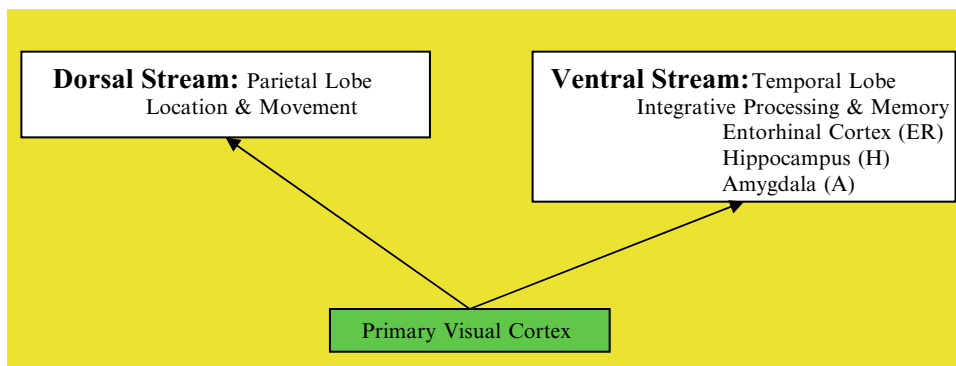
At the level of the membrane, G protein-coupled receptor (GPCR) signal transduction occurs in the retina, brain, and nervous system and has been attributed to signaling pathways leading to visual and cognitive function (Salem et al. 2001; Nui et al. 2004). G proteins are binding proteins that use neurotransmitters to collectively activate receptors (referred to as coupled activation) (Zigmond et al. 1999). Action of the neurotransmitter utilizes a second messenger system for the regulation of the
Fig. 5.1 Visual processing is initiated when the photoreceptors of the retina receive a visual stimulus that triggers signal transduction. The impulse travels down the optic tract where signal transductions are sent to the opposite cerebral hemisphere after crossing at the optic chiasm. After passing the optic chiasm, the optic tract sends the signal to the lateral geniculate nucleus of the thalamus, which relays visual signaling to the primary visual cortex


Fig. 5.2 When visual information is sent to the primary visual cortex it is disseminated to various cortical areas by two main pathways, the dorsal and ventral streams. The dorsal stream projections are sent to the parietal lobe to process information pertaining to location and movement. The ventral stream projects to the temporal lobe where more integrative processing occurs, e.g., object and facial recognition involving the entorhinal cortex (*ER*), hippocampus (*H*) and amygdale (*A*)

synthesis of protein kinases. The protein kinase produced as a result of the GPCR depends upon the neurotransmitter coupling the reaction (Zigmond et al. 1999). The specific type of protein kinase generated will initiate a phosphorylation reaction at the site of the ion channel causing excitation or inhibition. In the visual system, the rod photoreceptor is stimulated or hyperpolarized due to the GPCR involving the receptor metarhodopsin II (triggered by rhodopsin) coupled with transducin (the visual G protein) activating the production of the protein kinase phosphodiesterase (Nui et al. 2004). Fatty acid composition of the membrane bilayer has been shown to alter the rate of GPCR coupling (Niu et al. 2001; Mitchell et al. 2003; Nui et al. 2004). In those investigations GPCR coupling was reduced in the absence of DHA.

5.4 Testing and Assessment of the Visual System in Infants and Toddlers

A robust area of research with regard to nutrition and infant development is in the area of visual processing. The majority of the visual research linked to cognitive functioning has been reported during the past three decades (Kellman and Banks 1998). ERG, FLP and VEP are the three main techniques employed for the assessment of infant visual function. The consideration of visual acuity is important to the assessment of cognitive development. There is a need for good vision in order to perform optimally on other developmental tests. If an infant scores poorly on a given developmental test, results could be clouded by poor vision and be mistakenly classified as poor mental processing.

Measures of infant visual development have focused on two main aspects of the visual system; retinal development using ERG and visual processing at the level of the primary visual cortex. Cortical measures of grated visual acuity include sweep VEP and behavioral assessments such as FLP (Fig. 5.3). Of the grated acuity measures, VEP measures cortical response directly and has less inherent variability. However, behavioral acuity measures provide the most direct measure of what an infant actually perceives.

Fig. 5.3 Visual acuity measures. Outline of methodologies measuring cerebral response to visual stimuli: Central response as in visual evoked potential is a direct measure of cortical activity. Behavioral response methodologies like forced-choice preferential looking rely on movement or behavior associated with the cortical stimuli
5.4.1 Electroretinogram

The ERG is a direct measure of the retinal response to a visual stimulus prior to reaching any of the cortical areas. In this procedure, electrodes placed on the cornea and surrounding eye tissue measure cellular electrical reactivity related to visual stimulus. ERG measurements therefore do not provide information regarding higher-level (i.e., cortical) visual processing (Table 5.1).

The work of Malcolm et al. (2003a) was focused on maternal DHA supplementation and infant ERG. These investigators supplemented pregnant women with fish oil from 15 weeks gestation to delivery. ERG assessments were performed in the early postnatal period circumventing the potential impact of infant feeding method or other socioeconomic variables. There were no significant differences in retinal reactivity between infants of mothers who were supplemented compared to controls. Maternal DHA concentrations were higher in the experimental group when compared to control, however the relationship between infant DHA status (umbilical cord blood) and maternal status was not significant. The finding that maternal supplementation of DHA was not related to infant status is contrary to the view that a relationship exists and may be related to the dose (200 mg DHA daily) chosen for the investigation. Wijendran et al. (2000) demonstrated a strong relationship between maternal and infant DHA status in pregnancies not complicated with gestational diabetes mellitus (GDM). In that investigation, in which control subjects were compared to women with GDM, the cord vein erythrocyte phospholipid DHA and arachidonic acid (wt%) were higher than the maternal phospholipid DHA and arachidonic acid in the control group with significantly positive correlations between maternal and fetal erythrocyte phospholipid for arachidonic acid and DHA ($r = 0.83$, $P = 0.003$; $r = 0.62$, $P = 0.04$, respectively) (Tables 5.2).

5.4.2 Forced-Choice Preferential Looking (FPL)

Assessment of visual acuity in infancy is complicated by the need for gathering nonverbal information. For this reason, forced-choice preferential looking procedures were developed in the area of visual acuity assessment to better understand and quantify the behavioral cues of infants. Preferential looking procedures use black and white stripes that are grated in a series of frequencies that correspond with the number of stripes per visual angle (commonly termed as cycles/degree) (Fig. 5.4).

Table 5.1 Key features of the electroretinogram

1. Electroretinogram measures retinal response to a visual stimulus.
2. Electrodes are placed directly on the cornea and surrounding eye tissue.
3. The eye is exposed to a visual stimulus, i.e. light.
4. Electrical reactivity of the eye cells is recorded and quantified.

This table lists the key facts of electroretinogram

Table 5.2 Key points on the role of DHA in maternal and infant nutrition

1. The essential fatty acid DHA has a central role in membrane fluidity and synaptic signaling impacting retinal reactivity and visual processing. DHA accumulates in high concentrations in specific regions of the brain, including cerebral cortex, synapses and retinal rod photoreceptors in mice, rats, baboons, and other mammals (Bazan and Scott 1990; Bowen and Clandinin 2002; Sarkadi-Nagy et al. 2003). DHA deficiency induced during the gestational period in rats significantly impact the amount of DHA that was incorporated into the neuronal growth cone (Auestad and Innis 2000).

2. The current recommendation for DHA intake during pregnancy that stemmed from an expert panel is 200 mg/day (Koletzko et al. 2008).

3. Single-cell oils (SCO) and marine sources are safe and can adequately provide DHA supplementation to both the mother and infant to prevent deficiencies. DHA deficiency can interfere with optimal infant visual and cognitive development.

This table lists key points relating to the role of DHA in maternal and infant health including adverse developmental outcomes associated with DHA deficiency during the gestational period, current intake recommendations for pregnant women, and safe supplementation sources
Fig. 5.4 Forced-choice preferential looking. In the Teller Acuity Card procedure, stripes are flipped from right (**a**) to left (**b**) with the location of the stripe unknown to the tester. Tester looks for a behavioral response (i.e., head movement toward the striped patch) (MPJ Original)

The point at which an infant is unable to resolve or see the contrasting stripes in a grated acuity procedure is considered the visual threshold. The term "forced choice" refers to the fact that the observer must choose or assess if the infant is looking to the left or right corresponding with the visual stimulus. The Teller Acuity Card Procedure (ACP) is a FPL procedure that has been standardized for use in a U.S. population. The ACP is portable and easily administered making it ideal in the research setting. As with any measure that relies on the interpretation of behavioral responses, there are a number of confounding variables that could skew findings. For example, a sleepy or fussy infant may lack interest in the visual stimulus and therefore alter results.

There are multiple published studies utilizing ACP/FPL procedures for the investigation of the relationship between DHA status and visual development in term infants (Innis et al. 1994, 1996, 1997; Carlson et al. 1996; Jorgensen et al. 1996; Auestad et al. 1997, 2001; Birch et al. 2000; O'Connor et al. 2001). Carlson et al. (1996) investigated term infants fed formula with varying levels of DHA. Using FPL, the supplemented group performed similarly to the group of infants fed human milk, which contains variable amounts of DHA depending upon the maternal diet and/or supplementation. Three of the studies in term infants relating to DHA status have shown statistically significant differences using ACP/FPL procedures (Birch et al. 1993a, b; Carlson et al. 1996; Jorgensen et al. 1996). Contrary to the findings of

Carlson et al., Auestad et al. (1997, 2001) reported no differences between supplemented and control groups using the ACP procedure. It is noteworthy to mention that the amount of DHA in these studies (Auestad et al. 1997, 2001) was considerably lower than those used in other studies (Birch et al. 1993a, b; Carlson and Werkman 1996; Jorgensen et al. 1996).

Only one investigation has reported on the impact of maternal DHA supplementation during pregnancy and infant visual acuity measured using the ACP. Judge et al. (2007) investigated the role of a DHA-functional food consumed during pregnancy on infant visual acuity at 4 and 6 months of age measured behaviorally using the ACP. In this randomized, longitudinal, double-blinded, and placebo-controlled trial, 30 pregnant women received either the DHA-functional food ($n = 16$) or the placebo ($n = 14$). There were significant main effects for visual acuity at 4 months of age ($P = 0.018$). The mean acuity score were, 3.8 ± 1.1 cycles/degree in the DHA group versus 3.2 ± 0.7 cycles/degree in the placebo group. At 6 months there was no group difference (Judge et al. 2007). Based on these results, it was concluded that DHA supplemented during pregnancy plays a role in the maturation of the visual system. This finding combined with evidence from studies conducted evaluating DHA supplementation during the postnatal period provide compelling evidence that DHA supplementation during pregnancy can have a profound impact on infant visual acuity development.

5.4.3 Visual Evoked Potential

VEP is a direct measure of cortical response and has less inherent subjectivity than the behavioral methods of visual acuity assessment. In this procedure, the infant is given an electroencephalogram by placing electrodes on the scalp to measure neural cell reactivity related to a visual stimulus. The majority of the studies performed using VEP have shown a positive relationship between DHA status and visual development (Makrides et al. 1993, 1995; O'Connor et al. 2001; Hoffman et al. 2003). Hoffman et al. (2003) investigated term infants who fed human milk for 4–6 months then fed either formula supplemented with DHA and arachidonic acid or control formula. Infants in the supplemented group had significantly better VEP than the control group. Makrides et al. (1995) also investigated the impact of DHA supplementation on visual processing in term infants and found that the supplemented and human milk–fed groups performed similarly on VEP measures and better than the group of infants who did not receive DHA. Similar findings have been reported for preterm infants. O'Connor et al. (2001) investigated preterm infants and reported significantly better VEP in DHA supplemented groups. In summary, the majority of studies to assess vision in term and preterm infants have demonstrated a positive association between processing and DHA status.

With regard to fetal development, Malcolm and coworkers (Malcolm et al. 2003a) examined maternal DHA supplementation and infant VEP. They supplemented pregnant women with fish oil from 15 weeks gestation to delivery. VEP assessments were performed at 2.5 and 6.5 months of age and there were no significant differences between infants of mothers who were supplemented compared to controls. This finding is in contrast to the study of visual acuity carried out by Judge et al. (2007).

5.5 Dietary Factors Influencing Visual Development

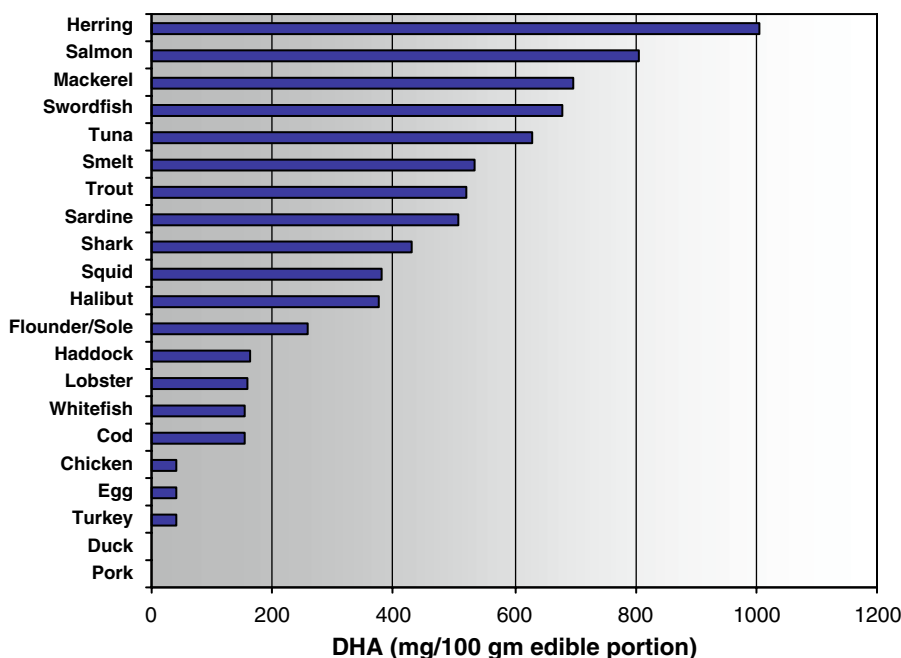
The last trimester of pregnancy is a critical interval for fetal neurological development. During this time DHA accumulates in neural tissue at an accelerated rate (Fox 1998). Reports of maternal DHA intake during pregnancy suggest that intakes are generally far below the recommended level of intake


Fig. 5.5 Dietary sources of docosahexaenoic acid (mg DHA/100 g edible portion). Herring, salmon and mackerel are examples of cold-water marine fish that are a rich dietary source of DHA. Source: U.S.D.A., Human Nutrition Information Service

which suggests that many infants are at risk for associated impairments in development (Cheruku et al. 2002; Olsen and Secher 2002; Loosemore et al. 2004). Figure 5.5 outlines common food sources of DHA and points to cold water marine fish as the best dietary sources. It is unknown how concerns about contaminants in fish relate to low DHA intake during pregnancy (Cheruku et al. 2002; Olsen and Secher 2002; Loosemore et al. 2004).

Compounding the problem of reduced maternal intake of DHA, the overall intake of fatty acids in the n-6 family is typically high in western industrialized countries such as the U.S. High intake of n-6 fatty acids is related to an abundance of processed and fried foods containing plant oils with linoleic acid. Linolenic and linoleic both compete for the Δ-6 desaturase and high intake of linoleic acid can inhibit conversion of linolenic acid to DHA (Simopoulos et al. 2000). In 2008 a panel of experts led by Koletzko et al. (2008) concluded that the optimal level of DHA intake during pregnancy is 200 mg/day.

DHA has a central role in membrane fluidity and synaptic signaling in neural tissue and DHA accumulates in high concentrations in specific regions of the brain, including the cerebral cortex, synapses, and retinal rod photoreceptors in mice, rats, baboons, and other mammals (Bazan and Scott 1990; Bowen and Clandinin 2002; Sarkadi-Nagy et al. 2003). DHA deficiency induced during the gestational period in rats significantly reduce the amount of DHA that was incorporated into the neuronal growth cone (Auestad and Innis 2000).

In humans, autopsy studies have demonstrated the importance of DHA in brain tissue. Clandinin et al. (1980) investigated fatty acid components of the fetal brain during the third trimester. Brain tissue fat content was analyzed upon autopsy at varying stages of gestation to determine the pattern of fatty acid accretion during pregnancy. That study demonstrated that the accretion of the essential

fatty acids linolenic acid and linoleic acid (the metabolic precursors for DHA and arachidonic acid, respectively) were low during the last trimester and that there is a substantial accretion of DHA and arachidonic acid. Evidence shows the importance of DHA intake for both maternal and infant health (Table 5.2).

5.5.1 Dietary Sources of DHA for Supplementation

Three main sources of DHA and arachidonic acid oil that have been considered for use in infant formulas are: marine, egg phospholipid, and SCO. Commercially available maternal supplements contain either marine or SCO. There are potential drawbacks associated with the use of marine and egg phospholipid oils in infant formulas.

5.5.1.1 Marine Oil

Early studies focused on the addition of DHA and arachidonic acid to human infants via marine oil which indicated a potential negative impact on growth. This adverse outcome was attributed to the eicosapentaenoic acid content of the oil and a possible competitive inhibition of the n-6 pathway responsible for the production of arachidonic acid (Carlson et al. 1992a, b, 1993). Makrides et al. investigated DHA vis-a-vis marine oil supplementation in term infants and reported a significantly lower DHA erythrocyte concentration in the experimental group receiving marine oil compared to the breast milk or placebo group (Makrides et al. 1995).

An additional safety concern for marine oil supplementation is increased bleeding time related to the eicosapentaenoic acid, a reflection of cyclooxygenase production. Cyclooxygenase inhibits platelet aggregation and causes vasodilatation. Impaired platelet aggregation decreases blood clotting and resulting in increased bleeding time.

Scientific evidence exists that lends credence to the notion that marine oil supplementation does not have a negative impact on growth or bleeding time. In a series of studies, Carlson et al. investigated the safety and efficacy of supplementation with marine oils in preterm infants (Carlson et al. 1992a, b). In study I, infants were given a nasogastric bolus of marine oil in the dose of 750 mg/kg/day for 4 weeks. In study II, the marine oil was mixed into the formula at doses of 116 mg/kg/day (0.2% DHA and 0.3% eicosapentaenoic acid) and 290 mg/kg/day (0.5% DHA and 0.75% eicosapentaenoic acid) of marine oil for a 2-week period. In study III, the dose of 116 mg/kg/day of marine oil was investigated for a 9-month period. The bolus dose of marine oil in study I resulted in poor fatty acid absorption. In studies I and II phosphatidylethanolamine arachidonic acid, a primary phospholipid component of the cell membrane, declined significantly over time for all infants (Carlson et al. 1992a, b). In study II, the infants in the marine oil group had significantly lower phosphatidylethanolamine arachidonic acid than the controls; however, the marine oil groups also had lower baseline arachidonic acid levels, which likely contributed to these findings. Conversely, eicosapentaenoic acid and DHA increased in the marine oil groups and decreased in the control groups. The infants receiving 290 mg/kg/day of marine oil had significantly lower phosphatidylcholine, a primary phospholipid component of the cell membrane also commonly known as lecithin, than the control and lower dose groups (i.e., 116 mg/kg/day). In study III, there were positive correlations between arachidonic acid and DHA in the marine oil group through 9 months of age.

Uauy et al. (1994) compared four groups of very low birth weight infants given human milk (control), formula with corn oil, formula with soy oil, and formula with soy and marine oil. In this study bleeding times were evaluated and no significant differences in bleeding time were reported for any of the groups and bleeding times were within normal ranges for all groups. Additionally, Uauy et al. considered anthropometric data for each of the groups. Anthropometric data included weight, length, head circumference, triceps skinfold, and subscapular skinfold. Measurements were collected at birth, 34, 40, 48, and 57 weeks' gestational age. There were no differences among any of the study groups, i.e., weight gain and growth were similar for all four groups.

Based on the few studies carried out in human infants, there are no associated adverse impacts on growth or bleeding time in a dose of fish oil below 116 mg/kg/d. It appears that DHA absorption is better with marine oil if mixed into the formula compared to a bolus dose. Likewise, multiple large studies have been conducted that provided marine oil during the gestational period and no negative pregnancy outcomes were reported. In fact, marine oil supplemented during pregnancy has been demonstrated to increase the average length of gestation resulting in significantly higher birth weight (Olsen et al. 1995).

5.5.1.2 Egg Yolk Phospholipid

Egg yolk phospholipid is composed primarily of phosphatidlycholine. A drawback of egg-derived oils is that it contains relatively low amounts of DHA and arachidonic acid. Therefore, large amounts need to be added to infant formula to reach the desired DHA and arachidonic acid levels. Given the limitations of supplementation, egg-derived phospholipid has not been studied for commercial use in pregnancy. Consuming large quantities of egg phospholipids cause concern because of the exposure to large doses of sterols and egg-related allergens. In the context of this review, few research groups have used egg-derived phospholipids as DHA and arachidonic acid sources. Of the studies that have been reported, none have reported adverse outcomes with regard to toxicity or growth (Carlson et al. 1996; Auestad et al. 1997, 2001).

5.5.1.3 Single-Cell Oils

DHA and arachidonic acid oils, single-cell oils (SCO), are produced via the fermentation, extraction, and purification of microalgae and microfungus (Boswell et al. 1996). These oils are used as a maternal supplement during pregnancy and in infant formulas. The marine alga used for the production of DHA is Crypthecodinium cohinii and the oil is 40–50% DHA with no Eicosapentaenoic acid. This DHA single-cell oil is commonly referred to as DHASCO (Boswell et al. 1996). Arachidonic acid is formed from the unicellular fungus strain Mortierella alpina and is 40–50% arachidonic acid. This arachidonic acid single-cell oil is commonly referred to as ARASCO (Boswell et al. 1996). The microorganisms used to produce SCO had never before been used in food products and therefore required Food and Drug Administration approval for use in infant formulas. The natural toxins inherent in the two microorganisms were of concern with regard to use in food. Sufficient evidence exists regarding the safety of SCO as these have been investigated extensively for use in infant formulas (Boswell et al. 1996).

In summary, SCO and marine oil are both considered safe and efficacious for consumption during pregnancy; however, research points to the efficacy of a low eicosapentaenoic acid formulation for this group (Carlson et al. 1992a, b, 1993). Single-cell oils have been investigated extensively for use in infant formulas and provide the best alternative to marine and egg-derived sources.

5.6 Summary

In summary, visual signaling involves a complex interaction between the retina, thalamus, and primary visual cortex. Other cortical regions of the brain as well as central brain structures are involved in processing visual stimuli. Measures of visual development in infancy assess retinal reactivity or cortical processing of the visual stimulus. Behavioral measures of visual acuity give insight on the processing of visual information. Retinal photoreceptors have a high DHA concentration and deficiency during fetal development and the postnatal period have been associated with interruptions in visual development.

Maternal intake of DHA during pregnancy is significantly below the recommended 200 mg/day for healthy pregnancy outcomes. In turn, the developing fetus is at risk for negative outcomes. Optimal visual development enables the infant to move toward more integrative cognitive processing and the achievement of established developmental milestones. Additional community-based efforts are necessary to educate communities regarding the important role of DHA for optimal developmental outcomes during both the prenatal and postnatal periods. Future work should focus on the evaluation of maternal DHA status and its relationship to visual development in older children and associations with other cognitive processes.

5.7 Applications to Other Areas of Health and Disease

The consideration of visual acuity is very important to the assessment of cognitive development for a number of reasons. First, there is a need for good vision in order to perform optimally on other developmental tests. If an infant scores poorly on a given developmental test, results could be clouded by poor vision and mistakenly classified as poor mental processing. Additionally, early visual perception probably guides the development of action systems to promote learning about the infant's physical and social worlds (Von Hofsten 1980; Bertenthal 1996). For example, the development of infant reaching is prompted by the visual stimulus of an object that an infant is interested in exploring.

Future work should focus on (1) the evaluation of maternal DHA status and the infant's ability to integrate visual stimuli, as in face and object recognition, and (2) the relationship of acuity assessed during infancy with later vision and other cognitive processes (Neuringer and Jeffrey 2003). Focused community-based programs are necessary for promoting adequate intake of DHA during pregnancy and ensuring optimal infant visual and cognitive development.

Summary Points

- Visual signaling involves the retina, thalamus, and primary visual cortex.
- Other cortical regions of the brain as well as central brain structures are involved in processing visual stimuli.
- Measures of visual development assess retinal stimulation (ERG) or cortical processing (VEP and FPL).
- Forced-choice preferential looking procedures are behavioral measures of visual acuity and lend insight to the integration of visual information.
- Retinal photoreceptors and neural cell bodies are comprised predominantly of the essential fatty acid docosahexaenoic acid.

- Deficiencies of docosahexaenoic acid during fetal and infant development have been associated with interruptions in normal visual processing.
- Alterations in G protein coupled signal transduction related to docosahexaenoic acid provides a plausible mechanism for observations of alterations in visual functioning.
- Maternal docosahexaenoic acid during pregnancy is significantly below recommendations (200 mg/day) for optimal pregnancy outcomes placing the developing fetus at risk.
- Dietary sources of docosahexaenoic acid for the purpose of supplementation include: Marine and single-cell oils.
- Poor visual processing can impede infant attainment of later developmental milestones that rely on integrative processing.
- Additional educational efforts are necessary to educate the community regarding the important role of docosahexaenoic acid in infant development during both the prenatal and postnatal periods.

Definitions of Key Terms

Photoreceptors: A neural cell that is specific to the retina with specificity for visual stimuli.

Visual cortex: The portion of the brain's cortex where visual information is sent for further processing.

Electroretinogram: A direct measure of the retinal response to a visual stimulus prior to reaching any of the cortical areas.

Forced-choice preferential looking: Preferential looking procedures use black and white stripes that are grated in a series of frequencies that correspond with the number of stripes per visual angle (commonly termed as cycles/degree). The point at which an infant is unable to resolve or see the contrasting stripes in a grated acuity procedure is considered the visual threshold.

Visual evoked potential: A direct measure of cortical response to a visual stimulus.

Docosahexaenoic acid: An essential long-chain polyunsaturated fatty acid, which is a metabolic end product of the omega-3 fatty acid biosynthetic pathway.

Marine oil: Oil derived from edible fish sources for the purpose of supplementation.

Egg yolk phospholipid: Phospholipid derived from egg yolk.

Single-cell oils: Oils that are produced from single-cell sources including microalgae and microfungus.

6.1 Introduction

It is a truism that eating behaviour (i.e. food choice and food intake) is determined by many different factors. Nonetheless, within the normal physiological boundaries of satiety and hunger one may argue that people simply eat what they like and avoid foods they do not like (Eertmans et al. 2001). Such hedonic eating behaviour is particularly apparent in children. For example, in the early twentieth century, most Dutch children (in addition to children in many other countries) still received a daily spoonful of cod liver oil before bedtime. Many of these individuals, now adults, still shiver at the memory of the often rancid taste of cod liver oil. However, there was good reason to subject children to this cod liver oil ordeal, as this oil was known to somehow prevent rickets (or rachitis; the softening of bones misshaping knees, wrists, and ankles). It wasn't until the 1930s that it was recognised that rickets is caused by vitamin D deficiency and that cod liver oil is rich in such vitamin D. This knowledge eventually allowed for the development of vitamin D supplementation and with it the standard practise of administering children cod liver oil dissipated. One will cease the consumption of aversive tastes when there is no pressing need for the consumption of such tastes.

People are born with a preference for sweet tastes and an aversion against bitter tastes, but more specific flavour preferences are developed during later childhood. Specific food likes and dislikes can differ between individuals and this suggests that these preferences are acquired through personal experience with certain flavours. In other words, one acquires a (dis)taste for certain foods by trying out these foods (Capaldi and Vandenbos 1991). How then does this work exactly? A prominent form

of such purported experiential learning involves Pavlovian conditioning, the learning of an association between a neutral conditioned stimulus (CS) (e.g. a flavour) and a biologically relevant unconditioned stimulus (UCS). In the case of conditioned taste aversion learning, the UCS usually comprises some degree of gastrointestinal discomfort. By pairing a specific flavour with such discomfort, one comes to associate the flavour with the discomfort and this then leads to future avoidance of the flavour (Pelchat and Rozin 1982). Pavlovian conditioning has then endowed the flavour CS a signalling function, it 'predicts' internal malaise (the UCS). Likewise, it was found in animals that a taste preference is conditioned for flavours paired with the recovery of illness (Green and Garcia 1971).

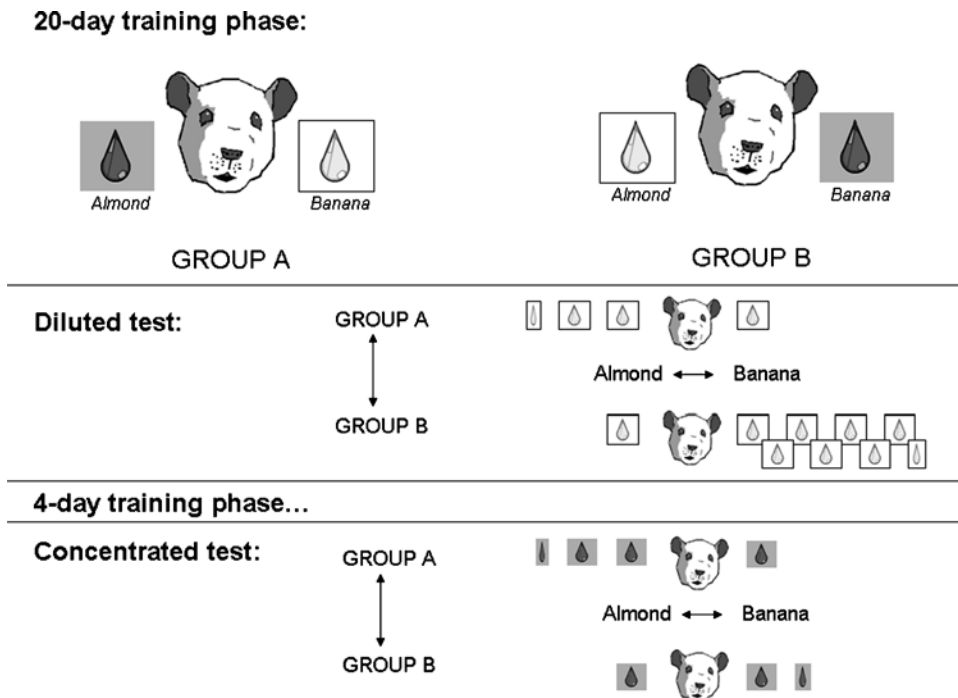
Another way of conditioning a food preference was demonstrated by Holman (1975). In one of his experiments, he gave rats on alternate days either a banana- or almond-flavoured mash. To this mash, he added saccharin to make it taste sweet. Rats, like humans, have an innate preference for sweet tastes. Holman varied the concentration of the saccharin of the different mashes. Rats were divided into two groups: A and B. Group A received 60 min access to the almond paired with concentrated saccharin and banana paired with diluted saccharin solution. For group B, the flavour to saccharin concentration (concentrated versus diluted) assignment was reversed. At test, the rats received 30 min access to 40 mL of both flavours now with an equal saccharin concentration. The rats showed a clear preference for the flavour previously paired with the concentrated saccharin. Figure 6.1 displays an illustration of the procedure, design, and results of this experiment. On the basis of these and similar findings, Holman concluded that the apparent reinforcing effect of saccharin is the hedonic quality of its sweet flavour. This form of learning has thus been termed flavour–flavour learning as the apparent


Fig. 6.1 Design, procedure and results of Eric Holman's (1975) experiment on flavour–flavour learning. Eric Holman (1975; Experiment 2) gave rats during a 20-day training period one flavour paired with concentrated saccharin on even days and another flavour paired with diluted saccharin on uneven days. On a first test, rats were given simultaneous access to both flavours, now both with diluted saccharin. Rats drank much more of the flavour previously paired with the concentrated saccharin. On a second test, after another 4-day period of training, the same pattern of results was obtained when both flavours were now presented with concentrated saccharin

Table 6.1   Key facts concerning flavour–flavour learning and its applications

A neutral flavour becomes more liked or less liked after having been paired with, respectively, an already liked or disliked flavour
Children can come to better like the flavour of fruits and vegetables through flavour–flavour learning

shift in flavour preference arises from the acquisition of an association between two flavours: a neutral flavour (e.g. almond) and an already liked flavour (e.g. the sweet taste of concentrated saccharin) (Fanselow and Birk 1982; Myers and Sclafani 2006).

Some researchers argue that a flavour–flavour association is qualitatively different from a preference arising from flavour–consequence learning. As the latter form of association is recognised as the result of Pavlovian conditioning, this implies that flavour–flavour learning may not be considered as a form of Pavlovian associative learning (Hermans et al. 2002) and this gives rise to the question what mechanism then underlies flavour–flavour learning. Other questions raised and discussed in the present chapter concern the generality of flavour–flavour learning, its neurological underpinnings and its application to promoting the development of healthy dietary habits in children (Table 6.1).

6.2   What is Flavour–Flavour learning?

Flavour–flavour learning comprises the transfer of affect to a neutral flavour CS by pairing that particular flavour with another already liked or disliked flavour UCS. The established shift in liking is always in the direction of the affective value of the evaluative UCS. This is why flavour–flavour learning is generally regarded as a form of evaluative conditioning. But what exactly is evaluative conditioning?

6.2.1   Evaluative Conditioning

In a particular study, Levey and Martin (1975) had participants categorise pictures of paintings as liked, neutral, or disliked. Subsequently, the participants received exposure to several neutral pictures paired with other liked pictures, or neutral pictures, or disliked pictures. At test, participants had to evaluate all pictures and it was found that they now rated the neutral pictures that had previously been paired with the disliked pictures more negatively and the neutral pictures that had been paired with the liked pictures as more positive. Martin and Levey (1978) termed this transfer of affect to an originally neutral stimulus due to pairings of this stimulus with another affective (positive or negative) stimulus evaluative conditioning.

Procedurally, evaluative conditioning is very similar to Pavlovian conditioning. With evaluative conditioning, the neutral stimulus is usually referred to as the CS and the affective stimulus as the UCS. Pairing these stimuli should then lead to the formation of an association between these two stimuli, allowing for the transfer of affect from the UCS to the CS. Despite the procedural similarity there are notable discrepancies between evaluative conditioning and other more typical Pavlovian conditioning paradigms such as fear conditioning. In the case of fear conditioning, the CS, a neutral stimulus (e.g. a tone or a picture), is paired with aversive stimulation, such as the administration of an electric shock or a very loud noise. Hermans et al. (2002) exposed participants to such a procedure, pairing pictures of faces (the CSs) with electrocutaneous stimulation (the UCS; i.e. an aversive electric shock). The participant learned to anticipate this adverse stimulation that was reflected by a strong expectation of the UCS when presented with the CS previously paired with the UCS. Hermans and colleagues also showed that participants came to dislike the CSs that had been paired with the

UCS, indicating evaluative conditioning. UCS expectations extinguish easily with non-reinforced exposures to the CS (Dibbets et al. 2008), but an acquired evaluative shift is highly resistant to such an extinction treatment (De Houwer et al. 2000).

Pavlovian conditioning can be described in terms of signal learning; one learns to recognise the CS as a signal for the UCS, and hence, when exposed to the CS, one expects the UCS. No such learning is required in case of evaluative conditioning; the CS then merely has to refer to the UCS (see also De Houwer et al. 2000).

In line with the reasoning that evaluative conditioning reflects some form of referential learning, Havermans and Jansen (2007a) argue that evaluative conditioning more specifically reflects a stimulus generalisation process. Within Pavlovian conditioning, it is well known that an acquired associative strength can generalise from one CS to other CSs. The extent of transfer of associative value is determined by the degree of similarity between the CS and the novel stimulus (Pearce 2002). According to Havermans and Jansen, such transfer is probably not limited to associative value. Indeed, it may also comprise the transfer of other relevant stimulus characteristics, such as affective value. This then means that pairing a neutral CS with an evaluative UCS merely provides one the opportunity for determining (or just passively experiencing) the similarity between the two stimuli. If there is some degree of stimulus similarity, and if this similarity is somehow noted, this may be enough to induce the transfer of affect from the UCS to the CS (Davey 1994; Field and Davey 1999). Figure 6.2 represents the stimulus generalisation model of evaluative conditioning as outlined by Havermans and Jansen.

6.2.2 The Flavour–Flavour Paradigm

Evaluative conditioning is not limited to the transfer of affect between visual stimuli such as the pictures of paintings. Indeed, it was soon recognised that flavour–flavour learning can also be understood in terms of evaluative conditioning. In fact the flavour–flavour paradigm is recognised as one of the more robust forms of evaluative conditioning (Field et al. 2008).
Fig. 6.2 A stimulus generalisation model of evaluative conditioning. Havermans and Jansen (2007a) argue that when a neutral CS X is paired with an affective UCS Y a configural X-Y representation is formed in memory. When subsequently X is presented, the representation of the UCS Y will be activated directly through its similarity with X and indirectly through the X-Y configural representation. The degree to which the representation of Y is activated determines the extent of affective value being transferred from Y to CS X

As described above, Eric Holman (1975) tested whether a rat's flavour preference could be influenced by the sweetness of saccharin associated with the flavour. It could and such flavour–flavour learning is not limited to rats; it has also been demonstrated in humans. Baeyens et al. (1995) found that pairing a flavour with the aversive taste of polysorbate-20 (the emulsifier Tween) led to decreased liking of that particular flavour (see also Baeyens et al. 1990, 1996, 1998a, b). These researchers, however, did not find evidence of positive flavour–flavour learning with pairings of a specific neutral flavour with a sweet taste. This may mean that negative flavour–flavour learning is more easily established than positive flavour–flavour learning, but the failure to induce positive flavour–flavour learning could also be attributed to the fact that the participants only moderately liked the sweet taste. It was already shown that it certainly is not impossible to induce positive flavour–flavour learning. Zellner et al. (1983) had students drink different flavours of tea. Some of these teas had to be tasted several times with sweet-tasting sucrose. At test, all participants again had to taste and evaluate the different teas, now left unsweetened, and the participants clearly and specifically liked the previously sweetened teas better. Yeomans et al. (2008) similarly found evidence of positive flavour–flavour learning when a specific flavour of dessert was paired with the sweet taste of either sucrose or aspartame. To ensure that the sweet taste (the flavour UCS) was well liked, Yeomans took care to only select self-identified sweet likers for participation in their study.

Interestingly, Brunstrom et al. (2001) found that unrestrained eaters showed enhanced preference for drinks most often paired with a sweet reward (e.g. chocolate chips, puffed rice or raisins), but this was not found among restrained eaters, suggesting that dietary restraint somehow devalues the sweet reward. This is precisely what Brunstrom et al. (2005) found in a series of two experiments. In one of these experiments, Brunstrom and colleagues paired different fruit juices of with a sweet reward (i.e. chocolate chips). One of the juices was paired on just 10% of trials with the sweet and another juice was paired 90% of the trials with the sweet reward. Unrestrained eaters came to prefer the 90% paired picture, but the restrained eaters came to prefer the less-often paired pictures. Brunstrom and colleagues thus argued that negative beliefs and attitudes regarding the UCS devalue the UCS and within restrained eaters may in fact function as an aversive stimulus, thus promoting the acquisition of a dislike. In a more recent study, however, Brunstrom and Fletcher (2008) failed to replicate this effect of dietary restraint on flavour–flavour learning, but instead found an effect of hunger state. When pairing tea with a non-caloric sweetener, only hungry participants came to like the flavour of this particular tea relative to other unsweetened teas. Similarly, Mobini et al. (2007) found that pairing a peach-flavoured tea with another sucrose drink, increased liking for the tea particularly when participants had been trained and tested hungry. Further, Yeomans and Mobini (2006) demonstrated that increased liking for odours paired with a sweet sucrose UCS was apparent only when participants were hungry. One may argue that hunger increases attention and liking for caloric cues, such as a sweet taste that generally signals carbohydrate energy (e.g. as in the case of sucrose, fructose and glucose), hence increasing the salience of the flavour UCS allowing for larger transfer of affective value to the CS flavour (see Fig. 6.3).

6.2.3 Neural Correlates of Flavour–Flavour Learning

Cues associated with a certain food UCS can come to affect subsequent food choice and food intake. The brain structures known to be involved in the expression of cue-induced food selection and acceptance, such as the hypothalamus, amygdala and OFC probably also play a role in the associative acquisition of food likes and dislikes (see Holland and Petrovich 2005). Indeed, although many brain areas are activated with exposure to the sight, smell and taste of food, studies on the evaluation of food stimuli ubiquitously point to the specific involvement of the amygdala, the OFC and the insula.

hunger

Neutral flavour X

Liked flavour Y

[X-Y]

positive value
Fig. 6.3 Flavour–flavour learning as stimulus generalisationIn terms of the stimulus generalisation model of evaluative conditioning as put forward by Havermans and Jansen (2007a), pairing a neutral flavour X with an already liked flavour Y, leads to the formation of a configural X-Y representation in memory. Subsequent presentation of X alone then leads to the activation of the configural X-Y unit and the representation of flavour Y. If one is hungry, the salience of the representation of Y is hypothetically bigger and allows for more transfer of affective value to flavour X

With oral taste neurons projecting directly to the insula, activation of this area has been associated with representations of taste intensity and quality (e.g. texture, taste intensity, bitterness, sweetness, sourness or saltiness) and is thus referred to as the primary gustatory cortex (Small et al. 1999; De Araujo and Rolls 2004). Adjacent to this area, the OFC is involved in representations of the purported *acquired* valence of food cues (e.g. the pleasure derived from the sight, smell and taste of food). This region, therefore, has been termed the secondary taste cortex. Rolls and colleagues showed that decreasing the subjective pleasure derived from eating a specific food item through repeated exposure to that food leads to a corresponding decrease in the activation within the OFC when presented with that specific food item (see Rolls 2000).

The amygdala is recognised to be activated by both pleasurable and aversive food cues (O'Doherty et al. 2001) and thus appears to respond nonspecifically to any valenced food stimulus. Recent research suggests that such activation of the amygdala requires deliberate and attentive processing of the presented food stimulus (Siep et al. 2009).

Considering the presumed involvement of the amygdala in the conditioning of likes and dislikes, Coppens et al. (2006) examined whether patients with a unilateral section of the temporal lobe (which includes the amygdala) exhibit impaired flavour–flavour learning as compared to a control. Participants received two flavours, one of which was served with the addition of Tween. The researchers hypothesised that given the fact that even unilateral damage to the amygdala (i.e. the ANC) attenuates fear conditioning; such damage would also disturb evaluative conditioning. However, all participants demonstrated clear negative flavour–flavour learning, acquiring a dislike for the Tween-paired flavour CS relative to the unpaired CS. The authors correctly point out that this does not mean that the amygdala does not play any role in the acquisition of food likes and dislikes as all the patients included in the study had only unilateral damage to the ANC. Clearly, more research is needed to determine the exact neurological underpinnings of flavour–flavour learning.

6.3 Applying Flavour–Flavour Learning to Increase Liking for Vegetables

Overweight (BMI > 25 kg/m²) is a rapidly increasing worldwide health problem. Especially obesity (i.e. severe overweight; BMI > 30) poses several health risks, such as coronary heart diseases and type II diabetes. It is estimated that currently in the USA approximately 25% of total health care costs are associated with obesity, a percentage representing billions of dollars (Levi et al. 2009). Currently, more than two-thirds of the US population is overweight or obese. Table 6.2 displays the present top five states with the highest obesity rates of the USA.

The number of overweight children has also increased dramatically in the past few decades. The health risks associated with obesity at a young age are less dire, but it is more difficult to attain a normal weight if one has been obese since childhood. Moreover, the health risks for obese adults who have been obese since their childhood are greater than for people who became obese in later adulthood (see e.g. Visscher et al. 2002).

Overweight and obesity are the result of a positive energy balance; more energy is consumed than expended. Particularly excessive caloric intake is now thought to have contributed to the steep rise in the incidence of obesity (Swinburn et al. 2009). Healthier eating, that is, consuming less high-calorie products should lower the prevalence of overweight. Indeed, Raynor and Epstein (2001) demonstrated that whereas consuming many different snacks is related to obesity, the consumption of a large variety of fruits and vegetables is associated with lean body weight. Therefore, getting people (especially children) to eat ample amounts of fruits and vegetables may prove to be an effective strategy in curbing the present obesity epidemic.

Recently, we reasoned that flavour–flavour learning might be a powerful technique to increase children's liking of vegetables, and hence their consumption of vegetables. To test whether such flavour–flavour learning actually increases children's liking of vegetables, we conducted an experiment. In this experiment 4- to 6-year-old children evaluated and rank ordered six different vegetables. Next, they were instructed to repeatedly consume small amounts of two of the six specific vegetables. These two flavours served as the flavour CSs and one of the two vegetables was now sweetened with glucose. After this repeated exposure procedure, all children again were instructed to evaluate and rank order the six vegetables. At this posttest, the children now specifically ranked the previously sweetened vegetable as better liked than before (Havermans and Jansen 2007b; see Fig. 6.4).

This positive flavour–flavour learning effect was also demonstrated in a more recent study by Capaldi and Privitera (2008). In a first experiment they had 2- to 5-year-old children repeatedly taste grapefruit juice mixed with the sweet taste of sucrose. This led to increased liking of unsweetened grapefruit juice. Moreover, this positive shift in liking proved stable for weeks. In a second experiment, undergraduate students were presented with several occasions in which they were instructed to consume one small stalk of cauliflower and another stalk of broccoli. One of the two vegetables

Table 6.2 Current obesity rates in the USA

	State	Obesity rate (%)
1	Mississippi	32.5
2	Alabama	31.2
3	West Virginia	31.1
4	Tennessee	30.2
5	South Carolina	29.7

Top five states with the most obese people in the USA, as reported by the Trust for America's Health in their sixth annual issue report (Levi et al. 2009) on the obesity epidemic in the USA
Fig. 6.4 Children's changes in hedonic ranking of vegetables as the result of flavour–flavour learning. Mean shift in ranking score (from pretest to posttest) for the CS paired with glucose (CS+) compared with the shift in ranking for the unpaired CS (CS−), as demonstrated by Havermans and Jansen (2007b) in the conditioning of vegetable flavour preferences in children

would be sweetened by having it dipped in sugar water. The assignment of vegetable to sugar water was counterbalanced between participants. Capaldi and Privitera found that the pairings of either cauliflower or broccoli with sugar increased liking of the taste of these vegetables.

In sum, the results from the studies discussed above suggest that the flavour–flavour learning paradigm can be applied to increase children's liking of fruits and vegetables. Importantly, this can be achieved even when the taste of the CS is initially disliked (e.g. the bitter taste of grapefruit), plus the achieved hedonic shift appears to be stable over a longer term.

6.4 Applications to Other Areas of Health and Disease

Children can develop strong food preferences and as a result may be particularly finicky about having to eat certain foods (Dovey et al. 2008). When such picky eating becomes a longer term habit of eating a very limited variety of food items, this food selectivity can form a serious health risk. One way to treat such food selectivity is through mere exposure. Williams et al. (2008), for example, used this method in six children being treated for extreme food selectivity. One case concerned a young girl diagnosed with autism who during treatment was exposed regularly to foods presented in meals and taste sessions. Meals would contain three table spoons of about three different foods (fruits, vegetables, meat, starch or dairy product), and taste sessions were used to introduce the child to a specific novel food. This mere exposure worked very well. She learned to accept and eat many different foods. Of the 49 different novel foods she learned to eat, she still ate 47 at 3 months after treatment.

Mere exposure thus seems to be a viable method to treat food selectivity. However, flavour–flavour learning may be even more powerful in the treatment of such food selectivity. Compared with a mere

exposure procedure, flavour–flavour learning requires relatively few learning trials. Such flavour–flavour learning may involve the pairing of a novel or nonpreferred food with an already liked food. Furthermore, this pairing should be simultaneous, that is, the two foods (liked and disliked) should be presented together, rather than sequentially, as was shown by Holman (1975) in his rat studies. In one experiment, Holman found that pairing a flavour CS (CS+; cinnamon or wintergreen) with saccharin induced a flavour preference relative to another unpaired flavour (CS−; cinnamon when CS+ was wintergreen, and vice versa). Holman, however, failed to induce a flavour preference for the CS+ in a following experiment when he inserted a 30 min interval between the consumption of the CS+ and the ingestion of a saccharin solution. The procedure, design and results of these experiments are illustrated in Fig. 6.5.

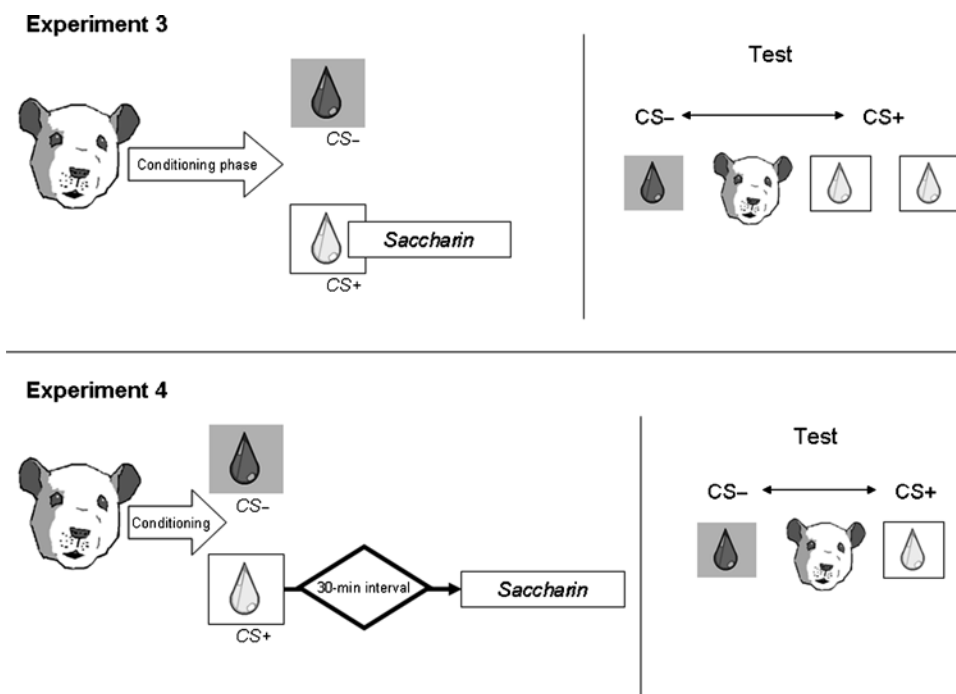
Piazza et al. (2002) compared simultaneous and sequential pairings of non-preferred foods with preferred foods in three children treated for food selectivity. One 11-year-old girl diagnosed with PDD ate lettuce with salad dressing and a few other creamy foods, but not much else. She received exposure to foods from different food groups (fruits and vegetables, starches and protein-rich foods) and these foods were paired with salad dressing. One group of foods (A) was always presented simultaneously with the salad dressing. Another group of foods (B) was paired sequentially with the dressing. The girl would only come to eat the foods from group A, not the foods from group B, corroborating the notion and previous findings that simultaneous pairings are superior in inducing an evaluative shift. Similar findings were reported for the other two cases in this study. It thus seems that food selectivity can be treated by means of evaluative conditioning, but note that the researchers did


Fig. 6.5 Holman experiments indicating that only simultaneous CS−UCS pairings induce a shift in CS flavour preference. An illustration of the procedure, design and main results of two experiments by Holman (1975; Experiments 3 and 4). Both experiments comprised comparing a shift in liking/preference between a CS+ paired with saccharin (the UCS) and another explicitly unpaired CS flavour (i.e. CS−). At test, the animals received the opportunity to drink from both (now unsweetened) flavours. The tests results from both experiments taken together clearly demonstrate that simultaneous (Experiment 3) but not sequential pairing (Experiment 4) of the CS+ with saccharin induces a flavour preference relative to CS−

not present the 'non-preferred' foods separately without the unconditioned flavour after the repeated pairings. This makes it impossible to assess any positive shift in liking of the flavour of the non-preferred food itself. Furthermore, as the authors themselves note, they did not conduct a follow-up test. Whether flavour–flavour learning is indeed beneficial and perhaps even superior to a mere exposure procedure in the treatment of food selectivity thus requires further empirical validation.

6.5 Conclusion

Evaluative conditioning is the transfer of affective value from an affective stimulus to another stimulus, due to pairing of the latter stimulus with the affective stimulus. As such, flavour–flavour learning – the transfer of affective value to a flavour being paired with an already liked/disliked flavour – can be regarded as a specific instance of evaluative conditioning.

Flavour–flavour learning is a robust form of evaluative conditioning and has been demonstrated in both animals and humans. Humans appear especially sensitive to the reinforcing sweet taste of sugar (Yeomans et al. 2008). The reason for this is unknown, but recent research suggests that humans possess orosensory receptors that specifically function to detect the presence of carbohydrates (apart from sweet taste). Oral maltodextrin (not sweet) and glucose (sweet) both directly activated brain regions known to be involved in the processing of the reward value of food, such as the insula, OFC and striatum (Chambers et al. 2009). One may hypothesise then that flavour–flavour learning in humans is probably much more effective when using some form of sugar and may even be evident when using non-sweet carbohydrates as UCS.

Flavour–flavour learning has proven to be a powerful technique to change someone's preference for a flavour and hence food. It is rapid and requires relatively little experience with the flavours themselves. In terms of nutrition and health, it has been shown that it can be applied to increase children's liking of fruits and vegetables even when the foods are initially disliked (Capaldi and Privitera 2008). However, whether the established positive change in hedonics also leads to a corresponding positive change in behaviour is an effect that is predicted but as of yet has not been examined empirically. The full benefits of flavour–flavour learning to nutrition thus still wait to be examined.

Summary Points

- Food choice and intake can be understood in terms of hedonic behaviour; that is, one prefers consuming foods one likes and tries to avoid having to eat foods one does not like.
- Food likes and dislikes are mostly acquired through direct experience with food.
- Flavour–flavour learning, a form of evaluative conditioning, comprises the transfer of affect (positive or negative) to a flavour by pairing that particular flavour with another already liked or disliked flavour.
- In humans, positive flavour–flavour learning seems to be mediated by hunger state.
- The amygdala is thought to play a critical role in the acquisition of flavour (dis)likes through flavour–flavour learning.
- Flavour–flavour learning can be applied to increase children's liking of fruits and vegetables and may be a beneficial technique in the treatment of severe cases of food selectivity.

Key Terms

Evaluative conditioning: A learning paradigm in which pairing a CS with a positive UCS results in a positive shift in liking for the initially neutral CS, whereas conversely, pairing such a stimulus with a negative UCS results in a negative shift in liking.

Flavour–flavour learning: A form of evaluative conditioning that allows for the learning of flavour preferences by pairing a flavour with an already liked flavour, such as the sweet taste of saccharin or sugar.

Food selectivity: Feeding disorder diagnosed in infants or children when the child is not eating adequately and the insufficient food intake cannot be attributed to any specific medical condition.

Hedonic eating behaviour: The principle that anticipated and derived pleasure guide food choice and food intake, respectively.

Pavlovian conditioning: The learning of a response to a CS due to its pairings with a biologically relevant UCS. This conditioned response typically reflects the anticipation of the UCS.

Stimulus generalisation: Transfer of prominent qualities of one stimulus – such as its associative and affective value – to another stimulus.

Chapter 7
Personality Traits in the Context of Sensory Preference: A Focus on Sweetness

Paul Richardson and Anthony Saliba

Definitions

Agreeableness: Degree toward being considerate, cooperative, and accommodating

Character: A combination of traits that are learned (e.g., responsibility)

Conscientiousness: Degree of self-discipline, persistence, and perfectionism

Disposition: The predominant tendency or pattern

Empathy: Capacity to recognize and share the feelings and emotions of others

Extraversion: Outgoing and highly sociable personality dimension

Harm Avoidance: Anticipatory worry and fear of uncertainty – similar to neuroticism

Impulsiveness: Inclination to act on the spur of the moment without considering long-term implications

Neuroticism: Propensity to experience emotional events negatively; linked with levels of anxiety and stress

Novelty Seeking: Sensation seeking – similar to venturesomeness and impulsivity

Openness: Willingness to explore new and unfamiliar experiences

Personality: An enduring pattern of a person's psychological and behavioral characteristics

Temperament: The collection of unconscious dispositions

Trait: A distinguishing characteristic of someone's personality

Venturesomeness: Thrill-seeking behavior, particularly for high-risk and potentially hazardous situations

7.1 Introduction

The consumption of food and drink is necessary to maintain life. However, there is widespread variation not only in the amount of food eaten, but also in the types of food consumed; the presence of preferences lies behind the mixed patterns of consumption. Certain tastes may be disliked by the vast majority of the population (e.g., bitter-tasting foods) while others (particularly sweet tasting), may be actively preferred (Mennella et al. 2005). The processes associated with these preferences are complex; multifactorial models have been developed in order to delineate the influences underlying the preferences but these can be broadly defined as *food effects*, that is, the physical and sensory properties of food and *non-food effects*, for example, person-specific reasons.

7.2 Sensory Properties of Food

The food-related effects (the sensory properties of food such as texture, appearance, and taste) have been of prime interest in choice behavior research; intuitively, any food perceived to be unpleasant along these dimensions is unlikely to be consumed. The texture of an edible substance (e.g., its viscosity, crispness, or grittiness) is known to relate directly to food selection in both primates and humans (Araujo and Rolls 2004). Similarly, the color and appearance of food has been demonstrated to interfere with judgments of flavor intensity and is known to influence the pleasantness and acceptability of foods. Children seem to be particularly sensitive to these effects, often refusing to consume a particular food if it *has bits in it* (De Moura 2007) or happens to be *green* (see later section on "Sweet Taste Preference"). However, it is how a food product tastes that has been the main focus of the food-choice research.

7.3 The Basic Tastes

The human tongue has receptors for what have been described as sweet, sour, salty, and bitter tastes. These are classically described as the four basic food tastes, and each have been associated with variable levels of like/dislike among the general population. Umami (savoriness) and fat both have a growing recognition in the literature as basic tastes that have corresponding receptors on the tongue and unique neural responses (Bachmanov and Beauchamp 2007). Other "tastes" such as spiciness are not unique, and what may be (erroneously) perceived as taste (the burning irritation) can then be construed as a pleasant or unpleasant sensation.

7.4 Individual Differences in Taste Preference

The sensation of taste arises from chemical stimulation of specialized cells, taste receptors, which are grouped in small clusters called taste buds. Although located throughout the oral cavity, taste buds are in the highest concentration on the human tongue in structures called papillae (see Fig. 7.1 below).
Fig. 7.1 A diagram of the human tongue. The location of the circumvallate, foliate, and fungiform papillae are indicated in bold (Amended from Gray 2000. Reproduced with permission)

Individual differences exist for the exact number present on the tongue and intuitively, taste intensity perception is correlated with the number of papillae present (Miller and Reedy 1990). This biological basis for individual difference in taste preference has thus far been difficult to study; however, with recent advancements in genetic research, it is now becoming clear that genetic differences account for some individual difference in taste preference (Drewnowski et al. 2001). This research thrust is exciting because a genetic basis for preference would transcend cultural boundaries, however it will be several decades before results can be used for any serious applied outcome.

Individual differences could also potentially stem from idiosyncratic likes and dislikes, demographics, psychological, and personality traits. It is entirely plausible that such individual differences could predict taste preferences, however in many published articles these individual differences are often considered "*annoying sources of variance in research…*" and "*referred to as nuisance variables…*" (Stevens 1996 p.303). Obvious differences such as gender and age tend to be included in research, but the less-obvious individual differences, particularly along the psychological dimensions are not. Yet, in other research fields such as health psychology, the opposite pattern is found and individual differences are taught and studied. The emphasis is one of inclusion, and variables such as personality are regarded as potentially important distal determinants of health behavior. They can provide "*useful evidence about the nature of mechanisms underlying sensory phenomena and thus are important in the generation of research hypotheses*" (Stevens 1996, pp. 303).

7.5 Gender Differences

Sex differences have been established in various food-related investigations such as cravings for particular food types, proportion of fruit and vegetables consumed, and avoidance of fats from meat (Goldberg and Strycker 2002). These effects appear to exist as early as primary school (Caine-Bish and Scheule 2009). In relation to sweetness, women do tend to rate sweeter tasting products as more pleasant than men are reported to do (e.g., Laeng 1993); in a study investigating sweet taste preference in obesity, nearly 32% of the female participants rated themselves as having a strong sweet taste preference in comparison to less than 13% of the male participants (Elfhag and Erlanson-Albertsson 2006). However, this apparent gender preference for sweet tasting products does not translate to females consuming greater quantities of sweet snacks (Grogan et al. 1997). This same study reported that women were more ambivalent toward eating sweet snacks than men (perceiving them to be significantly less healthy) and were also more influenced by social pressures than men (Grogan et al. 1997). It is not uncommon for research studies to employ single-sex studies to avoid such entanglements: in a recent study investigating sweet intake, liking, and the urge to eat, in relation to alcohol dependence, the authors decided not to recruit female participants due to the social ambivalence regarding sweet snacks (Krahn et al. 2006). We would recommend against this type of subject selection where it can be avoided, instead, we recommend examining the potential determinants of variation.

Males tend to be less sensitive to bitter and sour tastes than females. Acidity is a natural preservative and is an important ingredient in a range of products; bitterness tends to be minimized but is nevertheless a natural flavor in some foods (e.g., the important antioxidant activity in olive oil is related to polyphenols that elicit a bitter taste). Sweetness may be used to mask certain levels of sour and bitter tastes. It follows that females may seek higher levels of sweetness, firstly because of a natural preference and secondly to mask perceived acidity and bitterness given higher acuity than reported for males.

7.6 Personality

Personality can be described as the relatively enduring pattern of an individual's unique psychological and behavioral characteristics, which can exert some degree of influence over the thoughts and behavior of the individual (e.g., Dworetzky 1999). Different models of personality abound, but those based on trait theory suggest that these dispositions are relatively stable, enabling a high degree of predictability in a person's behavioral repertoire. Secondary traits (or states) tend to be more transient or only appear under certain conditions and can relate to attitudes and preferences. Biological models argue that particular aspects of personality are heritable (see Fig. 7.2) and that these can map onto specific neurotransmitters in the brain with predictable behavioral responses.

One theory of personality that is commonly reported in research is Cloninger's temperament and character model (Table 7.1), based on his work with people who possessed "extreme" personality profiles (Cloninger 1987). Temperament is depicted as a collection of unconscious dispositions that can differentiate people quantitatively. The four constructs of "temperament" include novelty seeking, harm avoidance, reward dependence, and persistence. In contrast, "character" refers to constructs that demonstrate an acquired or learnt component, such as the degree of self-directedness, co-cooperativeness, and self-transcendence (Cloninger 1993, 1994). See Table 7.2 for an explanation of these terms.
Fig. 7.2 Estimated heritability of personality factors from the Big five questionnaire. Similar data from two independent studies indicate a high degree of consistency in this estimation. Key: *O* openness, *C* conscientiousness, *E* extraversion, *A* agreeableness, *N* neuroticism

7.7 Temperament and Eating Behavior

It is the constellation of temperament qualities that has received most attention in research due to the forging of a direct link between personality and biological mechanisms. Temperament is assumed to have a constitutional or biological basis strongly influenced by heredity. Three strands of Cloninger's theory of temperament have been linked to neurotransmitter functioning in the brain, and are known to modulate eating behavior and the regulation of feeding. Specifically these are: dopamine (novelty seeking), serotonin (harm avoidance), and noradrenalin (reward dependence).

Cloninger posits that high novelty seeking is a proxy measure of dopamine activity within the mesolimbic regions of the brain (Cloninger 1994). Dopamine is a neurotransmitter thought to modulate the rewarding aspects of "motivating" stimuli, particularly during the learning of new likes and dislikes, the seeking out of new and novel experiences. Animal studies indicate that dopamine activity is linked more to the anticipatory desire and motivation (the *wanting*) rather than pleasure derived from consummation (the *liking*) (Robinson et al. 2005). Increases in dopamine activity in the mesolimbic and orbitofrontal regions of the brain have been associated with response to pleasant tastes and these same regions show a higher degree of activity when hungry compared to satiated (Tataranni et al. 1999). As such, dopamine is a primary candidate for involvement in food reinforcement, and by extension, in mediating taste preference.

Low levels of serotonin are typically reported in patients with clinical levels of anxiety and depression. Subscales of harm avoidance include anticipatory worry, fear of uncertainty, and shyness, all of which can be considered prototypical features of clinical anxiety (Cloninger 1993). Those with high levels of harm avoidance may actively avoid novel situations or those that may involve confrontation or punishment. More specifically, raising serotonin levels has been demonstrated to suppress appetite, lower food intake, and lower fat intake (for a review see Lam et al. (in press)).

Classical and operant conditioning are two processes that underpin the ability to learn, essentially the pairing of conditioned stimuli/cues with responses. The acquisition of paired associations is thought to be modulated by noradrenaline. Atypical noradrenaline functioning has

Table 7.1 Key terms of Cloninger's temperament and character theory of personality (Cloninger 1998)

	Descriptors of extreme variants	
Temperament dimension	High	Low
Harm avoidance	Pessimistic	Optimistic
	Fearful	Daring
	Shy	Outgoing
	Fatigable	Energetic
Novelty seeking	Exploratory	Reserved
	Impulsive	Rigid
	Extravagant	Frugal
	Irritable	Stoic
Reward dependence	Sentimental	Critical
	Open	Aloof
	Warm	Detached
	Sympathetic	Independent
	Industrious	Lazy
	Determined	Spoiled
	Ambitious	Underachieving
	Perfectionistic	Pragmatic
Character dimension		
Self-directedness	Responsible	Blaming
	Purposeful	Aimless
	Resourceful	Inept
	Self-accepting	Vain
	Disciplined	Undisciplined
Cooperative	Tenderhearted	Intolerant
	Empathic	Insensitive
	Helpful	Hostile
	Compassionate	Revengeful
	Principled	Opportunistic
Self-transcendent	Self-forgetful	Unimaginative
	Transpersonal	Controlling
	Spiritual	Materialistic
	Enlightened	Possessive
	Idealistic	Practical

been demonstrated in patients with posttraumatic stress disorder, who are overly sensitive to trauma-related cues (for review, see Yehuda 2002). Typically, it is thought of as governing the body's "fight or flight" response in times of acute stress, and on the TCI, its subscales are sentimentality, attachment, and dependence. Low levels of reward dependence are associated with being aloof, withdrawn, and detached; high levels are synonymous with being open, revealing, and dedicated (Cloninger 1993). Drugs that target noradrenaline receptors have been demonstrated to promote weight loss by suppressing appetite and producing early satiety.

7.8 Sweet Taste Preference

Sweetness has been referred to as an innate or naturally preferred taste, even in very young children, while salty, sour, and bitter are acquired tastes that need some perseverance, often extending into late childhood before being liked. Foods that are rated as pleasant and consumed in great quantities by

Table 7.2 Temperament personality constructs indicated with neurotransmitter systems and associated subsequent behavioral response (Amended from Cloninger 1998. The Genetics and Psychobiology of the Seven-Factor Model of Personality pp.68). In Kenneth R. Silk (1998) Biology of Personality Disorders

Temperament construct	Principal neurotransmitter	Relevant stimuli	Behavioral response
Novelty seeking	Dopamine	Novelty	Exploratory pursuit
		CS of reward	Appetitive approach
		CS or UCS of relief of monotony or punishment	Active avoidance, escape
Harm avoidance	Serotonin	Conditioned signals for punishment, novelty, or frustrative nonreward	Passive avoidance, extinction
Reward dependence	Noradrenaline	Reward conditioning (pairing CS and UCS)	Formation of appetitive CS

CS conditioned stimulus, *UCS* unconditioned stimulus

children in most western countries are those with a high sugar and fat content, while vegetables are regarded as universally disliked. This pattern of taste preferences appears to be universal and transcends cultures (Prescott et al. 1992).

Additional evidence for the innate preference of sweet tastes comes from studies involving neonates. A common methodology has been adopted by several studies – neonates are given solutions containing the basic tastants and facial expressions are observed immediately after ingestion (see Fig. 7.3). By observing positive facial expressions, sweet tastes were found to be universally accepted, while sour and bitter tastes were associated with tell-tale facial responses indicating an aversion (e.g., Steiner 1977). Recent research suggests this innate preference for sweet tastes may have a partial genetic basis (Mennella et al. 2005), and this regulates the consumption of sweet foods (Reed et al. 1997). Keskitalo and colleagues (2007) found a relationship between the frequency of consuming sweet foods and a genetic marker on chromosome 16. They had participants rate the pleasantness of various tastants, and reported preference for the extremely sweet solution, reporting an estimated heritability factor of 40% (Keskitalo et al. 2007). However, two caveats to this study are (1) the unequal gender split in favor of women (68% vs. 32%), and (2) the age range of participants (18–78 years). No data was published describing the demographics, but demographic variables were used as covariates in the analysis.

The innate tendency for a sweet preference might confer an adaptive advantage – a sweet taste signals the presence of sugars and thus of immediate high calorific value. In contrast, sour and bitter tastes are perhaps indicative of noxious substances and the decomposition of food and thus best avoided. Infants and older children often appear to be picky with food, particularly if they have not tasted it before. This mild neophobia illustrates the process of children learning what is safe to eat and what is not.

Neophobia has been identified in adults and can predict behavior pertaining to ingestion of novel vs. familiar foods and willingness to eat novel foods (Pliner and Hobden 1992). The authors categorized neophobia as a personality trait, and report that it correlates positively with measures of trait anxiety but negatively with novelty/sensation seeking (Pliner and Hobden 1992). Both of these traits have genetic links, suggesting that neophobia is also heritable. Indeed, one twin study estimated the heritability of neophobia at 67%, though this was only with female participants (Knaapila et al. 2007). This evidence is supportive for the notion that likes and dislikes of specific tastes and foods can be mediated by personality traits.

Fig. 7.3 Neonates displaying variable facial responses to basic tastes (Reproduced from Steiner 1997. With permission). Key: *1* rest, *2* water, *3* sweet, *4* sour, *5* bitter

One early study to investigate personality traits and taste preferences was completed in India by Venkatramaiah and Baby Devaki (1990). They asked 38 female postgraduate students to self-report food preferences via checklist, and measured personality traits with the Indian Personality Inventory (unpublished measure created by the same authors in 1980). The personality traits were derived from the Indian philosophy of Samkhya. They reported main effects for personality and food types, speculating that sweet foods were preferred most by those with high "tamas" scores (a trait that maps onto Cloninger's harm-avoidance trait). However, no post hoc analyses were ran to assess group differences for any tastes.

A recent study investigated the purported influence of trait anxiety on food taste preferences in Japan (Kato et al. 2006) (Fig. 7.4). The authors divided 73 university students into 2 groups according to the trait scores from the State-Trait Anxiety Inventory, and then tested for sensitivity to sweet, salty, and sour tastes. Of prime interest was the finding that the trait-anxiety group had a higher sensitivity to sweet tastes but not salty or sour. Kato and colleagues (2006) posited that people with high trait anxiety experience more stress on a daily basis, and that this was instrumental in causing the change to eating habits. However, the research was based on young university undergraduate students with no breakdown of gender. Given that the study did not employ a longitudinal design and no premorbid dietary measures were taken, it may be speculative to conclude that trait anxiety *caused* any changes to eating habits.

The link between trait anxiety and sweet preference is supported by an earlier study investigating personality and dietary habits (Kikuchi and Watanabe 2000). They tested 470 university undergraduate students who were required to keep daily records of their dietary habits recorded over a 2-year period, designed to capture the frequency and amount of 40 pre-specified food types consumed. Personality was measured using a modified version of the NEO Five Factor Inventory (Costa and McRae 1992). This provided scores on the "big five" factors of personality: openness, conscientiousness, extraversion, agreeableness, and neuroticism. High scores on each of the five personality factors

Fig. 7.4 A taste preference experiment in progress. This may usually take place in a partially secluded booth, in which the participant is able to make judgments on preferred food or drink tastes by sampling the products; this permits a fine degree of control and manipulation of several variables – in contrast to interview-based research, which relies on participants recollecting taste preferences in the absence of any actual tasting

had characteristic features; of specific interest was the finding that those with high neuroticism had a pronounced sweet taste preference irrespective of gender (Kikuchi and Watanabe 2000).

This finding was supported by Elfhag and Erlanson-Albertsson (2006) in a study of 60 clinically obese patients awaiting treatment at a clinic. Sweet (and fat) taste preference was assessed via structured interviews; on this basis, patients were assigned to one of four groups: strong sweet preference, strong fat preference, strong preference for sweet and fat, and no strong taste preference. Personality was measured with the Swedish University Scales of Personality. The Three Factor Eating Questionnaire was also used to provide measures of cognitive restraint (attempts to limit food intake), disinhibition (difficulties in limiting food intake), and hunger experience (subjective feelings of hunger). The results indicated that those who demonstrated a strong preference for sweet tastes (as opposed to no strong taste preference) showed higher levels of neuroticism; in particular, the neuroticism subscales that were critical for this distinction were lack of assertiveness and embitterment. Sweet taste preference bore no relation to any of the three eating characteristics (Elfhag and Erlanson-Albertsson 2006). The authors suggest these imply low self-confidence and self-esteem, and an externalized locus of control for difficulties. However, one earlier study (Stone and Pangborn 1990) instead found that preference for sweetness was higher in university students with an "outgoing" personality style, a trait that Elfhag and Erlanson-Albertsson conceded was the "*opposite of neuroticism and rather implies being more unconcerned and carefree*" (p. 64). However, the authors commented that the relation between the outgoing trait and liking for sweetness was not straightforward, as participants who did prefer sweeter drinks did not differ on personality measures from those who did not prefer the sweeter drinks (Stone and Pangborn 1990).

Overall, these recent studies all indicate that those with high levels of trait anxiety and neuroticism exhibit a sweet taste preference. It has been proposed that this may be characterized by "comfort eating," indicative of some reward deficiency syndrome (Wang et al. 2003) or possibly reflective of some "*self-medicating purpose that exceeds basic energy requirements*" (Davis et al. 2004 p. 132). There are indications that the opioid neurotransmitters may be involved in the rating of sweet tastes as pleasant and in reducing observed behavioral measures of stress after eating sweet tasting foods

(Dallman et al. 2003). Dallman and colleagues (2003) proposed that symptoms of chronic stress could be attenuated by the consumption of sucrose (a sweet tasting sugar) by way of dampening sympathetic activity in the hypothalamo–pituitary–adrenal (HPA) axis, a feedback system known to be dysfunctional in anxiety disorders (e.g., Yehuda 2002); it is thought that this is mediated through opioidergic pathways (Dallman et al. 2003).

We recently published a study investigating personality traits associated with a preference for a sweet white wine (Saliba, Wragg and Richardson 2009). Forty-five participants (with a near-equal gender split) were categorized as preferring either a base or sweet taste on the basis of their hedonic response to a dry white wine and another sample with fructose added at 20 g/L. Personality traits were assessed with the big five personality inventory and the Impulsiveness Venturesomeness and Empathy Scale (IVE - Eysenck and Eysenck 1991). We found that the sweet preference group had significantly lower levels of the openness to experiences trait but higher levels of impulsivity (see Fig. 7.5). Openness to experience has been portrayed as a proxy measure of the willingness to explore new and unfamiliar experiences, ideas, and feelings (Costa and McCrae 1992) and may be akin to the novelty-seeking trait in Cloninger's measure of temperament (Cloninger 1993). Previous studies suggest that those with high openness report healthier dietary practices (Goldberg and Strycker 2002). We speculated that infants with a preference for non-sweet taste do not receive sufficient dietary stimulation and so are open to new experiences in order to fulfill this. The finding that sweet taste was preferred by those with high levels of impulsivity is consistent with previous research (Davis et al. 2004).

Animal studies have reported a positive association between preference for sweet solutions and the subsequent intake of alcohol (Sinclair et al. 1992). In a study conducted in patients with alcohol dependency, Kampov-Polevoy and colleagues reported a preference for a solution containing the
Fig. 7.5 Graph depicting mean average scores of the dry vs. sweet wine taste preference groups on the Impulsiveness, Venturesomeness and Empathy (*IVE*) and Big five (OCEAN) personality questionnaires (data from Saliba et al. 2009). Note: the scores from the two personality tests are not comparable with each other, and are shown for illustrative purposes only. Key: *denotes significance at $p < 0.05$, $N = 45$

highest sucrose concentration (Kampov-Polevoy et al. 1998). They report that the nonalcoholic group preference for sweet tastes was associated with low novelty seeking, and conversely, sweet-disliking participants had high novelty-seeking scores. In stark contrast, the sweet-liking alcoholics showed high novelty-seeking scores as well as high harm-avoidance scores.

A study by Krahn et al. (2006) reported that alcohol-dependent patients reported a preference for the sweetest tastant during the first month of abstinence. Patients who reported abstinence at 6 months were less likely to prefer the sweetest tastant than those who did not maintain abstinence. The authors suggest sweet preferences could be a marker for future abstinence. Garbutt and colleagues suggest this "sweet-liking/sweet-disliking" phenotype can be considered a marker for cerebral opioid functioning (Garbutt et al. 2009). This hypothesis was tested in alcohol-dependent patients during a 12-week treatment program with naltrexone (an opioid receptor antagonist, which arguably blocks the pleasurable effects of alcohol). Patients were dichotomized into sweet-liking or sweet-disliking groups via a taste test given prior to treatment ($n = 15:25$ respectively), and had their responses and compliance to the naltrexone program recorded. Both groups had similar craving levels prior to treatment and similar retention levels following the study, though the sweet-liking group took longer to achieve the necessary 3-abstinent days prior to onset of treatment and were less likely to achieve two consecutive dry days during treatment. The sweet-disliking group also had significantly more abstinent days throughout. Interestingly, the authors also reported that sweet-liking patients with high cravings had a higher percentage of abstinent days compared to sweet-disliking patients also with high craving. However, Kranzler and colleagues (2001) argued that since children of alcoholic parents are at a greater risk of developing alcohol dependency, then preference for sweet taste must be a phenotypic marker for risk of alcoholism. They found no such pattern, and suggest that the effect published by Kampov-Polevoy and colleagues may be instead due to chronic drinking, as opposed to an underlying genetic predisposition.

7.9 Applications to Other Areas of Health and Disease

The World Health Organization has predicted that by 2015, over 700 million people worldwide will be obese (WHO 2006), a prevalence rate of almost 10%. Research investigating the factors associated with poor dietary lifestyle has been ongoing, such as knowledge of the effects of consuming too much food. Research suggests that although 95% of US adults believe that balance, variety, and moderation are the keys to healthy eating (Lachance 1992) and 83% are aware that what they eat can affect their future health, there is a discrepancy between dietary knowledge and actual intake (Shepherd and Stockley 1987). The fact that nutritional knowledge alone may be insufficient to promote changes in eating behavior suggests that psychological factors may be paramount in setting the stage for dietary change. The underlying drivers of consumption, particularly related to personality and taste preferences, are a current focus. Our own work (Saliba et al. 2009) showing a link between personality and taste preference highlights the need for a whole of modeling approach, one that takes into account underlying taste preference, personality type, as well as other variables such as food attitudes and cultural norms.

Of particular concern is the fact that high impulsivity (specifically, sensitivity to reward) has been linked to overeating (Davis, Strachan and Berkson 2004) and along with food preferences strongly predict an individual's body mass index (Davis et al. 2007). An individual who presents high in impulsivity and also has taste preferences that predispose them to overeating is at particular risk. Impulsivity has been linked to sweet taste preference (Saliba et al. 2009) and obesity (Fassino et al. 2002), although recent evidence has questioned whether sweet taste preference actually leads to

higher levels of obesity (Hayes and Duffy 2008). The same research suggests that fat preference may be more predictive of obesity, albeit along with sweet preference (Hayes and Duffy 2008); future research needs to determine the link between personality type, fat taste preference, and subsequent obesity levels.

Summary Points

- Individual taste preferences cause a widespread variation not only in the amount of food eaten, but also in the types of food consumed.
- Individual differences in the concentration of taste buds on the tongue affect taste acuity, which influences taste preferences. This research is exciting because a biological basis for preference would transcend cultural boundaries; however applied outcomes may be some decades away.
- It is entirely plausible that individual differences could predict taste preferences; however in many published articles these individual differences are often not examined. Yet in other research fields such as health psychology the opposite pattern is found and individual differences are taught and studied; variables such as personality are regarded as potentially important distal determinants of health behaviors.
- Women tend to rate sweeter tasting products as more pleasant, whereas males are more tolerant of higher levels of sourness. Although gender differences exist in the types of foods consumed, this does not appear to translate to clearly poorer dietary choices by either gender.
- Different models of personality abound, but those based on trait theory suggest that dispositions are relatively stable, enabling a high degree of predictability in a person's behavioral repertoire. Secondary traits (or states) tend to be more transient or only appear under certain conditions and can relate to attitudes and preferences.
- Sweetness has been referred to as an innate or naturally preferred taste, even in very young children, while salty, sour, and bitter are acquired tastes that need some perseverance, often extending into late childhood before being liked.
- Individuals with high levels of trait anxiety and neuroticism exhibit a sweet taste preference. This may be characterized as "comfort eating."
- Impulsivity is a personality dimension known to be associated with overuse syndromes. Individuals with a sweet taste preference report higher on impulsivity, which may be a concern if future research shows that overeating is linked to sweet taste preference.
- Preference for fatty tastes may be the strongest of all taste preferences in predicting obesity. Further research needs to establish the link between personality and fat taste preference.

Chapter 8
Changes to Taste Perception in the Food Industry: Use of Cyclodextrins*

Giani Andrea Linde, Antonio Laverde Jr, and Nelson Barros Colauto

Abbreviations

2HPβCD	2-Hydroxypropyl-β-cyclodextrin
2HPγCD	2-Hydroxypropyl-γ-cyclodextrin
3HPβCD	3-Hydroxypropyl-β-cyclodextrin
ADI	Acceptable daily intake
CD	Cyclodextrin
CGTase	Cyclodextrin glycosyltransferase
DHPβCD	2,3-Dihydroxypropyl-β-cyclodextrin
DMβCD	Ditrimethyl-β-cyclodextrin
DOSY	Diffusion-ordered spectroscopy
DSC	Differential scanning calorimetry
FAO	Food and Agriculture Organization
FDA	Food and Drug Administration
FTIR	Fourier transform infrared
G	Guest
G1βCD	Glucosyl-β-cyclodextrin
G2βCD	Maltosyl-β-cyclodextrin
GRAS	Generally recognized as safe
HEβCD	Hydroxyethyl-β-cyclodextrin
HIBβCD	2-Hydroxyisobutyl-β-cyclodextrin
HPβCD	Hydroxypropyl-β-cyclodextrin
NMR	Nuclear magnetic resonance
NOE	Nuclear Overhauser effect
RMβCD	Methylated-β-cyclodextrin
ROESY	Rotating-frame Overhauser spectroscopy
SBEβCD	Sulphobutylether-β-cyclodextrin

TGA   Thermogravimetric analysis
TMβCD   Trimethyl-β-cyclodextrin
UV   Ultraviolet
WHO   World Health Organization

Definition and Explanations of Key Terms or Words

Controlled release: Release of an ingredient gradually to produce a sustained effect
Cyclodextrin: Cyclical oligosaccharides with variable number of units of α-D-(+)-glucopyranoside bonded by α(1→4)
Equilibrium constant: In a chemical reaction is the quotient between the molar concentration of product and reagents after the reaction reached equilibrium and at a given temperature
Food color: An aspect of food caused by differing qualities of light that is absorbed, reflected, or emitted by food compounds.
Food coloring: A colorant, water soluble or insoluble, permitted by the Food and Drug Administration for use in foods.
Functional food: A food having components that provide a potential benefit to health, well-being, or disease-resistance beyond the benefit expected from its main nutritional components.
Inclusion complex: In host–guest chemistry, an inclusion compound is a complex in which one chemical compound (the "host") forms a cavity in which molecules of a second "guest" compound with chemical affinity can fit.
Sensory characteristics: A group of food characteristics such as color, flavor, odor, texture, and taste that produces a different level of pleasant sensations during food consumption.
Smart food packages: Packages that work as a reservoir of active ingredients that can be used to control the release of active components like antimicrobials, flavors, pigments, and antioxidants.

8.1 Introduction

Sensorial demands, like color, taste, flavor, as well as cost and convenience, are major determinants of food selection. Foods that are bitter, acrid, or astringent tend to be rejected by the consumer and this instinctive rejection may not be modified because it is a key mechanism for survival, developed along species evolution. In addition, alimentary behavior has been altered over time because of women's participation in the formal working market and lifestyle changes with less time availability. This has resulted in an increase of industrialized food consumption. The food industry has been responding to this demand by developing a variety of inexpensive and ready-to-consume products that meet the consumers' primary needs. However, there are few industrialized foods that still remain as functional foods.

Environmental and genetic variables provide several modifications in the sensory characteristics of foods. Therefore, in order to obtain food with standard sensory characteristics, the industry uses the addition of sugar, salt, fat, pigments, and flavors, to name a few, or removes unpleasant-tasting compounds. Various unpleasant tastes are related to bioactive molecules that are necessary to the regulation of metabolism and immune system, like phenols, flavonoids, isoflavones, terpenes,

glucosinolates, minerals, vitamins, and peptides. The reduction of these components in food and stressing sedentary lifestyles have been associated to the increase of obesity, diabetes, circulatory diseases, depression, and disorders of sleeping, learning, memory, pain, sexual behavior, appetite, and stress. In order to compensate this unbalance, the food industry has tried to provide functional foods that act on specific targets in the body, affecting positively consumer's health and nutrition. However, there is a dilemma for the consumer and the industry, which is the consumption and the offering of healthy food with pleasant taste.

This chapter introduces CD and its capacity to form inclusion complexes, reviewing the main application of these cyclic oligosaccharides to improve sensory characteristics like flavor, odor, taste, rheology, color, and food functionality. Also, CD safety and its potential use in "smart" packages to improve sensorial and functional quality and food safety are discussed. Although CDs are still minimally used in food, they are one of the best tools to help the food industry solve the dilemma between the demands of taste versus health foods.

8.2   Cyclodextrins: Characteristics and Mechanisms of Complex Formation

CDs are cyclical oligosaccharides (Table 8.1) with variable number of units of α-D-(+)-glucopyranoside bonded by α(1→4). The most common ones are α-, β-, and γ-CD with six, seven, or eight units, respectively; however, CDs with 9, 10, 11, or more units of α-D-(+)-glucopyranose are also known. These macrocycles are produced by the enzymatic conversion of starch through the action of CD glycosyltransferase (CGTase) (Szejtli 2004). Either as a solid crystal or in solution CDs have a toroidal shape. The toroid upper base, also known as secondary base, is surrounded by secondary hydroxyls bounded to C-2 and C-3 carbons of glucopyranose, while the inferior or primary base is surrounded by primary hydroxyls bounded to C-6 of glucopyranoses. A ring of hydrogen bonds is also formed intramolecularly between the 2-hydroxyl and the 3-hydroxyl groups of adjacent glucose units. This hydrogen bonding ring gives the CD a remarkably rigid structure (Szejtli 2004) and is responsible for the toroidal shape and the rigid structure of CDs. The hydrogen-bond network also affects the CD water solubility. The α-, β-, and γ-CD solubilities at ambient conditions are approximately 13, 2, and 26% (mass by mass), respectively. The lower solubility of β-CD compared with α-CD is due to a stronger hydrogen-bond network giving a higher rigid structure to β-CD and lower water solubility. The disruption of hydrogen bonding via molecular manipulation increases water solubility as for hydroxypropyl-β-CD (HPβCD), which increases 60% of the β-CD aqueous solubility (Davis and Brewster 2004). The CD cavity is surrounded by the H-3 and H-5 hydrogens of glucopyranoses and glucosidic oxygens, with the free electrons directed toward the cavity interior. This high electronic density from glucosidic oxygens, the arrangement of hydrogens, and the lack of free hydroxyls toward the cavity make it less hydrophilic than aqueous environment. Thus, hydrophobic molecules in aqueous solution can increase the chemical stability entering the CD cavity. The CD external area is surrounded by hydroxyls with hydrophilic characteristic (Fig. 8.1), which is responsible for CD aqueous solubility.

For inclusion complex formation, the geometry of the guest molecule is very important because it must fit in the CD cavity. CD inclusion is a stoichiometric molecular phenomenon in which usually only one guest molecule interacts with the cavity of the CD. In some low molecular mass molecules, more than one guest molecule may fit into the cavity, and in the case of some high molecular mass molecules, more than one CD molecule may bind to the guest. As a result, one-to-one molar ratios are not always achieved, especially with high or low molecular mass guests (Fig. 8.2). α-CD typically

Table 8.1 Key features of cyclodextrins

1. CDs are cyclic oligosaccharides of different sizes.
2. The most common CDs are α-, β-, and γ-CD with six, seven, and eight glucose units, respectively.
3. They are produced by bacterial enzymatic conversion of starch.
4. CD structure has a toroidal shape with a hydrophilic exterior and a hydrophobic interior.
5. The hydrophobic interior (host or cavity) may receive hydrophobic molecules (guests) to form an inclusion complex.
6. The host protects the guest, reducing contact with heat, oxygen, light, solvents, and other external factors.
7. The physical–chemical characteristics of the guest are modified after inclusion complex formation.
8. CDs mask sensory characteristics, reduce oxidation, stabilize flavor, convert liquid in powder, and enhance solubility, bioavailability, and control release of guests.
9. CDs are widely used in the food and drug industries to encapsulate many different guests.

This table shows the key features of CDs including molecular structure and shape, hydrophobic and hydrophilic characteristics, inclusion complex formation with CD and guest, and also function and applications of CDs. *CD* cyclodextrin
Fig. 8.1 Schematic representations of cyclodextrin. This figure shows the structures of the most used CDs, α-, β-, and γ-CDs (defined by $n = 1$, 2, and 3, respectively), evidencing the arrangement of α-D-(+)-glucopyranoside (glucose) bonded by $\alpha(1 \rightarrow 4)$, and the toroidal structure of CD with hydrophobic cavity and hydrophilic exterior. The secondary face diameter of the interior ring of CD is 0.47–0.53, 0.60–0.65, and 0.75–0.83 nm for α-, β-, and γ-CD, respectively, and that of the exterior ring is 1.46 ± 0.04, 1.54 ± 0.04, and 1.75 ± 0.04 nm for α-, β-, and γ-CD, respectively. *CD* cyclodextrin

complexes low molecular mass molecules with aliphatic side chains, β-CD works well for aromatics and heterocycles, and γ-CD can accommodate macrocycles and steroids (Del Valle 2004).

A second critical factor is the thermodynamic interactions among the different components of the system (CD, guest, solvent); it must have a favorable net energetic driving force that pulls the guest into the CD (Del Valle 2004). The driving forces for complex formation are Van der Waals forces, hydrophobic interactions, changes in solvation energy for both components and, to a lesser extent, hydrogen bonding. The highest stability of the complex occurs with higher hydrophobic guests, whereas polar or ionic guests are less stable (Szejtli 2004). The complex formation and dissociation are a dynamic equilibrium (Fig. 8.3), and the complexation is governed by driving forces expressed
Fig. 8.2 Free cyclodextrin (*CD*) and guest (*G*) to form CD–G complexes. This figure shows the CD–guest complex on a dynamic equilibrium and the formation of inclusion complexes with the entire molecule or only a portion of it and the dependency of the guest size and hydrophobicity in different molar ratios (1:1, 1:2, 2:1, 2:2) to form the CD–guest complex. *CD* cyclodextrin
Fig. 8.3 Driving forces to promote the inclusion complex formation of cyclodextrin (*CD*) with guest (*G*). This figure shows the inclusion complex formation with CD and guest, including the dimensional fit between host cavity and guest molecule, as well as the driving forces that push the guest into the CD cavity and the complex formation **Fig. 8.3** dynamic process expressed by an equilibrium constant, K_C. The numerical value of the equilibrium constant can be obtained from measuring the guest and CD concentrations, and this value indicates how the reaction is dislocated. *CD* cyclodextrin

by an equilibrium constant, K_C (Szejtli 2004). The numerical value of the equilibrium constant can be obtained from measuring the guest and CD concentrations.

In the crystalline form, only the surface of CD is available for complexation, but in solutions more CDs molecules are available and it increases the probability of complex formation. As the amount of solvent is increased, the CD and the guest may be so diluted that they do not get in contact as easily as they do in a more concentrated solution. Moreover, water is the most used solvent and it is desirable to keep just enough water to ensure complexation in a sufficiently fast rate. Besides, not all guests are readily solubilized in water, making complexation either very slow or impossible to happen in solution. Some high molecular mass components like oils must be vigorously mixed to allow better dispersion to contact with the CD. Temperature is another important factor to CD–guest formation. The increase of temperature increases molecular shocks which are positive for CD–guest formation; at the same time it increases the molecular vibration that destabilizes CD–guest complex and the guest could be released. Thus, moisture content and temperature are the most important factors to control CD–guest formation or release. A summary of the factors that affect CD inclusion complex formation is presented in Fig. 8.4.

A great technological effort made in the last years, with a lot of investment in research, enabled important cost reductions in the production of CDs, making their industrial use possible (Szejtli 2004). Besides natural CDs, new promising semi-synthetic derivative CDs are expanding new applications of CDs in the food industry (Davis and Brewster 2004).
Fig. 8.4 Variables that affect cyclodextrin inclusion complex formation. This figure shows the factors affecting CD inclusion complex formation. For inclusion complex formation, it is necessary that the driving forces push the guest to CD cavity and that CDs and guest get in touch. Thus, any variable that affects driving forces such as pH, kind of CD, and presence of other components affects the molecular shocks as temperature and kind of solvent could affect strongly the inclusion complex formation process. As many variables affect the inclusion complex formation, each CD inclusion complex formation must be evaluated case by case. *CD* cyclodextrin

8.3 Methods of Complex Preparation

CD complexes can be formed by different techniques that are selected according to guest properties such as solubility (Fig. 8.5), equilibrium kinetics, presence of other components, and final guest applications. The commonly used techniques are coprecipitation, slurry, paste, dry mixing, and supercritical carbon dioxide methods; all of them depend on a small amount of water to start the complexation thermodynamics (Hedges 1998; Del Valle 2004).

In coprecipitation, the guest is slowly added to a CD solution and, when the complex solubility is exceeded, it precipitates and can be separated. This method is used when the CD-complex has reduced solubility. Due to the limited solubility of CDs, high water volumes are necessary, limiting the use of coprecipitation for industrial scales (Hedges 1998). Slurry and paste (kneader) methods are similar, because the guest is added in molar proportions to a saturated solution containing 40–50% of CD for the first method and just water to moisten the CD for the latter. After CD-complex formation the mixtures are dried and ground to homogenize particle sizes (Del Valle 2004). Variations of the paste technique using extruders or melt granulators are reported (Suzuki et al. 1993). Due to simplicity, high productivity and easy scale up, the paste technique is more used in food industry (Del Valle 2004).

The dry mixing method is based on simple mixture of components without water addition. In general, it is a slow and inefficient method, restrict to liquid and/or volatile guests that work as solvent like essential oils (Hedges 1998). The supercritical carbon dioxide method consists of obtaining solid complexes and it is considered one of the most promising methods because a unique CD–guest molecular configuration could be obtained. Although it is a fast atoxic chemically stable method with low maintenance cost and promising results described in literature, it is still an experimental technique that has a very high initial cost (Palakodaty and York 1999).
Fig. 8.5 Solubility of cyclodextrin–guest complex. This figure shows how CD concentration affects guest solubility in water. An illustrated number of solubility profiles are presented. The complexes are usually classified as an A-type profile which represents the formation of soluble CD complexes and B-type which indicates the formation of complexes of limited solubility. *CD* cyclodextrin

8.4 Methods of Complex Determination

Most of the determination methods for inclusion complex are based on physical and chemical differences among the CD, the guest, and the inclusion complex CD-guest. Different techniques can measure these differences and have been used to evaluate the CD-complex formation. The differential scanning calorimetry (DSC) or thermogravimetric analysis (TGA) are very used, only if the guest has a melting point below the CD decomposition temperature (300°C). The inclusion complex formation is indicated by an increase of about 10°C in the guest boiling temperature (Hedges 1998). The spectrophotometric methods (UV–visible, fluorescence, and phosphorescence), Fourier transform infrared (FTIR) spectroscopy and Raman spectroscopy have also been used for analyses of complexes. Changes in the guest spectrum occur upon CD–guest formation because the guest is surrounded by the CD and does not interact with other guest molecules, and there is no crystalline guest structure to absorb energy. However there are interferences in the spectra from the CD, and some of the guest spectrum changes are very subtle and require careful interpretation (Li and Purdy 1992). Optical rotary dispersion, circular dichroism, mass spectroscopy, and X-ray crystallography have also been used to characterize complexes. The selection of some specialized techniques frequently depends on available equipment and the guest properties that make the particular technique more sensitive or reliable for the particular complex (Li and Purdy 1992).

Although it is possible to use several techniques to investigate the inclusion process, only analyses through nuclear magnetic resonance (NMR) spectroscopy can confirm the complex formation, determining the association constant and both stoichiometry and topology of the complex (Li and Purdy 1992; Schneider et al. 1998). The topology of the CD-complex can be obtained using a 2D rotating-frame Overhauser spectroscopy (ROESY). The presence of intermolecular nuclear Overhauser effect (NOE) between CD protons (H-3 and H-5) with guest hydrogen proves that the guest is inside the CD cavity for the reason that NOE cross peaks are observed when the protons are closer than 0.4 nm (Schneider et al. 1998). The association constants can be calculated by diffusion-ordered spectroscopy (DOSY) method, based on diffusion coefficient measurements of free guest and CD (Johnson 1999). Several researchers of the field do not use conclusive NMR techniques due to the difficulties to access equipment. However, the other mentioned techniques provide strong indications of complex formation and can be used with restrictions, when CD application does not need confirmation of inclusion complex formation.

Evaluation and characterization of complexes by molecular computational modeling is limited by the size and flexibility of CD and the numerous interactions in aqueous solution, which introduce restrictions to mathematical models (Lipkowitz, 1998). In general, computational modeling allows reasoning and complementing experimental observation.

8.5 Cyclodextrins to Improve Food Color

The food color is the first quality parameter evaluated by consumers before food flavor, taste, and texture. Thus, color intensity and brightness are key parameters to food quality control. The color in food is formed mainly by a group of nonpolar, and chemically and enzymatically unstable pigments. In order to restore color in food, it is usual to add natural or synthetic coloring pigments. The former are less chemically stable than the latter, but some doubts about the safety of synthetic pigments still remain. Therefore, natural coloring pigments are more indicated for good health, but they have low solubility and high rate of degradation, which limit their use as food coloring pigments.

Regarding this, CDs are very important as food color modulators due to both increased solubility and chemical stability of coloring components. The natural pigments curcumin, paprika (Tønnesen et al. 2002), and lycopene (Blanch et al. 2007) have an increase of water solubility and reduction of oxidation rate when included in CDs. In foods with natural coloring such as tomato ketchup, the addition of CDs (0.2%) protected the natural pigments even after heating at 100°C for 2 h (Kawashima 1980).

CDs have the advantage of being directly added to food to protect natural pigments as well to control coloring components produced during food processing. Furthermore, empty CDs can control the Maillard's reaction speed and stabilize the preformed cooked cured-meat pigment derived from red blood cells (Shahidi and Pegg 1991).

CDs can also be used to inhibit the probrowning polyphenol-oxidase reaction, by including substrates and cofactors such as chlorogenic acid, polyphenols, cinnamic acid, and Cu^{+2}. The polyphenol-oxidase reaction converts the colorless polyphenols to colored components and it occurs just after vegetable damage and during juice production (Irwin et al. 1994). An example is the addition of CDs (1–4%) to chopped ginger root, which stabilizes enzymatic browning during vacuum storage for 4 weeks at 5°C. In the case of apple juice and pear juice, the maltosyl-β-CD prevents ascorbic acid oxidation, a strong inhibitor of enzymatic browning. The secondary antioxidant effect of maltosyl-β-CD retains the color and the food antioxidant capacity (Del Valle 2004). However, the efficiency of CDs for polyphenol-oxidase control depends on the fruit. For peach juice, β-CD was incapable of inhibiting juice enzymatic browning, while α-CD and maltosyl-β-CD presented strong inhibition. For banana juice, the CD was a probrowning agent, leading to changes in color parameters (Sojo et al. 1999).

Although enzymatic browning can be controlled by CD addition, it is normally stopped by thermal shock in water. This technique extracts important components from foods like minerals, pigments, volatile components, and polyphenols. These components have important functions in the organism as cofactors and catalyzers of enzymatic reactions, antioxidants, chemical mediators, and electron transporters, among others. Thus, elimination or reduction of food thermal shock in water retains the natural healthy value of vegetables, improving the quality of industrialized food.

8.6 Cyclodextrins to Improve Food Flavor

Odor has an important role in the perception of food quality and it is one of the principal sensory factors for satiety during a meal. Reduced olfactory satiety caused by lack of natural food odors can enhance food intake (Rolls and Rolls 1997). The food aroma compounds are highly volatile, and heat and light unstable. Also, it can change with variations in the food after cultivation, processing, storage, packaging, and preparation (Szente and Szejtli 2004).

Controlling flavor retention and releases in food is an important goal for food industries. The use of encapsulated flavor is well-established and CDs are one of the simplest encapsulating systems for different flavors (Reineccius et al. 2003). CDs can protect chemical and sensorial characteristics of components because the aroma molecule fits in the CD cavity. Encapsulation effects are mainly the reduction of: evaporation, oxidation by light, heat, or pH attack, and transformation of oils into easily manipulated powder for addition to food. Encapsulation can also control aroma release by slow guest liberation, mask off-notes of aromatic molecules by affinity with CD cavity, and increase food flavor by water dissociation of aroma due to polar external part of CD (Reineccius et al. 2003). Even with aroma losses by temperature, there is a great potential for using CD to maintain food flavors during pasteurization and extrusion processes (Kollengode and Hanna 1997). Another interesting

application of CD is in frying oils, because it can remove free fatty acids and reduce smoke formation, foaming, browning, and deposition of oil residues on surfaces (Astray et al. 2009).

The specific nature of the interactions between CD and the aroma components is the CD's major strengths. They are also a weakness, in that only molecules with the right size, geometry, and polarity can fit inside the CD cavity and form a stable complex (Stella and He 2008). The retention of aromatic components inside the CDs is a complex phenomenon in which many factors take part, making the encapsulation method an important step for economical viability of the process. A main reason to choose the encapsulation method is the amount of water involved in the process because it must be removed during the drying process. Slurry and solid mixture are cited as best methods to large-scale production of aroma encapsulation. Proteins, carbohydrates, and emulsifier additions could also improve aroma retention inside the CD (Jouquand et al. 2004). Another important point is the drying process because it involves the energy addition that could destabilize the complex. Bhandari et al. (1999) listed several methods to dry β-CD lemon oil complex and showed that the spray-drying system was simpler and quicker, and achieved an easy-to-use fine powder that is the most indicated to scale up production.

The release of an aromatic component inside the CD depends on the guest affinity to the CD, pH, and food composition. However, the most important points are temperature and moisture content. Temperature affects molecular vibration and reduces the CD–guest affinity, increasing the guest dissociation speed (Kollengode and Hanna 1997). Dry mixtures of oils and CDs have retained 38–100% of their aromatic potential after 14 years (Szente and Szejtli 2004) whereas the presence of water speeds up the release of included aroma because of the complex dissociation (Labows et al. 1996). The main applications of CDs in aroma maintenance in food are shown in Table 8.2.

Although CDs have a great potential to protect aromas, there are some limitations of this technology for the food industry. The principal challenge is the standardization of encapsulated aroma. Aromas are generally a mixture of molecules with different affinities to the CD cavity and consequently with different dissociation speeds in the food. As a consequence, a mixture of aromatic components included in the CD can have a different final aroma than the original (Astray et al. 2009). Therefore, CDs are appropriate for protection and controlled release of aromas compounded of few components and with similar structure and polarity so that the affinity to the cavity does not significantly affect the complex dissociation. Because of the specific characteristics of each aromatic mixture and the intrinsic characteristics of the food, such as composition and pH, the use of CDs for protection and controlled release of aromas in food cannot be generalized, but needs to be analyzed on a case-to-case basis starting from food processing until the food reaches the final consumer.

Table 8.2 Application of cyclodextrin (CD) for food flavor improvement

Compound	Aroma	CD	Improvement	Source
Cyclic sulfur compounds	Shiitake mushroom flavor	α-CD–maltodextrin	Flavor retention	Yoshii et al. (2005)
Eugenol	Clove odor	β	79% odor retention during extrusion	Kollengode and Hanna (1997)
Five ester types	Pear aroma	α	Heat protection at 120 °C for 60 min	Tobitsuka et al. (2006)
Goat's milk	Goaty odor	β	Reduce goaty flavor	Meier et al. (2001)
l-menthol	Menthol odor	β	100% of odor remained in long-term storage and heat protection	Reineccius et al. (2004)
Rice flavor oil	Rice odor	α-CD–dextrin	Odor retention and conversion of oil to powder	Kawakami et al. (2009)

This table presents the main use of CDs in food formulations for flavor protection, delivery, or masking. *CD* cyclodextrin

8.7 Cyclodextrins to Improve Food Taste

The consumer's first criterion to choose food is its good taste and the second one is food with high calories at low cost (Drewnowski and Gomez-Carneros 2000). Considering that obesity has been treated as a public health issue, some industries have been developing healthier foods by reducing sugar, fat, and sodium, and adding polyphenols, phytosterols, vitamins, minerals, and soy products; this addition generally intensifies the bitter and astringent taste in foods (Ley 2008) and consequently decreases their appreciation and demand by consumers.

CDs can reduce the bitter taste in foods by CD inclusion complex formation that surrounds the bitter molecules that pass by the tongue, without signaling the taste. As the complexation occurs through a non-covalent interaction between the bitter molecule and the CD cavity, the guest is normally well liberated along the digestive system; therefore, CD addition in foods seems to be the best method to mask unpleasant taste and keep foods healthier. Furthermore, CDs can neither be considered tasteless nor only slightly sweet because a 0.5% β-CD solution is as sweet as sucrose (Szejtli and Szente 2005). Thus, the natural sweet taste of CDs might also mask bad tastes in food; however, it is not used for this purpose. Another method to eliminate bitter taste is removing bitter molecules from foods through retention in columns filled with CDs. In that case, healthier bitter compounds are removed from foods and the healthy food quality is reduced.

In soybean products, CDs can reduce up to 90% of the grassy smell, bitterness, and astringent taste from hydrolyzed soybean, in the presence of 10% of α-CD (Linde et al. 2009) or 5% of β-CD (Linde et al. 2010). In this case, nonpolar amino acids responsible for bitter taste are included in the CD cavity and pass by the tongue without signaling the taste. Several techniques were suggested to reduce or mask the bitterness of hydrolyzed proteins, but all of them presented disadvantages like loss of essential amino acids and bioactive peptides, osmolarity increase, high cost and industrial inviability of some enzymatic reactions, toxicity of organic solvents, and production of effluents. The use of CDs reduces the bitter taste of hydrolyzed proteins and retains amino acids and bioactive peptides in food, providing a use for healthier proteins that would be otherwise useless for alimentary purposes.

Another application of CDs is to reduce the bitter taste of citric juice like navel orange and grapefruit juices because CDs can form a strong inclusion complex with limonin and naringin. Limonin and naringin, when in low concentration, are important flavor components, but when there is a high concentration of these components due to fruit variety and/or harvest time, a strong bitter taste is present. Moreover, fresh citrus juice is not bitter but becomes so during storage and its rate depends on the pH and storage temperature. Due to the great volumes of produced juice, it is less costly to remove limonin and naringin using columns filled with α- or β-CD, which are recovered by the treatment with diluted alkali or ethanol. The polymer also reduces naringenin-7-β-rutinoside, coumarins, and flavonoids, but the total acidity and ascorbic acid content remain unchanged (Astray et al. 2009). In Table 8.3, the main applications of CDs to improve food taste are shown.

The success of molecular complexation process with bad taste molecules in CDs depends on the value of the association constant that is generally between 10^1 and 10^4 mol^{-1}. The temperature strongly affects the CDs success to remove unpleasant tastes. In cold foods, the equilibrium force causes the inclusion complex formation and CD–guest crystallization, whereas in hot mixtures, it leads to the guest release. Therefore, the use of CDs has succeeded for taste improvement when used in cold foods (Szejtli and Szente 2005).

β-CD is still the most versatile molecule to encapsulate substances. However, an important tool to be exploited by the food industry is the chemically modified CDs like di- and trimethyl-β-CD (DMβCD and TMβCD), randomly methylated-β-CD (RMβCD), hydroxyethyl-β-CD (HEβCD), 2- and 3-hydroxypropyl-β-CD (2HPβCD and 3HPβCD), 2,3-dihydroxypropyl-β-CD (DHPβCD), 2-hydroxyisobutyl-β-CD (HIBβCD), sulphobutylether-β-CD (SBEβCD), glucosyl-β-CD (G1βCD),

Table 8.3 Cyclodextrin (CD) use to improve food taste

Food	CD	Result	Source
Canned citrus and citrus juice	β	Reduce bitter taste of naringin, limonin, and hesperidin and prevent precipitation	Hedges (1998)
Coffee and tea	β	Reduce or eliminate disgusting taste by overbrewing or overlong steeping	Hamilton et al. (1970)
Extracts of artichoke leaves, aloe, and gentian	Chitosan–CD adducts	Mask bitter taste	Binello et al. (2004)
Fish oil	β	Eliminate unpleasant taste, smell, and stabilization against oxidation	Choi et al. (2009)
Ginseng	γ	Reduce bitter taste	Lee et al. (2008)
Hydrolyzed soy protein	α	Reduce bitter taste	Linde et al. (2009)
Hydrolyzed soy protein	β	Reduce bitter taste	Linde et al. (2010)
Naringin, limonin, and caffeine	β-CD–carboxymethyl chitosan	Reduce bitter taste	Binello et al. (2008)
Cooked rice	β	Improvement of odor and flavor after long storage	Kuwabara et al. (1988)
Skim milk hydrolysates	β	Reduce bitter taste	Helbig et al. (1980)

This table presents the main use of CDs in food formulations to mask or reduce unpleasant tastes as well to improve pleasant tastes and flavors. *CD* cyclodextrin

and maltosyl-β-CD (G2βCD) (Davis and Brewster 2004). Other important CD derivatives are sugammadex in which the 6-hydroxyl groups on γ-CD have been replaced by carboxythio acetate ether linkages and hydroxybutenyl-β-CD. Finally, there is a renewed interest in γ-CD itself and modified γ-CDs (Stella and He 2008), and also in macromolecules, which are linked to CDs like CD–maleyl chitosan, CD–carboxymethyl cellulose, CD–carboxymethyl chitosan, and CD–chitosan adducts (Binello et al. 2004). However, they have a potential use to improve the consumption of unpleasant taste healthier food; the use of these modified CDs in the food industry depends on the approval of regulatory organizations.

8.8 Cyclodextrins to Improve Food Rheology

Gelatinization is one of the most important characteristics of some carbohydrates and proteins. It reduces water activity in the food by linking the water to carbohydrates and proteins, modifying food rheology and extending shelf life. As a consequence of the gelatinization, exudation and evaporation of water is reduced in food and that is essential for the quality of the industrialized food.

Highly branched CDs are used in flour-based items like noodles, pie dough, pizza sheets, and rice cakes to impart elasticity and flexibility to dough. The texture of food gelatinization such as in wheat flour was modified by the addition of β-CD, which increases the solubility and swelling power of wheat starch granules. Furthermore, the addition of 1.5% β-CD increased the viscosity of the pastes fourfold, probably by disrupting starch–lipid complexes (Kim and Hill 1984). In meat products, ice cream, beverages, salad dressing, yogurt, mayonnaise, margarine, or butter creams, CDs can be used to stabilize emulsions due to their hydrophilic outer surface and hydrophobic cavity (Del Valle 2004).

CDs are still little used in the alteration of food rheology because the cost-benefit relation is not favorable. In foods in which CDs are used to change flavor or control flavor release, a secondary

positive effect is the improvement of food rheology. Even though the effect of CDs in food rheology is minimal, there is a potential use of this molecule in package biofilms with an effect in both rheology and controlled release of antimicrobial and/or antioxidant compounds in food.

8.9 Cyclodextrins to Improve Food Packages

Packages are essential elements to guarantee food quality from its production, transportation, processing, commercialization, and up to its consumption. Thus, packages are required to maintain food integrity, sensorial qualities and safety, besides being atoxic and biodegradable. Also, the food packages should work as a reservoir of active components like antimicrobials, flavors, pigments, and antioxidants that can be slowly released. Besides that, CDs can include off-flavors and improve the elasticity and barrier properties of food packages.

The controlled release of active compounds throughout shelf life is important because high concentrations of free bioactive components like antimicrobials, pigments, flavors, and antioxidants represent a risk for food quality and safety. The active-component release of food packages must have zero-order kinetics to keep the component concentration constant throughout shelf life (Baker 1987). CDs are able to reduce the diffusion kinetics of one order with the controlled release of guest. Thus, complexation is a potential key to a long-lasting active-component effect of such active packaging.

There are many examples of food packages with CDs to control the release control of active components such as iodine, used to preserve fish paste; ethanol and benzoic acid, used to prevent fungus growth (Szente and Szejtli 2004; Astray et al. 2009); allyl isothiocyanate, used to avoid mold growth on the surface of packaged cheese (Plackett et al. 2006); and the antifungal volatile hexanal, to reduce post-harvest berry diseases (Almenar et al. 2007). The release of flavors like d-limonene, natural pigments, and antioxidants, such as α-tocopherol, have also been reported (Siró et al. 2006).

In packages, CDs are generally used to control the guest release, but empty CDs can be added to encapsulate unwanted components produced along storage. In irradiated food, CDs prevent off-taste of cyclic monoterpene or are used as an interior coating of beer containers to encapsulate aldehydes and ketones (Bobo 1993).

The release of active compounds in packages works well with the increase of relative humidity along storage time, like in fresh-cut fruits or vegetables packages because of the natural water release from food that displace the equilibrium to guest release (Ayala-Zavala et al. 2008). Conversely, if the objective is the inclusion of unwanted components in food, CDs will trap better those components in food with reduced moisture content.

The addition of CDs in packaging films has improved sensory properties while maintaining food quality and safety. There is a potential use of CDs in edible films, from renewable carbon sources like alcohols and carbohydrates, but it is still underutilized and this could result in the creation of new packages in the food industry.

8.10 Cyclodextrins in Health Foods: Potential Use

The increase of obesity and the problems related to an unbalanced diet has led consumers to look for healthier food options. However, consumers in general buy food because of its taste instead of its nutrition or health values; furthermore, this instinctive rejection of disgusting tastes may not be changed because it is a key mechanism for survival (Rouseff 1990). Therefore, the industry has offered light and

functional foods to consumers, but the maintenance of pleasant taste has become the main challenge to broaden industrialization and consumption of healthy foods. Thus, bitterness in food products has been described as a sensory defect and demands for good taste and good health seem to be incompatible.

Also, reduction of sugar, fat, and sodium in the industrialization of light food, intensifies bitter and astringent tastes (Ley 2008). Vegetal components like phenols, flavonoids, isoflavones, terpenes, glucosinolates, and hydrolyzed proteins that have important antioxidant, anticarcinogenic, and a wide spectrum of tumor-blocking activities, are bitter, acrid, or astringent (Drewnowski and Gomez-Carneros 2000). Then, in order to avoid consumers' refusal of food, the bad taste components are generally removed to improve and homogenize taste. It creates some paradoxes, for example, whereas there are proposals of enhancement of glucosinolates in broccoli sprouts for health's sake, the industry has removed them for better taste (Drewnowski and Gomez-Carneros 2000).

Another way to reduce undesirable tastes is the use of recombinant DNA to produce transgenic cultivars with less bitter tastes such as transgenic citrus fruit free of limonin. However, plant varieties that have been selected for palatability by humans are usually more susceptible to diseases, leading to an increased use of synthetic pesticides, creating another paradox to produce good quality food (Benavente-Garcia et al. 1997).

CDs have an important potential in the development of good taste food and its health components. A summary of the main applications of CDs in food is presented in the Fig. 8.6. CDs can complex flavonoids and terpenoids and mask the bitter taste of citrus juice, for example, without changing the
Fig. 8.6 Food applications of cyclodextrins. This figure shows the applications of CDs. The lipophilic cavity of CD provides protection that reduces the contact of the guest with heat, oxygen, light, solvents, among others. Based on these characteristics, the CDs are widely used to encapsulate many different guests with applications in the food and drug industries. *CD* cyclodextrin

bioactive potential of those substances. Del Valle (2004) reported the improvement of health component properties with CD complexation for apple juice and medicinal mushrooms. Linde et al. (2009, 2010) reported that natural α- and β-CDs reduced the bitter taste of hydrolyzed soy protein upto 90%, which represents a potential solution for masking the bitter taste of foods with soybean and bioactive health peptides that are used to prevent diseases.

CDs are also used to remove fat and cholesterol from dairy products such as milk, cheese, yogurt, and whipping cream, fat from egg yolks and lard, and to add components such as phytosterol in mayonnaise, and phytosterol and evening primrose oil in butter (Astray et al. 2009). CDs can produce hardening fats and oils without both hydrogenation and trans fats, resulting in an emulsion with high content of polyunsaturated fatty acids derived from fish and vegetal oils. Plus the emulsion produced by CD presented better sensory characteristics and increased storage stability by delaying acidity (Choi et al. 2009). CDs can be used to increase water solubility and reduce oxidation of thyme oil, an important component that maintains higher polyunsaturated fatty acids levels in cell membranes and with potential use as an antileishmanial drug or a component of a functional food (Mourtzinos et al. 2008).

Another important application of CDs for the development of healthy foods is the improvement of solubility and bioavailability of Coenzyme Q10 (ubiquinone) that plays a fundamental role in converting energy from carbohydrates and fatty acids, and it is also a very effective antioxidant (Madhavi and Kagan 2006). CDs can also be added to potato starch, improving the satiating, glycemic, and insulimemic properties of a meal, suggesting that either gastric emptying is delayed or some of the glucose is absorbed more distally in the small intestine reducing insulin secretion (Raben et al. 1997).

The idea that food must taste good and should prevent diseases introduces a dilemma for the food industry because it has to meet the demands of taste and health without hindering any of them. That is why the development of functional foods presents several challenges and CDs represent new possibilities for the food industry regarding the expansion of the functional food consumption.

8.11 Cyclodextrin Toxicity

Orally administered CDs are practically non toxic, due to lack of absorption in the gastrointestinal tract. Furthermore, a number of safety evaluations have shown that γ-CD, 2-hydroxypropyl-β-CD, sulphobutylether-β-CD, sulphated-β-CD, and maltosyl β-CD appear to be safe even when administered parenterally (Del Valle 2004). However, parenteral and intravenous use of CDs, specifically β-CD, has to be done carefully because it may cause nephrotoxicity due to the formation of a low solubility CD–cholesterol complex, which blocks glomerular filtrations in the kidney; in high doses, CDs may cause hemolysis of human erythrocytes.

In the United States, CDs are generally recognized as safe (GRAS) by the Food and Drug Administration (FDA), in Japan, they are considered natural products when used in foods, whereas in Australia and New Zealand, CDs are classified as novel foods (Cravotto et al. 2006). The acceptable daily intake (ADI) recommended by the Food and Agriculture Organization/World Health Organization (FAO/WHO) for β-CDs is 5 mg kg^{-1} day^{-1}, but for α- and γ-CDs, no ADI has been defined because of their favorable toxicological profiles. But adversely, the United States Environmental Protection Agency has established a maximum permissible level for residues of α-, β- and γ-CDs in various food commodities (Astray et al. 2009).

CDs are resistant to α-amylases and partially resistant to β-amylases, hydrolyzed by the colon microbiota where insignificant amounts are absorbed by the digestive system (Antenucci and Palmer 1984).

The absorbed CDs are essentially excreted in the urine without undergoing metabolism. The absorption of α-, β-, and γ-CDs by oral administration in rats is 1.0, 0.6, and 0.02%, and LD_{50} in mg kg^{-1} is 10,000, 5,000, and 8,000, respectively (Stella and He 2008). Natural and hydrophilic and lipophilic derivative CDs have low permeation capacity and low toxicity when orally administered (Irie and Uekama 1997).

The remarkable effects of oral administration of CDs in rats were soft feces or diarrhea and cecal enlargement. These effects were observed with HP-β-CD, SBE-β-CD, and α-CD, β-CD, and γ-CD in high doses (10–20 g kg^{-1}) (Lina and Bar 2004), but α-CD caused membrane irritation (Del Valle 2004). The effects of CDs on the gastrointestinal tract are similar to those of low digestible carbohydrates such as lactose, and these effects represent physiologically adaptive responses to a large load of poorly digestible carbohydrates and other osmotically active nutrients with minimal relevance to humans (Grice and Goldsmith 2000).

As reported by Del Valle (2004), there is still skepticism within the regulatory agencies regarding the use of CDs, although this seems to be a bigger issue in the FDA than in other agencies. The quantity applied in food has quite lower concentrations of CDs than those that cause toxicological problems. The simple fact that there are now numerous approved products containing CDs (Szente and Szejtli 2004) is a good sign for its future use. The more the products containing CDs and modified CDs undergo rigorous evaluation, the more the agencies will trust CD addition to food better.

8.12 Applications to Other Areas of Health and Disease

8.12.1 Cyclodextrins in Pharmaceutical Applications

Bioavailability and controlled release of drugs are especially important in the pharmaceutical industry and both of them depend on water solubility in active principle. Efficient modern drugs usually present higher molecular mass and lipophilicity, and lower water solubility making bioavailability and controlled release more difficult (Lipinski et al. 1997; Lipinski 2001; Davis and Brewster 2004). Thus, bioavailability difficulties have been more common, and the use of drug delivery formulators has been necessary in order to accomplish drug delivery. In drug formulation, the active principle must be absorbed through the gastrointestinal tract or membranes in order to reach a pharmacologically desired action. Retrospective studies show that more than 40% of drugs fail because they have poor water dissolution or poor permeability (Prentis et al. 1988; Davis and Brewster 2004).
CDs are useful pharmaceutical delivery formulators because they can interact with drug molecules to form highly stable and water-soluble inclusion complexes and could control the drug release (Stella and He 2008). CDs can be used in pharmaceutical formulations to enhance solubility, bioavailability, and stability. They can also convert liquids and oils to free-flowing powders, preventing admixture incompatibilities and reducing drug evaporation and hemolysis (Davis and Brewster 2004). In oral administration, only insignificant amounts of intact CDs are absorbed in the gastrointestinal tract because of their bulky and hydrophilic nature. The absorbed CDs are essentially excreted in the urine without undergoing metabolism, thus, the elimination of CDs strongly depends on renal clearance (Stella and He 2008). The hemolytic effect of CDs has been reported in vitro studies; however, the toxicological implication in vivo is considered negligible. The hemolytic activity of CDs correlates well with their ability to solubilize cellular membrane lipids (Stella et al. 1999). In addition, due to the reduced CD toxicity, mainly in oral drug formulations, CDs are largely used in the pharmaceutical industry. The main drugs with CDs are presented in Table 8.4.

Table 8.4 Approved and marketed drug–CD formulations

Drug–CD	Administration route	Trade name	Country/continent
Chlordiazepoxide–β[c]	Oral	Transillium	Argentine
Meloxicam–β[c]	Rectal	Mobitil	Egypt
Chloramphenicol–randomly methylated-β[a]	Eye drops	Clorocil	Europe
Cisapride–β[c]	Rectal	Propulsid	Europe
Dextromethorphan–β[c]	Oral	Rynathisol	Europe
Hydrocortisone–2-hydroxypropyl-β[a]	Buccal	Dexocort	Europe
Indomethacin–2-hydroxypropyl-β[c]	Eye drops	Indocid	Europe
Nimesulide–β[a]	Oral	Nimedex, Mesulid	Europe
Omeprazole–β[a]	Oral	Omebeta	Europe
Tiaprofenic acid–β[a]	Oral	Surgamyl	Europe
Piroxicam–β[a,b]	Oral	Brexin, Flogene	Europe, Brazil
Alprostadil–α[a,b]	Intravenous	Prostavasin, Caverject, Edex	Europe, Brazil, Japan, United States
Voriconazole–sulphobutylether-β[a]	Intravenous	Vfend	Europe, United States
Flunazine–β[c]	Oral	Fluner	India
Benexate–β[a]	Oral	Ulgut, Lonmiel	Japan
Cefotiam hexetil HCl–α[a]	Oral	Pansporin T	Japan
Cephalosporin–β[c]	Oral	Meiact	Japan
Dexamethasone–β[a]	Dermal	Glymesason	Japan
Iodine–β[a]	Topical	Mena-Gargle	Japan
Nitroglycerin–β[a]	Sublingual	Nitropen	Japan
Mitomycin–2-hydroxypropyl-β[a]	Intravenous	Mitozytrex	United States
Tc-99m Teboroxime–2-hydroxypropyl-γ[c]	Intravenous	Cardiotec	United States

This table presents the main use of CDs in pharmaceutical formulations to achieve better drug performance such as enhance solubility, bioavailability, and stability; convert liquids and oils to free-flowing powders; reduce evaporation and stabilize flavors, odors, and tastes; and reduce hemolysis and prevent admixture incompatibilities. *CD* cyclodextrin

8.13 Conclusion

Food purchase and choice behavior directly influences consumers' lifestyle and health. Most foods, considered healthy or functional because they prevent or help the treatment of diseases, have low acceptability due to the presence of bioactive components with unpleasant tastes such as fibers, phenols, flavonoids, isoflavones, terpenes, glucosinolates, and others. Furthermore, functional foods have a high concentration of bioactive components and also a higher degradation and oxidation speed, which reduce their shelf life.

Because of their capacity of inclusion complex formation, CDs can help the maintenance and protection of bioactive components in foods. Moreover, these cyclical oligosaccharides can be used to improve the sensory characteristics of functional foods with bioactive components and unpleasant taste. CDs are widely used for increasing solubility and controlled release of flavors in foods as well as to enhance taste, mainly for drinks. But these compounds are very minimally used to control

off-flavor and off-taste encapsulation along shelf life. The cost of CD addition to modify food rheology is not yet worthwhile. However, CDs have a great potential in the improvement of rheology of bio-degradable films for "smart" food packages production with controlled release. They also increase the solubility and chemical stability of healthy compounds such as pigments and antioxidants. CD toxicity is low when ingested orally and their addition to food and drugs is accepted in several countries.

A greater amount of functional foods offered by food industries, which depends on the demand for these products, have grown but it is still small in the traditional industrialized food market world-wide. Healthy foods have a higher production cost either because of the technological development needed for their production, the use of higher cost ingredients, shorter shelf life, or smaller production scale. Thus, while the food industry has to solve the dilemma between the demands of tasty versus healthy foods, society has the dilemma of paying or not for healthier foods. In addition, few countries have educational and nutritional policy and laws to give fiscal incentives to functional food production while overtaxing unhealthy foods. Presently, changes in eating habits and awareness of the need for healthier food intake are necessary.

Summary Points

- A lot of healthy bioactive substances present in functional foods have the capacity to reduce the risk of illness.
- Healthy bioactive substances in general have unpleasant sensory characteristics.
- Pleasant sensory characteristics versus healthy food is a dilemma between consumers' and industries' demands.
- Cyclodextrin may form inclusion complexes with many healthy bioactive substances.
- Molecules encapsulated by cyclodextrin can enhance solubility, bioavailability, and stability; reduce flavor evaporation and mask both odors and tastes; and convert oils into free-flowing powders.
- Cyclodextrins are widely used in the pharmaceutical area and have low toxicity when orally ingested.
- Cyclodextrins are utilized to encapsulate flavors and pigments, protecting against evaporation and oxidation and also to control the release of guest molecules.
- Cyclodextrins can be added to foods to encapsulate unpleasant taste molecules and have a potential application in inclusion of unpleasant taste bioactive compounds in health foods.
- Cyclodextrins can be used to create "smart" food packages with the release of healthy compounds plus the possibility to extend food shelf life.
- Cyclodextrins improve gel rheology and can potentially improve biodegradable film rheology used for "smart" food packages production.
- Cyclodextrins are an excellent tool to help the food industry introduce new solutions for the dilemma of pleasant sensory characteristics in foods versus healthy foods.
- The increase in the society's demand for healthy foods and their willingness to pay for them will allow new commercial application of new techniques such as use of cyclodextrins.

Chapter 9
Infantile Olfactory Learning

Katsumi Mizuno

9.1 Introduction

In this chapter, I review how infants acquire olfactory preferences, how they discriminate their own mothers, and how olfactory learning benefits both mothers and neonates. I also examine how favorable olfactory stimuli/exposure affords smooth adaptation to this world to neonates. Since a strong bond between the mother and the infant is the key to the neonate's survival, individual olfactory recognition is essential for the development of mother–infant attachment (Table 9.1). During the early neonatal period, infants acquire individual olfactory recognition in three ways: (1) general preference for the odor of own mother's amniotic fluid and breastmilk, which is obtained genetically or in utero; (2) olfactory learning immediately after delivery, which is a critical time period in olfactory learning; and (3) classical conditioning as well as mere exposure to mother's odor, which are enough to allow infants to learn their mother's odor. I shall explore these three categories in detail herein.

9.2 Olfactory Learning in Utero

9.2.1 Olfactory Memory in Utero

Memory begins prenatally and the period of birth merely marks a transition from memory functioning in utero to memory functioning ex utero. Prenatal learning is thought to account for the preference of human neonates for their own mother's voice (DeCasper and Fifer 1980). The olfactory organs are functional at 12 weeks' gestation (de Vries et al. 1985), earlier than the auditory system. Bartocci et al. (2001) found that cortical hemodynamic modifications occur in preterm infants born at a mean of 33.7 weeks after exposure to preparations commonly used in the NICU (a disinfectant and an adhesive remover). Even in these premature infants, the odors of these solutions elicited a significant decrease in blood oxygenation in the orbitofrontal olfactory area. This change was different from that caused by exposure to colostrum and vanilla, which elicited an increase in blood oxygenation in the same region (Bartocci et al. 2000). In general, pleasant odors elicit approach behavior whereas unpleasant odors induce avoidance behavior. The change in brain blood volume to these olfactory stimuli likely relates to the infant's behavior.

Table 9.1 Key features of infantile olfactory learning

1. Human fetus is capable of leaning odor of amniotic fluid
2. Human neonate has a olfactory preference which is acquired in utero, or genetically determined
3. The odor of amniotic fluid plays roles in soothing the neonate and in preparatory response for oral feeding
4. Maternal discrimination is acquired through olfactory stimuli during the first couple of days after birth
5. Olfactory learning immediately after birth is important in successful breastfeeding
6. The odor of amniotic fluid/colostrums and breast milk is mainly determined by maternal diet
7. Neonates' preferences change from amniotic fluid/colostrum to mature milk over time
8. Maternal diet during pregnancy and lactation affects the weaning process and later dietary preferences of children

This table lists the key facts of infantile olfactory learning including the beneficial aspects of olfactory learning in mother–infant bonding, successful breastfeeding, and later healthier diet

Memory is essential for normal functioning and it is not surprising that such an important psychological function is established in some form before birth. Fetal memory may serve a number of specific functions, dependent upon the learning of particular stimuli prenatally. Human neonates recognize the odor of substances that were introduced into the amniotic fluid or ingested by their pregnant mother (Smotherman and Robinson 1982). Prenatal memory may be important in the development of attachment and maternal recognition. During pregnancy, the mother's Montgomery glands tend to enlarge; these glands provide olfactory stimuli for the infant after birth by emitting flavored secretions composed of milk mingled with sebum. Thus it is clear that, during pregnancy, the mother's body physically prepares for the olfactory interaction that follows the delivery of her infant.

9.2.2 Olfactory Memory Helps Neonates Adapt to Outside of the Womb

Odor cues from lactating women affect the behavior of infants in many ways, ranging from arousal modulation to the fine-tuning of interactions with the mother. The newborn young of several mammalian species are attracted to the odor of amniotic fluid; these chemical cues also appear to calm neonates and help them adapt to their new postnatal environment. For example, the odor of the lactating breast reduces arousal states in active newborns (Schaal et al. 1980; Schaal 1986; Sullivan and Toubas 1998) and increases them in somnolent newborns (Russell 1976; Soussignan et al. 1997; Sullivan and Toubas 1998). Such cues elicit positive head (nose) orientation (Macfarlane 1975) and increase oral activity (Russell 1976; Soussignan et al. 1997). Odor cues may stimulate active approach behavior such as directional crawling (Varendi and Porter 2001), which may be involved in the neonatal ability to reach a nipple (Widström et al. 1987; Righard and Alade 1990). The odor of amniotic fluid is an attractant and helps the infant locate an object to suck. Immediately after birth, neonates display a clear preference for an unwashed breast that retains its biological odor. Significantly more infants select such a breast rather than the odorless alternative for their initial sucking bout (Fig. 9.1). An olfactory memory acquired in utero may be important for the establishment of breastfeeding and later diet.

Two natural sources of potentially odorous substrates have received empirical attention. The first is amniotic fluid and the second is colostrum/milk, both of which are emitted from the main milk ducts that open at the tip of the nipple. Accumulating evidence shows that odor cues carried in human colostrum and milk are attractive to neonates (Marlier and Schaal 1997; Mizuno and Ueda 2004; Mizuno et al. 2004). Interestingly, neonatal responsiveness to these milk cues does not seem to depend on breastfeeding experience as infants that are exclusively fed cow's milk–based formulas react to them as strongly as breastfed infants (Marlier and Schaal 2005). Another potential
Fig. 9.1 Babies' preference of breast for sucking (Varendi et al. 1997). Comparison of breast choice for sucking is shown. *Y* axis indicates the number of babies who chose the washed breast, naturally smelling breast, and amniotic fluid treated breast. *Left column*: Unwashed breast is preferred over washed breast for infants at a mean postnatal age of 67±10 h. *Middle column*: Amniotic fluid–treated breast is preferred over natural odor breast for infants at a mean postnatal age of 68±15 h. *Right column*: Natural odor breast is preferred over amniotic fluid–treated breast for infants at a mean postnatal age of 165±26 h

source of mammary odor cues are distributed around the areola in the form of small skin protuberances, called Montgomery's glands. These result from the coalescence of sebaceous glands and miniature lactiferous acini (Smith et al. 1982). These glands enlarge during pregnancy and lactation and become more visible on the areolar surface. After delivery, they begin to secrete a milklike fluid (Schaal et al. 2006). The resulting blend may have a positive effect on the perceptual impact of the secretions. The surface temperature of lactating breasts is elevated; as such, evaporation of the secretions increases. This enables the odor to effectively stimulate the neonatal olfactory system. If such an effect exists, it might distinctively affect neonatal response speed and rate. In most lactating women, the number of visible Montgomerian glands ranges from a low of 1 to a high of 40-plus. Their functional involvement has recently been examined in breastfeeding interactions, based on the evidence that the number of areolar glands correlates positively with neonatal weight gain and with maternally reported perception of infant sucking activity (Schaal 1988). Taken together, the above findings suggest that milk and areolar secretions may be significant sources of behaviorally active cues for neonates.

9.2.3 *Origin of the Odor of Amniotic Fluid*

The odor of amniotic fluid is determined by fetal excretion as well as the mother's food. The ingestion of garlic or spicy food by pregnant women significantly alters the odor of their amniotic fluid (Hauser et al. 1984; Mennella et al. 1995). The spices are absorbed from the maternal gastrointestinal tract and transferred to the amniotic fluid (Hauser et al. 1984). Animal and human data indicate that the fetus emits odorous materials into the amniotic fluid as well and that these are externalized into the pregnant mother's excretions. This fetal odor generation and externalization may also explain

why mothers and fathers can detect similarities between their own infant's amniotic fluid odor and maternal body and urine odors (Beauchamp et al. 1994; Varendi et al. 1996).

9.2.4 Neonates Are Attracted to the Odor of Amniotic Fluid

9.2.4.1 Preference to Own Amniotic Fluid Odor

The individually unique quality of amniotic fluid is evidenced by the fact that newborn infants are selectively responsive to the odor of amniotic fluid. When an infant is simultaneously exposed to the odors of his/her own amniotic fluid and the amniotic fluid of another infant, the infant will orient his/her head more quickly and for a longer duration to the former stimulus than to the latter (Schaal et al. 1998). Varendi et al. (1998) presented different odors to neonates for 90 min after their birth and found that neonates exposed to amniotic fluid odor cried significantly less than neonates exposed to control odor (Fig. 9.2). Prenatal familiarization with amniotic fluid odors that are likely to continue to be encountered immediately after birth may help the baby adapt to the otherwise new postnatal environment (Varendi et al. 1996; Schaal and Marlier 1998). This similarity between amniotic fluid and colostrum helps neonates to move toward the breast and locate the mother's nipple.

9.2.4.2 Amniotic Fluid Plays an Important Role in Locating an Object to Suck

When newborn infants are placed in the prone position between their mother's breasts immediately after delivery, they display a consistent sequence of activity, namely, crawling movement, which brings the infants into contact with one of the nipples, and then active sucking, which eventually occurs within about 1 h after delivery (Widström et al. 1987; Varendi et al. 1994). If amniotic fluid is applied to
Fig. 9.2 Median crying time with amniotic fluid odor, breast odor, and no odor (Varendii et al. 1998). Median crying time (s) during postnatal 31–90 min in infants assigned to amniotic fluid odor (AF), breast odor (B), and unexposed group (C) used as control. Paired comparison: AF versus B: $p=0.02$, AF versus C: $p=0.02$, B versus C: $p=0.27$. *Y* axis indicates crying time; *X* axis indicates AF, B, and C odor exposure groups

only one breast, the infant will orient to that breast. In other words, if the mother's nipple/areola is washed thoroughly, it would be difficult for a neonate to orient to the mother's breasts effectively. Within the first hour after birth, significantly more neonates spontaneously select a breast treated with amniotic fluid than an untreated breast (Marlier et al. 1998). Varendi et al. (1998) demonstrated that just after birth, more neonates suck their hands if they are not washed. If they are washed, less than half put their hands to their mouth. If the hands smell of amniotic fluid, neonates exhibit searching movements when their hands come close to their nostrils. Based on these observations, it can be said that the odor of amniotic fluid is attractive and helps the baby locate objects to suck.

9.2.5 Similarity of Olfactory Cues Between Amniotic Fluid and Colostrum

There is a distinct similarity between the amniotic fluid and the colostrum of the same woman – these odors are treated as similar by neonates (Marlier et al. 1998). When offered breast for the first time, neonates recognize the colostrum as it has a similar taste to the amniotic fluid. Marlier et al. (1998) found that 2-day-old, breastfed infants demonstrate a similar response to amniotic fluid and colostrum. Her group demonstrated that these infants preferentially orient to gauze pads bearing the odor of amniotic fluid (Schaal et al. 1995). The attractiveness of amniotic fluid and breast odor is thought to be acquired in the prenatal period or genetically. The individually unique quality of amniotic fluid is evidenced by the fact that newborn infants are selectively responsive to the odor of their own amniotic fluid. When an infant is simultaneously exposed to the odors of his/her own amniotic fluid and of the amniotic fluid of another, the infant will orient his/her head more quickly and for a longer duration to the former stimulus than to the latter (Schaal et al. 1998). It is thus evident that the human fetus can detect and store the unique chemosensory information available in the prenatal environment.

It is of interest that bottle-fed infants manifest a greater motivation than breastfed infants to orient to their own amniotic fluid odor than to the unfamiliar amniotic fluid odor. This may result from the decreased opportunity to smell his/her preferred colostrum/amniotic fluid odors. It is evident that neonates demonstrate strong attraction to amniotic fluid odor. This preference remains until an average of 3.3 days after birth.

9.2.6 Alteration of Olfactory Preferences

Neonates' preferences change from amniotic fluid/colostrum to mature milk over time (Fig. 9.1). Bartocci et al. (2000) found that the smell of colostrum increased the blood flow in the orbito-frontal cortex, but that the changes in blood oxygen saturation decreased after 5 days of age. As long as mothers do not change their diet abruptly, there is a consistency in the odor of colostrum and mature milk. Mothers who experience the greatest change in diet before and after birth have the greatest difficulty in establishing breastfeeding. It is thus evident that neonates retain their olfactory memories even if they do not have the opportunity to taste colostrum. In animal studies, rabbit kits raised by mothers fed different diets during pregnancy and lactation show a clear preference for the diet of their mother upon weaning (Bilkó et al. 1994). Litters of rat pups were exposed in utero to taste/odor stimulation through the injection of an apple juice solution into the amniotic fluid. The offspring exposed to the apple juice solution in utero showed an increased preference for apple postnatally (Smotherman 1982).

The mother's diet affects both the amniotic fluid and her breastmilk. More than 20 years ago, Hauser et al. reported the case of an infant that smelled of spices. The spices were absorbed from the maternal gastrointestinal tract and transferred to the amniotic fluid, where they were swallowed by the fetus (Hauser et al. 1984). Prenatal familiarization with the flavor of colostrum contributes to the establishment of breastfeeding. If mothers abruptly change their diet after delivery, infants experience difficulty in establishing breastfeeding due to the reduced degree of prenatal–postnatal olfactory continuity (Hepper 1996).

9.2.7 The Role of Odor of Amniotic Fluid in Parent–Neonate Attachment

Infant–mother bodily contact is believed to be the species-typical pattern of immediate postpartum child care. Mothers and newborns engage in mutually beneficial interactions. As described above, skin-to-skin contact and exposure to maternal odors facilitate infant adaptation to the early postnatal environment. Individual recognition is essential for the development of mother–infant attachment and olfactory cues play an important role in the development of this attachment. When infants touch or lick the areola and nipple shortly after delivery, their mothers make more of an effort not to leave their infants and they talk to them more than mothers whose infants did not initiate this areola or nipple touching or licking (Widström et al. 1987). The amniotic odor that diffuses in the delivery setting has not been explored as a part of the intimate experience of parturition, although it is often noted as being remarkable by midwives and obstetricians. Schaal and Marlier (1998) found that human parents are able to distinguish among the odors of amniotic fluid samples associated with different infants. The parents are also able to recognize the odor of their infant's amniotic fluid. Both parents are not only aware of an amniotic scent that diffuses into the delivery room, but they can accurately identify the olfactory signature carried in their own infant's amniotic fluids.

The similarity of the infant's amniotic fluid odor to their mother's odor is interesting and may be related to several determinants involving either environmental or genetic processes, or probably the interaction of both processes.

Various functional consequences of the perception of amniotic fluid odor may be hypothesized in human parenting: potential impact on the formation of the mother's first impression of the actual newborn; conscious or unconscious recognition of a kin odor from the very beginning, through either maternal recognition of self-odor cues on the infant or paternal recognition of maternal cues in the infant's odor; and promotion of rapid individualization of the infant and the resulting amplification of the parents' nurturing tendencies. The infant's amniotic fluid odor, together with all the other cues they emit, may contribute to the initial steps of the developmental dynamics of feelings of maternal and paternal attachment.

9.2.8 Preference to Breast Odor Is Genetically Obtained

The attractiveness of breast odor is also thought to be obtained in the prenatal period or genetically. Mizuno and Ueda (2004) examined full-term, healthy babies who had been completely separated from their mothers for a certain period postpartum. In this situation, it is possible to separate postnatal olfactory learning from genetically determined (or in utero acquired) preferences. They concluded that preferences for maternal odors acquired independently from postnatal experience have a

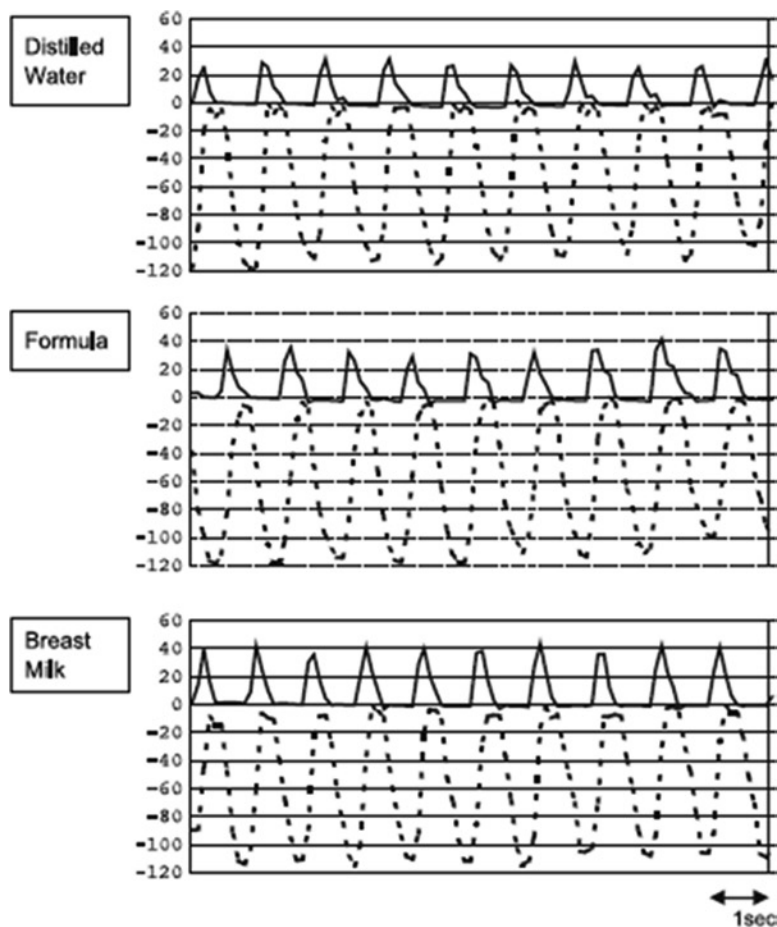
greater effect than postnatal olfactory learning on sucking activity even in the absence of triggering signals. Although the infants had been fed exclusively with formula before the study, they sucked more frequently and with higher expression pressure when exposed to their own mother's milk odor (Fig. 9.3). Sucking pressure did not change with the exposure, probably because the suction movement itself is to some extent determined involuntarily. The olfactory preference acquired in utero may persist for a longer time period. Porter and Winberg (1991) reported that 2-week-old, bottle-fed infants responded preferentially to a breast pad from an unfamiliar lactating woman when paired with a pad treated with their familiar formula. These infants displayed a preference for an odor to which they had no obvious postnatal exposure over an odor that they had encountered numerous times in the reinforcing context of feeding. Such attraction to maternal breast odors is presumably acquired independently from postnatal experience.


Fig. 9.3 Difference in sucking pressure waves between own mother's milk odor, formula odor, and no odor (Mizuno and Ueda 2004). Traces of sucking pressure waves obtained from the same infants. The solid line indicates expression pressure and the broken line indicates sucking pressure. With own mother's milk odor (lower trace), expression pressure and sucking frequency are higher compared to the formula (*middle*) or control (*upper trace*). Sucking pressure: negative intra-oral pressure which is generated during sucking behavior. Expression pressure: positive intra-oral pressure which is generated by compression between tongue and upper palate

9.3 Olfactory Learning Immediately After Birth

Recent physiological research suggests that norepinephrine plays an important role in early olfactory learning (Brennan et al. 1990; Sullivan 1992). Norepinephrine neurons in the locus coeruleus synapse with the olfactory bulbs and are, at least in rats and sheep, a prerequisite for learning specific odor cues. During the first hour after human birth, plasma levels of catecholamines are increased 20–30-fold as compared to measures from older infants (Lagercrantz 1996). Olfactory learning resulting from a brief period of exposure shortly after birth could be an important process through which neonates become acquainted with the salient features of their postnatal environment. Varendi et al. (2002) exposed infants to an odor (cherry or passion fruit) for 30 min shortly after birth. During tests conducted at 80 h of age, infants were exposed to the familiar odor and the novel odor. The infants spent more time turned toward the familiar odor than the novel one. From this result, it can be said that brief exposure immediately after birth appears to be sufficient for olfactory learning. Romanshik et al. (2007) recently demonstrated that neonates exposed to an odorant for 30 min beginning 4–37 min after birth rapidly became familiar with that olfactory stimulus and retained a memory trace of it over an interval of a couple days. Neonates exposed to the same odor at 12 h after birth, however, did not become familiar with the odor (Fig. 9.4). Newborn babies might be physiologically prepared to learn to recognize the olfactory signature of their mother while interacting with her during the first postnatal hours. Mother–infant skin-to-skin contact immediately after delivery could play an important role in infant learning of maternal odor.

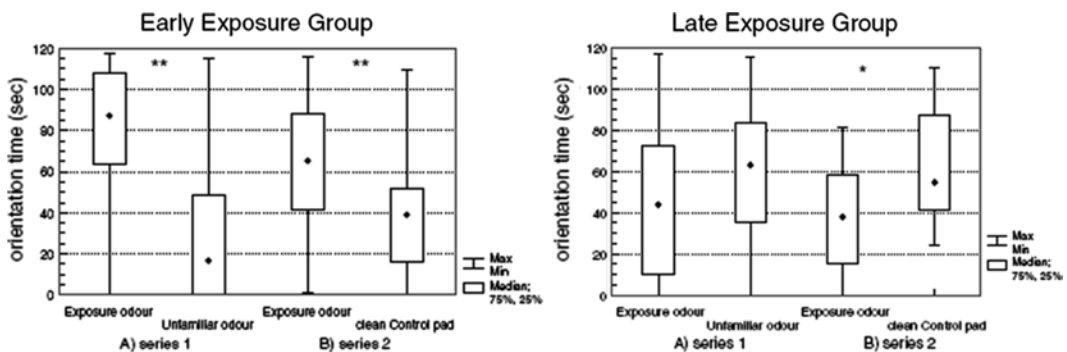
Neonates' sucking behavior and physical stimulation of the breasts within the first hour after birth induce short-term hormonal responses in the mother, including an increase in oxytocin levels (Widstrom et al. 1990; Matthiesen et al. 2001). Given the role of oxytocin in the onset of maternal behavior in nonhuman mammals such as ewes and rats (Pedersen 1997), various authors have speculated that this same hormone (and perhaps other endocrine substances) might also be implicated in the control of maternal responsiveness in humans (Uvnas-Moberg 1998; Numan and Insel 2003). Close contact between the mother and her newborn infant is the biological norm that has evolved in our species. When human birth takes place in a "natural" setting, the mother's odor is arguably the first biologically meaningful odor that confronts the newborn. Enhanced olfactory learning immediately after delivery could have a positive effect on attachment and on early mother–infant interactions and may thereby contribute to the infant's continued well-being.


Fig. 9.4 Duration of orientation to odor – early exposure and late exposure – (Romantshik et al. 2007). Early exposure group (*left column*): Duration of orientation to each of the paired stimulus odors by neonates exposed to the odor within 30 min. Late exposure group (*right column*): Duration of orientation to each of the paired stimulus odors by neonates exposed to the odor at 12 h postpartum. Behavioral evidence of efficient olfactory learning and memory was only found when exposure occurred immediately after birth

9.4 Olfactory Learning and Successful Breastfeeding

Skin-to-skin mother–infant contact immediately after birth is known to be beneficial to the neonate as it stabilizes body temperature, decreases stress and the risk of hypoglycemia, and is soothing. In addition, skin-to-skin contact for more than 30 min immediately after delivery results in the early identification of own mother's milk odor (Mizuno et al. 2004), which could lead to early individual discrimination. Enhanced discrimination between own mother's and another mother's milk odor leads to longer breastfeeding duration (Fig. 9.4), partly because individual discrimination plays a major role in creating a strong bond. Infants who experience mother–infant skin-to-skin contact are able to better identify their mother's breastmilk odor. Even for this short period, early infant touching of the mother's areola and nipple could enhance the mother–infant bond, although this short action does not result in longer breastfeeding duration (Fig. 9.5).

What length of time should we recommend that mothers hold their infants immediately after birth in order to extend breastfeeding duration? Mikiel-Kostyra et al. (2002) reported that the duration of skin-to-skin contact is important in the elongation of breastfeeding duration. Effective sucking may be a critical component of this intervention in regards to long-term breastfeeding success. Timing may be critical as most healthy full-term infants will spontaneously grasp the nipple and begin to suck by approximately 55 min post birth (Syfrett and Anderson 1996). In addition, breastfeeding while maintaining skin-to-skin contact stimulates hormones such as oxytocin, which promotes maternal attachment, and prolactin, which promotes lactation and maternal behavior. Extensive skin-to-skin contact immediately after birth promotes early mother–infant interaction and bonding (Kennell and Klaus 1998).
Fig. 9.5 Odor discrimination and breastfeeding duration (Mizuno et al. 2004). The relationship between odor discrimination and breastfeeding duration is shown. *Y* axis indicates breastfeeding duration (months); *X* axis indicates differences in mouthing movement while exposed to own mother's milk odor and another mother's milk odor
Fig. 9.6 Breastfeeding rate of infants with and without extensive skin-to-skin contact immediately after birth (Mizuno et al. 2004). The breastfeeding rate in groups is shown as a Kaplan–Meier curve. Group A comprises infants who experienced extensive skin-to-skin contact immediately after birth. Group B comprises infants who did not have skin-to-skin contact after birth. *X* axis indicates infant age (mo); *Y* axis indicates percentage of mothers who breastfeed their infants

The early identification of own mother's milk odor from another woman's milk odor may partially explain the early mother–infant interaction.

Schaal et al. reported that neonates can identify their own mother's odor at 3 days of age (Schaal et al. 1980). Mizuno et al. (2004) reported that infants can identify their own mother's breastmilk odor at 4 days of age. These findings could be explained by postnatal odor entrainment. Skin-to-skin contact with the mother immediately after birth creates an optimal environment for the adaptation of newborn infants to extrauterine life. During the early postpartum period, mothers may be especially open to improving their interactions with their infants, which can affect their later parenting (Curry 1982). Some studies indicate that it can also have a long-lasting effect on the duration of breastfeeding. There have been a few studies with a 1-year period of observation. de Château et al. (1984) followed 20 mothers who had extra contact with their infants during the first hour postpartum. They breastfed on average for 2.5 months longer than mothers in the control group. Mikiel-Kostyra et al. studied a group of 1,250 Polish children by the questionnaire method at 3 years of age and concluded that skin-to-skin contact and maternal education were two independent variables that positively influenced the duration of exclusive breastfeeding (Mikiel-Kostyra et al. 2002). In conclusion, prolonged skin-to-skin mother–infant contact immediately after birth is beneficial as it aids in the early identification of mother's odor and leads to a longer breastfeeding duration (Fig. 9.6).

9.5 After Birth: Classical Conditioning – Olfactory Learning of a Novel odor

In animals, in addition to the natural body odor of the mother, artificial odors have been shown to operate as olfactory signals. In addition to classical conditioning, the mere exposure of mother's odor is sufficient for infants to learn their mother's identifying odor.

Sullivan et al. (1991) studied an olfactory classical conditioning procedure in 1-day-old neonates. They gave ten 30-s pairings of a novel olfactory conditioned stimulus (a citrus odor) and tactile stimulation in the form of stroking as the reinforcing unconditioned stimulus. Infants who received

the forward pairings of the odor and stroking exhibited conditioned responses to the citrus odor. From these findings, they concluded that complex associative olfactory learning is seen in neonates within the first 48 h of life.

Engen and Lipsitt (1963) demonstrated that neonates respond to artificial odors presented to them with changes in activity and respiration.

Balogh and Porter (1986) perfumed the beds of newborn for 24 h and were able to show that girls preferred this odor in a choice test given an hour after they were removed from the perfumed bed.

Schleidt and Genzel (1990) found that neonates are able to recognize their own mother's body odors and orient toward them. Infants recognize perfume applied to their own mother's bodies. In this study, breastfeeding mothers perfumed their breasts for 2 weeks and their infants were then tested in a choice test situation. At the age of 1 week, infants oriented their heads significantly more often to the side where they smelled their mother's perfume than to the side where they smelled a control odor.

Davis and Porter (1991) exposed an artificial odorant for 22 h to neonates within the first 2 days after birth. When tested on days 16–18 postpartum, these infants displayed preferential orientation to the exposure odor when paired with a novel odorant. It is thus evident that the effects of early exposure of the stimulus properties of odors can endure over a 2-week interval, indicating that infants retain a memory trace of the exposure odor throughout that time period.

Infants evidently learn very quickly to associate odors with other stimuli if both are experienced in important situations – the most important infant situation of all being close body contact with the mother.

9.6 Olfactory Learning Through the Odor of Breastmilk

Human milk is more than just a complex mixture of substances that best meets the nutritional requirements of the infant. It is a food that varies in flavor because selected volatiles from the mother's diet are transmitted to her milk. Mennella et al. have conducted very interesting research in this area. When human milk is flavored with garlic, infants breastfeed longer and suck more overall than when this flavor is absent, at least under conditions in which the mothers have been ingesting bland diets for several days (Mennella and Beauchamp 1991). Several hypotheses can be put forth to account for this increased responsiveness. The change to garlic-flavored milk may act as a sucking stimulant, a phenomenon similar to that observed in adults when a change in the type and flavor of available foods stimulates intake.

Mennella et al. then examined how infants who had experienced the odor of garlic previously reacted to the odor. Prior and repeated consumption of garlic by nursing mothers modified infant behavior during breastfeeding when the mothers again consumed garlic (Mennella and Beauchamp 1993). Infants of mothers who had repeatedly consumed garlic capsules during the experimental period breastfed for similar periods of time during the 4-h test session in which their mothers consumed garlic (d 11) compared with the session in which their mothers ingested the placebo (d 4). In contrast, infants who had no or minimal exposure to garlic volatiles in their mother's milk during the experimental period spent more time breastfeeding when their mothers ingested garlic than when their mothers ingested the placebo. The garlic flavor became unstimulating to infants who were repeatedly exposed to it in mother's milk. Continued or repeated exposure to an odor results in a relatively rapid suppression of its perceived intensity, presumably because the olfactory receptors have fatigued (Rovee 1972; Todrank et al. 1991).

Studies on other animals (Capretta et al. 1975) suggest that experience with a variety of flavors during breastfeeding, in contrast to the invariant flavor experience of formula feeding, could increase infant willingness to accept a variety of flavors. Breastfed infants consume more of a novel vegetable than formula-fed infants (Sullivan 1992). Besides garlic, a wide variety of flavors (e.g., alcohol, mint, and cheese) ingested by the lactating mother are transmitted to her milk. Whether exposure to these flavors in mother's milk affects the infant's later preferences, development of food habits, and willingness to accept new foods at weaning or thereafter remains an important research area.

The amount of alcohol ingested by a breastfed infant is a small fraction of that consumed by the mother, but even this small amount may have an effect on the infant. The ingestion of alcohol by a lactating woman alters the odor of her milk (Mennella and Beauchamp 1991) Infants suck more frequently during the first minute of feeding after their mothers consume alcohol. The changes in the odor over time are consistent with the changing concentrations of ethanol in the milk. From this finding, it is evident that the breastfed infant may be receiving sensory information about the mother's dietary choices. In nonhuman animals, early and long-term exposure to flavors in the mother's milk affects later flavor preferences (Galef and Henderson 1972, Galef and Sherry 1973; Capretta et al. 1975; Campbell 1976), including that for alcohol (Mainardi et al. 1989).

9.7 Applications to Other Areas of Diet and Behavior

One possibility is to use favorable odors as a treatment for neonates. Marlier et al. demonstrated that the introduction of a pleasant odor in the incubator is of therapeutic value in the treatment of apneas in preterm infants (Marlier et al. 2005).

The human infant, like other mammalian young, has the opportunity to learn about the food choices of the mother because a variety of flavors from her diet are transmitted to human milk (Sullivan 1992). Studies on other animals indicate that this early exposure to characteristics of the mother's diet influences the weanling's responses to flavors and foods. Similar effects have been postulated but not proven for humans. Currently, many researchers are examining dietary factors in the hopes of preventing children from becoming overweight or having metabolic syndrome (Beauchamp and Mennella 2009). Determining if maternal diet during pregnancy and lactation affects the weaning process and later dietary preferences of children should be a priority. I expect that one of keys to decreasing pediatric obesity and metabolic syndrome is a healthy maternal diet, extended breastfeeding, and strong maternal–infant attachment resulting from olfactory learning.

Summary Points

- Fetuses have olfactory memory.
- Maternal diet influences the odor of the amniotic fluid and breastmilk.
- Amniotic fluid supports the neonate in adapting to the world.
- Olfactory preferences change over time after birth.
- Olfactory learning immediately after birth results in earlier discrimination of mother's odor.
- Olfactory learning immediately after birth results in longer breastfeeding duration.
- Neonates/infants become accustomed to different kinds of odors through breastmilk.

Definition of Key Terms

Amniotic fluid: Liquid surrounding the fetus in the womb.

Colostrum: Breastmilk secreted up to 3 days postpartum.

Montgomery glands: Sebaceous glands on the areola of the nipple that emit secretions composed of milk mingled with sebum

Oxytocin: A hormone that plays a key role in milk ejection and promotes maternal attachment.

Olfaction: The sense of smell.

Skin-to-skin contact: Here, refers to mother–neonate skin-to-skin contact immediately after birth.

Abbreviations

CCK   Cholecystokinin
GLP-1   Glucagon-like peptide 1
PYY   Peptide YY

10.1 Introduction

Overweight and obesity are caused by an imbalance between energy intake and energy expenditure. Some of the food factors associated with this imbalance are energy-dense diets (Rolls 2009) and an increased consumption of energy-yielding beverages (Mattes 2006). Therefore, insight in factors influencing food intake is warranted. Food intake is regulated by cognitive, sensory, post-ingestive, and post-absorptive processes. Blundell and coworkers (see, e.g., Blundell et al. 1994) refer to these processes as the satiety cascade (Fig. 10.1). The terms "satiation" and "satiety" mentioned in this cascade will be explained later.

There is a need for food products that help to lower or maintain body weight. Food properties that increase the process of satiation (meal termination) and/or induce longer-term feelings of satiety (increase the intermeal interval) may help to control weight. The satiating capacity of a certain food depends on food properties like macronutrient composition, energy density, fiber, and volume. This chapter focuses on the role of food texture in food intake regulation. Texture is one of the food characteristics that is supposed to play mainly a sensory or cognitive role.

10.2 Texture Perception

Szczesniak (2002) defines texture as "the sensory and functional manifestation of the structural, mechanical, and surface properties of foods detected through the senses of vision, hearing, touch, and kinesthetics." Texture is an essential part of the whole spectrum of sensory properties of a food.

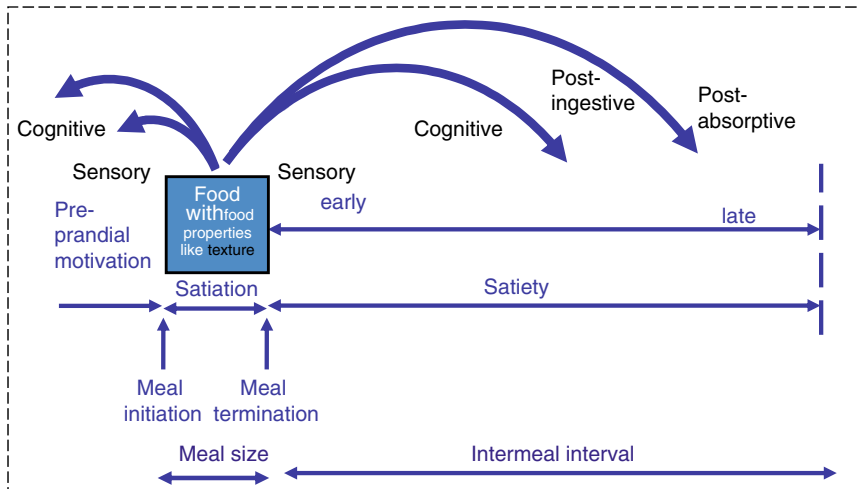
e-mail: annette.stafleu@tno.nl


Fig. 10.1 Satiety cascade (Adapted from Blundell et al. 1994). The satiety cascade of Blundell is used often to illustrate processes involved in food intake regulation

During sensory perception of food, people use all their senses of which vision, hearing, touch, smell, and taste are the most important (Van Vliet et al. 2009). During eating, texture plays a role in: (1) initial perception during the first bite, (2) masticating factors during chewing, and (3) changes induced during mastication and swallowing, such as rate of breakdown of the food, moisture absorption, and oral coating (Van Vliet et al. 2009).

10.3 Mastication

Mastication can be defined as the process by which food taken into the mouth is converted into a form suitable for swallowing (Szczesniak 2002). During this process, the food is also assessed for palatability and a decision is made as to whether to swallow or reject it. There are basic biomechanical constraints that determine the duration and amount of oral processing prior to swallowing. In the oral cavity, food is subjected to several mechanical and chemical processes. Solid food is fragmented by the teeth, diluted and broken down by saliva, heated or cooled by the temperature of the mouth, formed into a soft, coherent bolus, and finally swallowed (Hutchings and Lillford 1988; Prinz and Lucas 1997; Van der Bilt et al. 2006). Hardness is known to influence the masticatory process. Dry and hard products require more chewing cycles and therefore more time is needed to break down the food and to add enough saliva to form a bolus suitable for swallowing (Van der Bilt et al. 2006). Low-viscosity liquids are already in a form suitable for swallowing and require minimal processing.

10.4 Satiation and Satiety

In order to understand the effects of texture on food intake, it is important to distinguish between satiation and satiety (see Rogers and Blundell 1979 Blundell et al. 1994) and how they are measured (see Table 10.1). Apart from other reasons such as eating out of boredom or specific social contexts, we start eating when we get hungry and stop when we are full. Satiation is the process that determines

when we stop eating, and therefore determines meal size. Satiation is mainly driven by early processes (<20 min), such as sensory, cognitive, and early pre-absorptive factors. Satiation may be measured by ad libitum food intake of a meal. Satiety is the process which suppresses the internal drive to eat (appetite). Satiety can be quantified by measuring the intermeal-interval. In both satiety and satiation studies rating scales are used to assess appetite. Most investigators use the terminology developed by Rogers and Blundell (1979): hunger, desire to eat, prospective consumption, and fullness (Fig. 10.2). Further, gastric emptying and level of gastrointestinal hormones (such as Ghrelin, CCK, PYY, GLP-1) are used in food intake regulation studies to study the mechanism (gastrointestinal processing) behind the effect (De Graaf et al. 2004). To study the effect of texture on satiation and satiety different approaches have been used. Most studies used a preload-test meal design (see Fig. 10.3). In these kinds of studies, a fixed amount of foods different in texture is given and the amount eaten in the test meal is the primary outcome measurement. Other studies are primarily interested in meal termination. In these studies, foods different in texture are offered in abundance and ad libitum intake of these foods (meal size) is the primary outcome measurement (see Fig. 10.4).

Table 10.1 Key points or features of satiety and satiation

	Features	Measurements
Satiation	Meal termination	Ad libitum intake
		Appetite ratings
		Stomach distension
		CCK, GLP-1
Satiety	Intermeal interval	Preload-test meal
		Appetite ratings
		Spontaneous next eating event
		Stomach emptying
		Glucose, Insulin
		Ghrelin

This table describes the features of satiation and satiety and the measurements used in satiation and satiety research *CCK* cholecystokinin; *GLP-1* glucagon-like peptide 1; *PYY* peptide YYFor biomarkers of satiation and satiety, see De Graaf et al. (2004)

How hungry are you?

Not hungry
at all   Extremely
                                                                                     hungry
Fig. 10.2 In both satiety and satiation studies rating scales are used to assess appetite (hunger, desire to eat, prospective consumption and fullness (Rogers and Blundell 1979)). This is an example of a visual analogue scale: subjects are asked to indicate their feeling of hunger by placing a vertical line on the scale

Preload-test meal design	Appetite ratings	Fixed amount of foods with different textures (*preload*)	*Ad libitum* test meal *(test meal)*	Appetite ratings

Fig. 10.3 Example of a design in which textures differences were tested in a preload-test meal design

Ad libitum intake design	Appetite ratings	*Ad libitum* consumption of foods with different textures	Appetite ratings

Fig. 10.4 Example of a design in which foods with different textures were offered *ad libitum*

10.5 Liquids

Beverages have become a significant source of dietary energy (Bleich et al. 2009). Several studies showed that liquid foods elicit weaker suppressive appetite responses (Haber et al. 1977; Hulshof et al. 1993; Mattes and Rothacker 2001; Tsuchiya et al. 2006) and a weaker compensatory response in energy intake than solid or semisolid foods (Tournier and Louis-Sylvestre 1991; Mattes 1996; DiMeglio and Mattes 2000; Mourao et al. 2007). This effect is not only apparent in short-term preloads studies, but is also observed in longer-term intervention studies (De Castro 1993; Tordoff and Alleva 1990). Soups seem to be an exception: for example in a study by Mattes (2005) soups led to reductions of hunger and increases of fullness that were comparable to solid foods.

The evidence of a weak satiety value of energy-yielding beverages is strongest for clear beverages (Mattes 2006). Rolls (2009) hypothesized that beverages composed of few nutrients, such as sugary drinks, fail to engage hunger mechanisms and are recognized as beverages that influence thirst. In a 7-day period observational study McKiernan et al. (2009) could not find an association between thirst or hunger and the ingestion of energy-yielding beverages. Perhaps the human appetite system is not well equipped to sense liquid calories (Zijlstra et al. 2008; Wolf et al. 2008).

10.6 Viscosity

Viscosity refers to the thickness of a food.

10.6.1 Ad Libitum Intake

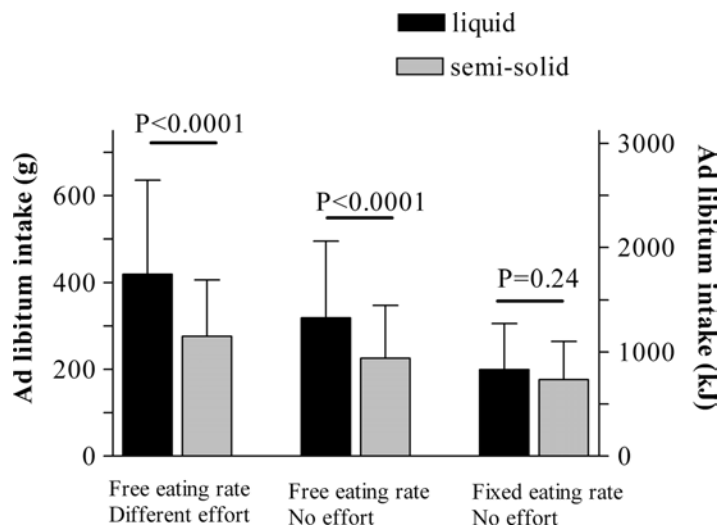
Zijlstra et al. (2008) showed that chocolate-flavored milk-based foods differing in viscosity (starch modification) led to clear differences in ad libitum intake, both in a realistic setting in a cinema and in a laboratory setting. Ad libitum intake decreased as viscosity increased. This effect of viscosity on intake could not be attributed to palatability, macronutrient composition, and energy density or volume. However, it was possible that eating rate or effort needed to consume the product influences meal termination. In the laboratory setting effort and eating rate were controlled for by means of a peristaltic pump. The difference in intake could be partially explained by the higher eating rate of liquids, while effort did not have an effect (for more details see Fig. 10.5). The effect of viscosity on ad libitum intake was replicated in several other studies (De Wijk et al. 2008; Mars et al. 2009).


Fig. 10.5 The tested products in this study were chocolate dairy products with different viscosities: a liquid product (milk like) and a semi-solid product (custard like). The products were equal with respect to liking, energy density and nutrient composition. Difference in mean intake of the liquid and semi-solid food was comparable to that of another study in a realistic setting (cinema) (~34%). This difference was hardly affected by controlling for effort (~29%). However, the difference in mean intake of the liquid and semi-solid food was much lower when controlled for eating rate (~14%). Zijlstra et al. (Inter J Obes 2008;32:676–683)

10.6.2 Fixed Preload

Mattes and Rothacker (2001) studied the influence of viscosity on appetitive responses. The used shakes differed in viscosity, but were similar in weight, volume, temperature, energy, and macronutrient content, energy density, rate of consumption, cognitive expectations, palatability, appearance, and requirements for mechanical processing. Significantly greater and more prolonged reductions of hunger scores were observed with the thicker shakes. No differences were found in the size or time to first meal or 24-h energy intake. Russell and Delahunty (2004) did not find an effect of viscosity of a fixed amount of rice milk on hunger scores and time to lunch.

Zijlstra et al. (2009a) explored the effect of viscosity of chocolate-flavored liquid and semi-solid milk-based products on the gastrointestinal hormones ghrelin, CCK, and GLP-1. Subjects were offered a fixed amount of these products and several blood samples were drawn. After 90 min subjects were offered a chocolate cake to consume ad libitum. Although the appetite ratings showed that the semisolid product was apparently more satiating than the liquid product, no clear effects of viscosity on the gastrointestinal hormones or on the ad libitum intake of the cake were found.

Vuksan et al. (2009) showed that a highly viscous polysaccharide preload led to a reduced intake of pizza 90 min later, compared to a medium- and low-viscosity fiber preload. No differences were found in appetite scores and 24-h intake. The drinks were identical in taste, appearance, caloric, and macronutrient content. The only difference was the viscosity of the fiber, which developed in different viscosities in the gastrointestinal tract. Therefore, effects seem to occur beyond the mouth and therefore sensory (texture) perception does not seem to play an important role in this study.

Juvonen et al. (2009) examined the effects of modified oat bran on sensations of appetite and satiety-related gastrointestinal hormone responses. The oat bran beverage with low viscosity induced a greater postprandial increase in satiety and plasma glucose, insulin, CCK, GLP-1, and PYY, and a greater decrease in postprandial ghrelin than the beverage with high-viscosity oat bran. This does not fit in the hypothesis that satiety increases when viscosity increases. An explanation might be the earlier availability of fiber in the gastrointestinal tract due to a faster gastric emptying after the low-viscosity oat bran beverage consumption.

10.7 Food Form

In an early study of Haber et al. (1977), subjects had to consume a fixed amount of apples, apple purée, or apple juice. The apple juice was consumed more than ten times faster than the apple and nearly three times faster than the purée. In a study of Mattes and Cambell (2009) subjects consumed 300 kcal loads of apple (solid), applesauce (semisolid), and apple juice (beverage) at a meal or as a snack. The apple juice showed the weakest appetitive response, followed by the applesauce, while the apples (solid) elicited the highest appetitive response. The interval between test food consumption and the spontaneous next eating event of more than 100 kcal was shortest for the beverage. Also Flood-Obbagy and Rolls (2009) studied the effect of apples in different forms and their results suggested also that solid fruits affect satiety more than pureed fruit or juice. The consumption of the apples was followed by an ad libitum lunch. Fullness rating differed after the preload consumption in the order: apple > applesauce > juices > control. Total lunch energy intake (including the preload) was reduced after eating the apple (solid) as preload.

Mourao et al. (2007) studied the effect of food form on appetite and energy intake in matched beverage and solid food forms. They compared watermelon and watermelon juice (high carbohydrate), cheese and milk (high protein), and coconut meat and coconut milk (high fat). In all cases, the beverage food form elicited a weaker compensatory dietary response than the matched solid food form. Total energy intake was 12–19% higher on the beverage days compared to the solid food days, which was due more to a weak effect on satiety than on satiation.

Not all studies showed an effect in the same direction. Santangelo et al. (1998) reported that meal consistency influences both gastric emptying rate and satiety sensation. In their study a homogenized vegetable-rich meal was found to be more satiating than when the meal was offered in clearly separated solid and liquid components. The overall gastric emptying rate was slowed after the homogenized meal (followed by a CCK peak later).

Flood and Rolls (2007) investigated meal intake after consuming preloads of different soups with the same energy density: broth and vegetables served separately, chunky vegetable soup, chunky-pureed vegetable soup, and pureed vegetable soup. Subjects consumed less of the test food after eating the soup compared to no soup, but the type of soup did not significantly influence test meal intake.

10.8 Mechanism

The mechanisms underlying the effect of texture on satiety are not well understood. Physical properties such as viscosity and texture could affect chewing, oro-gastric handling of foods, and absorption (Rolls 2009).

Chewing solid foods may give a satiety signal, which is not induced by swallowing a liquid (Haber et al. 1977; Mattes 1996; Rolls 2009). From a recent paper by Cassady et al. (2009) it was concluded that masticating nuts, and likely other foods and nutrients, results in important differences in appetitive and physiologic responses.

10.8.1 Cognitive and Sensory Factors

Cognitive and sensory factors could play a role in the effect of food form on satiety. People might have different beliefs about the satiating capacity of solid foods compared to beverages. Expected satiation might influence portion sizes (Brunstrom and Shakeshaft 2009). It may be that the mechanisms through which texture affects food intake work through differences in perception due to differences in oral processing. Also the satiating capacity of soups is thought to be in part cognitive: a soup is believed to be nutritive and impacts appetite more than thirst (Mattes 2006).

Eating rates of liquid foods are higher than eating rates of (semi-)solid foods (Haber et al. 1977; Kissileff et al. 1980; Zijlstra et al. 2008). Based on the study of Zijlstra et al. (2008) it may be hypothesized that the mechanisms through which texture affects food intake works through a higher/ longer sensory exposure time and/or a longer transit time of the product in the oral cavity. A liquid remains a short period in the mouth, while a semisolid product is eaten more slowly and thus stays longer in the mouth. This increases the exposure time to sensory receptors in the oral cavity and therefore there is more opportunity for exposure to taste, smell, texture, and so on (Zijlstra et al. 2008). It is shown that bite size and oral processing indeed affect ad libitum food intake of a semi-solid product (Zijlstra et al. 2009b). Also, smaller food sizes (nibbles versus bars) resulted in lower intake (Weijzen et al. 2008) and small sip sizes reduced the ad libitum intake of soft drinks compared to large sip sizes (Weijzen et al. 2009).

A factor that plays a role in the termination of food intake is the degree of sensory-specific satiety for that food. This refers to a decrease in the reward derived from consumption for the food eaten compared to a not eaten food (see, e.g., Rolls et al. 1981). For example, after consumption of a plate of macaroni, one's pleasure for macaroni is decreased, while the pleasure of custard remains the same or increases. Foods may differ in their degree of sensory-specific satiety. For some foods, the pleasure derived from consumption will decline sooner than for others. Texture-specific satiety might play a role in meal termination. Guinard and Brun (1998) showed that pleasantness of texture, and desire to eat hard test foods decreased after eating a hard lunch food. This might also have played a role in the study of Weenen et al. (2005). They suggested that eating cheese biscuits might have given rise to a higher degree of boredom than eating pears in light syrup, caused by the dryness and thus amount of saliva required to form a bolus that can be swallowed.

10.8.2 Gastrointestinal Processes

Gastrointestinal processing can partly explain the effect of viscosity on intake. Soluble dietary fiber may alter viscosity of gastrointestinal contents and this may result in effects on satiety and food intake (Dikeman and Fahey 2006). Juvonen et al. (2009) did find an effect of bran viscosity on gastric empty-ing and an effect on satiety hormones. Also Santangelo et al. (1998) found effects of physical state of a meal on gastric emptying and CCK release. An effect of viscosity on satiety hormones could not be found in the study of Zijlstra et al. (2009a). An explanation might be that the starch used by Zijlstra et al. (2009a) was already broken down to glucose by enzymes in saliva before it reached the stomach. The mechanism of how viscosity, gastric emptying, and satiety interact is not clear yet. Tieken et al. (2007) examined whether solid meal-replacement products differed from liquid meal-replacement products in appetite and appetite-regulating hormones. They did find differences in appetitive responses, insulin and ghrelin, but not in CCK and leptin, between the products. However, as the authors mentioned, although the products had a similar energy content, the macronutrient composi-tions differed, which might have affected the appetite and hormonal responses.

10.8.3 Learned Associations

Zijlstra et al. (2008) suggest that differences in satiety responses between liquids and solids are partly based on learned behavior during infancy. Since the viscosity and caloric density of human breast milk appear to vary together, breast feeding may provide an important initial exposure to a general rule that thicker substances contain more calories than thinner substances (McDaniel et al. 1989; Davidson and Swithers 2004). This indicates that the mouth feel of a product already could have an effect on the relationship between viscosity and intake. Mars et al. (2009) indicated that the higher viscosity of a food, and thus the longer orosensory stimulation, may facilitate the learned association between sensory signals and metabolic consequences. However, current trends in eating patterns and food supply (high energy drinks and low-energy solids) may alter learned associations between hunger or thirst and the post-ingestive consequences of eating and drinking (McKiernan et al. 2008).

10.9 Conclusions

Most studies on the effect of food form on satiety compared liquids with a solid form. From these studies it appeared that liquids are less satiating than solids. In addition, there seems to be an independent role of viscosity on satiation. More research is necessary to study textures with less pronounced differences than liquid versus solid foods, for example, the effects of texture differences within solid products. Also, the gastric role in food texture warrants further investigation.

10.10 Applications to Other Areas of Health and Disease

Several studies showed that viscosity and texture differences influence satiation (meal termination) and to a lesser extent satiety. Consumption of an energy-yielding beverage poses a greater risk for consuming more energy than a semisolid or solid food. From a review of Malik et al. (2006) it appeared that both short-term and long-term studies have shown that energy ingested from sugar-sweetened beverages add to the total energy intake during the day. Liquid calories may lead to a positive energy balance and subsequent weight gain (DiMeglio and Mattes 2000). This knowledge can be applied both in the underweight and overweight situation.

Summary Points

- Food properties that increase the process of satiation (meal termination) and/or induce longer-term feelings of satiety (increase the intermeal interval) may help to control weight.
- Liquid foods elicit weaker suppressive appetite responses and a weaker compensatory response in energy intake than semisolid foods or solid foods.
- Ad libitum intake of foods decreases as viscosity increases.
- The mechanisms underlying the effect of texture on satiation and satiety are not well understood.
- It may be hypothesized that the mechanisms through which texture affects food intake work through a higher/longer sensory exposure time and/or a longer transit time of the product in the oral cavity.

Definitions of Key Terms

Mastication: The process by which food taken into the mouth is converted into a form suitable for swallowing.

Satiation: The process that determines when we stop eating, and therefore determines meal size.

Satiety: The process that suppresses the internal drive to eat (appetite).

Sensory-specific satiety: The decrease in pleasantness of a product after eating that product to satiety, compared to the pleasantness of selected uneaten control products.

Texture: The sensory and functional manifestation of the structural, mechanical, and surface properties of foods detected through the senses of vision, hearing, touch, and kinesthetics.

For definitions see Rogers and Blundell (1979), Rolls et al. (1981), Szczesniak (2002).

11.1 Introduction

Eating is one of the most common actions in everyday life. What about tasting food? Is there any such thing as sensory education or educating the sense of taste? We shall take the example of one country, France – well known for its culinary culture – to see what factors implicitly or explicitly

C. Reverdy (✉)

construct our sense of taste. Then we shall see how explicit sensory education at school could change eating preferences and behavior. And finally, we shall compare sensory education to other forms of education and lay out the prospects of this method.

11.2 Can the Sense of Taste Be Educated?

11.2.1 Learning in Life

As with other omnivores, human eating preferences and habits are mainly learned. Learning varies with the particular food culture, but the general mechanisms are comparable.

Children's tastes are influenced by their mother's feeding habits, first of all by straightforward conditioning in the womb (Schaal et al. 2000), and then via the mother's milk and gradual diversification of diet (Maier et al. 2006). Later, they are shaped by what is eaten at family meals, then in playgroups and at school meals. To pure conditioning are thus added mechanisms such as incident and non-intentional learning by simple exposure to new foodstuffs (Zajonc 1968; Pliner et al. 1993), parental teaching, whether to encourage or to discourage (Birch 1980; Hanse 1994), and imitation of peer behavior (Birch 1980). With the exception of parental teaching, these mechanisms influence behavior in an implicit way, without reaching the cognitive level and without the child being conscious of them. Thus the variety of culinary experience stimulates the development of preferences more or less positively depending on the atmosphere of the feeding situation and on the individual's own olfacto-gustatory sensitivity.

This process develops and enriches sensory experience in terms of what flavors are known. The range of sensory experiences thus depends on circumstances, but also on individual personality (Pliner and Salvy 2006), as in neophobia – where the individual is afraid to try foods that are new to him or her (Loewen and Pliner 1999).

Children are dependent on what foodstuffs they happen to be given; teenagers, on the other hand, become more independent and make their own choices. They can get past their neophobia and extend their sensory experience. This then stabilizes in adulthood, in the encounter with the partner's eating habits, and then those adopted by the couple (Köster 1990).

Simple exposure (Zajonc 1968) to traditional foodstuffs and learning mechanisms (i.e., culture) strongly influence the development of preferences; other mechanisms determine the orientation and dynamics of preference. These influences are the subject of the psychology of exploratory behavior and motivation (Dember and Earl 1957; Berlyne 1970; Walker 1980) and are shown schematically in Fig. 11.1.

Berlyne (1970) explained how a stimulated organism expresses maximal preference for an optimal stimulus activation level, preference being lesser for any other stimulus level. Dember and Earl (1957) further showed how the optimal level changes after exposure to stimuli that are more stimulating than the individual's previous optimum level (pacer): the optimum shifts toward the level of the more stimulating stimuli. Exposure to stimuli that are less stimulating than the optimal level, on the other hand, do not alter the optimum but rather lead to boredom, as predicted by Walker (1980). These theories, based on visual stimuli, have been confirmed using olfacto-gustatory stimuli (fruity drinks) (Lévy et al. 2006). Walker (1980) showed that stimulus complexity as perceived by the subject decreases with exposure – which would explain why novelties at first seem too complex but then come to be more appreciated with time; with yet more exposure, they begin to lose their perceived complexity and may become commonplace.
Fig. 11.1 Inverted-U relationship between liking and the arousal potential of a stimulus, as suggested by Berlyne's (1967) arousal theory (*solid curve*), and the shift (*broken curve*) of the original inverted-U curve and the optimal individual level of psychological complexity upon exposure to a "Pacer" (B), as suggested by the arousal theories of Dember and Earl (1957) and Berlyne (1967) (From Lévy et al. 2006). Liking changes with perceived complexity depending on the optimum of the individual

This phenomenon, known as *product boredom*, is well known in marketing (Köster and Mojet 2007).

Thus, taste can evolve under various mechanisms and according to experience. Food preferences are flexible and subject to mainly implicit learning. The question therefore arises as to whether food preferences might also be modifiable over a shorter term by explicit learning such as sensory education.

11.2.2   What Is Sensory Education?

11.2.2.1   Definition

Sensory education develops the senses by focusing attention on them.
The sense of taste is developed by information regarding taste perception (which involves all five senses: taste, smell, touch, sight, and hearing) and by practical training to enhance sensory acuity.

Sensory education is to be distinguished from sensory training. The former concerns the sense of taste in general and is intended for nonexpert consumers, whereas the latter applies to a particular type of foodstuff and is intended for expert analysts.

11.2.2.2   Examples of Sensory Education

Encouraging children to explore their bodies is not a new idea. As early as 1930, Rampillon & Gruyer-Wantrin already explained that "young children should learn to use their senses, just as they need to learn to acquire other skills".

In France, many nonprofit organizations, such as *Agropolis-Museum*, *Pomme et Sens*, and (the oldest) the *Institut du Gout*, work in schools and playgroups, running taste education sessions, with a hedonistic approach, developing the pleasure associated with tasting.

The *Institut du Goût* (*Taste Institute*) introduces teachers to the *Classes du Goût* (*Taste Classes*) method developed in France by Jacques Puisais in the 1970s. This learning method, aimed at children around the age of 9, seeks to develop food curiosity, refine taste, and enrich food vocabulary. In 2001, Daviet explained the three main lines of this method: the first is "knowledge of the senses, balanced diet, production of some foods, and vocabulary enrichment"; the second is "know-how – for example, how to compose meals and menus"; the third is "self-awareness of the body and of sensations". The first version of the module, in 10 sessions, came out in 1984, after more than 10 years of trials and prototypes run in schools in Tours and Paris (Puisais and Pierre 1987; Puisais 1999). It was then applied in schools in many regions of France, for more than 20 years. For example, the method is used by the association *Les Sens du Goût* (*Senses of Taste*), from the Avesnois region, which runs a comprehensive, permanent, and extensive program of developing and education of taste in the local area. In particular, the association runs information, education, and training campaigns for the population as a whole, to raise awareness of local identity and the sense of belonging to a specific area (Pautrel 2002). Subsequently, the creation of the *Institut du Goût* in 1999 gave the method a new lease of life, while respecting its original nature. Thus, in 2002, a CD-ROM[1] (Puisais et al. 2002) presented a second version, in 12 sessions. Transmission to teachers is based not only on the CD-ROM, but also by training courses run by the *Institut du Goût*. In recent years, this French teaching method has been translated and adapted for other European countries (Sweden, The Netherlands, Finland).

Thus, the transmission of taste education is now developing in research programs such as Sapere. This program, set up in 1994, is based in Brussels. Sapere – from the Latin for both knowledge and taste – began as an international association and went on to become an international non-profit-making foundation. It brings together experts from the human sciences, research, industry, and the education and communication sectors. Its partners include many celebrities, scientific institutes, corporations, and associations such as EPODE (*Ensemble Prevenons l'Obésité Des Enfants*: Preventing Childhood Obesity Together). Since its inception, Sapere has promoted Jacques Puisais's method throughout Europe – for instance, in the Scandinavian countries (Jonsson et al. 2005). In other countries (The Netherlands, Switzerland), the focus has been on implicit methods for 6–9 year olds.

This type of sensory education for healthy children is quite recent. Sensory education also exists as a form of therapy.

11.2.3 Application to Other Areas of Health and Disease

11.2.3.1 Obesity and Sensoriality

Sensory education of taste can further be expected to improve food habits and therefore help to limit overweight and the prevalence of obesity. The new generation of dietary education (e.g., EPODE) encourages adding a sensory dimension in their programs, with tastings and cooking. Nevertheless, it must be stressed that the effect of sensoriality on limiting overweight and obesity is quite indirect and needs further investigation to be proven.

---

[1] This program is only available in the form of a compact disc – read only memory.

11.2.3.2 Disability and Sensoriality

General sensory education, not specifically targeting taste, has been extended to work with disabled (blind, deaf) children. In France, Patty Canac, a perfume specialist, runs rehabilitation for cranial trauma, cerebral hemorrhage, and prolonged coma victims. She helps these patients find a taste for life again, using olfactory stimulation to awaken memory by the pleasure of playful learning (Canac et al. 2008).

11.3 What Factors Educate Our Sense of Taste?

11.3.1 Culture

It is well known that food preferences are linked to exposure to a given foodstuff (Wardle et al. 2003) and that we tend to consume the food that is part of our particular culinary culture. We are thus conditioned to appreciate more highly the foodstuffs of our own culture.

11.3.2 Family

Food education within the family involves exposure to foods: children are encouraged to *taste*. The parents play a role and may reinforce neophobia to a greater or lesser extent, whether directly or by showing a strong emotional reaction to their children's not eating (Hanse, l994). Such parental pressure and restriction regarding food are measurable on the Kids' Child Feeding Questionnaire (KCFQ) (Carper et al. 2000).

11.3.3 School Meals

Half of French children take lunch at school (Stratégies 2006). This plays a role in their food education. However, it amounts to only a small number of their annual meals and cannot in itself ensure balanced diet. The elementary taste education provided at school is regulated by the French Education Ministry's *Le Bulletin Officiel* (2001), which encouraged diversity of diet and the development of taste. It is also suggested the following main lines of activities around the issue of food (see Table 11.1).

These recommendations advise providing children with explicit information, but also enriching their implicit experience via tastings and education concerning odors and spices.

Table 11.1 Key points of the main lines suggested by the French Ministry of Education (2001) for activities around the issue of food

1. "Educating pupils' taste and promoting culinary heritage and products of good gustatory and nutritional quality
2. Highlighting precise vocabulary concerning flavors, especially for children who confuse terms, so that they are able to define their sensations clearly
3. Explaining the secrets of the production and composition of foods
4. Tasting local specialties
5. Discovering odors, spices, and essences"

The French Ministry of Education suggested five main lines for activities around the issue of food from food vocabulary to culture of food

Even so, food education as provided by the family and school meals may prove insufficient to ensure healthy eating; dietary education programs have therefore been set up by the authorities.

11.3.4 French Ministry of Health

Taste education and dietary education are often associated. At the present time – in France as in other industrial countries – there is a worrying increase in the prevalence of childhood overweight and obesity in the 5–12-year-old age group from 3% in 1965 to 16% in 2000 (Rolland-Cachera et al. 2001).

Daniel Thomas (2003) stressed the importance of changing behavior with respect to obesity-related cardiovascular risk. It was with this in mind that the French authorities set up the PNNS in 2001, to improve public health by acting on the main determinants of diet. Information and education for young people is one strategic axis of the PNNS (*Programme National Nutrition Santé*: French national diet and health program), stressing the importance of early and lasting dietary education, concerning both food and physical exercise. The Ministry of Health and the Ministry of Education are working together on this. One of the priorities of the circular on *School children's health: 5-year prevention and education program* (dated December 1st, 2003) was dietary education and the prevention of overweight and obesity. For this, dietary education and taste and consumption education are to be included in curricula as of primary school, as supports for teaching and in conjunction with school activities in general. Several programs are already being implemented in schools. Information documents and PNNS-approved intervention tools have been made available (Kerneur et al., information on the Internet). Each guide contains simple and accessible information and practical advice adapted to the individual's habits so as to combine health, pleasure, and the requirements of day-to-day living in meeting the objectives of the PNNS. The guide to children's diet is called *Health comes by eating and moving: a child and teens diet guide for all parents*.

Traditional dietary education also seeks to provide information, but often in terms of *good* and *bad*, which is liable to give rise to feelings of guilt.

The environmental factors influencing food preference are summarized in Fig. 11.2.
Fig. 11.2 Environmental factors impacting food preference. Culture, society, school, and family have influences on the food preferences

11.3.5 School: *Classes Du Goût*

As described above, *Classes du Goût* modules can be run in schools. We shall now detail their principles and content.

The teaching approach in each session is structured according to the following model. First, there is a questions phase, helping the children explore the theme of the day; then, a tasting phase, which provides information and enables the children to reach a practical understanding of how the gustatory system works; finally, the children's various responses and answers are brought together, with complementary input on the initial questions. The module comprises 12 sessions of 90 min, on the following topics: "the five senses"; "taste"; "vision"; "olfaction"; "touch and hearing"; "aroma"; "flavor"; "preparation of a dish"; "food preferences"; "regional specialties"; "recapitulation"; and "the festive meal". Table 11.2 presents the program of this sensory education module.

Table 11.2 Key points of the description of the sensory education program (Reverdy et al. 2008)

	Title and aim of the session	Organization of the session	Conclusion and/or contribution of the session
Lesson 1	"The five senses" This session evokes the pupils' understanding of the way in which one makes contact with foods.	The teacher presents a 3-step tasting procedure (before, during, and after) using the five senses to describe a food. This session allows children to enrich their vocabulary on what they feel sensorially and emotionally.	– All five senses are necessary to establish contact with the world of foods. – This contact always comes about in three phases (before, during, and after the tasting).
Lesson 2	"Taste" This session lets the pupils discover the basic tastes (sweet, salty, sour, bitter, and umami) and other mouth sensations (prickling, burning, and astringency).	The teacher presents varied tastings to let pupils discover their own taste perception and to find out that the answers they give are similar to others', yet still very personal.	– Food offer a wide variety of tastes and chemical sensations in the mouth. – Knowing how to express different tastes and sensations. – Showing the diversity between individuals in gustative perception.
Lesson 3	"Vision" This session lets the pupils understand how vision creates expectations that allow them to anticipate food taste.	Tasting making use of colorants, to show how visual perception creates expectations that can modify other perceptions.	– Colors have an impact on other sensory perceptions. – Establishment of precise vocabulary for visual perception.
Lesson 4	"Olfaction" This session shows pupils how difficult it is to recognize odors.	Odor bottles (more or less familiar odors, fruity odors, etc.) are presented to evoke pupils' memories and lead to identification.	– Showing the relationship between an odor and the evocation of its source and associated memories. – Identifying certain familiar odors.
Lesson 5	"Touch and hearing" This session aims to enrich vocabulary for touch and to show how touch and hearing complement each other.	Samples of different materials (silk, wool, velvet, etc.) are presented. Foods of varying hardness, crispness, and crumbliness are tasted.	– Various sensations are linked to touch during tasting: tactile, auditory, and thermal perception. – Enriching vocabulary on touch and hearing. – Linking together food texture, consistence, and temperature.

Table 11.2 (continued)

	Title and aim of the session	Organization of the session	Conclusion and/or contribution of the session
Lesson 6	"Aroma" This session shows how aromas in mouth are perceived by retro-nasal olfaction and how the same food eaten cold or warm gives off different aromas.	Various highly aromatic foods are tasted, and the teacher explains how one can get rid of the aromatic sensations by using ortho- or retro-nasal routes.	– Distinction between direct (odor) and indirect (aroma) olfaction. – The temperature of food modifies sensation.
Lesson 7	"Flavor" This session studies the sensations of sessions 2, 4, and 6 simultaneously.	The pupils learn to identify these different sensations when simultaneously present in complex foods, and to identify their development over time.	– Definition of flavor. – Forms of interaction between the senses involved. – Synthesis of all themes dealt with so for (important information and vocabulary).
Lesson 8	"Preparing a dish" In this session, with the help of a professional, the pupils prepare food from a recipe.	This cooking workshop takes place with a professional.	– Experiencing the pleasure of preparing a dish. – Understanding the variety of possible ways to eat a given food. – Discussion of eating habits.
Lesson 9	"Food preferences" The pupils are asked to argue for their preferences and to stimulate their curiosity for new foods.	Tasting unfamiliar food: each group is required to search for taste information about one fruit and then to encourage the others to taste it.	– Individual food preferences differ a lot. – Talking about your preferences and arguing for them. – Accepting the taste of new foods.
Lesson 10	"Regional specialties" The pupils note differences in local and international specialties and how cultural history may explain them.	The teacher and pupils bring in local specialties for tasting.	– Presenting regional culinary specialties brought in by the pupils, and thinking about their origin. – Enlarging knowledge by tasting specialties from other regions and cultures.
Lesson 11	"Recapitulation" In this session, the pupils have to remember the knowledge built up during the previous lessons.	Quiz, synthesizing acquired knowledge.	– Remembering acquired knowledge that can be of help in assessing food.
Lesson 12	"The festive meal" This last session is an opportunity for the pupils to transfer the things they have learned during the previous lessons by evaluating a meal prepared for them.	The pupils eat a meal at a restaurant.	– Applying acquired knowledge. – Taking part in a relaxing experience: the pleasure of eating together. – Developing skills linked to table manners and *savoir-vivre*. – Assessing the effect of preservation on the taste of food.

The sensory education program of *Classes du goût* contains 12 lessons with theoretical knowledge and practical activities

Our cultural, family, social, and school environments can implicitly influence food behavior. How can explicit sensory education at school alter food preferences and behavior?

11.4 How Far Can Sensory or Dietary Education Change Food Preferences and Behavior?

11.4.1 Edusens in France

A program over a period of years to assess the benefits of sensory education has been set up by the European Center of Taste Science in Dijon, France.

The first part of the study focused on young adults, while the rest concerned 8–11 year olds.

11.4.1.1 Assessment of Sensory Education in Young Adults

The aim of the study was to run a sensory education program for young adults and then to assess its impact on their consumer behavior, complexity perception, and preferences. The assumption was that educating *attention to taste* would shift preferences from simple to more complex versions of food, due on the one hand to improved sensory performance (sensitivity, identification, discrimination, and description) and on the other hand to a reduction in the perceived complexity of complex variants, making them less *unsure* and more pleasant (in line with the theories of Berlyne (1970) and Walker (1980)). In the first step, a panel of 67 consumers assessed perceived complexity and stated their preferences for sets of chocolate, coffee, and tea of varying aromatic complexity. Sensory acuity was measured on a battery of tests developed for the study. Then, in the second step, the subjects were divided into two groups of equal size. One of the groups underwent 12 sessions of sensory education, with practical exercises and theoretical data, while the other group did not. At the end of the module, the two groups returned to the laboratory to do the same tests as in the first step. The results confirmed the initial hypotheses that complexity defined a priori by the formulae corresponded to perceived complexity for all the foodstuffs, and that initial preferences correlated negatively with aromatic complexity.

Evolution following sensory education showed a change in the experimental group's assessments. Their descriptive performance was improved. The perceived complexity of the two most complex variants decreased, particularly with regard to variables that were *hard to describe and identify*. These changes led to increased preference for these two items, whereas no change was observed in the control group (Reverdy et al. 2004).

11.4.1.2 Evaluation of Sensory Education in Children

This study was run with a panel comprising an experimental group of 100 children and a control group of the same size. The experimental group took part in 12 one-and-a-half-hour sessions of taste education in class (J. Puisais's *Classes du Goût*) during the primary school year. The entire panel took part in three measurement sessions comprising three laboratory assessments each, before the sensory education module (T0), just after it (T1), and in the following school year, some 9 or 10 months after the module (T2), in order to test durability of impact.

The results showed increased liking in both groups for the more aromatic and intense variants at T1, with this increase persisting in time (T2) only in the experimental group. Thus, repeat assessment

(or exposure) had a stronger effect than education initially (T1), the education effect appearing only later (T2) in the form of a consolidation of the exposure effect (Reverdy et al. 2010a). Education increased children's neophilia, but only temporarily (Reverdy et al. 2008). Education improved description of tasting experience toward more objective rather than subjective criteria, and this improvement was lasting. Finally, education shifted the categorization strategy for unknown odors toward a strategy based on less hedonic criteria (Reverdy et al. 2010b, c).

A new method for measuring food choice was set up for the study, but showed no sensory education effect on choice behavior.

In conclusion, sensory education as carried out here showed some impact on food preference and behavior, but not durably, and mainly affected description of tasting experience (Reverdy 2008).

Some of these conclusions were anticipated by Ton Nu (1996), who assessed the first version of the *Classes du Goût* in France. In 144 9–12 year olds, 69 of whom had had *Classes du Goût*, she found a positive education impact on verbalization of sensation and on attention to food quality, but none on the desire to taste new foods or on consumption patterns for unfamiliar and familiar items. Even so, the children who had been in the *Classes du Goût* claimed to be more tempted to taste new foods and were interested in the history of foodstuffs. These findings put the validity of declarative assessment in doubt when not followed by congruent behavior. The validity of Ton Nu's results is moreover limited by the lack of any pretest to enable intra-subject comparison before and after education.

11.4.2 *Classes Du Goût* in Finland

A second study, conducted in Finland (Mustonen et al. 2009), evaluated the effect of sensory education on taste and odor awareness and food ratings in school children. Two hundred and forty-four school children, aged 7–11 years, from two schools in Helsinki area, were involved. In each school, two distinct treatments – educated (96 children) and uneducated (79 children) – were applied for a 2-year period. The sensory education contained ten lessons of the *Classes du Goût* and five lessons familiarizing the children with different food categories. During the 2-year period, the two groups were assessed four times each on the following parameters: free odor naming, taste identification of six solutions, descriptive characterization of two breads, rating attention paid to the sensory properties of food, willingness-to-try rating for unfamiliar vs. familiar foods, and aided odor naming (5 odors, 10 verbal labels). During the test period, the "educated" children improved their skills to identify tastes and odors and to characterize foods, while the control group exhibited no evolution. However, "education" effects were mainly to be found in younger children, and were small and not always consistent over the 2-year period. However, children activated their odor and taste perceptions and improved their ability to describe sensory properties of food after sensory education.

Finally, *Classes du Goût* sensory education can influence food preferences and behavior, whether in France or in Finland, as summarized in Fig. 11.3.

11.4.3 Dietary Education

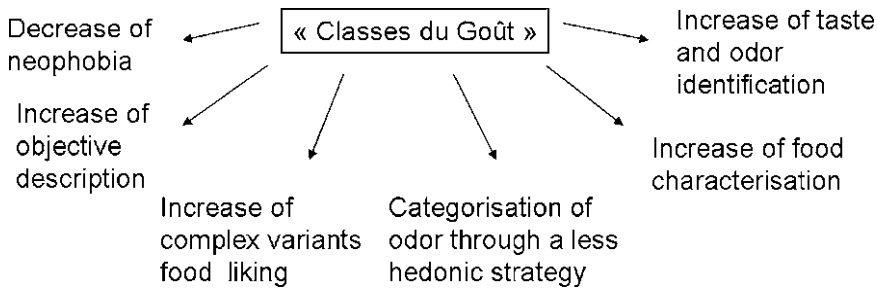
The effects of dietary education were measured in a French study conducted in the towns of Fleurbaix and Laventie, and called *Fleurbaix – Laventie Ville Santé*. This epidemiological study started in 1992 in these two towns in the Nord-Pas-de-Calais region of France, with the initial objective of assessing dietary education in young children. The first phase consisted in a dietary survey in the region, which had been chosen due to the high local prevalence of overweight. Children were then


Fig. 11.3 Measured effects of the *Classes du Goût*. The effects of *Classes du Goût* were measured on neophobia, description, liking of complex food, odor categorization, food characterization, and taste and odor identifications

given dietary information. Subsequent change in food behavior in the entire family was observed, validating the hypothesis that children who received dietary education at school would encourage the whole family to adopt better food consumption behavior (Borys et al. 1993; Borys and Lafay 2000; Borys 2003). A positive approach, based on the pleasure of eating, was found to have more effect on families' food behavior than the restrictive approach of other dietary interventions.

This first phase (1992–1997) was followed up by a second, of 5 more years (1997–2002), to explore the determinants of weight gain and the respective impacts of diet, hormones, biological and genetic factors, and physical activity.

In phase 3 (2002–2007), the population was offered the possibility of health coaching. Twice-yearly follow-up of a cohort extended to all age groups assessed dietary and behavioral status in the population in comparison with dietary recommendations (Borys et al. 1993; Basdevant et al. 1999; Brouet 2003).

Moreover, initial results showed the EPODE approach to have a positive influence, reducing childhood obesity in the local areas involved, compared to increasing obesity in control areas.

In the pre-EPODE era, traditional dietary education was mainly based on restriction and avoidance. Unfortunately, it failed to include sufficiently the sensory pleasure associated with mealtimes. This may explain the poorer effectiveness of dietary campaigns in the UK, based almost exclusively on restriction and the analysis of dietary risk.

11.5 Conclusion and Perspectives

11.5.1 Comparison Between Sensory Education at School and Other Forms of Education (Dietary and Family)

11.5.1.1 Comparison with Dietary Education

The explicit information and implicit experience provided by *Classes du Goût* have a more or less lasting effect on children depending on the particular behavior being studied. This teaching method is particularly rich in sensory experience, with attention to each child's individual differences. It is nuanced, unlike dietary education which tends to involve a dualistic approach in terms of *good* and *bad* behavior. Moreover, dietary education is often limited to simple information transmission, divorced from any sensory experience.

Classes du Goût offer implicit sensory experience in a positive context enriched with explicit information as in dietary education.

11.5.1.2 Comparison with Family Education

Within the family, children are often encouraged to extend their range by tasting new foods, which they learn, by repetition, to like over time. Such exposure to foods, however, does not always come with a positive feeling, if it involves parental pressure. *Classes du Goût* offer *tastings*, introduced by prior information. Moreover, they take place in a context of playful, peer-group learning.

Like at home, children extend their food experience in *Classes du Goût*. However, the method associates implicit experience to explicit information. Moreover, how a food is perceived in the context of an exchange with the parents may be very different from how it is experienced in an exchange with the teacher in the presence of the other children.

The comparison of food education types are described in Table 11.3.

Table 11.3 Key points of the comparison between types of food education: sensory, dietary, and parental

Characteristics of the education type	Sensory education at school	Dietary education	Parental education
Sensory experience	Yes	No	Yes
Tasting introduced by prior information	Yes	No	No
Information without tasting	No	Yes	No
Highlighting individual differences	Yes	No	No
Exchange	Peer groups and teachers	Nutritionists	Parents
Dualistic approach (good, bad)	No	Yes	Yes/no
Parental pressure	No	No	Yes

Sensory education at school focus on experience and information; dietary education focus on information; parental education focus on experience

11.5.2 Advantages and Limits of Sensory Education at School

11.5.2.1 Advantages of the Method

This teaching method has the interest of focusing the children's attention on their own sensations, finding their own responses rather than some preestablished or conventional response. Its originality compared to other school subjects (such as mathematics) enables children who are doing badly at school to find a space for expression and success, as Öström and Annett (2008) reported in Swedish children.

Classes du Goût may not really change food behavior, but do provide general knowledge of the raw materials of food and food education including how dishes are cooked. Given the contemporary food system which encourages consumption of processed foods, this approach seeks to promote healthier eating, closer to the natural products. In this way, it helps combat the fast-food culture.

Advertising for processed foods targeting children, such as biscuits, has an impact on the type of consumption. The *Classes du Goût* culture favors a counterculture. However, as we have seen, its impact is slight in comparison with the effectiveness of implicit learning by food exposure.

11.5.2.2 Limits of the Method

The great effectiveness of exposure puts into perspective the effects of explicit education of the *Classes du Goût* type, which finally provides mainly a gastronomic culture for the children without actually changing their eating habits.

Moreover, while the *Classes du Goût* approach stresses a combination of the pleasure of eating and explicit learning, it must be said that implicit learning by exposure also involves the post-ingestion effects of food, which are probably more important than explicit information for the formation of eating habits and the development of food appreciation. Aversion subsequent to bad post-ingestion experiences is much more persistent than attraction caused by good experience, as the avoidance reaction provoked by aversion reduces the chances of correction by new experience, whereas attraction increases the chance of coming up against a bad experience.

11.5.3 Action!

The findings of EduSens, showing increased appreciation of complex food items following a small exposure (just three times is enough), should encourage the authorities to seek to change eating behavior by means of exposure to healthy food. A method focusing on the effects of exposure to varied and complex flavors and odors has the advantage over the *Classes du Goût* approach of being applicable in young children whose language development is incomplete. School meal campaigns, such as the traditional *Taste Week* in October, are to be encouraged, even if the benefit has yet to be properly assessed.

Finally, in the light of the success of the session in which the children got actively involved in preparing a dish and learned to adjust the quantities of ingredients according to their preferences, it would seem that food education should involve active participation in learning to cook, especially as the capability and pleasure of cooking well will be essential when the child reaches adulthood, in order to be able to prepare enjoyable and balanced meals. The kitchen is surely a wonderful place to discover and transmit the pleasure of eating well, as Marie-Claire Thareau Dupire (2006) suggests. This finding was further confirmed in the *Let's make a meal together* session in phase 3 of the EduSens project, which got the families involved. This is why we strongly encourage any cooking activity that enables children to put different ingredients together so as to make a dish adjusted to their own tastes.

Key Point

- **Sensory education:** context, courses of action, and effects

---

Definitions

Classes du Goût: (*Taste Class*) is a method developed in France by Jacques Puisais in the 1970s. This learning method, aimed at children around the age of 9, seeks to develop food curiosity, to refine taste, and enrich food vocabulary

Food preferences: Preferences for food are obtained by comparison, whereas *liking* is absolute information. Thus, preferences can be used to compare several variants of a range, as in the EduSens project.

Neophobia: The fear to try foods that are new to the subject

Sensory education: Develops the senses by focusing attention on them. The sense of taste is developed by information regarding taste perception (which involves all five senses: taste, smell, touch, sight, and hearing) and by practical training to enhance sensory acuity. It is general and intended for nonexpert consumers.

Sensory training: Is training with food, odor, or solutions in order to improve taste ability and is intended for expert analysts in sensory analysis.

Summary Points

- The content of sensory education of taste at school is information regarding taste perception and food processes, and practical training to enhance sensory acuity and to enrich food vocabulary.
- Scientific studies showed the following effects of sensory education in children:
  - Improved description and characterization of food
  - Improved identification of odor and taste
  - Temporary decrease in neophobia
  - Increased liking for more complex food products
  - More expert odor categorization
- The advantages of sensory education at school are to focus on children's own sensations and responses and provide knowledge concerning food.
- Sensory education at school does not really change food habits and its explicit information seems less important than the post-ingestive effects of food.
- An alternative to sensory education could be cooking lessons to encourage better food habits.

NTS	Nucleus tractus solitarius
OLETF	Otsuka Long-Evans Tokushima Fatty

12.1 Introduction

A growing number of humoral factors are released from the gut during feeding and they play a prominent role in the cascade of events bringing a meal to an end. The chief among them is cholecystokinin (CCK), the first gastrointestinal peptide implicated in the control of food intake and subsequently coined "satiation signal." Detected for the first time in 1928 by Ivy and Oldberg and later characterized by Mutt and Jorpes (Jorpes and Mutt 1956), it was not until 36 years ago when Gibbs et al. published the landmark paper showing that the biologically active, synthetic, CCK octapeptide (CCK-8) reduced food intake in the rat (Gibbs et al. 1973). Since then, the

e-mail: mcovasa@jouy.inra.fr

investigation into the role of CCK on food intake continued unabated making CCK one of the most intensely studied gut peptide. Consequently, its suppressive effects on food intake have been demonstrated in several species including humans (see Ritter 2004a, b). CCK controls food intake by coordinating visceral functions to optimize digestion and absorption and by interacting with other short- and long-term meal-related signals. CCK may also contribute to satiation by reducing caloric consumption, thus exerting its role in the control or regulation of other systems, such as body adiposity. This chapter addresses: (1) the role of CCK on alimentary organs that participate in control of food intake, (2) mechanisms by which CCK controls meal size, (3) interactions of CCK and other hormones that control food intake, and (4) disruptions in CCK signaling pathways leading to disordered phagia.

12.2 CCK Controls Gastrointestinal Functions to Optimize Digestion

In addition to its role in controlling food intake, CCK elicits multiple effects on the GI tract including stimulation of pancreatic secretion and gallbladder contraction, bile secretion into the duodenum, inhibition of gastric secretion and emptying, as well as motor functions like lower oesophageal sphincter relaxation and intestinal and colonic motility (see Little et al. (2005)). Together, these actions promote reducing the rate of passage of nutrients in the interest of efficient and complete digestion. That is, CCK may control food intake, particularly protein and fats solely in the interest of GI functions. For a list of main functions of CCK, see Table 12.1.

12.3 CCK Controls Food Intake via Vagal Afferents

Vagal sensory afferents synapsing from the gastric, celiac, and intestinal branches of the vagus to the hindbrain are the pathway both endogenous and exogenous CCK use to reduce food intake (Smith et al. 1981; Yox and Ritter 1988). Evidence for this comes from the fact that vagal afferent fibers express CCK receptors and CCK application to vagal afferent preparations results in vagal discharge (Ritter et al. 1989; Raybould and Lloyd 1994). Additionally, sensory fiber removal either by surgical or chemical means attenuates CCK and intestinal nutrient-induced suppression of food intake (Ritter 2004a, b). Finally, vagal sensory fibers innervating gastric and intestinal mucosa are sensitive to CCK (Ritter et al. 1989). These effects are largely due to a paracrine action of CCK on peripheral,

Table 12.1 Key features of CCK in eating behavior

1. CCK is released from the duodenal enteroendocrine I-cells of the small intestine.
2. All three macronutrient classes stimulate release of CCK in humans; however in rodents, only fats and protein cause CCK secretion.
3. CCK's primary pathway to induce satiation is through a paracrine mode of action through CCK-1Rs.
4. CCK elicits physiological effects on a variety of digestive organs including the stomach, intestine, colon, gallbladder, and pancreas.
5. CCK activates hindbrain neurons through vagal afferent sensory nerve fibers.
6. CCK serves as a satiation signal to limit short-term food intake; however its synergistic effects with other long-term homeostatic energy signals implicate it in reducing bodyweight.

Table illustrating the key points of CCK in controlling eating behavior summarizing stimulation of secretion, release, and effects of the hormone

capsaicin-sensitive vagal afferent fibers. However, CCK-producing cells are strategically positioned in very close proximity with vagal afferent terminals in lamina propria, and few synapses-like appositions between them have been reported. Therefore, a neural mode of action has been suggested (Reidelberger et al. 2004) although the largely held view is that locally released CCK diffuses to its action sites through a paracrine mechanism.

In addition to a vagally mediated pathway, CCK sites acting through non-vagal mechanisms may also serve to decrease food intake (Reidelberger 1992; Blevins et al. 2000). CCK localized in the central nervous system also has been reported to decrease food intake (Blevins et al. 2000). Released by neurons from the spinal cord to forebrain, CCK is a potent neuropeptide (Hokfelt et al. 2002). CCK-1 and CCK-2 receptors also are highly expressed in many brain regions, including areas known to control food intake and regulate energy balance. Intraventricular (ICV) or parenchimal administration of CCK into several hypothalamic and hindbrain areas decreases food intake (Blevins et al. 2000) while central infusion of CCK receptor antagonists (Corp et al. 1997; Dorre and Smith 1998) or CCK antisera (Della-Fera et al. 1981) increases food intake. Also, mechanical and chemical stimulation of the GI tract induces release of CCK from brain regions controlling food intake (Schick et al. 1989). Further, reduction of intake by infusion of carbohydrates or feeding of diets that do not result in substantial CCK release can be attenuated or reversed by antagonists of CCK receptors (Brenner and Ritter 1996). Finally, whereas vagal afferents mediate CCK-induced suppression of food intake, they are not required for the increased food intake following systemic administration of CCK-1R antagonists (Reidelberger 1992). Therefore, CCK from other sources can reach CCK-1Rs present outside the abdominal vagal terminals and inhibit food intake. Indeed, administration of devazepide, a CCK-1R antagonist that crosses the BBB, results in increased food intake in both vagotomized and non-vagotomized rats, while A-70104 another CCK-1R antagonist that does not penetrate the BBB increased intake only in non-vagotomized rats (Reidelberger et al. 2004). These results suggest that increased food intake is due to an action of the antagonists at CCK receptors located on peripheral sites. However, it also suggests that devazepide increases food intake by acting either on remnant vagal afferents or by accessing other non-vagal CCK receptors (Ritter 2004a, b). It is known that CCK receptors and CCK-containing neurons and terminals are present in the hindbrain that may also participate to CCK's effects on the vagal hindbrain (Hill and Woodruff 1990).

12.4 CCK Controls Food Intake via Intestinal Nutrients

CCK is released from discrete enteroendocrine I-cells concentrated primarily along the proximal duodenal and jejunal mucosa. The apical surface of the CCK cells comes in contact with food components triggering a series of intracellular events resulting in the peptide release from the basolateral cell membrane into the circulation (Liddle 1997) (see Fig. 12.1). Several molecular forms of CCK have been identified and they are derived from the 95 amino acid pro-CCK (CCK-5 to CCK-83) with CCK-8 and CCK-58 being the most biologically potent in suppression of food intake (Glatzle et al. 2008).

Reduction of food intake by intraintestinal nutrient infusions is thought to exercise controls of food intake, which normally are activated when components of a meal enter the duodenum from the stomach. In the rat and other mammals, plasma CCK concentrations are elevated in response to intraintestinal products of fat digestion, unhydrolyzed protein, and inhibitors of pancreatic trypsin (Liddle et al. 1986; Weller et al. 1992; Brenner et al. 1993). Some, but not all, intestinal nutrients stimulate secretion of the gut peptide, cholecystokinin. For example, carbohydrates and amino acids do not release CCK in the rat (Brenner et al. 1993); although in humans, CCK is released in response
Fig. 12.1 Diagram depicting the stimulation of release of cholecystokinin (*CCK*) (*small black circles*) from a duodenal I-cell by luminal nutrients (*small open circles*) on the apical portion of the cell. CCK is released on the basolateral side of the cell into the circulation or binds to localized CCK-1R on vagal afferent terminals, which activate upstream hindbrain neurons

to both l-phenylalanine (Ballinger and Clark 1994) and glucose (Parker et al. 2005). CCK reduces food intake by acting at CCK-1Rs, located on small unmyelinated vagal sensory neurons (South and Ritter 1988), indicating that the substrate that mediates CCK-induced satiation is similar, if not identical, to that which mediates reduction of food intake by intestinal nutrients. Participation of CCK-1Rs in reduction of food intake by intestinal nutrients is well supported by the fact that CCK-1R antagonists attenuate or abolish reduction of food intake by intraintestinally infused triglycerides (Woltman et al. 1995), long chain fatty acids (Yox et al. 1992), oligosaccharides (Brenner and Ritter 1996), and protein (Woltman and Reidelberger 1999). In addition to reversing the reduction of food intake observed following exogenous CCK (Brenner and Ritter 1995) injection or intestinal nutrient infusion, CCK-1R antagonists increase food intake when they are administered alone (Moran et al. 1992; Brenner and Ritter 1995). Taken together, these results suggest a direct relationship between CCK-1Rs and control of food intake by intestinal nutrients.

There is accumulating convincing evidence indicating that CCK mediates nutrient-suppression of food intake mainly through a paracrine rather than an endocrine mode of action. For example, both suppression of food intake and inhibition of gastric emptying by intraintestinal carbohydrate infusions, which do not elevate plasma CCK, are attenuated by a CCK-1R antagonist (Brenner et al. 1993). On the other hand, infusions of proteins that markedly increase plasma CCK concentrations have a marginal effect on reduction of sham feeding (Brenner et al. 1993). Furthermore, administration of a peptide CCK-1R antagonist impermeable to the BBB attenuated the satiating effects of CCK and intestinal nutrients (Brenner and Ritter 1995) and increased food intake when given alone (Brenner and Ritter 1995). Finally, the endocrine source of CCK must undergo hepatic portal degradation, which renders most of the biologically active CCK ineffective in suppressing food intake (Reeve et al. 2003). Consistent with this, very low concentrations of CCK (1–5 picomolar range) is detectable in the blood circulation and the only endocrine form of CCK found in the rat is CCK-58 (Reeve et al. 2003). Together, these data overwhelmingly point to a peripheral site of action whereby a local source of CCK acting in proximity of vagal afferent fibers may be sufficient to mediate reduction of food intake. This is also supported by studies showing that low doses of intraperitoneal (IP) which likely mimic the paracrine mode of action on vagal afferents (Canova and Geary 1991), or near-arterial administration of CCK-8 reduces food intake more than higher doses when administered intravenously (Cox et al. 1995). Whether sufficient amounts of systemically administered CCK

are able to penetrate the lamina propria and elicit a physiological and behavioral effect is unknown. Thus, the exact identity of this source of CCK outside "I" cell remains to be located. Studies examining receptor affinity indicate a relationship between local concentrations of CCK in the GI tract and CCK-1R affinity. It is thought that low affinity receptors are localized near areas with high CCK concentration while high affinity receptors are in areas with low CCK levels (Pandya et al. 1994; Talkad et al. 1994). For example, administration of an agonist of high affinity CCK-1Rs does not decrease food intake (Weatherford et al. 1993). Additionally, work done in vagal afferent preparations shows the majority of CCK-1Rs expressed on vagal afferent neurons are thought to be low affinity CCK-1Rs (Simasko et al. 2002). Together, these data suggest that gastrointestinal CCK acting locally on vagal afferent sensory fibers is responsible for nutrient induced satiation.

Although the paracrine effects of CCK on peripheral vagal afferents are well documented, a direct action of CCK on the nucleus tractus solitarius (NTS) neurons have been reported. This source of CCK could originate either from CCK-producing neurons located in the hindbrain or from the systemic circulation through the leaky portion of the BBB, including NTS (Baptista et al. 2007).

12.5   CCK Reduces Food Intake via CCK-1 Receptors

The targets of CCK action, CCK-1 and CCK-2 receptors (formerly CCK-A and CCK-B), belong to the G-protein coupled transmembrane classification (Kopin et al. 1992; de Weerth et al. 1993). Several studies have identified and cloned the genes encoding these receptors (Kopin et al. 1992; Wank et al. 1994). For a list of sites where CCK-1Rs are located, see Table 12.2. Selective CCK-1 and CCK-2 receptor antagonist studies indicate that reductions of food intake by systemic injections of CCK are mediated primarily via CCK-1Rs (Melville et al. 1992; Moran et al. 1992). Accordingly, reductions in food intake by systemic CCK administration can be significantly attenuated or abolished by administration of a selective CCK-1R antagonist [for review see Ritter et al. (1999)]. Activation of these receptors is mediated via vagal sensory neurons primarily innervating the proximal duodenum and the stomach (Moran et al. 1990, 1997). In addition, independent administration of CCK-1R antagonists increase food intake, supporting CCK as a physiological satiety signal. At the cellular level, binding sites for CCK receptors are identified on vagal sensory neurons, and 30–40% of vagal sensory neurons express CCK-1R mRNA. Furthermore, use of isolated vagal sensory neuron preparations demonstrates that calcium influx occurs after CCK application and is attenuated by CCK-1R antagonist (Simasko et al. 2002). Finally, electrophysiological data show that CCK-1Rs also mediate activation of vagal afferent fibers by intestinal stimuli (Eastwood et al. 1998).

Table 12.2   Distribution of CCK-1R

  - ◦ Nucleus tractus solitarius (NTS)

Peripheral and central locations where CCK-1Rs have been detected

Together, these findings are strong evidence that CCK-1Rs are necessary for suppression of food intake by CCK. Indeed, the fact that exogenous administration of CCK is ineffective in animal models lacking CCK-1Rs has demonstrated unequivocally the contribution of CCK-1R in control of food intake by CCK and nutrients.

12.6 Changes in CCK Sensitivity by Nutrients

Responses to gastrointestinal satiation signals are not fixed. Rather they appear to vary widely with changes in the dietary and endocrine milieu. For example, studies in both rats and mice adapted to a high-fat (HF) diet become less sensitive to both exogenous (Covasa and Ritter 1998; Nefti et al. 2009) (Fig. 12.4), and endogenous CCK via intestinal infusion of oleate (Covasa et al. 2000). Similarly, human subjects adapted to a HF diet have increased plasma CCK following a standard meal compared to control subjects and reported greater hunger following intestinal lipid infusion (Boyd et al. 2003). These effects were associated with an increase in the average daily food consumption and body weight.

The exact mechanisms by which maintenance of a HF diet leads to a reduction in sensitivity to satiation signals such as CCK and nutrients are not known. However, similarly, reduction in sensitivity to the anorectic effects of acute CCK injection was also demonstrated in rats receiving chronic infusion of CCK via osmotic minipump (Covasa et al. 2001). This persistent elevated plasma CCK, accompanying long-term exposure to a diet rich in fat leads to several adaptive changes in nutrient- and CCK-signaling pathways. For example, relative to rats fed a low-fat (LF) diet, rats fed a HF diet exhibit increase pancreatic secretory and plasma CCK responses to intestinal fat. They also secrete reduced amounts of pancreatic amylase in response to CCK (Chowdhury et al. 2000) and increased amounts of pancreatic lipase (Gidez 1973).

In normal Sprague-Dawley rats, chronic HF feeding selectively reduces vagal and enteric neuronal sensitivity to intestinal oleic acid or CCK injection (Covasa et al. 2000). Because fat is a potent stimulus for CCK release, it may be that modifications at the level of CCK-1Rs play an important physiologic role. This is supported by evidence that continuous CCK infusion leads to downregulation of the receptor gene expression in rat pancreatic acinar cells (Ohlsson et al. 2000) and hypothalamo–pituitary–adrenal axis (Malendowicz et al. 2003). Indeed, mice maintained on a HF diet for 15 days have a decreased Fos expression in the NTS in response to CCK or nutrient load and a decreased mRNA level of CCK-1R transcripts in nodose ganglia (Nefti et al. 2009). However, in the rat, Broberger and colleagues (Broberger et al. 2001), using in situ hybridization techniques, reported that feeding an HF diet does not appear to alter vagal CCK-1R mRNA expression in the nodose ganglia. It remains to be determined whether alterations in CCK-1Rs in other tissues accompany the diminished sensitivity of endogenous satiety mechanisms resulting from chronic consumption of dietary fat. CCK-1R affinity and capacity are also reduced in rats adapted to an energy-restricted diet (Kawano et al.). Also, rat pancreatic acinar tumor AR42J cells express the CCK-1R subtype, and CCK-8 reduced CCK-1R mRNA expression to 56% after exposure (Kawano et al. 1992).

It is also possible that reducing the number of binding sites at the neuronal membrane surface downregulates vagal sensitivity. In addition to the abnormalities in the binding of CCK to its receptors in genetically obese rats, there are also CCK neuronal changes associated with dietary-induced obesity. For example, early signs of obesity in neonatal overfed weanling rats are associated with a significant decreased number of CCK-positive neurons in the paraventricular hypothalamic nuclei (Plagemann et al. 1998). Studies of CCK-receptor function in pancreatic acini and Chinese hamster ovary cells (Rao et al. 1997) indicate that receptor internalization and

phosphorylation are important mechanisms for CCK-induced desensitization in vitro. Therefore, reduced sensitivity to CCK could be mediated either by altered receptor protein translation or increased sequestration of previously translated receptors. Downregulation of transduction cascades has also been associated with CCK-induced desensitization of pancreatic amylase secretion (Otsuki and Williams 1983). Therefore, a change in postreceptor transduction is yet another potential mechanism for reduced vagal sensory response to CCK. The current data suggests that modifications at the level of the CCK-1Rs plays an important physiological role in the adaptation of feeding behavior; however, the relationship between decreased sensitivity to CCK or nutrient infusion in animals adapted to a HF diet and the functional characteristic changes occurring in the peripheral CCK-1Rs has not been elucidated.

12.7   CCK Interacts with Other Hormones to Control Food Intake

CCK-induced satiation is enhanced when combined with other anorectic signals. For example, serotonin or 5-hydroxytryptamine (5-HT) released from the enterochromaffin (EC) cells in response to carbohydrates serves to terminate a meal in coordination with CCK. While cholecystokinergic and serotonergic systems independently control meal size, when both systems are concomitantly activated, it results in an enhanced suppression of food intake (Burton-Freeman et al. 1999; Helm et al. 2003; Hayes et al. 2004a, b). This enhanced suppression of intake is reversed by simultaneous blockade of CCK-1 and 5HT3R (Hayes et al. 2004a, b; Hayes and Covasa 2005). Further, concomitant blockade of CCK-1 and 5HT3R synergistically enhances food intake and suppression of food intake by CCK is attenuated following blockade of peripheral or central 5-HT3 receptor antagonists (Hayes and Covasa 2006a, b) (Fig. 12.2). These findings demonstrate that CCK and 5-HT systems cooperate interdependently to control food intake. 5HT3 receptor mediated CCK-induced satiation is thought to occur through indirect mechanisms as part of a feedback cascade via inhibition of gastric emptying. Evidence of this comes from the inability of 5-HT receptor antagonists to attenuate CCK-induced reduction of sham feeding. Further, 5-HT receptor antagonism attenuates CCK-induced gastric distention and inhibition of gastric emptying (Hayes and Covasa 2006a, b). Finally, mice that lack specific subtypes of 5-HT receptors, which are localized only in the CNS, have a decreased responsiveness to exogenously administered CCK (Asarian 2009). The interactions between CCK and 5-HT are vagally mediated, which is based on the following evidence: (1) both CCK and 5-HT cause a profound activation of proximal small intestine afferent fibers, which is blocked by vagotomy or capsaicin; (2) 5 out of 9 nodose ganglion neurons that were activated by CCK-8 respond to intraluminal perfusion of 5-HT; (3) a subthreshold dose of CCK-8 that produced no measurable responses augmented the neuronal response to luminal 5-HT perfusion. This potentiation effect was eliminated by a CCK-1R antagonist.

In addition to the interaction between CCK and 5-HT, CCK and mechanical stimuli, such as gastric distension, exert synergistic or cooperative effects on the control of food intake in a variety of species, including rats, monkeys, and humans (Moran and McHugh 1982; Feinle et al. 1996). For example, intake after either a gastric distention, a test meal, or a preload is reduced when combined with lower doses of CCK (Moran and McHugh 1982; van de Wall et al. 2005). These effects are mediated by vagal CCK-1Rs. Furthermore, gastric distension enhances CCK-induced hindbrain c-Fos expression, and vagal excitation (Wang et al. 2007). Thus, CCK-1Rs may act by enhancing responses to gastric detention. Given the interaction between leptin and CCK discussed above and that all leptin-responsive gastric vagal afferents are responsive to CCK, leptin may enhance the responses of gastric afferents to distension or CCK.

Other anorexigenic and orexigenic factors involved in the control of food intake and bodyweight also interact with CCK either to enhance or inhibit its satiating effects. First, apolipoprotein A-IV
Fig. 12.2 5-HT3 receptor antagonism attenuates cholecystokinin (*CCK*)-induced satiation. Intraperitoneal administration of cholecystokinin (CCK, 1.0 μg/kg) significantly reduced rat chow intake at 30, 60, and 120 min compared with control in food-deprived rats. Concomitant administration of ondansetron, a 5-HT3 receptor antagonist (Ond; 1.0 mg/kg ip) and CCK significantly attenuated CCK-induced reduction of 30-, 60-, and 120-min rat chow intake. *$P<0.05$ versus saline at given time. †$P < 0.05$ versus corresponding CCK at given time (Reprinted from Hayes et al. 2004a, b)

(APO A-IV), a satiety factor secreted from small intestine epithelium in response to chylomicron formation, requires CCK and the CCK-1R for inducing satiation (Lo et al. 2007). Extracts from chylous lymph applied to vagal afferent preparations activates vagal neurons via a CCK-1R-dependent mechanism (Glatzle et al. 2003). Further, while subthreshold doses of either APO A-IV or CCK do not decrease food intake, combination of the two significantly reduces food intake (Lo et al. 2007).

Second, ghrelin, the potent orexigenic hormone released from the stomach is modulated by peripheral CCK. There is a functional relationship between ghrelin and CCK in short-term control of food intake. For example, the stimulation of food intake and neuronal activity in the hypothalamus induced by ghrelin is abolished by intraperitoneal CCK. Vagal afferent neurons express the ghrelin receptor, GHS-1, and peripheral administration of ghrelin resulting in increased food intake is attenuated by surgical and chemical ablation of the vagus. Also, in vitro, ghrelin inhibits the stimulatory effect of CCK on vagal afferent neurons (Date et al. 2002). Third, there is a significant amount of evidence, demonstrating that gonadal hormones such as estradiol decreases eating, at least in rats, by increasing the satiating action of CCK (Asarian and Geary 1999).

12.8 Participation of CCK in Long-Term Energy Balance and Body Weight Regulation

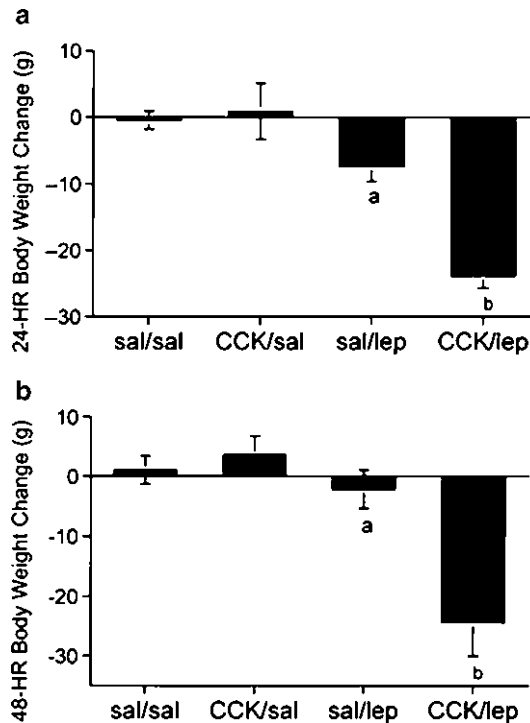
Although CCK is clearly involved in the control of ingestion and individual meals, how these actions translate into the roles for CCK in overall meal-to-meal regulation or energy balance has not been obvious. Recent work examining potential interactions between CCK and adiposity signals such as insulin or leptin suggest a role for CCK in overall energy balance. Figlewicz et al. (1995) first showed that ICV


Fig. 12.3 Synergistic action of cholecystokinin (*CCK*) and leptin to reduce bodyweight. CCK-leptin (lep) treatment reduces body weight significantly more than does saline (sal)-lep at 24 (**a**) and 48 h (**b**) after treatment. CCK (1 μg/kg) was given intraperitoneally and leptin (5 μg) was given into the lateral ventricle. [a]Sal-lep-treated rats lost significantly more body weight (compared with baseline day before treatment) than sal- or CCK-treated rats (*P*<0.01 for both); [b]CCK-lep-treated rats lost significantly more weight than sal-lep-treated rats (*P*<0.01) (Reprinted from Matson and Ritter 1999)

infusion of insulin enhances the satiety response to CCK in baboons. Data from a number of studies have indicated that leptin's actions in food intake may depend in part on its ability to modulate the efficacy of within-meal satiety signals such as CCK. Leptin potentiates the satiety actions of CCK in short-term tests (Emond et al. 1999). For example, a subthreshold dose of intraventricular leptin significantly increases the magnitude of feeding suppression produced by peripherally administered CCK. Leptin/CCK combinations also result in elevated levels of c-Fos expression in the hypothalamic paraventricular nucleus (Wang et al. 1998) and within the nucleus of the solitary tract (Wang et al. 2000), beyond those produced by either stimulus alone. Combinations of leptin and CCK have feeding inhibitory effects over the long term, beyond those produced by leptin alone (Fig. 12.3) (Matson and Ritter 1999). Furthermore, CCK/leptin combinations result in greater decreases in body weight over 24 h than does leptin alone (Matson et al. 2002). These findings demonstrate that communication between hypothalamic circuits that respond to changes in adiposity signals and those that respond to meal-generated signals are essential for long-term regulation of energy homeostasis and adipose tissue mass.

12.9 Disordered Satiation and the Role of CCK

A growing number of reports indicate that obese subjects, including humans, exhibit disruptions in their responses to satiation signals. For example, obese humans reported feeling less hungry than lean controls (French et al. 1993), and they were less sensitive to infusion of gastrointestinal peptides such

as bombesin (Fig. 12.4) (Lieverse et al. 1994). Rats made obese by overfeeding were less sensitive to the satiating effects of CCK (Voits et al. 1996; Covasa and Ritter 1998; Covasa et al. 2001), but see also (Torregrossa and Smith 2003).

Animal models of obesity such as obese Zucker, OLETF, and Osborne-Mendel rats have all been reported to be less sensitive to reduction of food intake by fats suggesting that obesity may be associated with a reduced responsiveness to intraintestinal stimuli such as CCK and fats. For example, the Zucker rat, homozygous for the *fa* gene, and heavily used as a model of genetic obesity exhibits reduced sensitivity to intraperitoneal and ICV administration of CCK (McLaughlin and Baile 1979). CCK-stimulated amylase secretion from pancreatic acini and binding capacity of 125I-labelled CCK-8 were decreased in obese versus lean Zucker rats (Niederau et al. 1997), suggesting the differences in CCK's satiety effect between lean and obese rats may be due to differences in CCK-receptor binding and action at peripheral vagal sites. However, recent studies in dietary-induced obese (DIO) mice showed an increase in expression of CCK-1R in the nodose neurons (Paulino et al. 2009), which do not correlate with functional data showing reduced neuronal vagal sensitivity in mice and rats maintained on a HF diet (Nefti et al. 2009). The reason for this discrepancy is not known although altered coupling between receptor and intracellular signaling pathways or changes in synaptic activity at the NTS level have been suggested (Paulino et al. 2009).

Similarly, the OLETF rat, an outbred strain of Long Evans rats, which lacks functional CCK-1Rs, is hyperphagic, and becomes obese and diabetic (Moran and Bi 2006). Consistent with this mutation, little or no CCK-1R mRNA is detected in the pancreas of the OLETF rat (Funakoshi et al. 1994). Furthermore, pancreatic acini from OLETF rats are completely insensitive to
Fig. 12.4 High-fat diet attenuates *CCK*-induced reduction of food intakefatCCK-induced reduction of food intake in rats adapted to low-fat (*LF*) and high-fat (*HF*) diets. Data shown are percent reduction of 30 min food intake following 17 h food deprivation. CCK caused significantly greater reduction of intake at 0.5 and 0.25 μg/kg dose in low-fat adapted rats than in high-fat adapted rats ($P < 0.01$) (Reprinted from Covasa and Ritter 1998)

stimulation of enzyme secretion by CCK (Otsuki et al. 1995). This absence of CCK sensitivity is specific in that OLETF acinar cells do secrete amylase in response to bombesin, carbamylcholine, and secretin. Also, pancreatic CCK binding in OLETF rat is completely absent (Otsuki et al. 1995).

OLETF rats exhibit accelerated rates of weight gain compared to control rats beginning at 5 weeks of age, and results in body weights, which are ~40% higher than the control Long Evans Tokushima strain. They are less sensitive to within-meal satiety signals and this has been attributed to their lack of CCK-1Rs. For example, systemic administration of CCK has no suppressive effect on food intake (Moran et al. 1998) or gastric emptying (Shoji et al. 1997) in OLETF rats. OLETF rats ingest larger meals and are less sensitive to inhibition of food intake by some intraintestinal nutrients (Covasa and Ritter 2001) and gastric distention than LETO control rats (De Jonghe et al. 2006). Therefore, OLETF rats exhibit a broad range of satiation deficits that are controlled by CCK-1Rs. However, not all OLETF satiation deficits are directly related to the absence of CCK receptors (Moran 2008) and genetic ablation of the CCK-1Rs in Fisher 344 rats was not associated with overeating and obesity (Blevins et al. 2009).

12.10 Applications to Other Areas of Health and Disease

Although predominantly viewed as a short-term satiation signal, there is also evidence that CCK plays a role in the pathogenesis of obesity in humans. For example, genetic studies show that CCK-1R gene promoter polymorphism is associated with body fat suggesting a major functional role of CCK-1Rs in the development of obesity (Arya et al. 2004). Similarly, using genotype associations, recent studies revealed that obese carriers of variants in the CCK gene have an increased risk of eating large portion sizes, with a 60% increased risk for carriers of the CCK_H3 haplotype (de Krom et al. 2007). However, the frequency of single gene mutations, in general, and in the CCK-1R in particular, reported in humans, are relatively small and therefore, unlikely to play a major role in the current obesity epidemic.

Studies examining changes in circulating CCK concentrations in obese individuals after various dietary manipulations as well as studies using CCK-1Rs agonists to curb appetite and reduce energy intake have yielded mixed results. For example, compared to lean controls, moderately and morbidly obese women have significant lower fasting plasma CCK concentrations and exhibit a blunt postprandial CCK response (Baranowska et al. 2000; Zwirska-Korczala et al. 2007). This corresponds with an increase in fasting CCK concentrations and diminished feelings of hunger reported in elderly subjects (Sturm et al. 2003). However, plasma CCK concentration in obese subjects remains elevated following consumption of a fatty meal (French et al. 1993). Manipulation of endogenous CCK levels either through diet (e.g., addition of long chain fatty acids), by inhibiting CCK degradation, or through chronic exogenous administration of CCK have all been shown to decrease caloric intake and/or bodyweight. However, whether these approaches can lead to sustained changes in CCK responses without development of tolerance effects, resulting in consistent reduction in appetite in obese subjects require further investigation. Pharmacological studies employing CCK-1R agonists have been promising, with, at least, initial studies showing a significant weight loss (Roses 2004). Uncovering the most effective strategy of manipulating the CCK system either alone or in combination with other anorexigenic peptides in treating obesity remains an area of intense investigation.

Key Terms

CCK: Peptide satiation signal cleaved from the pre-cholecystokinin precursor and released from the proximal duodenum of the small intestine in response to nutrients.

Endocrine: Entry of peptide or hormone into the bloodstream to exert effects on distant tissues

Enteroendocrine cells: Specialized intestinal cells that release peptides and hormones in response to nutrients. The apical portion of the cell faces the lumen of the intestine to sense nutrients while the basolateral portion is responsible for hormone secretion.

Fos: Protein that is a product of the immediate-early c-fos gene. Used in immunohistochemical experiments as a marker of neuronal activation

Paracrine: Action of a peptide or hormone on local or nearby cells without entering the circulatory system.

Summary Points

- CCK is released by the "I" type enteroendocrine cells localized predominantly in the proximal small intestine.
- CCK release is stimulated by the presence of nutrients, especially digestion products of fats and proteins, in the intestinal lumen.
- CCK coordinates digestion and absorption of nutrients and exerts a variety of biological functions within the gastrointestinal tract including stimulation of gallbladder contraction, stimulation of intestinal motor activity and inhibition of gastric emptying, and stimulation of bile and pancreatic enzyme secretion.
- CCK is one of the most potent satiation signals, inhibiting food intake in multiple species including humans.
- CCK exerts its physiological actions via CCK-1 and CCK-2 receptors; however, CCK reduction of food intake is primarily mediated by CCK-1R located on vagal sensory neurons.
- CCK acts to reduce food intake mainly through a paracrine mode of action, though a direct action of CCK on hindbrain neurons has also been suggested.
- Chronic exposure to diets, particularly rich in fats, results in decreased behavioral and neuronal responses to CCK.
- CCK interacts with short-term anorexigenic signals as well as long-term adiposity signals to enhance suppression of food intake and body weight.
- CCK still remains a potential target for use in curbing appetite and treatment of obesity, either alone or in combination with other peptides involved in the control of food intake and energy balance.

Chapter 13
The Role of Ghrelin in Eating Behavior

Mihai Covasa and Timothy Swartz

Abbreviations

AP	Area postrema
ARC	Arcuate nucleus
CCK	Cholecystokinin
CNS	Central nervous system
DMH	Dorsomedial hypothalamus
DVC	Dorsal vagal complex
Fos-Li	Fos-like immunoreactivity
GH	Growth hormone
GHS-1Ra	Growth hormone secretagogue
GI	Gastrointestinal
GLP-1	Glucagon-like peptide-1
GOAT	Gastric O-acyl transferase
HF	High-fat
ICV	Intraventricular
IP	Intraperitoneal
IV	Intravenous
mRNA	messenger RNA
NTS	Nucleus tractus solitarius
PVN	Paraventricular nucleus
PYY	Peptide tyrosine-tyrosine
VMH	Ventromedial hypothalamus

13.1 Introduction

Of all hormones and peptides secreted from the gastrointestinal (GI) tract, only one discovered thus far has been shown to promote food consumption. Discovered in 1999, ghrelin, the potent orexigen, is a 28 amino acid peptide released mainly from specialized endocrine cells of the mucosal layer in the stomach. It exerts its physiological effects on stimulating eating and growth hormone (GH)

secretion by binding to the GH secretagogue receptor-1a (GHS-R1a). Compared to other peptides released from the GI tract, ghrelin is unique due to its increased circulating levels during fasting, which together with its ability to increase food intake indicates the possibility of a role in initiating a meal. To increase food intake, ghrelin activates neurons of hindbrain and hypothalamic nuclei heavily involved in the short- and long-term control of food intake and energy balance. In addition to its direct effects of stimulating food intake, ghrelin also decreases energy expenditure and promotes the storage of fatty acids in adipocytes, denoting its potential importance in pathological conditions, such as obesity. Furthermore, ghrelin is implicated in other disease states characterized by loss of body mass, such as age-related and pathological anorexia. This chapter will focus on (1) factors regulating ghrelin secretion and circulating levels, (2) mechanisms underlying ghrelin-induced hyperphagia, (3) interaction of ghrelin with other signals that control food intake, and (4) the role of ghrelin on long-term energy homeostasis in pathological conditions.

13.2 Ghrelin Modulates Gastrointestinal Functions

Ghrelin exerts several physiological effects on the gastrointestinal system to decrease the time of transit for ingested nutrients through the GI tract. Most notably, ghrelin has a significant effect on accelerating gastric emptying and enhancing motility of the distal small intestine and colon (Asakawa et al. 2001). In addition to these motility effects on the GI tract, ghrelin also stimulates gastric acid secretion as well as enzymatic secretion from alimentary organs (Masuda et al. 2000; Sato 2003). Thus, ghrelin enhances the digestion of bolus in the stomach and propulsion of chyme through the GI tract in preparation for the next meal. Also, by decreasing the transit time of nutrients in the intestine, ghrelin limits post-ingestive feedback from GI satiety signals that serve to terminate a meal. To increase motility and enzymatic secretions of the GI tract, ghrelin arising from two sources, central and peripheral tissues, controls these mechanisms.

13.3 Ghrelin Is Distributed Through Both Central and Peripheral Tissues

Ghrelin is the endogenous ligand for the GHS-R1a receptor (now referred to as "the ghrelin receptor"). Both ghrelin and its receptor are located in peripheral and central tissues. Within the central nervous system (CNS), ghrelin is localized in hypothalamic and pituitary nuclei of the forebrain that are heavily implicated in the control of food intake or GH secretion. Despite the initial finding that ghrelin stimulates GH secretion (Kojima et al. 1999), the most potent biological function of the peptide is stimulation of food intake through a GH-independent mechanism (Wren et al. 2000). The arcuate nucleus (ARC) of the hypothalamus, which is involved in controlling food intake, expresses the highest concentration of centrally distributed ghrelin (Lu et al. 2002). Although ghrelin is distributed throughout the central nervous system, peripheral ghrelin from the GI tract, most notably the stomach, is thought to be the primary site for ghrelin secretion (Hosoda et al. 2000). In support of this, partial or complete, gastrectomy (removal of the stomach) markedly reduces circulating ghrelin levels by approximately 70% (Jeon et al. 2004). Ghrelin is produced in the mucosal layer of the stomach by the endocrine X/A-type cells (Date et al. 2000), which are distributed throughout the stomach, but are highly concentrated in the fundic area (Yabuki et al. 2004). Gastric X/A-type cells increase in number throughout fetal period, reaching a maximum during infancy. Likewise, ghrelin levels in the stomach are low during development. One month following birth, however, ghrelin

concentrations reach a peak and show no further increase. While the stomach is the main site of ghrelin secretion, ghrelin is detected throughout all layers of the GI tract, salivary glands, and alimentary organs, such as the pancreas (van der Lely et al. 2004), all of which contribute to circulating levels of the peptide. In the circulation, ghrelin is represented by two forms: des-acyl ghrelin and acyl ghrelin (*n*-octanoyl-modified ghrelin) (Hosoda et al. 2003). The former version is five to ten times more abundant in plasma than the latter; however, the less common acyl-peptide is thought to be the active form in nearly all physiological, behavioral, and endocrine processes, including food intake. To yield the biologically active acyl-ghrelin, the enzyme gastric O-acyl transferase (GOAT) must cleave the pre-proghrelin peptide (Yang et al. 2008). While the finding of two forms or ghrelin as well as the enzyme responsible for yielding the active form of ghrelin have been recent in respect to the discovery of ghrelin, both total ghrelin and active ghrelin plasma concentrations have been shown to be highly correlative following experimental manipulations (Yokota et al. 2005). A variety of factors control ghrelin secretion from the stomach into the peripheral circulation, with energy and macronutrient content of a meal being the main ones.

13.4 Ghrelin Secretion Is Regulated by Energy Status and Nutrients

Remarkably, measurable ghrelin levels are consistent between sexes and across age groups; however, age-related anorexic rats' plasma ghrelin levels fail to increase after 72 h fasting (Wolden-Hanson 2006). While this implicates age as a factor in modulating ghrelin levels, it more likely underscores the importance of food components regulating secretion of the peptide. As such, during periods of food deprivation, across a large range of ages, plasma ghrelin is substantially elevated while refeeding or recovery from the deprivation rapidly blunts elevated circulating levels (Ariyasu et al. 2001; Tschop et al. 2000) (Fig. 13.1). The increased levels of plasma ghrelin during these deprivation challenges are associated with up-regulation of ghrelin receptors leading to increased food intake (Tups et al. 2004).

Ghrelin levels are also influenced by the timing of a meal. In schedule-fed rats, rising ghrelin levels coincide with preprandial period or onset of a meal (Drazen et al. 2006). Similarly, in humans, ghrelin levels substantially increase before the onset of a meal and adjust according to meal times
Fig. 13.1 Total serum ghrelin levels in rats either fed or after a 48-h fast. Food deprivation induces increased ghrelin secretion as evidenced by increased serum levels following fasting (Adapted from Tschöp et al. 2000)

(Cummings et al. 2001). Long-term markers of altered energy homeostasis, such as adiposity, also correlate with circulating ghrelin concentrations. Obesity, a pathological state characterized by increased body mass, is characterized by an alteration of secretion and circulating ghrelin concentrations. Specifically, an increased body mass index (BMI) directly correlates with decreased plasma ghrelin levels (Ariyasu et al. 2001). Because obesity is associated with suppressed ghrelin levels, it is not surprising then that anorexic patients with significantly lower BMIs exhibit chronically elevated circulating ghrelin concentrations (Otto et al. 2001). The decreased concentration of circulating ghrelin in obese individuals is thought to be due to excess energy intake; whereas in anorexic patients, a constant caloric deficit causes elevated plasma ghrelin concentrations, in attempt to restore proper energy balance. In both pathological states, however, ghrelin levels begin to return to normal concentrations when the individual is nearing normal body weight (Cummings et al. 2002). Furthermore, in addition to food intake and energy balance, the composition of an ingested meal is an important regulator of ghrelin secretion.

Despite ghrelin being released from the stomach, an organ sensitive to mechanical rather than chemical signals (volume vs. specific nutrients of a meal), and macronutrient content of the meal has a significant effect on modulating ghrelin release. Nutrients from all three major macronutrient classes suppress ghrelin secretion; however, carbohydrates and proteins are most potent inhibitors. Specifically, in humans, a carbohydrate solution significantly decreases ghrelin secretion in a biphasic manner, while protein suppresses circulating ghrelin significantly more 40-min postprandially than an equicaloric and equivolumetric lipid drink (Foster-Schubert et al. 2008) (Fig. 13.2). In rodents, gastric
Fig. 13.2 Effects of macronutrients on suppression of circulating plasma acyl-ghrelin concentrations. Both carbohydrate and protein inhibit ghrelin secretion more effectively than lipid (Reprinted from Foster-Schubert et al. 2008)

infusions of glucose more potently inhibit ghrelin secretion than infusions of fatty acids and amino acids. These effects, however, are dependent upon intestinal absorption of nutrients as gastrically infused glucose solutions fail to suppress circulating ghrelin concentrations when the gastric pylorus is occluded (Williams et al. 2003). Furthermore, treatment with orlistat, a potent lipase inhibitor, abolishes long-chain fatty acid–induced reduction of plasma ghrelin levels (Feinle-Bisset et al. 2005). Together, these pieces of evidence demonstrate the importance of short- and long-term food intake as well as macronutrient content of a meal to regulate ghrelin secretion. Because circulating levels of the peptide are largely affected by the timing of a meal, it appears that ghrelin may have a physiological role in meal initiation.

13.5 Ghrelin Increases Food Intake

Ghrelin is the only known potent peripheral peptide hormone that is an orexigenic. This is supported by several pieces of evidence. First, both central and peripheral administration of ghrelin results in increased food intake and associated appetitive ratings (Tschop et al. 2000; Wren et al. 2001a, b) (Table 13.2). In rodents, exogenous ghrelin induces food intake during the light cycle, a period associated with minimal food consumption (Wren et al. 2001b). Second, administration of either a ghrelin receptor antagonist or an anti-ghrelin immunoglobulin (IgG), which inactivates biologically active ghrelin, causes a decrease in food intake in several feeding paradigms (Asakawa et al. 2003; Nakazato et al. 2001). Furthermore, ghrelin decreases latency to eat and increases meal number. Interestingly, both humans and rodent models retain sensitivity to the peptide and repeated administration results in exponential increase in cumulative food intake leading to increased bodyweight and adiposity (Druce et al. 2005; Tschop et al. 2000; Wren et al. 2001b) (Table 13.3). Altogether, these findings support the hypothesis that ghrelin is an orexigenic signal controlling food intake. Currently, two routes of action, endocrine and paracrine, thought to underlie peripheral ghrelin-induced hyperphagia (Fig. 13.3).

Table 13.1 Key features of ghrelin in eating behavior

1. Ghrelin is the endogenous ligand for the growth hormone (GH) secretagogue receptor-1a (GHS-1Ra), now named "the ghrelin receptor."
2. Ghrelin is released from the X/A-type cells in the mucosal layer of the stomach.
3. Currently, ghrelin is the only known endogenous peripheral peptide hormone that potently increases food intake.
4. All three macronutrient classes inhibit release of ghrelin; however, products of carbohydrate and protein digestion are more potent inhibitors than fats.
5. Ghrelin utilizes endocrine and paracrine pathways to induce hyperphagia by activating neurons involved in the control of food intake. Specifically, ghrelin activates downstream neurons that produce orexigenic central neuropeptides.
6. Ghrelin elicits physiological effects on a variety of digestive organs including the stomach, intestine, and pancreas.
7. Circulating ghrelin is considered to be an inverse adiposity signal. That is, ghrelin levels are significantly suppressed in obese individuals and markedly elevated in individuals with a low body mass index.

Key points illustrating the role of ghrelin in controlling eating behavior. It summarizes stimulation of ghrelin secretion, release, and main effects of the hormone

Table 13.2 Food intake following peripheral administration of ghrelin in rats

Ghrelin dose (nmol)	Food intake (g)

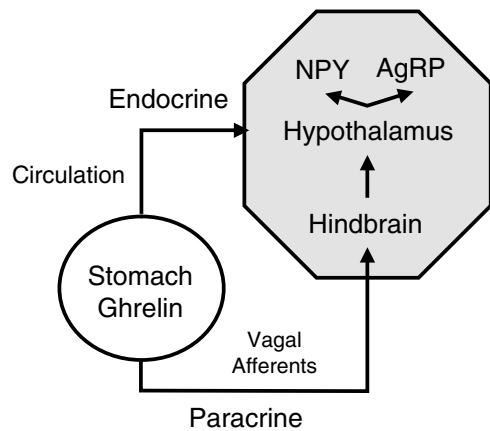
Ghrelin increases bodyweight gain compared to saline treatment

Fig. 13.3 Pathways through which peripheral ghrelin activates CNS nuclei and promotes food consumption. Ghrelin binds locally to the ghrelin receptor on vagal afferents innervating the stomach and relays information to the hindbrain, which activates hypothalamic nuclei. Ghrelin also can enter the circulatory system, diffuse into hypothalamic nuclei, and activate neurons producing NPY and AgRP


13.6 Ghrelin Controls Food Intake via Endocrine and Paracrine Mechanisms

Administration of ghrelin intravenously (IV) that results in physiological circulating levels in both animals and humans increases food intake (Hashimoto et al. 2007; Wren et al. 2001a) in both fasted or fed conditions (Hashimoto et al. 2007). In addition, IV administration of either ghrelin or a ghrelin receptor agonist stimulates neuronal activation in brain nuclei involved in the control of food intake as evidenced by Fos-like immunoreactivity (Fos-Li, a marker of neural activation) (Lawrence et al. 2002). This evidence, together with the fact that ghrelin producing gastric oxyntic cells are situated in close proximity to vascular capillaries (Date et al. 2000), lend support to the fact that endogenous ghrelin increases food intake through an endocrine route of action. However, there is also substantial evidence demonstrating a paracrine pathway, involving vagal afferents. The vagus cranial

nerve relays information from visceral organs to the hindbrain that integrates sensory and motor information. Many of the gut peptides released from the intestine bind to their receptors on the vagus to transmit information and exert physiological, endocrine, and behavioral effects. In support of a vagally-mediated pathway underlying ghrelin-induced food intake is the presence of the ghrelin receptor on gastric vagal afferents and ghrelin receptor mRNA in nodose ganglion cell bodies of the vagus (Date et al. 2002). Ghrelin administered in the peritoneal cavity also increases food intake by approximately 500% of baseline and is effective in increasing food intake for at least 1-h post injection (Wren et al. 2001b). It is largely thought that IP administration simulates the high concentrations of the gut peptide released by the stomach near local vagal afferents. Direct support of a vagally mediated mechanism of action is that vagotomy attenuates ghrelin-induced stimulation of food intake in humans as well as in rodents (Date et al. 2002; le Roux et al. 2005). The specific afferents responsible for the behavioral effects of ghrelin are thought to be vagal sensory afferents as application of the potent neurotoxin, capsaicin, which destroys a majority of vagal sensory fibers, attenuates increases of food intake stimulated by ghrelin administration (Date et al. 2002). While these data show that peripheral ghrelin increases food intake through two mechanisms of action, the downstream neurons that receive and mediate ghrelin-induced hyperphagia are located in the hypothalamus and hindbrain nuclei.

13.7 Ghrelin Increases Food Intake Through the CNS

The precise mechanisms by which peripheral ghrelin gains access to brain nuclei expressing the receptor are not completely known. Evidence shows that the blood–brain barrier is slightly permeable to the peptide and ghrelin is able to freely diffuse into hypothalamic nuclei involved in the control of food intake. As such, ghrelin acts on the hypothalamus to increase food intake. This is based on the following: (1) acute or chronic administration of ghrelin into either the lateral or third ventricle, which allows access to hypothalamic nuclei, results in a robust increase of meal size (Kinzig et al. 2006) or increases meal frequency (Faulconbridge et al. 2003) followed by substantial body weight gain (Tschop et al. 2000); (2) ICV administration of a ghrelin immunoglobulin attenuates food-deprivation–induced feeding, a time when ghrelin is typically most potent (Bagnasco et al. 2003); and (3) central administration of ghrelin induces neuronal activation (Lawrence et al. 2002). These data clearly demonstrate a role for the hypothalamus in ghrelin-induced increase of food intake. Among the four hypothalamic nuclei – the dorsomedial (DMH), the ventromedial (VMH), the paraventricular (PVN), and the arcuate (ARC) – that display immunoreactivity for ghrelin or the ghrelin receptor (Cowley et al. 2003) and mediate ghrelin's actions (Wren et al. 2001b), it is believed the ARC and PVN are the primary nuclei involved in ghrelin-induced increases of food intake. Compared to other hypothalamic nuclei, the ARC exhibits significantly higher ghrelin immunoreactivity and increased neural activation after exogenous ghrelin (Hewson et al. 2002). Furthermore, rats with ARC neuronal ablation do not increase their intake in response to ghrelin and do not compensate for caloric deficit (Tamura et al. 2002) demonstrating the influence of ghrelin signaling within ARC in maintaining energy balance. Similarly, administration of ghrelin directly into the PVN increases food intake equally to that of ICV infusion (Currie et al. 2005). This suggests that the ARC mediates short-term increases while the PVN is responsible for mediating long-term increases of food intake stimulated by ghrelin (Bagnasco et al. 2003). From these data, the hypothalamus is undoubtedly a mediator of ghrelin-induced hyperphagia.

Ghrelin can also access ghrelin receptors located in the hindbrain, an area heavily involved in food intake, including the nucleus tractus solitarius (NTS), area postrema (AP), and dorsal motor

nucleus of the vagus (DMV) (Guan et al. 1997) either via vagal afferents or through porous blood–brain barrier structures. Indeed, both central and peripheral administration of ghrelin or ghrelin receptor agonists significantly increase neuronal activation in the NTS, AP, and DMV (Lawrence et al. 2002; Takayama et al. 2007). Furthermore, ICV administration into the fourth ventricle, which perfuses the hindbrain, increases food intake in similar magnitudes to third ventricle administration that accesses forebrain hypothalamic nuclei (Kinzig et al. 2006). The effective dose that stimulates food intake in the DVC (10 pmol) is significantly lower than threshold orexigenic dose of ghrelin for the ARC (30 pmol) as well (Faulconbridge et al. 2003). Finally, destruction of the AP also results in decreased sensitivity to exogenous ghrelin (Gilg and Lutz 2006). Together, these data indicate the importance of the hindbrain in mediating ghrelin-induced hyperphagia

While the hindbrain, as well as the hypothalamus, is important in regulating ghrelin-induced increases in food intake, they are not considered to mediate this phenomenon independently. Peripheral satiety signals acting through the hindbrain are integrated at the level of the hypothalamus which modulates intake. As such, destruction of hindbrain–forebrain neuronal circuits results in an attenuation of sensitivity to ghrelin-induced hyperphagia. Additionally, ablation of these relays causes a substantial decrease in neuronal activation in the ARC induced by ghrelin (Date et al. 2006). Thus, ghrelin released from the stomach utilizes a vagally- and hindbrain-mediated pathway to signal hypothalamic nuclei to increase food intake. While ghrelin profoundly stimulates food intake through a hindbrain–hypothalamic pathway, its magnitude of increased consumption is remarkably similar to that caused by other orexigenic agents in the hypothalamus, specifically, Neuropeptide Y (NPY) and Agouti-Related Peptide (AgRP) (Wren et al. 2000, 2001b).

13.8 Ghrelin Interacts with Central Neuropeptides to Increase Food Intake

The majority of neurons expressing NPY are located in the ARC, and approximately half of these neurons co-express AgRP. Both peptides are potent orexigenic signals, but differ in the duration of their effects. Specifically, NPY stimulates short-term increases of food intake while AgRP increases long-term feeding (Tang-Christensen et al. 2004). A wealth of data consisting of both neuroanatomical and behavioral evidences lends support to the interaction between ghrelin and these peptides. Ghrelin producing neurons in the forebrain synapse directly with the somatic or dendritic portion of NPY neurons in the ARC and ghrelin receptor is localized on presynaptic terminals of NPY neurons (Cowley et al. 2003). Together, these data suggest indirectly that ghrelin may modulate feeding behavior through NPY and AgRP neurons.

Studies examining neuronal activation provide direct evidence for the interaction between ghrelin and neurons producing these peptides. For example, ghrelin induces significant increases of intracellular calcium in NPY expressing neurons (Cowley et al. 2003) and ICV administration of an effective orexigenic dose of ghrelin activates ARC neurons expressing NPY as evidenced by Fos-Li (Lu et al. 2002; Wang et al. 2002). Further support of the interaction between these peptides is that in vitro studies examining hypothalamic tissues show increased expression of NPY and AgRP when incubated with a ghrelin receptor agonist (Goto et al. 2006). Similarly, in vivo, NPY and AgRP expression is up-regulated following either acute or chronic central administration of an effective dose of ghrelin (Kamegai et al. 2001). Therefore, ghrelin is able to activate neurons producing NPY and AgRP as well as modulate expression of these potent central orexigens. Conversely, endogenous NPY and AgRP modulate ghrelin-induced hyperphagia. For example, the absence of ARC NPY/AgRP signaling results in an abolished or attenuated sensitivity to ghrelin (Tamura et al. 2002). Additionally, central application of antibodies for NPY or AgRP or antagonists for NPY or AgRP

receptors results in an attenuation of ghrelin-induced hyperphagia (Nakazato et al. 2001; Shintani et al. 2001). Finally, mice engineered with a null gene for NPY and AgRP have a completely abolished response to both central and peripheral ghrelin administration as well (Chen et al. 2004). Collectively, these data support the hypothesis that NPY and AgRP are mediators of ghrelin-induced stimulation of food intake. In addition to the interaction between ghrelin and these central orexigenic peptides, there are antagonistic interactions between ghrelin and peripheral satiety peptides secreted from the GI tract.

13.9 Ghrelin Interacts with Peripheral Satiety Signals

Several studies have shown that ghrelin interacts at various levels with other gut signals to control food intake. For example, vagal afferent neurons that contain the ghrelin receptor also co-express receptors for satiety signals, such as cholecystokinin (CCK), glucagon-like peptide-1 (GLP-1), and peptide tyrosine-tyrosine (PYY) receptors. Additionally, administration of ghrelin down-regulates expression of these peptide receptors (Burdyga et al. 2006; de Lartigue et al. 2007). Ghrelin and CCK have opposing effects. While CCK causes vagal activation, ghrelin potently inhibits activation of the vagus (Date et al. 2002), and ghrelin administered to vagal afferent tissue blocks upstream anorexigenic peptide expression induced by CCK (de Lartigue et al. 2007). Furthermore, ghrelin-induced activation of neurons in the hypothalamus is potently suppressed by administration of CCK. As a result of these opposing effects, administration of CCK prior to ghrelin treatment abolishes ghrelin-induced increase of food intake (Date et al. 2005).

The interaction of ghrelin is not limited to CCK. Administration of ghrelin IV prior to GLP-1 attenuates GLP-1–induced satiation. Additionally, infusion of ghrelin at a level that has no effect on gastric emptying attenuates delayed gastric emptying induced by GLP-1, supporting the powerful action of ghrelin to reduce satiation by affecting GI motility. Finally, ghrelin interacts with PYY. Ghrelin infusion preceding administration of PYY attenuates PYY-induced inhibition of food intake even at a dose of ghrelin that does not stimulate food intake alone. Similarly to GLP-1, PYY-induced delayed gastric emptying also is attenuated by a sub-threshold dose of ghrelin (Chelikani et al. 2006). This evidence shows that ghrelin is a major player in interacting with other gastrointestinal peptides to influence gut functions and food intake.

13.10 Ghrelin Increases Intake of Palatable Foods

While it has been established that hindbrain and forebrain nuclei underlie ghrelin-induced hyper-phagia, brain nuclei that are associated with overconsumption of palatable foods also express the ghrelin receptor. Therefore, it is possible that ghrelin may increase the preference or consumption of palatable foods. The two nuclei involved in palatable food intake that predominantly express the receptor for ghrelin are the ventral tegmental area (VTA) and nucleus accumbens (NAcc) (Guan et al. 1997). Akin to direct injections of ghrelin into hindbrain or hypothalamic nuclei, administration of ghrelin directly into the VTA stimulates food intake in freely fed rats (Naleid et al. 2005). Furthermore, central administration of ghrelin during preference tests with isocaloric high-fat (HF) and low-fat (LF) diets also increases consumption of a usually highly preferred HF meal compared to an LF meal. Surprisingly, the preference of the HF meal after ghrelin injection is established even in rats that normally prefer the LF meal (Shimbara et al. 2004). In contrast to this finding, use of a

synthetic ghrelin receptor agonist in carbohydrate preferring S5B rats increases consumption of carbohydrates while ghrelin increases consumption of fat in Osborne-Mendel rats, which normally prefer fat (Liu et al. 2004). Studies examining intake of energy-dense chow and a highly diluted sucrose solution following ghrelin administration have shown that rodents increase intake of both nutrient sources; however, intake of the energy-dense chow increases to a greater magnitude than that of the dilute sucrose solution (Bomberg et al. 2007). In light of these findings, it appears that ghrelin may stimulate intake of palatable foods, regardless of the preferred nutrient. Additionally, energy density appears to be an important determinant in food intake induced by ghrelin as it increases consumption of fat and highly energy dense chow. Further experiments controlling both palatability and energy density are needed to elucidate whether one or both properties of ingested foods plays a role in ghrelin-induced intake of palatable foods. Moreover, knockout models encoding a null gene for the ghrelin receptor gain weight, but are not susceptible to obesity induced by a highly palatable, HF diet (Zigman et al. 2005). Whether this is due to a decreased preference for the diet or absence of appetite due to inefficient ghrelin signaling has not been determined. Nevertheless, these data collectively show that ghrelin has a role in increased intake of palatable foods. In addition to ghrelin increasing both normal and palatable food intake, it also has a role in increasing adiposity.

13.11 Ghrelin Increases Body Adiposity

While ghrelin increases bodyweight through the initiation of meals or increase of meal size, it also causes increases in body adiposity independently of increased food intake (Theander-Carrillo et al. 2006). To accomplish this, it is thought that ghrelin causes a shift in energy metabolism away from fats to other fuel sources, most likely carbohydrates. In this regard, administration of ghrelin decreases respiratory quotient of animals, which denotes a decrease in lipid metabolism (Asakawa et al. 2001). Also, ghrelin activates the expression of triglyceride storing enzymes that shuttle circulating fatty acids into white adipose tissue, promoting increased body fat. At the same time, the increase in fatty acid storage enzymes is accompanied by decreases in thermogenic enzymes that are active in brown adipose tissue and muscle. Thus, by increasing anabolic pathways of energy storage factors and decreasing catabolic enzyme activity, ghrelin exerts a net effect of increasing adiposity through two routes of action. Therefore, ghrelin allows freely circulating fatty acids in the circulation to be more efficiently stored in adipocytic tissue (Theander-Carrillo et al. 2006). From these findings, it is plausible that chronically increased endogenous levels of ghrelin increase food intake and decrease energy expenditure, creating a scenario with proneness for weight gain and subsequent obesity. Indeed, there is a correlative relationship between obesity and ghrelin. Thus, it may be that ghrelin has implications in treating the current obesity epidemic.

13.12 Applications to Other Areas of Health and Disease

While the worldwide population is becoming increasingly obese, only few mutations in the ghrelin pathway have been reported. In individuals with Prader–Willi syndrome, a disorder characterized by overconsumption of food and obesity during adolescence, ghrelin may be one of the underlying contributors to the exhibited hyperphagia as circulating levels are substantially elevated in these individuals. In general, however, despite the fact that ghrelin levels are decreased in obese

individuals without consistent meal-related preprandial increases and postprandial decreases in plasma concentrations, ghrelin therapeutics may be effective in treating obesity. The finding that ghrelin levels increase with the reduction of weight in obese individuals may denote that ghrelin contributes to the subsequent rebound in weight after diet-induced weight loss. Additionally, the unusually low levels in obese individuals may signify an enhanced sensitivity to the peptide. Together, these findings suggest that antagonists or antibodies for the ghrelin receptor or ghrelin may be useful in treating obesity. Indeed, ghrelin receptor antagonists reduce food intake and weight gain in both lean and obese rodent models (Asakawa et al. 2003; Salome et al. 2009); however, use of these drugs in humans, ironically, results in increased food intake and weight gain (Halem et al. 2004). Furthermore, ghrelin vaccines, which are potent antisera reducing endogenous levels of the peptide, reduce food intake and body weight in lean and obese rodents similarly to ghrelin receptor antagonists (Zorrilla et al. 2006). In humans, ghrelin vaccines result in no noticeable changes in body weight. Thus, current treatments are ineffective in treating obesity in humans, and further investigation into new ghrelin vaccines may reveal other feasible options in the treatment of obesity through ghrelin signaling.

Currently, gastric bypass is the most effective intervention to ameliorate obesity. Initial findings pointed to ghrelin secretion being nearly abolished in individuals with the bypass procedure accompanied by significant weight loss (Cummings et al. 2002) (Fig. 13.4). However, it has been subsequently shown that ghrelin levels normalize or increase after postoperative weight-loss is regained (Holdstock et al. 2003). Decreased circulating ghrelin levels have been associated with decreases in appetitive ratings as well (Cummings and Shannon 2003). Similarly, less invasive surgical interventions, such as
Fig. 13.4 Gastric-bypass modulates circulating ghrelin levels. In obese individuals, circulating ghrelin concentrations are decreased compared to normal-weight individuals; however, after surgical intervention, plasma ghrelin levels are almost completely abolished, nearing undetectable concentrations (Reprinted from Cummings et al. 2002)

gastric bands and intestinal sleeves, which limit exposure of nutrients to the stomach or intestine, result in decreased circulating ghrelin levels or attenuation of weight-loss induced increases in plasma ghrelin concentrations (Aguirre et al. 2008). However, further research is needed to elucidate the specific mechanisms that underlie the decreased ghrelin levels observed in these individuals. In addition to obesity, ghrelin is a targeted therapeutic intervention in disease states characterized by loss of appetite and bodyweight, such as cancer, anorexia, and cardiac cachexia. In these patients, therapy with exogenous ghrelin is very efficacious as it typically increases food intake, associated appetitive scores, as well as bodyweight (Nagaya et al. 2005; Neary et al. 2004).

Summary Points

- Ghrelin is a 28 amino acid peptide hormone that is the endogenous ligand for the growth hormone (GH) secretagouge receptor-1a (GHS-R1a) now referred to as "the ghrelin receptor."
- Ghrelin is produced and secreted by the X/A-type cells in the mucosal layer of the stomach. It is currently the only known peripheral peptide hormone that increases food intake. The biologically active form of ghrelin in the circulation that increases food intake is acyl-ghrelin.
- Both short- and long-term food intake modulate circulating ghrelin levels. Specifically, ghrelin increases during preprandial and decreases during postprandial periods. Chronic food deprivation significantly elevates plasma ghrelin concentrations.
- All three macronutrient classes suppress ghrelin secretion, but carbohydrates and proteins are significantly more effective than fat in inhibiting ghrelin secretion.
- Ghrelin is thought to be an adiposity signal as circulating ghrelin concentrations correlate inversely with body mass index (BMI).
- Peripheral ghrelin increases food intake through an endocrine as well as a paracrine mechanism of action. The two regions of the central nervous system that are thought to underlie ghrelin-induced increase of food intake are the hypothalamus and hindbrain.
- Two potent hypothalamic orexigenic signals, Neuropeptide Y (NPY) and Agouti-Related Peptide (AgRP), are mediators of ghrelin-induced hyperphagia.
- Ghrelin increases consumption of palatable foods regardless of macronutrient preferred.
- Ghrelin increases adiposity independent of increased food intake by inhibiting catabolic and activating anabolic metabolic pathways.

Definitions

Ghrelin: The only known potent peripheral signal that induces hyperphagia as well as inducing adiposity.

Endocrine: Entry of peptide or hormone into the bloodstream to exert effects on distant tissues

X/A-type cells: Specialized gastric cells in the mucosal layer that produce and release ghrelin. The basolateral portion of the cell is responsible for hormone secretion and is positioned next to capillaries.

Fos: Protein that is a product of the immediate-onset c-fos gene. Used in immunohistochemical experiments as a marker of neuronal activation

Paracrine: Action of a peptide or hormone on local or nearby cells without entering the circulatory system.

Chapter 14
The Role of Glucagon-Like Peptide-1 (Glp-1) in Eating Behavior

Mihai Covasa and Timothy Swartz

Keywords: Diffusion tensor imaging • Fetal alcohol spectrum disorder • Brain • Fetal alcohol syndrome • MRI • DTI

Abbreviations

AP	Area Postrema
ARC	Arcuate nucleus
CNS	Central Nervous System
DMV	Dorsal Motor Nucleus of the Vagus
DPP-IV	Dipeptidyl peptidase IV
GI	Gastrointestinal
GLP-1	Glucagon-like peptide-1
GLP-1R	Glucagon-like peptide-1 receptor
HF	High-fat
ICV	Intracerebroventricular
IP	Intraperitoneal
IV	Intravenous
mRNA	Messenger RNA
NTS	Nucleus Tractus Solitarius
PVN	Paraventricular nucleus
PYY	Peptide tyrosine-tyrosine

14.1 Introduction

Numerous peptides are produced and released from the enteroendocrine L-cells lining the distal small intestine and colon. Among these are peptides from the proglucagon family, which are derived from expression of the proglucagon gene. A number of other glucagon-like peptides have also been identified with similar biological activities that are representative of the proglucagon family. These

Table 14.1 Key features of GLP-1 in eating behavior

1. GLP-1 is mainly released from the enteroendocrine L-cells of the ileum and colon
2. All three macronutrient classes stimulate release of GLP-1
3. GLP-1 has potent regulatory effects on gastrointestinal functions
4. GLP-1 induces satiation through both central and peripheral pathways, which mediate different gastrointestinal stimuli
5. GLP-1 activates hindbrain neurons through vagal afferent sensory nerve fibers and is also locally produced by hindbrain neurons
6. GLP-1 potentiates nutrient-induced insulin secretion, which classifies it as an incretin
7. GLP-1 analogs are effective in normalizing blood glucose levels in diabetics and reduce body weight in obese individuals

Table illustrating the features of GLP-1 in controlling eating behavior summarizing stimulation of secretion, release, and effects of the hormone

peptides have a profound role in gastrointestinal (GI) functions including secretion and motility, gut proliferation, potentiation of insulin secretion, and inhibition of food intake. One such peptide is glucagon-like peptide-1 (GLP-1). GLP-1 exerts physiological and behavioral effects by binding to the GLP-1 receptor (GLP-1R), which is expressed by central and peripheral nervous systems as well as alimentary organs, such as the pancreas. In addition to the L-cells of the GI tract, neurons of the central nervous system (CNS) produce GLP-1. To decrease food intake, GLP-1 acts through paracrine and endocrine pathways, which stimulate neuronal nuclei involved in the control of food intake. Furthermore, locally produced GLP-1 in the brain also serves to control food intake. The finding that GLP-1 potentiates insulin secretion denotes its role in pathological disease states, such as obesity, which is often accompanied by insulin resistance, and diabetes mellitus. This chapter focuses on (1) distribution of GLP-1 and factors regulating GLP-1 secretion, (2) mechanisms underlying GLP-1 induced satiation, (3) the interaction of GLP-1 with other signals controlling food intake, and (4) the role of GLP-1 in pathological conditions (Table 14.1).

14.2 GLP-1 Is Distributed Throughout Central and Peripheral Tissues

GLP-1 is the posttranslational product of pre-proglucagon gene expressed in the pancreatic α-cells, intestinal L-cells, as well as the CNS. It is synthesized by intestinal L-cells in two forms: GLP-1$_{1-37}$ and GLP-1$_{1-36}$ and undergoes further cleavage to produce the biological active fragments: GLP-1$_{7-36}$ and GLP-1$_{7-37}$ (Holst et al. 1987; Mojsov et al. 1987). Both peptide isoforms are equally potent in their biological activities; however, the GLP-1$_{7-36}$ amide is the major circulating form (Orskov et al. 1994). The two forms of GLP-1 are rapidly inactivated by the dipeptidyl peptidase-4 (DPP-IV) enzyme leaving approximately 10–15% of active GLP-1 in the systemic circulation, which is further degraded by DPP-IV. Thus, GLP-1 has a very short half-life in the circulation (~1–2 min) (Deacon et al. 1996). To exert endocrine, physiological, and behavioral effects, GLP-1 binds to the GLP-1R. The GLP-1R is a G-protein transmembrane-bound receptor and is coupled to a stimulatory G-protein to exert its downstream cellular cascade of events. The GLP-1R was first identified and cloned from rat pancreatic islets followed by the cloning of the human variant (Dillon et al. 1993; Thorens et al. 1992). Since its discovery, two exogenous ligands derived from the venom of the Gila monster, a reptilian species native to the Southwestern United States, have been discovered for the GLP-1R (Parker et al. 1984). The first is exendin-4, which is an agonist for the receptor and the second is exendin-9 that serves as an inverse agonist, but typically referred to as an antagonist for GLP-1Rs.

Both GLP-1 and its receptor are distributed throughout both central and peripheral tissues. In the CNS, the peptide and its receptor are widely distributed throughout hindbrain, midbrain, and forebrain nuclei. Because of the dichotomous nature of some of these nuclei, GLP-1 appears to play a role in many physiological and neurological functions. Although the brain may be a vast supply of the peptide, the major source is thought to be the GI tract. Because of this, GLP-1 is widely recognized as one of the predominant distal gut satiety signals released from the ileum of the small intestine as well as the large intestine. Enteroendocrine L-cells largely localized in these regions of the GI tract are the major source of GLP-1, with two predominant factors regulating its secretion: a neuro-humoral reflex and nutrients in the lumen of the intestine.

14.3 Regulation of GLP-1 Secretion

Intestinal L-cells located mainly in the distal ileum and colon secrete GLP-1 in response to a variety of nutrient, neural, and endocrine factors. Initially, due to the kinetics of meal-induced GLP-1 release, the primary mechanism of GLP-1 secretion was thought to be through an indirect, neuro-humoral reflex. Specifically, GLP-1 secretion is highest 10 min post meal ingestion when nutrients are not yet thought to make contact with GLP-1 secreting L-cells (Roberge and Brubaker 1991). While this mechanism induces secretion of GLP-1, nutrients are also thought to directly regulate release of the peptide (Dube and Brubaker 2004). Two pieces of indirect evidence support this. First, infusion of glucose directly into the proximal small intestine results in elevated circulatory GLP-1 levels comparable to distal small intestine infusion of glucose (Holst 2004). Second, recent advances in the ability to tag and detect L-cells throughout the GI tract have identified large populations of GLP-1 secreting cells that are also present in the proximal intestinal tissues that most likely mediate this rapid release of the peptide (Theodorakis et al. 2006).

The L-cells of the GI tract are open-type endocrine cells, with the apical surface strategically positioned to sense intraluminal intestinal nutrients. Binding of nutrients to apical surface membrane proteins is thought to stimulate release of GLP-1. Some of the candidate receptors thought to induce GLP-1 release are gustducin and T1R family receptor subtypes (Rozengurt and Sternini 2007). Inside the cells, a vesicular transport system shuttles GLP-1 to the basolateral portion of the cell and releases the peptide into the circulation or lymph. Thus, GLP-1-secreting cells are in an excellent position to release the hormone in response to mixed meals or single nutrients. Indeed, ingested nutrients cause secretion of GLP-1 from the GI tract. Specifically, peptone or products of protein digestion, such as amino-acids, result in secretion of GLP-1 both in vitro and in vivo (Cordier-Bussat et al. 1998; Layer et al. 1995). Fatty acids, triglycerides, and carbohydrates are also potent stimuli for GLP-1 secretion (Chu et al. 2008). GLP-1 is secreted from cell models via mechanisms that are normally dependent on glucose, including sodium-glucose transporters, and potassium-ATP sensitive pumps (Tolhurst et al. 2009). The increase of circulatory GLP-1 is prolonged in response to complex carbohydrates and fiber as well, which can be attributed to the slow digestion of these nutrients allowing for greater intestinal transit time, and increasing exposure of nutrients to GLP-1 secreting L-cells. While fasting typically results in low levels of GLP-1, blockade of enzymatic GLP-1 degradation results in increased circulatory levels, denoting some constitutive release of the peptide (Mari et al. 2005). Altogether, these data show that nutrients stimulate GLP-1 secretion, thus demonstrating the role of GLP-1 in control of food intake.
Fig. 14.1 Effect of IV infusion of GLP-1 at increasing rates on food intake in humans. At a free buffet meal, GLP-1 infusion dose-dependently decreased energy intake. *$P < 0.05$, **$P < 0.001$ (Adapted from Gutzwiller et al. (1999))

14.4 GLP-1 Decreases Food Intake

Administration of GLP-1 into either the periphery or central tissues results in a subsequent dose-dependent decrease of food intake in several species (Flint et al. 1998; Gutzwiller et al. 1999; Turton et al. 1996) (Fig. 14.1). Similar to injections of other peripheral satiety agents, such as CCK, GLP-1 limits food intake by decreasing meal size; however, at high doses, GLP-1 also decreases meal number. Furthermore, chronic administration of the GLP-1R agonist, exendin-4, results in reduced body-weight gain and adiposity (Larsen et al. 2001; Mack et al. 2006). Conversely, blockade by exendin-9 in fed rats increases food intake (Williams et al. 2009). In humans, peripheral administration of GLP-1 reduces food intake and gastric emptying. However, the role of endogenous GLP-1 in control of food intake in humans is not entirely clear since no studies thus far examined the effect of exendin-9 on energy intake. In contrast, mice lacking the GLP-1R exhibit normal eating behavior and are of normal body weight (Scrocchi et al. 1996). This has been attributed to compensatory up-regulation of other satiation signals derived from the gastrointestinal tract, especially hormones co-secreted with GLP-1 from the intestinal L-cells. Together, these data provide strong support that GLP-1 has an important role in energy balance.

14.5 GLP-1 Controls Gastrointestinal Functions

GLP-1 has potent regulatory effects on the GI tract, including gastrointestinal emptying, motility, and enzymatic secretion, thus controlling postprandial metabolical effects. Administration of GLP-1 slows gastric emptying, an effect analogous to the effects of nutrients on gastrointestinal motor functions. This is associated with the relaxation of the proximal stomach (Schirra et al. 2000), increased meal retention in the distal stomach (Little et al. 2006), the suppression of antral and duodenal pressure waves and stimulation of tonic and phasic pyloric pressures (Brennan et al. 2005; Schirra et al. 2000). Treatment with the GLP-1-specific receptor antagonist, exendin-9, blocks the effects of

GLP-1 on gastric emptying in rats (Tolessa et al. 1998) and attenuates the effects of intraduodenal glucose on the stimulation of tonic and phasic pyloric motility and the suppression of antral and duodenal pressure waves in humans (Schirra et al. 2006), suggesting that endogenous GLP-1 plays a physiological role in mediating the effects of nutrients on gastrointestinal motility. The main effect of GLP-1 on GI motility is through the "ileal brake" mechanism, which serves to slow gastric emptying. GLP-1 also decreases gastrin-stimulated gastric acid secretion, allowing more time for digestion of food (Schjoldager et al. 1989). In addition to its effects on the stomach, GLP-1 potently inhibits distal intestinal and colonic motility, and inhibits pancreatic exocrine enzymatic secretions. These actions result in increased transit time for ingesta and delays the process of digestion and absorption of nutrients. The effects of GLP-1 on GI motility and enzymatic secretions are mediated by vagal afferents since vagal deafferentation results in attenuation of GLP-1-induced delay of gastric emptying and inhibition of pancreatic enzymatic secretions (Imeryuz et al. 1997). Collectively, these findings demonstrate that GLP-1 modulates GI functions, which are accompanied by changes in food intake and metabolical profile.

14.6   GLP-1 Controls Food Intake via Vagal and Endocrine Pathways

The enteroendocrine L-cells secreting GLP-1 are situated in juxtaposition to capillaries, thus it is reasonable to assume that some of the peptide from this source makes its way into the circulation. This suggests that GLP-1 may reduce food intake by acting through an endocrine mechanism. Indeed, after a meal, circulatory levels of the peptide are substantially increased. The hepatic portal vein, which receives incoming venous blood from the GI tract as well as the intestinal epithelium, however, contains high concentrations of DPP-IV, ready to quickly degrade GLP-1 and yield an inactive form of the peptide. Thus, GLP-1 must first pass through an intermediate pathway before reaching the circulation. One such route is the lymphatic system. By circulating through the chylous lymph from the GI tract, GLP-1 enters the circulatory system at the level of the subclavian vein, an area with extremely low levels of DPP-IV, thus avoiding immediate degradation (D'Alessio et al. 2007). Once in the circulation, the active form of GLP-1 exerts its effects on the gut. For example, intravenous (IV) infusions of the peptide that result in physiological circulating levels reduces food intake in rodent models (Ruttimann et al. 2009). Similarly, infusion of GLP-1 in humans results in a dose-dependent decrease of food intake and a concomitant enhancement of satiety (Verdich et al. 2001). Together, these data clearly support an endocrine role of the peptide in controlling food intake. In addition to this route of action, GLP-1 also utilizes a paracrine pathway to decrease food intake.

Vagal afferents from the hepatic and intestinal branches of the vagus innervating the GI tract mediate the effects of GLP-1 on food intake. This is supported by research demonstrating that nodose ganglion cell bodies of the vagal afferents express immunoreactivity for the GLP-1R and application of GLP-1 to in vitro vagal afferent preparations results in activation of vagal nerve fibers (Nakabayashi et al. 1996; Nakagawa et al. 2004). Additionally, vagotomy or selective vagal deafferentation attenuates suppression of food intake and gastric emptying by intraperitoneal administration of GLP-1 (Abbott et al. 2005). Furthermore, sensory fibers are thought to be responsible for this pathway as capsaicin treatment, which selectively destroys most of these fibers, attenuates exendin-4 suppression of food intake (Talsania et al. 2005). Evidence for an endogenous role of GLP-1 to control food intake is that intraperitoneal administration of the GLP-1R antagonist, exendin-9, in rodents results in increased food intake during various feeding paradigms. Specifically, in fully sated rodents, GLP-1 antagonism results in an almost 100% increase of food intake. Additionally, while peripheral

administration of GLP-1 decreases food intake, peripheral, but not central blockade of GLP-1R using exedin-9 results in attenuation of GLP-1-induced satiation (Williams et al. 2009). Collectively, these findings point toward a local physiological role of GLP-1 secreted from peripheral organs. While peripheral GLP-1 undoubtedly is effective acting through endocrine and paracrine modes of action, several brain nuclei appear to be involved in GLP-1-induced satiation as well.

14.7 GLP-1 Decreases Food Intake via the CNS

GLP-1 is able to access CNS nuclei that control food intake. The blood-brain barrier is permeable to GLP-1 and the peptide freely diffuses into hypothalamic nuclei involved in the control of food intake that lack a structural barrier. However, the likelihood that a relevant physiological amount of the peptide evading the DPP-IV degradation reaches the brain to elicit an effect is rather low. It is more likely that brain-derived GLP-1 acts directly on hindbrain and hypothalamic neurons to control appetite. For example, intracerebroventricular (ICV) administration of GLP-1 into the forebrain or direct administration into the paraventricular nucleus (PVN) of the hypothalamus results in suppression of food intake (Kinzig et al. 2002; McMahon and Wellman 1998; Schick et al. 2003). Similarly, destruction of arcuate (ARC) hypothalamic neurons results in abolishment of GLP-1-induced satiation (Tang-Christensen et al. 2000). While the hypothalamus certainly mediates GLP-1 to control food intake, some data elude that the peptide in the forebrain may decrease food intake by inducing aversive effects. As such, ICV administration, which may lead to diffusion into the amygdala as well as site-specific injections into this nucleus, leads to aversive effects; however, direct administration into the PVN reduces food intake without nonspecific effects or any associated illness (Kinzig et al. 2002). Therefore, the hypothalamus is indeed responsible for GLP-1-induced satiation, without aversive effects. Furthermore, other brain nuclei, localized in the hindbrain are thought to participate in GLP-1-induced suppression of food intake.

GLP-1 also acts on GLP-1Rs located in the hindbrain nuclei that control food intake, such as the nucleus tractus solitarius (NTS), area postrema (AP), and dorsal motor nucleus of the vagus (DMV) via either vagal afferents or through the leaky blood-brain barrier. In this regard, fourth ventricle administration of GLP-1 causes a significant suppression of food intake (Hayes et al. 2008, 2009; Hayes et al. 2008; Kinzig et al. 2002). After acute blockade of hindbrain GLP-1Rs, the effect on food intake is quite pronounced with intake remaining elevated for 24 h following injection. Within the hindbrain, the NTS seems to mediate the actions of GLP-1 since direct administration of exendin-9 at subthreshold ICV doses into this nucleus results in increased food intake (Hayes et al. 2009). These findings strongly support the role of central GLP signaling pathways in control of food intake. Indeed, GLP-1 is a potent neurotransmitter that is produced in the hindbrain. Specifically, neurons of the NTS are a rich source of GLP-1 and they synapse directly with neurons in the hypothalamus that express GLP-1R (Tang-Christensen et al. 2001). Thus, two sources of GLP-1, one arising from periphery and one produced locally in the brain participate in GLP-1-induced satiation. Recently, the functions of the GLP-1 coming from these two sources have been examined. Specifically, peripheral, gut-derived GLP-1 has been shown to mediate nutrient-induced satiation while central GLP-1 controls distention-induced satiation signals arising from the stomach (Hayes et al. 2009; Williams et al. 2009) (Fig. 14.2). Altogether, GLP acting in brain nuclei either produced locally or from the periphery has a profound effect on inducing satiation. Interestingly, the extent to which GLP-1 reduces food intake is similar to the reported effects of antagonists for potent orexigens in the hypothalamus.

Fig. 14.2 Effect of hindbrain GLP-1R antagonism on gastric balloon distention-induced satiation. Hindbrain administration of GLP-1R antagonist, Ex-9, reduces gastric distention-induced suppression of food intake in overnight-food deprived rats. *P<0.05 (Adapted from Hayes et al. (2009))
14.8 GLP-1 Reduces Food Intake via Central Neuropeptides

Regulation of energy homeostasis involves interaction with multiple neuropeptides produced in the brain. The hypothalamus produces both orexigenic and anorexigenic signals governing food intake. While these peptides directly affect food intake, they are normally modulated by peripheral signals arising from endocrine organs, such as the GI tract. For example, production of two hypothalamic orexigenic peptides, NPY and AgRP that are heavily involved in regulation of energy intake and expenditure are modulated by GLP-1 signaling. The inhibitory effects of GLP-1 are associated with hypothalamic mRNA expression of NPY and AgRP (Seo et al. 2008). Hypothalamic anorectic signals appear to be modulated by GLP-1 as well. As such, GLP-1 administration increases gene expression of pro-opiomelanocortin (POMC) as well as induces secretion of the peptide (Ma et al. 2007; Seo et al. 2008). Similar to POMC, GLP-1 attenuates deprivation-induced suppression of cocaine amphetamine regulated transcription (CART) expression in hypothalamic nuclei (Seo et al. 2008). Furthermore, GLP-1R antagonism via central exendin-9 administration results in attenuation of CART-induced suppression of food intake (Aja et al. 2006). Together, these data provide compelling evidence for GLP-1 and GLP-1Rs modulating the actions of central neuropeptides, suggesting that the anorectic effects of GLP-1 are mediated through hypothalamic peptides. These interactions between GLP-1 and signals controlling food intake are not limited to central neuropeptides. Many signals arising from peripheral organs interact with GLP-1 to control food intake as well.

14.9 GLP-1 Interacts with Other Peripheral Satiety Signals to Control Food Intake

Most peptides released from the gut in response to meal related stimuli interact with each other at various levels to control physiological determinants of food intake. For example, another gut peptide, peptide tyrosine-tyrosine (PYY) also produced by the intestinal L-cells in response to the presence of nutrients, particularly fats, in the intestinal lumen, decreases intestinal motility and causes a

significant reduction in food intake. These peptides share similar physiological and behavioral effects; however, they suppress food intake independently, but act in a synergistic manner to control meal size. In the rat, administration of either PYY or GLP-1 at doses that are inefficient in reducing food intake when given alone, results in a significant suppression of food intake when given in combination (Neary et al. 2005). Likewise, in healthy lean patients, infusion of subthreshold doses of both GLP-1 and PYY results in significantly reduced intake of a free buffet meal (Neary et al. 2005). While both of these signals are relayed on vagal afferents and neurons of the hindbrain express receptors for PYY and GLP-1R, the mechanism by which these peptides decrease food intake is thought to involve two separate pathways. Specifically, GLP-1 decreases food intake through a vagal sensory mechanism as capsaicin treatment, which destroys vagal sensory fibers, results in attenuation of exendin-4-induced suppression of food intake. The same treatment, however, does not affect suppression of food intake following PYY administration (Talsania et al. 2005). Other neurotransmitters secreted from the GI tract, notably 5-hydroxytryptamine (5-HT), also coordinate GLP-1-induced suppression of food intake. In a mouse model lacking the 5-HT2C receptor, the anorectic effects of GLP-1 are abolished (Asarian 2009).

In addition to interacting with short-term satiety signals and neurotransmitters secreted from the GI tract, GLP-1 also interacts with long-term energy homeostatic signals, such as the adiposity hormone leptin, to decrease food intake. When subthreshold doses of GLP-1 or exendin-4 are combined with subthreshold doses of leptin, the result is a significant reduction of food intake over 24 h in rodents (Bojanowska and Nowak 2007). Despite both peptides being secreted by peripheral endocrine organs, molecular data suggests that central pathways involving both hypothalamic or hindbrain nuclei are involved in this synergistic interaction. For example, in cultured brain tissue slices from the hypothalamic nuclei, application of leptin results in increased expression of GLP-1R (Sanz et al. 2008). Furthermore, the leptin receptor is expressed in the NTS on GLP-1-producing neurons. Thus, leptin may regulate the secretion or the effectiveness of GLP-1 signaling. Indeed, application of leptin to GLP-1-producing cells results in secretion of the peptide. Likewise application of the GLP-1R antagonist, exendin-9, results in attenuation of leptin-induced reduction of food intake and body weight (Nowak and Bojanowska 2008). Together, these findings demonstrate the importance of the interaction between leptin and GLP-1 in controlling food intake and body weight.

One of the most widely studied functions of GLP-1 is the effect it has on modulating secretion of insulin and counterregulatory hormones. The incretins are a family of peptides or hormones that stimulate insulin secretion. Data from both animal models and humans show that GLP-1 potentiates nutrient-induced insulin secretion (Kreymann et al. 1987; Mojsov et al. 1987), an action mediated by GLP-1Rs located on pancreatic β-cells. In addition to insulin, GLP-1 controls the release of the counterregulatory hormone, glucagon, which is responsible for activating catabolic pathways to increase blood glucose levels in times of deprivation. As such, administration of GLP-1 or GLP-1R agonists results in decrease of plasma glucagon (Orskov et al. 1988). Together, stimulation of insulin secretion and inhibition of glucagon release serves to decrease blood glucose levels. Given the ability of GLP-1 to regulate anabolic and catabolic pathways and its interaction with the homeostatic regulatory hormone, leptin, GLP-1 may be an important signal in long-term energy balance. Indeed, pathological states characterized by a dysregulation of energy homeostasis alter GLP-1 signaling pathways from secretion to receptor binding.
Fig. 14.3 Effect of intravenous (IV) infusion of GLP-1 on food intake in obese patients. After a fixed breakfast, IV GLP-1 decreases energy intake significantly more than saline during both lunch and dinner (Adapted from Naslund et al. (1999))

14.10 Pathological States Alter GLP-1 Signaling

Two major pathologies are associated with alteration in GLP-1 signaling: obesity and diabetes. In morbid obese patients, baseline circulatory concentrations of the peptide are dramatically reduced (Holst et al. 1983). Furthermore, prandial and postprandial increases in circulatory GLP-1 are almost abolished in obese patients (Naslund et al. 1998). Despite this, IV infusion of the peptide decreases the size of subsequent meals (Fig. 14.3). In these individuals, this compromised secretion is thought to be controlled by body weight. As such, when an obese individual is nearing normal body weight, GLP-1 secretion markedly increases (Verdich et al. 2001). Due to the fact that postprandial circulating levels of GLP-1 are partially restored during periods of weight loss, body weight may regulate L-cell sensitivity. The mechanism for this phenomenon is not clear; however, two hypotheses have been put forward that are not mutually exclusive. First, it is possible that loss of bodyweight restores sensitivity to luminal nutrients. Secondly, obesity is a disease often associated with insulin resistance. Normally, L-cells are responsive to insulin. Thus, loss of bodyweight, which is usually associated with increased insulin sensitivity, may restore GLP-1 secretion as well (Rask et al. 2001). Together, these data suggest that the pathological state of obesity not only correlates, but also results in suppressed secretion of GLP-1 from L-cells.

Similarly, diabetes is associated with impaired secretion and function of GLP-1. Non-insulin-dependent diabetes mellitus (NIDDM), also known as type 2 diabetes, is characterized by reduced insulin sensitivity to normally insulin-responsive tissues (predominantly muscle and adipose tissue) and hyperinsulinemia. In NIDDM, there is a gradual decrease in the mass of insulin-producing B-cells and later stages of the disease are characterized by complete loss of insulin secretion. In these patients, glucagon levels are typically elevated as well. More recently, NIDDM has also been associated with absence of the incretin effect, which may contribute to impaired insulin secretion and increased glucagon levels (Nauck et al. 1986). As a result, in majority of diabetic patients, secretion of GLP-1 is decreased, as is the sensitivity to the peptide at normal physiological levels that potentiates insulin secretion (Rask et al. 2001). At supraphysiological levels, however, diabetic individuals retain some sensitivity to the incretin effects of peptide as seen by normalization of

glucose-induced secretion following GLP-1 infusion (Nauck et al. 1997). Similar to obesity, the impairment in GLP-1 secretion may be secondary to the diabetic state. Data collected from individuals genetically at risk for NIDDM support this hypothesis. First, first-degree relatives of individuals with diabetes and individuals with glucose intolerance have normal secretory profiles of GLP-1 following an oral load or IV infusion of glucose (Nyholm et al. 1999). Furthermore, examination of identical twins discordant for NIDDM reveals that only the diabetic individual has an impaired GLP-1 secretion whereas the healthy twin maintains otherwise normal postprandial peptide secretion (Vaag et al. 1996). Altogether, these data implicate GLP-1 as an important player in this very intricate puzzle characterized by metabolic dysregulation manifested in pathological states such as obesity and diabetes.

14.11 Applications to Other Areas of Health and Disease

The findings that two disease states currently plaguing individuals worldwide may be caused by or result in reduced secretion or sensitivity to GLP-1 gives promise to the use of treatments that directly or indirectly manipulate GLP-1 signaling and alleviate these pathologies. Numerous clinical trials are being performed to evaluate strategies to enhance the understanding of how this peptide may be used to decrease the incidence of obesity and diabetes. For example, one of the primary treatments for diabetes, alpha-glycosidase inhibitors, such as acarbose, markedly reduces proximal intestinal absorption of nutrients, thus, allowing greater exposure of nutrients to the distal intestine leading to increase GLP-1 secretion and normalization of blood glucose levels (Qualmann et al. 1995). Presently, however, the most effective treatment for individuals suffering from both obesity as well as diabetes is surgical intervention. Following operation, gastric bypass patients show complete reversal of diabetic complications and rapidly lose weight. Additionally, GLP-1 levels are markedly elevated due to diversion of nutrients directly from the stomach into resected areas of the distal small intestine and increased L-cell sensitivity due to weight loss (Patti et al. 2005). Because plasma concentrations of the peptide increase, GLP-1 becomes again effective in stimulating insulin secretion in these individuals.
Fig. 14.4 Effect of Liraglutide treatment on fasting serum glucose levels in diabetic patients. Compared to placebo treatment, Liraglutide (0.6 mg/kg) significantly improves impaired fasting serum glucose levels in patients with non-insulin dependent diabetes mellitus (NIDDM) (Reprinted from Harder et al. (2004))
Fig. 14.5 Effect of Liraglutide treatment on body weight loss in obese individuals. Once daily subcutaneous injection of the GLP-1 agonist, Liraglutide, decreases body weight more than placebo control over 20 weeks in obese patients (Adapted from Astrup et al. (2009))

In addition to indirectly manipulating GLP-1 secretion, other treatments focus on utilizing the GLP-1 pathway directly in treating diabetes and obesity. Two main drugs are used as GLP-1R agonists and marketed for diabetic patients: exenatide and liraglutide. They are synthetic analogs of GLP-1 and are relatively resistant to enzymatic degradation by DPP-IV, maintaining prolonged circulatory levels of the peptides between 6 and 12 h post administration (Degn et al. 2004; Kolterman et al. 2005). GLP-1 analogs have been effective either alone or in coordination with other diabetes treatments, effectively normalizing blood glucose and other associated measures (Buse et al. 2009) (Fig. 14.4). In addition, they cause delayed gastric emptying in diabetics with increased gastric emptying rates, allowing for a more sustained delivery of nutrients to the intestine to aid severely fluctuating blood glucose concentrations (Kendall et al. 2006). The same drugs cause a significant reduction in body weight in obese, nondiabetic patients (Astrup et al. 2009) (Fig. 14.5). In addition to GLP-1 analogs, the finding that most GLP-1 is enzymatically degraded rapidly following entry into the portal vein has spurred interest in inhibitors of the DPP-IV enzyme. Clinical trials have shown that DPP-IV inhibitors used as either co- or monotherapeutic agents normalize or decrease plasma blood glucose levels (Deacon and Holst 2006). One problem plaguing this therapeutic strategy, however, is that DPP-IV is ubiquitous and plays a role in important immune-related functions, such as production of cytokines. Thus, the use of DPP-IV inhibitors have resulted in a range of side effects, including elevated blood pressure. Despite this, currently two drugs acting on DPP-IV are used for diabetes treatment. Collectively, these data provide substantial evidence for GLP-1 pathways as an effective target in the treatment of diabetes, and other metabolic diseases characterized by insulin resistance.

Summary Points

- GLP-1 is a member of the proglucagon peptide family. It is a satiation signal released from the enteroendocrine L-cells of the distal gastrointestinal tract
- GLP-1 release is stimulated by a neural-humoral reflex as well as the presence of nutrients in the intestinal lumen.
- GLP-1 exerts a variety of biological functions within the gastrointestinal tract including intestinal motility, gastric emptying, and pancreatic enzymatic secretion.
- GLP-1 is a potentiator of nutrient-induced insulin secretion.

- GLP-1 exerts its physiological actions as well as satiation via GLP-1 receptors.
- GLP-1 reduces food intake via peripheral and central mechanisms of action.
- Peripheral GLP-1 reduces food intake through both endocrine and paracrine pathways while GLP-1 produced in the brain acts on neurons that are synapsed with GLP-1ergic neurons.
- GLP-1 regulates expression and production of centrally produced neuropeptides to reduce food intake.
- GLP-1 interacts with short-term anorexigenic signals and long-term adiposity signals to enhance suppression of food intake and body weight.
- GLP-1 secretion is significantly decreased in pathological states, such as obesity and diabetes. However, a majority of its function is retained in these individuals.
- Currently, GLP-1, and GLP-1Rs are targets in ameliorating metabolic diseases, such as diabetes and obesity, as GLP-1 analog administration normalizes blood glucose and reduces body weight.

Key Definitions

Apical: Portion of cell that faces the lumen of the gastrointestinal (GI) tract.

Basolateral: Portion of the cell that is opposite the apical side of the cell. Typically faces capillaries or maintains connections with the nervous system.

GLP-1: Peptide hormone that is a posttranslational product derived from the proglucagon gene. Major functions include decreasing GI motility, food intake, and potentiating nutrient-induced insulin secretion.

Endocrine: Entry of peptide or hormone into the bloodstream to exert effects on distant tissues

L-cells: Cells of the small intestine and colon that are responsible for secreting GLP-1 and other peptide hormones. The apical portion of the cell senses nutrients while the basolateral portion of the cell is responsible for hormone secretion.

Paracrine: Action of a peptide or hormone on local or nearby cells without entering the circulatory system.

Potentiate: The ability of a molecule to enhance the actions of another molecule.

Chapter 15
The Role of PYY in Eating Behavior and Diet

Jennifer L. Scheid and Mary Jane De Souza

Abbreviations

AgRP	Agouti-related protein
BMI	Body mass index
CART	Cocaine- and amphetamine-regulate
DPP-IV	Dipeptidly peptidease IV
FHA	Function hypothalamic amenorrhea
NPY	Neuropeptide Y
PYY	Peptide PYY
POMC	Pro-opiomelanocortin

15.1 Introduction

Food intake and eating behavior are controlled by many gastrointestinal hormones that are secreted from the gut region including the stomach and the intestine. These hormones have unique roles in the digestive process, but also interact with the vagus nerve and/or can cross the blood brain barrier and act as signals to the brain to initiate hunger. Gut hormones, such as peptide YY (PYY), control food intake by signaling satiety to the brain, and since PYY can control food intake, this hormone has a pivotal role in eating behavior and may also play a role in the clinical consequences of over or under eating as observed in clinical models of obesity and anorexia nervosa (Table 15.1).

Table 15.1 Key features of PYY

1. The primary function of PYY is to act as satiety signal and control food intake.
2. PYY is secreted in response to food intake.
3. PYY is secreted from the endocrine L cells of the intestine.
4. PYY concentrations are elevated in women with anorexia nervosa.
5. PYY concentrations are elevated in women with functional hypothalamic amenorrhea.
6. PYY concentrations are suppressed in obese patients.

This table lists the key facts of Peptide YY (PYY) including basic physiology of PYY and the specific populations that have altered concentrations of PYY

15.2 General Physiology of PYY

15.2.1 Secretion and Meal Responses

PYY is a gastrointestinal peptide secreted from the endocrine L cells of the intestine in response to food intake (Batterham et al. 2003; Huda et al. 2006; Adrian et al. 1985; Kim et al. 2005). The two forms of circulating PYY are PYY_{1-36} and PYY_{3-36}. PYY_{3-36} is the major form of circulating PYY after a meal, while PYY_{1-36} is the main form of circulating PYY during a fasted state (Grandt et al. 1994). An enzyme, dipeptidyl peptidase IV (DPP-IV) is an important regulator of the expression of PYY_{3-36}; PYY_{1-36} is released from the L cell in the lumen of the intestine and then DPP-IV removes tyrosine-proline (Ballantyne 2006) from PYY_{1-36} to create the active form of PYY, PYY_{3-36} (Grandt et al. 1992). PYY_{3-36} is highly selective for the Y2 receptor and acts as an agonist for the Y2 receptor (Grandt et al. 1992). PYY, once released peripherally, can cross the blood brain barrier and act centrally at the level of the arcuate nucleus in the hypothalamus to contribute to eating behavior. PYY_{3-36} activates the Y2 receptors to inhibit neuropeptide Y (NPY) and agouti-related protein (AgRP), as well as pro-opiomelanocortin (POMC) and cocaine- and amphetamine-regulate (CART), also in the arcuate nucleus, to decrease food intake (Batterham et al. 2003). The ability of PYY_{3-36} to bind to the Y2 receptor indicates the key pivotal role of this peptide in body weight regulation. Hypothalamic Y2 receptors are involved in both food intake and body weight regulation at the level of the hypothalamus (Sainsbury et al. 2002).

Circulating PYY is an anorexigenic hormone involved in short-term energy homeostasis, i.e., PYY signals satiety following food intake. PYY concentrations rise in response to a caloric load after a meal (Huda et al. 2006; Korner et al. 2005; Kim et al. 2005) and stay elevated for several hours (Adrian et al. 1985). PYY starts to rise a few minutes after the calories are ingested and peak PYY concentrations occur 30 min after caloric intake (Degen et al. 2005) (Fig. 15.1). After a meal, PYY is elevated, while after short-term fasting (2–3 days), total PYY concentrations are suppressed 40–60% below baseline in lean men and women (Chan et al. 2006). Peak PYY concentrations are achieved in proportion to the amount of calories ingested (Huda et al. 2006; Degen et al. 2005). While PYY is a short-term satiety signal involved in the regulation of caloric intake following a caloric load and subsequent meals following a caloric load, PYY is also a signal for long-term energy homeostasis, i.e., during conditions such as anorexia nervosa (Misra et al. 2006; Pfluger et al. 2007; Nakahara et al. 2007) and obesity (le Roux et al. 2006; Stock et al. 2005; Batterham et al. 2003).

The rise in plasma PYY concentrations after a meal is also influenced by the macronutrient content of the meal (Batterham et al. 2006). PYY concentrations are released from the intestine in response to specific macronutrients as evidenced by the higher increase in PYY following high- versus normal-protein meals (Batterham et al. 2006). Lipids also modulate the release of PYY from the
Fig. 15.1 Total PYY concentrations following a small meal and a large meal. Total plasma PYY ($PYY_{3-36} + PYY_{1-36}$) concentrations achieved during two meals with different caloric contents. The larger meal (1,500 kcal) induced a greater total PYY response compared to the smaller meal (500 kcal). Results are expressed as mean ± SEM, $n = 12$ (Reprinted from Degen et al. (2005). With permission)

intestine (Lin and Chey 2003; Feinle-Bisset et al. 2005). In normal-weight subjects, a high-protein (65% protein, 17% fat, and 17% carbohydrate) meal elicted the greatest increase in total PYY and PYY_{3-36} compared to high-fat (17% protein, 66% fat, and 17% carbohydrate) and high-carbohydrate (17% protein, 18% fat, and 65% carbohydrate) meals, while the high-fat meal still had a greater increase in total PYY and PYY_{3-36} compared to the high-carbohydrate meal (Fig. 15.2) (Batterham et al. 2006).

Pharmacological administration of PYY_{3-36} supports a role for PYY in altering eating behavior in both animal (Chelikani et al. 2005) and human models (Sloth et al. 2007; Batterham et al. 2003; Degen et al. 2005; le Roux et al. 2006; Batterham et al. 2002). Peripherally administered PYY_{3-36} has been shown to decrease appetite and 24-h food intake by 33% in humans (Batterham et al. 2002) (Fig. 15.3). In another study, PYY_{3-36} infusion in both lean and obese individuals decreased caloric intake by 30% during a buffet meal (Batterham et al. 2003).

15.2.2 Fasting Measures Versus Meal Responses

Baseline PYY concentrations are typically measured following an overnight fast. Two to three days of fasting will suppress total PYY 40–60% below baseline concentrations (Chan et al. 2006). The meal responses of PYY_{3-36} and total PYY concentrations have been investigated following the intake of a caloric load. Both PYY_{3-36} and total PYY concentrations rise following a caloric load (Degen et al. 2005; Pfluger et al. 2007; Batterham et al. 2003). Total PYY concentration increased 208% compared to fasting concentrations of total PYY following a heavy breakfast of approximately 1,000 kcal, while PYY_{3-36} concentration increased 125% compared to fasting PYY_{3-36} concentration following the same heavy
Fig. 15.2 Total PYY concentrations following meals with different macronutrient compositions. Total plasma PYY ($PYY_{3–36}$ + $PYY_{1–36}$) concentrations in normal weight individuals following high-protein (PROT), high-fat (FAT), and high-carbohydrate (CHO) meals. The high-protein meal elicited the greatest increase in total PYY compared to high-fat and high-carbohydrate meals, while the high-fat meal still had a greater increase in total PYY compared to the high-carbohydrate meal. Results are expressed as mean ± SEM, $n = 10$ (Reprinted from Batterham et al. (2006). With permission)

Fig. 15.3 The effects of $PYY_{3–36}$ infusion on food intake and appetite. (**a**) Caloric intake during a buffet meal following either saline or $PYY_{3–36}$ infusion. The lines represent individual subject data. (**b**) Caloric intake during the 24 h periods following either saline or $PYY_{3–36}$ infusion. ***$p < 0.0001$ versus saline. Results are expressed as mean ± SEM, $n = 12$. (**c**) Appetite scores expressed as percentage change from baseline following either saline or $PYY_{3–36}$ infusion. *$p < 0.05$ versus saline, **$p < 0.01$ versus saline. breakfast (Pfluger et al. 2007). The rise in PYY concentrations compared to fasting is clearly related to the amount of calories ingested; total PYY concentrations were measured following a light lunch of 500 kcal and a heavy lunch of 1,500 kcal and, although total PYY increased significantly compared to fasting concentrations of PYY following the light lunch, the increase in PYY was small compared to the increase in total PYY concentrations following a heavy lunch of 1,500 kcal (Degen et al. 2005) (Fig. 15.1).

15.2.3 Assays and Measurement Concerns

Total PYY and PYY_{3-36} concentrations can be measured in plasma. When measuring total PYY, an antibody is used that recognizes both PYY_{1-36} and PYY_{3-36}. For research purposes, scientists are also interested in measuring PYY_{3-36} because of the peptide's direct ability to activate the Y2 receptor and influence food intake and eating behavior. When measuring PYY_{3-36}, an antibody is used that only has cross-reactivity for the active form of PYY, PYY_{3-36}. When measuring PYY_{3-36}, a DPP-IV inhibitor needs to be used to stop DPP-IV from cleaving PYY_{1-36} into PYY_{3-36}. The addition of the DPP-IV inhibitor needs to occur immediately after the blood is drawn for the most accurate results. The effects of long-term storage on total PYY and PYY_{3-36} concentrations are unknown; however, if total PYY breaks down during long-term storage of samples, then the relative concentrations of PYY_{1-36} and PYY_{3-36} would likely be compromised.

15.3 Clinical Populations: PYY and Anorexia Nervosa

15.3.1 Fasting PYY in Anorexia Nervosa and Functional Hypothalamic Amenorrhea

Anorexia nervosa is related to the cognitive suppression of food intake, i.e., starvation and undernutrition, that leads to a chronic energy deficiency (De Souza and Metzger 1991). Interestingly, the etiology of exercise-associated functional hypothalamic amenorrhea (FHA) is also related to energy deficiency and in these women and in women with anorexia nervosa the energy deficiency involves a decrease in resting energy expenditure, and suppression of triiodothyronine, insulin-like growth factor-1 and leptin concentrations and elevated ghrelin and cortisol concentrations (De Souza et al. 2007b; De Souza and Williams 2004). Evidence is accumulating that fasting and post-prandial PYY concentrations are chronically elevated in populations of energy-deficient women, including women with anorexia nervosa and FHA (Misra et al. 2006; Pfluger et al. 2007; Nakahara et al. 2007; Scheid et al. 2009; Russell et al. 2009). Patients with anorexia nervosa, i.e., a population exhibiting chronic energy deficiency, have consistently been observed to exhibit elevated fasting PYY concentrations (Misra et al. 2006; Pfluger et al. 2007; Nakahara et al. 2007). Exercising women with FHA, secondary to an energy deficit, also demonstrate elevations in fasting PYY concentrations (Scheid et al. 2009; Russell et al. 2009).

15.3.2 PYY Meal Responses in Anorexia Nervosa

Investigators have consistently observed that women with anorexia nervosa have an elevated total PYY and PYY_{3-36} in response to a meal (Nakahara et al. 2007; Otto et al. 2007). Nakahara et al. (2007) have shown that PYY_{3-36} concentrations are elevated at baseline and following intake of a 400 kcal standard

meal (20% protein, 22% fat, and 58% carbohydrate) in women with anorexia nervosa compared to normal weight controls (Fig. 15.4). Since PYY is an anorexigenic hormone, elevated PYY may play a role in reduced food intake in both women with anorexia nervosa and exercising women with FHA, such that circulating elevated PYY may cause a decrease in hunger and total caloric intake and may contribute to the energy deficiency in these populations of women.

15.3.3 PYY Responses to Weight Gain in Anorexia Nervosa

Although PYY_{3-36} concentrations are elevated in women with anorexia nervosa, weight gain in women with anorexia nervosa after treatment for the disease causes decreases fasting and postprandial PYY_{3-36} concentrations compared to before treatment, but this weight gain in women with anorexia nervosa following treatment does not normalize fasting or postprandial PYY_{3-36} concentrations compared to healthy controls (Nakahara et al. 2007) (Fig. 15.4).

Notably, elevated PYY concentrations have been hypothesized to be more than just a marker of energy deficiency but rather may play an important role in modulating eating behavior in women with anorexia nervosa. Misra et al. (2006), who observed elevated PYY concentrations in a population of adolescent girls with anorexia nervosa, suggested that elevated PYY may be involved in the pathogenesis of anorexia nervosa by way of reducing food intake. PYY is an anorexigenic hormone
Fig. 15.4 PYY_{3-36} concentrations following a meal in women with anorexia nervosa before treatment and after treatment. Plasma PYY_{3-36} concentrations in women with anorexia nervosa before treatment following intake of a standard meal compared to controls. After treatment, women with anorexia nervosa decrease their PYY concentrations after a meal, but women with anorexia nervosa after treatment still have elevated circulating plasma PYY_{3-36} concentrations after a standard meal compared to controls. *$p < 0.05$ versus controls. Results are expressed as mean ± SEM, $n = 40$ (Reprinted from Nakahara et al. (2007). With permission)
Fig. 15.5 Fasting total PYY concentrations in exercising women with functional hypothalamic amenorrhea. Fasting total PYY concentrations in women who are sedentary and have ovulatory menstrual cycles (SedOv) and exercising women, who have ovulatory menstrual cycles (ExOv), compared to exercising women with amenorrhea (ExAmen). ExAmen women had higher fasting total PYY compared to SedOv and ExOv women. *$p<0.05$ SedOv and ExOv. Results are expressed as mean±SEM, $n=48$ (Reprinted from Scheid et al. (2009). With permission)

and elevated PYY reduces food intake in lean individuals (Batterham et al. 2003). Exercising women with FHA are also an undernourished clinical population in an energy deficit. Similar to women with anorexia nervosa, exercising women with FHA demonstrate elevations in fasting PYY concentrations (Scheid et al. 2009; Russell et al. 2009) (Fig. 15.5). This finding suggests that elevated PYY may cause a decrease in relative caloric intake and may compound the psychological struggle in women attempting to recover from anorexia nervosa and consume food for the purpose of weight gain. Thus, in general, elevated PYY in women with anorexia nervosa and exercising women with FHA may contribute to energy deficiency by way of causing a compensatory decrease in food intake and may represent a component of the underlying mechanism involved in suppressed food intake in these women.

15.3.4 PYY and Eating Behaviors in Anorexia Nervosa and FHA

PYY may play a role in modulating eating behaviors and suppressing food intake by interfacing with other gastrointerestinal peptides at the level of the hypothalamus. Interestingly, ghrelin concentrations are also elevated in women with anorexia nervosa (Germain et al. 2007; Nakahara et al. 2007; Monteleone et al. 2008; Germain et al. 2009; Harada et al. 2008) and in exercising women with FHA (Scheid et al. 2009; De Souza et al. 2004, 2007b). Elevated ghrelin concentrations in energy-deficient populations, such as women with anorexia nervosa or FHA are, in part, the body's attempt to increase food intake; and an increase in food intake would then, presumably, help to reverse energy deficiency. Ghrelin is an orexigenic hormone and infusions during a buffet meal are associated with an increase in food intake (Wren et al. 2001). Elevated PYY in the presence of elevated ghrelin may cause a relative ghrelin resistance in women with anorexia nervosa (Misra et al. 2006), i.e., in spite of chronically elevated ghrelin there is no compensatory increase in food intake. Ghrelin resistance may represent the

underlying mechanism explaining why undernourished women with elevated ghrelin concentrations are not increasing food intake. Interestingly, PYY has been shown to inhibit ghrelin neurons (Riediger et al. 2004) and may represent a physiological mechanism explaining ghrelin resistance. Women with elevated PYY concentrations such as women with anorexia nervosa consistently express behaviors including restricting food intake even in the presence of elevated physiological signals, like ghrelin, to increase food intake. Elevated PYY may be disrupting food intake signals in the uncoupled relationship between elevated ghrelin and food intake in women with anorexia nervosa.

Although there is no direct evidence to date to demonstrate that PYY is involved in the etiology of anorexia or exercise-associated FHA, Scheid et al. (2009) found an association between fasting PYY concentrations and drive for thinness. High drive for thinness includes disordered eating behaviors that encompass a fear of gaining weight and a preoccupation with body weight and body shape (Cobb et al. 2003; Otis et al. 1997). High drive for thinness has been physiologically linked to an energy deficiency in exercising women (De Souza et al. 2007a), and it is therefore not surprising that PYY is also associated with a high drive for thinness. However, if PYY is indeed a physiological signal that is suppressing food intake, this signal may be compounding disordered eating behaviors in women with anorexia and exercising women with FHA.

15.4 Clinical Populations: PYY and Obesity

15.4.1 Fasting PYY in Obesity

PYY concentrations are suppressed in some (Batterham et al. 2003; le Roux et al. 2006; Roth et al. 2005; Alvarez Bartolome et al. 2002), but not all studies of (Pfluger et al. 2007) obese patients, a population exhibiting a long-term positive energy imbalance. Fasting PYY is negatively correlated with body mass index (BMI) demonstrating that individuals with suppressed fasting PYY concentrations have elevated BMIs and may be overweight/obese (Guo et al. 2006). Suppressed PYY in obesity may play a role in increased food intake in this population given PYY's important role in promoting satiety. Indeed, Batterham et al. (2003) suggest that suppressed PYY concentrations may be involved in the pathogenesis of obesity, suggesting that obese individuals may be predisposed to low circulating PYY concentrations, leading to an increase in food intake and weight gain.

15.4.2 PYY Meal Responses in Obesity

Obese patients demonstrate an attenuated total PYY response to a caloric load (le Roux et al. 2006; Stock et al. 2005; Batterham et al. 2003). Total circulating PYY concentrations are consistently suppressed in obese individuals compared to lean individuals prior to, during, and following a buffet lunch (Fig. 15.6). The attenuated PYY response to a caloric load during obesity leads to an increase in food intake and is one of the factors that make weight control difficult in obese populations (Batterham et al. 2003). le Roux et al. (2006) investigated the meal response in both obese and lean subjects and found that the obese group had a consistently attenuated PYY response during a 1,000 kcal liquid meal and also during a liquid meal that totaled almost 3,000 kcal. They found that the obese group needed to consume almost double the caloric load to achieve the same PYY concentration as the lean group, potentially demonstrating that an attenuated PYY response to a caloric load may lead to overeating and weight gain in obese individuals.
Fig. 15.6 Total PYY concentrations following a meal in obese and lean individuals. Total circulating PYY concentrations in an obese group (*triangles*) compared to a lean group (*circles*) during infusion of saline and after a buffet lunch. Total circulating PYY concentrations are consistently suppressed in the obese group compared to the lean group during infusion of saline and after a buffet lunch. Results are expressed as mean ± SEM, $n = 24$ (Reprinted from Batterham et al. (2003). With permission)

15.4.3 PYY Responses to Weight Loss in Obesity

Prospective studies that utilize weight loss interventions to create an energy deficit offer valuable insights into the role of PYY in long-term energy homeostasis, but results have been inconsistent and thus difficult to interpret. Consistent with the concept that fasting PYY concentrations are elevated in situations following long-term energy deficiency, fasting PYY concentrations are elevated in obese children after weight loss (Roth et al. 2005) and adolescents (Jones et al. 2009) after exercise training. Roth et al. (2005) investigated the effects of a 1-year outpatient program that included exercise, nutrition education, and individual counseling on fasting total PYY concentrations in obese children. Roth and colleagues demonstrated that in the quartile of children with the greatest BMI reduction the greatest percentage increase in total PYY concentrations was observed. Jones et al. (Jones et al. 2009) investigated the effects of a 32-week exercise training program on PYY concentrations in obese adolescents and demonstrated that total PYY concentrations were increased following the training compared to baseline PYY concentrations, indicating that exercise training in the absence of weight loss may affect circulating PYY concentrations, however the mechanism behind this increase in PYY is unknown.

Unfortunately, the weight loss literature regarding PYY is very inconsistent and while obese children who lose weight have an increase in circulating PYY concentrations (Roth et al. 2005), other studies in obese adults have reported that PYY concentrations decrease after weight loss (Pfluger et al. 2007; Lien et al. 2009), indicating that PYY concentrations may be regulated differently in adults and children. The inconsistencies in the literature regarding PYY concentrations following weight loss may also be due to the notion that some obese individuals may be predisposed to low circulating PYY concentrations (Batterham et al. 2003), meaning that they already have low PYY concentrations and that these low PYY concentrations may respond differently to weight loss.

An additional complication in the weight loss literature is that fasting PYY concentrations may not be sensitive to smaller changes in weight, particularly in normal weight populations. For example, in

our laboratory (Leidy et al. 2004; Scheid et al. 2010 unpublished) we implemented a well-controlled and intensive 3-month exercise and diet intervention that produced weight loss (2–4 kg) in normal weight women 18–30 years old. The weight loss produced was associated with changes in energy balance evident by elevated ghrelin concentrations and suppressed resting metabolic rate (Leidy et al. 2004). However, we (Scheid et al. 2010 unpublished) observed that total PYY concentrations were not altered by diet and exercise-induced weight loss in these women. Future research will need to investigate the relationship of weight loss and initial PYY concentrations and if changes in PYY concentrations following weight loss impact eating behavior and weight maintenance.

15.4.4 PYY Infusion Studies in Obesity

Since PYY is a peripherally circulating hormone that signals satiety, pharmacological administration of PYY has reportedly been referred to as having a potential application as a weight loss drug. Pharmacological administration of PYY_{3-36} has been shown to decrease food intake in both animal (Chelikani et al. 2005) and human models (Sloth et al. 2007; Batterham et al. 2003; Degen et al. 2005; le Roux et al. 2006; Batterham et al. 2002). Peripherally administered PYY_{3-36} has been shown to decrease appetite and 24-h food intake by 33% in humans (Batterham et al. 2002) (Fig. 15.3). Batterham et al. (2003) investigated the effects of PYY_{3-36} infusion in both lean and obese individuals and found that PYY infusion decreased caloric intake by approximately 30% in both the lean and obese individuals during a buffet meal. The authors suggest that these data indicate that obese subjects may in fact not be PYY resistant, but rather that they may simply be PYY deficient. These studies also suggest that the administration of PYY_{3-36} may be a future weight loss aid by potentially decreasing caloric intake during meals (Batterham et al. 2003).

15.4.5 PYY and Eating Behaviors in Obesity

Suppressed PYY in obesity may play a role in increased food intake in this population given PYY's important role in promoting satiety. Indeed, fasting total PYY concentrations are suppressed in obese patients, and of greater concern, obese patients demonstrate an attenuated total PYY response to a caloric load (le Roux et al. 2006; Stock et al. 2005; Batterham et al. 2003). Since obese individuals have an attenuated response during food intake, obese individuals likely do not experience the same satiety signals as lean individuals. Obese individuals may need to consume almost double the caloric load to achieve the same PYY concentration associated satiety as the lean group (le Roux et al. 2006). Suppressed PYY may therefore represent a physiological factor that leads to increased food intake in obese individuals and may make weight loss difficult for these people.

Macronutrient meal composition can also affect PYY_{3-36} secretion in obese populations and lead to alterations in food intake. The rise in plasma PYY_{3-36} concentrations after a meal is influenced by the macronutrient content of the meal; however the PYY_{3-36} response to macronutrients differs between lean and obese individuals. A high-protein meal is associated with the greatest increase in total PYY and PYY_{3-36} compared to high-fat and high-carbohydrate meals in both lean and obese individuals (Batterham et al. 2006). On the other hand, a high-fat meal is associated

with a greater increase in total PYY and PYY$_{3-36}$ compared to a high-carbohydrate meal only in the lean group, suggesting that a high-protein diet would be beneficial for obese individuals, potentially increase satiety, and may assist with weight control or weight loss (Batterham et al. 2006). Misra et al. (2009) fed obese and lean adolescent girls high-fat, high-carbohydrate, and high-protein meals and measured the % change in PYY$_{3-36}$ and active ghrelin concentrations. The investigators reported suppressed PYY$_{3-36}$ concentrations in the obese girls after the high-fat meal, but no difference between the lean girls after the high-carbohydrate and high-protein meals. Interestingly, food intake following the high-fat meal was increased in the obese girls, suggesting that suppressed PYY$_{3-36}$ concentrations in obese girls' influences subsequent food intake. The findings of Misra and colleagues (Misra et al. 2009) further indicated that a high carbohydrate meal caused an increase in ghrelin concentrations in obese girls also leading to an increase in food intake and that high-protein meals did not alter PYY$_{3-36}$ secretion or ghrelin secretion in the obese girls and did not increase food intake compared to the controls. These findings suggest that macronutrient composition of meals such as high-protein meals could increase satiety in obese populations and contribute to weight control.

15.4.6   PYY and Genetic Obesity

While elevated PYY has been suggested to play a role in the pathogenesis of anorexia nervosa, Batterham et al. (2003) suggest that suppressed PYY concentrations may be involved in the pathogenesis of obesity. Boey et al. (2006) investigated the relationship between suppressed total PYY and a genetic predisposition toward obesity and diabetes and suggested that suppressed fasting PYY concentrations may indeed indicate a genetic predisposition that is associated with obesity and type 2 diabetes. Suppressed fasting PYY concentrations are also observed in females with first-degree relatives who have type 2 diabetes (Boey et al. 2006) further supporting the idea that obesity may be linked to a PYY deficiency.

15.5   Applications to Other Areas of Health and Disease

15.5.1   PYY and Reproduction Suppression

Women with anorexia and FHA both experience suppressed reproductive function and elevated PYY concentrations (Misra et al. 2006; Russell et al. 2009; Scheid et al. 2009). Many metabolic and gastrointestinal hormones are hypothesized to cross the blood brain barrier and interact with NPY in the arcuate nucleus and POMC in the paraventricular nucleus to effect the hypothalamic-pituitary-ovarian axis as well as appetite (Budak et al. 2006). There is evidence that PYY may be directly participating in the downregulation of reproductive function. Animal models in Syrian hamsters have shown that infusions of PYY inhibit estrous (Keene et al. 2003). Human studies have shown that the human placenta contains PYY (Xiao et al. 1998). There is a plausible role for PYY to be one of the metabolic and gastrointestinal hormones involved in the suppression of reproductive function. More research is needed to explore the extent of PYY's role in modulating female reproductive function.

15.5.2 PYY and Suppressed Bone Health

Women with anorexia and FHA both demonstrate a decrease in bone mineral density (Cobb et al. 2003; Utz et al. 2008; De Souza et al. 2008; Drinkwater et al. 1984; Salisbury and Mitchell 1991). Women with amenorrhea experience increased bone resorption related to estrogen deficiency and a decrease in bone formation related to an energy deficiency (De Souza et al. 2008). Elevated PYY is associated with suppressed bone mineral density (Utz et al. 2008; Misra et al. 2007) and suppressed markers of bone formation (Misra et al. 2006). An elevation in PYY associated with an energy deficiency may be directly participating in a central mechanism to suppress bone formation and decrease bone mineral density in energy-deficient populations. Utz et al. (2008) investigated women with anorexia nervosa and found a negative correlation between mean PYY concentrations (samples over 12 h) and bone mineral density. A plausible mechanism explaining the relationship between elevated PYY concentrations and a decrease in bone mineral density comes from the animal literature. Y2 deficient mice have shown that hypothalamic Y2 receptors regulate bone formation and suppression in Y2 receptor activation increases bone volume (Baldock et al. 2002). PYY_{3-36} activates the hypothalamic Y2 receptor and downregulates NPY release and through this central mechanisms related to a downregulation of NPY, PYY appears to be decreasing bone mineral density (Utz et al. 2008).

15.6 Conclusions

PYY is a satiety hormone involved in short-term food intake highlighted by the rise in PYY_{3-36} following a meal, as well as pharmacological administration of PYY_{3-36} causing a decrease in caloric intake. PYY concentrations are altered in conditions reflecting long-term disturbances in energy homeostasis such as anorexia nervosa and obesity. Elevated PYY may be involved in the pathogenesis of anorexia nervosa and elevated PYY concentrations may play a role in preventing compensatory increases in food intake, while suppressed PYY concentrations may be involved in the pathogenesis of obesity and may play a role in preventing weight control.

Summary Points

- Peptide YY (PYY) is a gastrointestinal peptide secreted from the endocrine L cells of the intestine in response to food intake.
- PYY_{3-36} is the major form of circulating PYY after a meal.
- PYY_{3-36}'s ability to bind to the Y2 receptor indicates the key pivotal role of this peptide in body weight regulation.
- Peak PYY concentrations are achieved in proportion to the amount of calories ingested.
- Peripherally administered PYY_{3-36} has been shown to decrease appetite.
- Fasting and post-prandial PYY concentrations are chronically elevated in women with anorexia nervosa.
- Fasting PYY concentrations are elevated in exercising women with functional hypothalamic amenorrhea (FHA).
- Elevated PYY in the presence of elevated ghrelin may cause a relative ghrelin resistance in women with anorexia nervosa or FHA.
- Fasting PYY concentrations are suppressed in most studies of obese patients.

- PYY concentrations are consistently suppressed in obese individuals compared to lean individuals after a meal.
- A high-protein diet would be beneficial for obese individuals, potentially increase satiety, and assist with weight control or weight loss.

Key Terms

Anorexia nervosa: A psychological disorder that leads to a chronic suppression of food intake and severe undernutrition.

Body Mass Index (BMI): An estimate of body composition by using the formula, body mass/height.

Dipeptidyl peptidase IV (DPP-IV): An enzyme that removes tyrosine-proline from PYY_{1-36} to create the active from of PYY, PYY_{3-36}.

Function hypothalamic amenorrhea: No menses for more than 90 days, caused by a decrease in the hypothalamic hormone regulating reproduction, gonadotrophin-releasing hormone.

Ghrelin: A gastrointestinal, orexigenic hormone, secreted from the stomach that causes an increase in food intake.

Peptide YY: A gastrointestinal, anorexigenic hormone, secreted from the intestine in response to food intake.

Postprandial: A term used for "after a meal."

Chapter 16
The Role of Enterostatin in Eating Behavior and Diet

Charlotte Erlanson-Albertsson

Keywords Fat intake • Satiety • Blood cholesterol • Serotonin • Cholecystokinin • F1-ATPase

Abbreviations

α-MSH	α-melanocyte-stimulating hormone
ACTH	Adrenocorticotropic hormone
AgRP	Agouti-related protein
AMP	Adenosine monophosphate
AMPK	AMPkinase
ADP	Adenosine diphosphate
ARC	Arcuate nucleus
ATP	Adenosine triphosphate
cAMP	Cyclic adenosine monophosphate
CCK	Cholecystokinin
CNS	Central nervous system
CRH	Corticotropin releasing hormone
CSF	Cerebrospinal fluid
ERK	Extracellular regulated kinase
GLP-1	Glucagon-like peptide 1
GIP	Gastrin inhibitory peptide
5-HT	Serotonin
MAP	Kinase Mitogen activated protein kinase
MCR	Melanocortin receptor
NMRI	Naval Medical Research Institute
NPY	Neuropeptide Y
PVN	Paraventricular nucleus
UCP	Uncoupling protein
VEGF	Vascular endothelial growth factor

A number of peptides and aminergic compounds have been suggested to have selective effects on the ingestion of macronutrients. Thus protein intake will be stimulated by growth hormone (Dickson and Vaccarino 1994), whereas neuropeptide Y (NPY) will stimulate carbohydrate intake (Stanley and Leibowitz 1985). For stimulation of fat intake at least two different peptides have been described, galanin (Leibowitz 1994) and agouti-related peptide (AgRP) (Hagan et al. 2001) (Table 16.1). As opposed to these stimulating effects on food intake a couple of peptides have been suggested to inhibit macronutrient intake. Cholecystokinin (CCK) has been described to decrease intake of carbohydrate during the first 30 min after injection, but during the following 1–5 h suppress protein intake as well as fat intake in a three-choice macronutrient diet (McCoy et al. 1990). Thus CCK has a more complex role in promoting satiety.

We have identified enterostatin as a peptide that specifically inhibits fat intake (Erlanson-Albertsson et al. 1991a). Enterostatin is released from pancreatic procolipase during fat digestion (Erlanson-Albertsson 1992a); it is therefore important to know that satiety for fat is observed only after hydrolysis of dietary fat in the intestine (Degen et al. 2007). This suggests that fat hydrolysis is coupled to satiety for fat. The following article describes the properties of enterostatin and the conditions that are essential to promote satiety for fat. A number of reviews have been written about enterostatin, among others (Erlanson-Albertsson and York 1997). The key features of enterostatin are listed in Table 16.2.

Table 16.1 Regulation of fat intake and interaction with enterostatin

Hormone	Effect	Interaction with enterostatin	Reference
Galanin	Stimulates fat intake	Effect inhibited by enterostatin	Nagase et al. (1997)
Agouti-related peptide	Stimulates fat intake	Expression suppressed by enterostatin	Lin et al. (2007)
Beta-casomorphin	Stimulates fat intake	Effect inhibited by enterostatin by competition	Berger et al. (2004); Lin et al. (1998)
Kappa-opiate agonist	Stimulates fat intake	Effect inhibited by enterostatin	Barton et al. (1995); Ookuma et al. (1997)
Mu-opiate agonist	Stimulates fat intake	Effect of enterostatin unknown	Kelley et al. (2002)
Serotonin	Inhibits fat intake	Released by enterostatin	Blundell et al. (1995); Koizumi and Kimura (2002)
CCK	Inhibits fat intake	Releasor of enterostatin	Mei et al. (1993a)
NPY	Inhibits fat intake	No interaction with enterostatin	Lin et al. (1993a)

This table lists the hormones that are responsible for regulation of fat intake, both stimulating and inhibiting and how enterostatin interacts with these hormones

Table 16.2 Key features of enterostatin

1. Enterostatin is a pentapeptide that promotes satiety for fat intake
2. Enterostatin is released from pancreatic procolipase during fat digestion in the intestine
3. The satiety occurs through the release of the reward signal serotonin and by suppression of the hunger signal AgRP
4. The receptor for enterostatin is the beta-subunit of F1-ATPase
5. Both enterostatin expression and the receptor are increased by high-fat diet
6. Sucrose impairs the effect and expression of enterostatin
7. Enterostatin is important to promote satiety using strict high-fat diets without sucrose
8. Enterostatin lowers blood cholesterol and insulin levels
9. Enterostatin stimulates fatty acid oxidation in myocytes, hence promoting the utilization of fat as energy substrate
10. Dietary protein stimulates enterostatin expression
11. Diets with fat and protein from green plants stimulate the expression of enterostatin and are satiating in human

AgRP agouti-related peptide
This table lists the key properties of enterostatin including its effects on appetite regulation, the regulation by various diets, the effect on metabolism, and mechanism of action

16.1 The Discovery of Enterostatin

The first discovery of enterostatin as a feeding-related peptide was in 1988 when during immunization of rabbits with enterostatin, the animals lost their appetite. The basis for immunization of rabbits with enterostatin was the fact that we had found that all colipase molecules produced by pancreas were secreted in the form of procolipase molecules. This was strange with the knowledge that colipase is not an enzyme that needs to be protected as the other enzymes of exocrine pancreas like trypsin or phospholipase. We therefore wondered if enterostatin was indeed released in vivo as we had found in vitro. With the knowledge that the rabbits did not want to eat we started systematic feeding studies in rat and found that enterostatin decreased food intake after intraperitoneal administration (Erlanson-Albertsson and Larsson 1988a). It was very difficult to get this article published but I was lucky to be invited to write a chapter in the French Journal *Biochimie*, in an issue devoted to professor Pierre Desnuelle, a grand French scientist who died in 1985 and whom I worked together with during my postdoctoral scholarship in Marseille during 1972–1973.This was the first publication on the effect of enterostatin, which was named procolipase activation peptide (Erlanson-Albertsson and Larsson 1988a). Shortly afterward a very similar article repeated and verified the findings of a suppressed food intake in rat after peripheral injection of enterostatin in a dose dependent way (Erlanson-Albertsson and Larsson 1988b).

16.2 Central Effect of Enterostatin – The Start of a Lifelong Cooperation

Under the circumstances, I was lucky to attend a conference on obesity in Stockholm, where Professor George Bray, USA, was invited to give a plenary lecture. I found the opportunity to ask him if he was interested to go further with this peptide. George Bray became immediately interested – he had just got a position in Baton Rouge as head of the Pennington Biomedical Research Centre; another coworker was on his way to Baton Rouge for a research position – David York. This was how the story of enterostatin continued.

The first experiment performed in USA was the administration of enterostatin centrally in rat and also by this way of administration there was a suppressive effect on food intake (Shargill et al. 1991). If the food intake had been stimulated with clonidine, an alpha 2-adrenergic agonist, there was no inhibitory effect, suggesting that the anorectic effect was not mediated through the alpha 2-adrenergic system. This publication was the first to name the procolipase activation peptide *enterostatin* (Shargill et al. 1991).

16.3 Enterostatin as a Specific Modulator of Fat Intake

As mentioned above, enterostatin is a pentapeptide released from the N-terminal end of pancreatic procolipase by proteolytic cleavage (Fig. 16.1). The residual product called pancreatic colipase is a protein cofactor for pancreatic lipase during intraduodenal hydrolysis of fat (Erlanson-Albertsson 1992b). Since enterostatin and colipase are released more specifically during the intake of fat, the idea that enterostatin might specifically regulate the intake of fat as opposed to carbohydrate and protein was forwarded by Bray and his colleagues. Experiments were thus performed to elucidate whether enterostatin had any specific effect on fat intake. And this was really so.

a   The formation of enterostatin

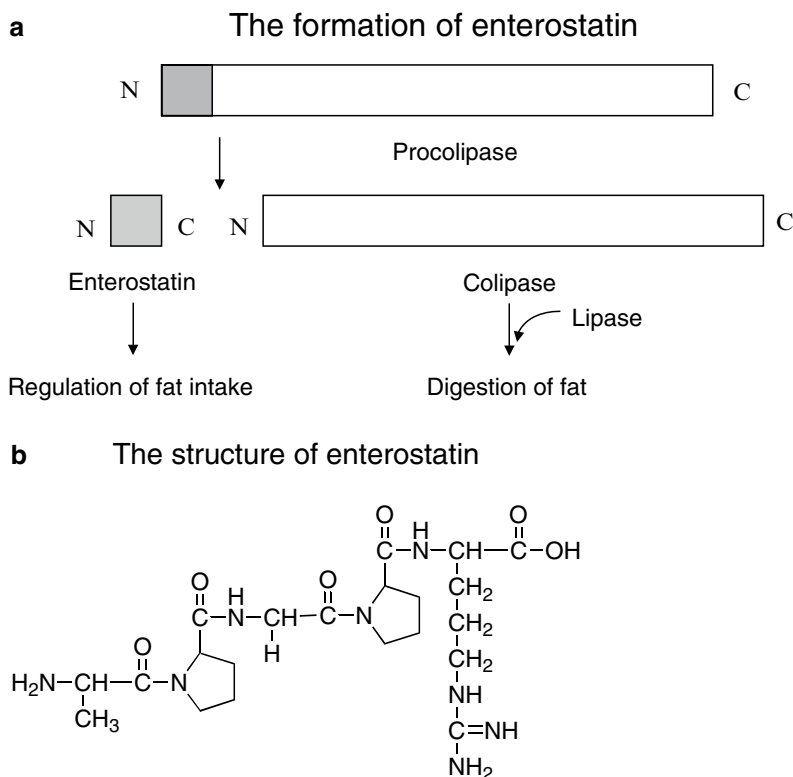
b   The structure of enterostatin


Fig. 16.1 (**a**) Enterostatin is a pentapeptide that is cleaved from the amino terminus of pancreatic procolipase. While colipase acts as protein cofactor for pancreatic lipase during fat digestion, enterostatin promotes satiety for fat in a feedback system. (**b**) The amino acid sequence of human enterostatin, Ala-Pro-Gly-Pro-Arg, a sequence highly conserved among different animal species. The two proline ring structures make the peptide a very stable compound

In the first experiment, Osborne-Mendel rats, rats that are specifically prone to eat fat, were offered a three-choice diet between fat, protein, and carbohydrate (Okada et al. 1991). After fasting overnight the rats were subsequently injected with enterostatin intraperitoneally. A dose-dependent reduction was observed for fat intake, but not with either protein or carbohydrate intake. In another regimen, the rats were given a two-choice diet between high-fat diet and low-fat diet; after enterostatin injection, there was a reduction of food intake only in the high-fat-fed rats (Okada et al. 1991). The experiments suggested that enterostatin could act as a feedback signal to regulate the intake of fat (Fig. 16.1).

In another setup, Sprague-Dawley rats were given a free choice of a low-fat diet (5.2% fat by weight; 14.1% by energy) and a high-fat diet (17.8% fat by weight; 32.8% by energy) in separate containers. After injection of enterostatin into the lateral ventricle, the rats selectively decreased the intake of the high-fat diet by 45% ($p < 0.05$), while the intake of the low-fat diet was unaffected compared to saline injection. A fragment of enterostatin after intracerebroventricular injection had totally lost the selective effect on the consumption of a high-fat and a low-fat diet (Erlanson-Albertsson et al. 1991a). It was concluded that the effect of enterostatin to selectively inhibit fat intake was observed both after central administration and after peripheral administration. Furthermore, it was not specific to any special strain of rat (Fig. 16.2).

Fig. 16.2 Enterostatin specifically reduces high-fat food intake in Sprague-Dawley rat with a two-choice diet between a high-fat (32.8 % by energy) and a low-fat diet (14.1% by energy). The animals were fasted overnight and then injected icv with enterostatin at a dose of 200 ng. Food intake was measured after 30 min. The animals receiving enterostatin had a significantly reduced food intake compared to control when eating high-fat diet ($p < 0.05$) but not when eating low-fat diet). Deviations are SEM

The effect of enterostatin on food intake
16.4 Long-Term Effects of Enterostatin

It was important to find out if enterostatin could be given repeatedly without any development of tolerance. Enterostatin was thus infused chronically into the lateral ventricle of Osborne-Mendel rats for 11 days (Okada et al. 1993a). A lowered food intake was observed in the treated animals compared to the vehicle-treated controls, in turn leading to a significantly reduced body weight gain (Okada et al. 1993a). This suggested that there was no long-term tolerance effect as has been observed for other appetite-regulating peptides such as CCK (Crawley and Beinfeld 1983; Duncan et al. 2005). Another important finding was a significant reduction of serum insulin levels in the enterostatin-treated animals (Okada et al. 1993a). The reduced insulin levels might be a consequence of a reduced body weight or a direct effect of enterostatin on insulin secretion as demonstrated (Erlanson-Albertsson et al. 1994). The endocrine changes observed at the end of the experiment supported the argument that enterostatin remained effective throughout the infusion period.

The studies also demonstrated that corticosterone was significantly increased in rats receiving chronic infusions of enterostatin into the lateral ventricle and that the level of hepatic glucocorticoid receptor was decreased in these animals as measured by Western blot (Okada et al. 1993a). The elevation of serum corticosterone levels by enterostatin suggests that the hypothalamic-pituitary-adrenal axis has been activated. The CRH peptide is known to reduce fat intake, but experiments with a CRH-antagonist, which failed to block the feeding response of enterostatin suggests that this peptide is not involved in the mechanism of action of enterostatin.

In another type of long-term treatment, rats were given a two-choice diet between high-fat diet and low-fat diet. After adaptation, the animals were chronically infused with enterostatin for 9 days (0.5 μg/h) or artificial cerebrospinal fluid (CSF) into the lateral ventricle of rats. Enterostatin reduced intake of the high-fat diet with the maximum depression at day 4, without any compensatory increase in low-fat food intake (Lin et al. 1997). The body weight of enterostatin-infused rats declined significantly

and was associated with a reduction in fat pad as well as liver weight compared to the CSF-infused control rats (Lin et al. 1997). Serum triglycerides and insulin were likewise decreased, whereas corticosterone was elevated in enterostatin-infused rats. These studies thus demonstrated that enterostatin reduced fat intake in long-term studies and that there was no overeating of low-fat diet to compensate for the reduced food intake (Lin et al. 1997).

16.5 Long-Term Effects of Enterostatin When Added to Food

In the first publication of enterostatin, it was noted that enterostatin when added to food decreased food intake in rat (Erlanson-Albertsson and Larsson 1988b). A similar approach was done in long-term studies in mouse (Rippe et al. 2000). Thus high-fat food was prepared, containing 63% fat, 24% protein, and 13% carbohydrate, in the absence of enterostatin (control) and in the presence of enterostatin (116 ug added per gram food). Female NMRI mice were fed during 25 days a high-fat diet with and without enterostatin during which body weight and food intake was measured (Rippe et al. 2000). It was found that food intake was significantly reduced as well as body weight in the animals receiving enterostatin added to food. In these experiments, brown adipose uncoupling protein expression was measured and found to be elevated in the enterostatin-treated animals. This suggests that the decreased body weight was not only a consequence of a decreased food intake but also an increased diet-induced thermogenesis (Rippe et al. 2000). A long-term feeding experiment is demonstrated in Fig. 16.3, where enterostatin was added to the diet for 55 days in NMRI mice.

The effect of enterostatin on body weight
Fig. 16.3 Effect of enterostatin on body weight in female NMRI mice fed a high-fat diet during 55 days. The high-fat diet contained 63% fat, 24% protein, and 13% carbohydrate. Enterostatin was added to the high-fat food dissolved in the lipid phase at a concentration of 166 μg enterostatin per gram food. A significant decrease in body weight was observed in the enterostatin-fed mice compared to control mice ($p < 0.01$). The staples are SEM

16.6 Enterostatin Induces a Normal Feeding Reaction

When identifying a peptide that suppresses appetite it is always important to find out if the suppression is natural and that there is no aversion. In a study to investigate eating behavior, enterostatin was found to induce an early satiety (Lin et al. 1993b). The time course of feeding, grooming, exploration, and sleeping behaviors was measured following injection of enterostatin prior to presenting food. The observation time was 1 h. It was found that enterostatin shortened the time spent eating (21%) compared to saline-injected controls (27%) without any delay in the onset of feeding. Grooming activity appeared earlier following enterostatin, whereas physical activity was reduced (18% vs 27%). Resting time was prolonged (47% vs 27%). There was no change in the drinking behavior. These studies support the concept that enterostatin decreases food intake by producing early satiety (Lin et al. 1993b).

To know if the reduced food intake following injection of enterostatin was related to any aversion reaction, a two-bottle conditioned aversion test was performed (Mei and Erlanson-Albertsson1992), where the effect of enterostatin when injected at such doses that inhibited fat intake was compared with lithium chloride, which is known to produce an aversion reaction. It was found that enterostatin produced no aversion, the animals behaving like the saline-injected animals, while lithium chloride produced a clear aversion reaction (Mei and Erlanson-Albertsson 1992). It was concluded that the inhibition of food intake exerted by enterostatin is not due to malaise.

16.7 The Occurrence of Enterostatin

An important goal was to find and develop antibodies that could be used for a specific assay of enterostatin. To our luck, an assay for measuring pancreatic procolipase activation peptide was published in 1991 with the goal to have an early and sensitive method for measuring acute pancreatitis (Bowyer et al. 1991). Dr. Hermon-Taylor and his group demonstrated through their method the release of immunoreactive enterostatin from human pancreatic juice upon addition of trypsin, while there was no immune reactivity from human pancreatic procolipase prior to the trypsin treatment. One problem with assaying serum enterostatin was the rapid loss of immune reactivity with a half life of 5 min. The loss of reactivity was however significantly slowed by the addition of 20 mmol/L Zinc ions (Zn^{2+}), while ethylenediaminetetra-acetic acid (EDTA) and other protease inhibitors were ineffective (Bowyer et al. 1991).

16.8 Enterostatin in Serum

With the immunoreactive method serum enterostatin was identified and measured in normal and morbidly obese human subjects (Bowyer et al. 1993). It was found that normal subjects displayed a biphasic release of enterostatin in the circulation postprandially, whereas the morbidly obese patients had a weaker response (Bowyer et al. 1993). Enterostatin was also identified in the urine, suggesting that enterostatin reaches the circulation shortly after feeding in human and is thereafter excreted in the urine. In postmenopausal women, the levels of enterostatin was elevated compared to lean control, but were not raised after a meal, suggesting a lack of responsiveness in the obese subjects. This supports earlier observations of a weak response in obese subjects to enterostatin (Prasad et al. 1999).

Fig. 16.4 Fasting levels of plasma enterostatin in Sprague-Dawley rat fed a low-fat diet (14.1% fat by energy), a high-fat diet (32.8% fat by energy), and a high-fat/sucrose diet (added with 23% sucrose) at the start and at the end of the 7-day regimen. Whereas high-fat diet for 7 days induced a significant increased level of enterostatin ($p < 0.05$), this increase was abolished and not observed in the high-fat/ sucrose fed animals. Deviations are SEM and six animals in each group

Effect of fat and sucrose diets on enterostatin
Studies have been performed to investigate if enterostatin binds to any protein in the circulation. At least three different proteins were found to bind enterostatin with a molecular size of 300, 205, and 60 kDa, albumin being one possible binding protein (Wu et al. 2002). The presence of enterostatin-binding protein(s) in the circulation retards the uptake of enterostatin into the brain or other local target tissues and also prevents a rapid degradation.

In rat, enterostatin was demonstrated to increase postprandially after a meal (Mei et al. 2002). The magnitude of response was dependent on the type of meal given. With high-fat and high-fat/high-sucrose meals, the response was greater in magnitude and duration than that consuming a low-fat meal (Mei et al. 2002). Plasma enterostatin levels after high-fat feeding were found to be similar to those after intravenous administration of exogenous enterostatin known to inhibit high-fat food intake. After 7 days of feeding, the enterostatin levels were however reduced in the high-fat sucrose group compared with the high-fat-fed animals (Fig. 16.4). The lowering of enterostatin response in the presence of sucrose may be one important factor for the overeating occurring when fat is combined with sugar. The reduced enterostatin response in the presence of sucrose is probably due to higher insulin levels known to suppress enterostatin synthesis (Duan and Erlanson-Albertsson 1990).

Gel chromatography of pooled postprandial plasma extracts followed by high-performance liquid chromatography analysis showed that plasma enterostatin was identical to synthetic enterostatin. Affinity cross-linking of plasma proteins with ^{125}I-enterostatin on sodium dodecyl sulfate-polyacrylamide gel electrophoresis, followed by autoradiography, revealed a single band with a molecular weight of about 66 kDa, indicating the presence of a potential enterostatin-binding protein in plasma.

16.9 Enterostatin in Intestinal Content

After learning this method, we identified enterostatin immunoreactivity in rat intestinal content (Mei et al. 1993a). Following intravenous infusion of cholecystokinin the concentration of intestinal enterostatin increased from a basal level of 2.0 µM to around 6.0 µM within 60 min. The release of

Table 16.3 Regulation of enterostatin synthesis and release

Factor	Effect	Site of effect	References

Orlistat	No effect	Pancreas	Mei et al. (2006)

This table demonstrates the regulation of enterostatin synthesis by various hormones, by different diets, and by treatment with Orlistat, a medicament that is used as an antiobesity drug that inhibits fat digestion and absorption

enterostatin into the intestinal content was parallel to the release of pancreatic lipase and colipase (Mei et al. 1993a). We also found that high-fat diet significantly raised the level of enterostatin in the intestine (Table 16.3). This increase occurred already 24 h after the start of a high-fat diet regimen, indicating a rapid response of enterostatin release and high-fat feeding. There was also a parallel increase in pancreatic lipase and colipase activities following the start of the high-fat feeding, suggesting a close link between fat intake, fat digestion, and satiety for fat.

In the intestinal lumen enterostatin is degraded within 30 min by epithelial brush border peptidases, mainly eliminating the C-terminal arginine residue (Huneau et al. 1994). Another powerful degrading enzyme is dipeptidylaminopeptidase IV, which readily cleaves dipeptides containing proline as second residue, as occurs in enterostatin. Through the use of enzyme inhibitors the survival of enterostatin was significantly prolonged (Bouras et al. 1996), in a similar way as has been demonstrated and used therapeutically for glucagon-like peptide. In spite of peptide degradation during normal conditions an intact trans-epithelial passage of enterostatin was demonstrated (Bouras et al. 1995) in a similar way as has been demonstrated and used therapeutically for glucagon-like peptide. In spite of peptide degradation during normal conditions an intact trans-epithelial passage of enterostatin was demonstrated (Huneau et al. 1994). It was concluded that although immunoreactive enterostatin exhibits a low apparent permeability coefficient in rabbit ileum, the high luminal concentration of enterostatin may be sufficient for production of biological effects after absorption into the serum.

Also in human, enterostatin immunoreactivity has been identified, being present in equimolar concentration to colipase, i.e. around 1 μM (Erlanson-Albertsson and York 1997).

16.10 Enterostatin in Intestinal Cells

In the gastrointestinal tract, enterostatin was found to be present in the gastric mucosa, secreted by chief cells (Okada et al. 1993c; Sorhede et al. 1996b). Cloning of gastric procolipase revealed that this molecule is identical to the pancreatic procolipase (Winzell et al. 1998). Strangely enough high-fat diet decreased the expression of gastric procolipase, which is in contrast to pancreatic procolipase that is increased by high-fat feeding (Table 16.3). Enterostatin was present in the gastric juice, pepsin, and acid being responsible for the cleavage of gastric procolipase into enterostatin and colipase. The role of gastric colipase is unknown, but may be important to prepare lipase-catalyzed fat digestion already in the stomach. The released gastric enterostatin may be involved in the onset of early satiety (Winzell et al. 1998).

Enterostatin was also identified in endocrine cells in the antral part of the stomach and in the small intestine of rat (Sorhede et al. 1996a). The immunoreactive cells were more frequent in the antrum and duodenum and became gradually fewer toward the distal small intestine. In some of the labeled endocrine cells, a coexistence of enterostatin with serotonin was revealed by immunocytochemical double staining, implying that the cells were enterochromaffin cells (Sorhede et al. 1996a). Serotonin is another satiety-promoting signal specific for fat (Blundell et al. 1995; Halford et al. 2004). Whether enterostatin and serotonin are simultaneously released by fat intake is not known but certainly deserves to be measured. Serotonin has is released after central administration of enterostatin; thus there are multiple interactions between enterostatin and serotonin.

16.11 Enterostatin in the Brain

Enterostatin has been identified in the brain in the form of procolipase (York et al. 2006; Rippe et al. 2007). Procolipase and enterostatin immuno-reactivity was demonstrated in PVN, ARC, supraoptic nuclei, amygdala, and dorsal median thalamus (York et al. 2006). These regions are associated with the regulation of food intake and energy expenditure. Procolipase was seen as dense particles in the cytoplasm, whereas enterostatin immune reactivity was observed in nerve fibers. This suggests that procolipase is produced and processed in the neuronal cell body, whereas enterostatin is transported down the nerve fiber to be released at the nerve terminal (York et al. 2006).

Since enterostatin is particularly active when injected into the amygdala, the endogenous production of enterostatin in this nucleus suggests that this might be important for regulation of fat intake. Enterostatin was also present in cells lining the third ventricle, where it could be secreted into the cerebrospinal fluid, as confirmed by Imamura et al. (1998). Thus, the procolipase gene is expressed in the brain, translated to protein, and cleaved to release enterostatin.

In further studies, the hypothalamic procolipase expression was found to be stimulated by a high-fat diet in a similar fashion as the pancreatic procolipase (Rippe et al. 2007) (Table 16.3). Since diets rich in fat are energy-dense, the stimulation of hypothalamic procolipase seems to be an adequate event to induce satiety and energy balance during fat intake. Other palatable food like mono- and disaccharides (glucose, fructose, and sucrose) had no significant effect on the expression of hypothalamic procolipase, indicating that the procolipase expression is unresponsive to sugars (Table 16.3). Fasting overnight caused a threefold down-regulation of hypothalamic procolipase, which is in agreement with the activity of a satiating agent. There was no expression of classical lipase in the hypothalamus, supporting a role of procolipase in the hypothalamus in the production of enterostatin (Rippe et al. 2007).

The presence of enterostatin and its precursor procolipase in the pancreas, the stomach, and in the central nervous system tells us that enterostatin is a typical gut–brain peptide regulating food intake both in the gut and in the brain.

16.12 Feeding Effects after Peripheral and Central Administration of Enterostatin

Dietary fat intake was reduced after intragastric (White et al. 2000), intraduodenal (Mei and Erlanson-Albertsson 1996b) and intraperitoneal (Okada et al. 1992) administration of enterostatin (Table 16.4). These administrations are close to the main production site of enterostatin in the gastrointestinal tract and gave a response with a short delay. The response in the gastrointestinal tract is dependent on vagal afferent signaling pathways, as demonstrated by several studies (Fig. 16.5). This explains why the response to enterostatin occurred fairly rapidly after intraintestinal administration (Table 16.4). After intravenous administration of enterostatin, a delayed effect on food intake was observed (Mei and Erlanson-Albertsson 1992), indicating that the targeting of enterostatin to its receptor protein is not an immediate process in this situation. Enterostatin binds to plasma proteins in the circulating blood, which reduces the rate of uptake into the brain. The administration of enterostatin near the celiac artery (Lin et al. 2000) or intra-cariotic (Lin et al. 2000) gave an immediate effect on feeding and at low doses of enterostatin. The enterostatin effect after intra-cariotic injection was independent of vagal afferent nerves consistent with a central site of action for enterostatin (Lin et al. 2000).

Reduction of fat intake after intracerebroventricular administration of enterostatin was demonstrated in rat, sheep, and baboon (Lin et al. 1994). The low dose required compared to peripheral administration and the early response suggests a direct mode of action of enterostatin (Table 16.3). Investigations of the various nuclei in hypothalamus demonstrated that PVN (Lin and York 1998a) and amygdala (Lin and York 1998a) were the most sensitive nuclei to give an enterostatin response. In these nuclei, enterostatin was demonstrated to decrease meal size and to reduce meal duration. The local production of procolipase (Rippe et al. 2007; York et al. 2006) in these regions may produce enterostatin that acts centrally. Enterostatin may also be taken up by the blood-brain barrier to reach these target nuclei (Koizumi et al. 2002).

Table 16.4 Inhibition of fat intake by enterostatin and onset of action

Administration	Dose (nmol)	Onset of action (min)	Reference
Food additive	200	<30	Rippe et al. (2000)
Intragastric	100	<30	White et al. (2000)
Intraduodenal	11	<30	Mei and Erlanson-Albertsson (1996b)
Intraperitoneal	40	15	Okada et al. (1992)
Intravenous	13	60–120	Mei and Erlanson-Albertsson (1992)
Intracarotid arterial	2	<5	Lin et al. (2000)
Near celiac arterial	2	<5	Lin et al. (2000)
Intracerebroventricular	0.3	<30	Lin et al. (1994)
Paraventricular nucleus	0.1	<10	Lin and York (1998a)
Amygdala	0.01	<5	Lin and York (1998a)

This table demonstrates the onset time of action for enterostatin after injection at various sites in the body. The intraintestinal site of action is around 30 min and the most likely time span for enterostatin to act

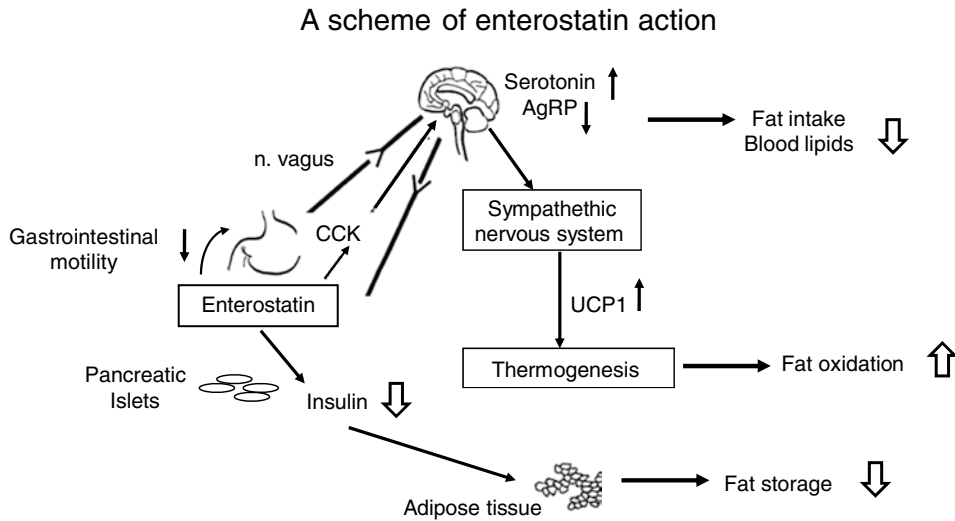
A scheme of enterostatin action


Fig. 16.5 A schematic picture on the effects of enterostatin. Enterostatin is released from the intestine, where it activates CCK-dependent pathways to promote satiety, acting both peripherally to decrease gastric emptying and centrally to release serotonin. In this pathway, the vagal afferent nerves from the intestine to the brain is crucial. Suppression of fat intake by enterostatin also involves a melanocortin pathway, suppressing AgRP. In the islets enterostatin inhibits insulin secretion, which is important to decrease fat storage in the adipose tissue. At the same time, enterostatin stimulates thermogenesis through the activation of the sympathetic system and induction of UCP1, important for stimulation of fat oxidation. Low blood lipids occur through a CCK-dependent pathway. Enterostatin is induced by high-fat feeding and therefore adapts the organism to regulate fat intake and promote utilization of fat as energy source

16.13 Metabolic Effects of Enterostatin

In addition to its effect on feeding behavior, enterostatin has metabolic effects, directly promoting fatty acid oxidation in muscle (Lin et al. 2006), inhibiting insulin secretion (Ookuma and York 1998), lowering serum cholesterol (Takenaka et al. 2003, 2008a) and promoting corticosterone release (Okada et al. 1993a; Takenaka et al. 2003). These effects are closely coupled to the feeding behavior effect of enterostatin. In addition, enterostatin has been found to display various inhibitory gastrointestinal effects linked to satiety (Erlanson-Albertsson et al. 1991b; Lin and York 1997). Finally, a couple of general effects on physiology has been documented such as stimulation of memory (Ohinata et al. 2007; Takenaka et al. 2001), suppression of analgesia (Takenaka et al. 2001, 2003) and inhibition of angiogenesis (Park et al. 2008). The effects are summarized in Table 16.5.

16.13.1 Inhibition of Insulin Secretion

Inhibition of insulin secretion by enterostatin was first observed in isolated islets, where a dose-dependent inhibition of insulin secretion was observed (Mei et al. 1993b; Erlanson-Albertsson et al. 1994; Ookuma and York 1998) (Fig. 16.5). Enterostatin inhibited insulin secretion from islets incubated in the presence of glucose in a dose-dependent manner. Enterostatin also inhibited insulin

secretion stimulated by phorbol acetate (TPA) and the kappa-opioid agonist U50,488 (Ookuma and York 1998). The enterostatin inhibition of insulin secretion was blocked by 8-Br-cAMP, suggesting that enterostatin may suppress insulin secretion through the reduction of cAMP, but other mechanisms may also be possible (Ookuma and York 1998). In insulin-producing cells (INS-1 cells) enterostatin targeted the F_1-ATPase β-subunit with a simultaneous perturbation of ATP production, a raised thermogenesis and a reduced insulin secretion (Berger et al. 2002) (Table 16.6).

A lowering of insulin levels were observed in short-term as well as in long-term experiments after administration of enterostatin in vivo (Okada et al. 1993a; Mei and Erlanson-Albertsson 1996a; Mei et al. 1997). This inhibition occurred also after stimulation of insulin release with intestinal incretins like GLP-1 and GIP (Rodriguez-Gallardo et al. 1999).

16.13.2 Lowering of Blood Cholesterol

A hypocholesterolemic effect of enterostatin was demonstrated in mice after oral administration of enterostatin (Takenaka et al. 2003). In further studies, it was demonstrated that this reduction in cholesterol levels occurred independent of the food suppressive effect of enterostatin and that this effect was dependent on cholecystokinin action (Takenaka et al. 2008a). Since enterostatin was found to increase the excretion of bile salt into the feces, it was suggested that the hypocholesterolemic effect of enterostatin could be due to an increased secretion of bile. There may however be other explanations for the lowering of cholesterol levels by enterostatin, related to reduced insulin levels and increased fatty acid oxidation. The endogenous role of enterostatin in lowering cholesterol levels is evident from enterostatin knockout mice, who demonstrate significantly increased serum cholesterol levels (Miller et al. 2009).

16.13.3 Promotion of Corticosterone

Corticosterone is a hormone that promotes utilization of fat as energy substrate sparing glucose. Several studies have indicated enterostatin to promote corticosterone release and that the effect of enterostatin to promote satiety for fat is dependent on corticosterone (Mei and Erlanson-Albertsson 1996a; Lin et al. 1997). The anti-analgesic effect of enterostatin was also mediated through corticosterone release from the adrenal cortex in mice (Takenaka et al. 2001; 2003), suggesting the importance of corticosterone release in some enterostatin-induced effects.

16.13.4 Inhibition of Gastric Motility and Gastric Emptying

Since hunger and satiety are strongly correlated with changes in gastrointestinal motility, the effects of enterostatin were investigated on gastric emptying and intestinal motility. Enterostatin was found to inhibit pancreatic secretion as well as to inhibit intestinal motility when administered intraintestinally in pig (Erlanson-Albertsson et al. 1991b) (Fig.16.5). These effects were observed only after intestinal administration and not after intravenous injection of enterostatin. It is thus clear that certain effects of enterostatin are observed only after local administration and may need a direct interaction with a receptor on the cellular level. The inhibition of motility may be linked to a CCK receptor-dependent pathway.

In rat enterostatin was shown to reduce gastric emptying (Lin and York 1997), which is an essential target mechanism for gastrointestinal satiety peptides. The inhibition of gastric emptying may be mediated through vagal afferent fibers or be explained by the release of amylin, a pancreatic islet hormone released by enterostatin (Arsenijevic et al. 2005) and known to strongly inhibit gastric emptying (Table 16.5).

16.13.5 Stimulation of Memory

Several gastrointestinal peptides have memory-enhancing effects, for instance CCK. This was found to be the case also for enterostatin. Using passive avoidance test enterostatin was found to improve step-through latency after oral and central administration in normal mice (Ohinata et al. 2007),

suggesting that enterostatin enhances memory consolidation. Two signaling pathways of orally administered enterostatin to the CNS were hypothesized. One way is through afferent vagal pathways as has been demonstrated for regulation of fat intake (Lin et al. 2000). Another pathway is a direct uptake of enterostatin into the brain as has been demonstrated (Koizumi et al. 2002). At present, it is not clear whether the memory-enhancing effect of orally administered enterostatin is mediated by the vagal pathway or by a direct passage of enterostatin across the blood-brain barrier. The memory enhancing effect of enterostatin was completely abolished through a CCK-receptor antagonist, indicating the CCK-signaling system to be obligatory for the memory-enhancing effect of enterostatin.

16.13.6 Suppression of Analgesia

Feeding promotes release of reward molecules, among them opiates, serotonin, and dopamine. It is not surprising that a peptide that stops eating also stops analgesia. In an experiment using morphine to induce analgesia during tail-pinch studies in mice, it was found that enterostatin inhibited the analgesia (Takenaka et al. 2001). The mechanism for this inhibiting effect of enterostatin was not due to an antagonistic effect of opiates on the receptor level, but instead was found to be dependent on CCK signaling (Takenaka et al. 2008b). Cholecystokinin is known to antagonize morphine analgesia in rat via a CCK-B-receptor (Pu et al. 1994).The effect of enterostatin to reduce fat intake thus may involve a decrease in analgesia. We must be aware of these facts!

16.13.7 Inhibition of Angiogenesis

In order to develop an adipose tissue angiogenesis is an important event. Adipose tissue is a highly vascularized tissue that has the capacity to expand throughout life. A network of capillaries surrounds each adipocyte and in order for an expansion of new adipose tissue mass the vasculature has to develop. Some studies suggest that blocking of angiogenesis in the adipose tissue can help to induce loss of fat mass. By the use of angiogenic blockers in obese mice loss of body fat has been induced (Rupnick et al. 2002). In human obesity, a number of angiogenic factors are increased in the circulation, including VEGF A, C, and D, as well as the inflammatory cytokine interleukin-6 and insulin. With this background, the effect of enterostatin on angiogenesis was studied. Using liver cells (Hep G2 cells) it was demonstrated that enterostatin inhibited angiogenesis and that this occurred through suppression of angiogenic factors like VEGF (Park et al. 2008). It is possible hence that this anti-angiogenic effect of enterostatin may contribute to the loss of adipose tissue that is observed following enterostatin administration. The release of fatty acids increases the availability for fatty acids to be oxidized (Fig. 16.5).

16.14 Mechanism of Action of Enterostatin

Enterostatin acts through both direct and indirect pathways. The direct pathway involves the interaction of enterostatin with its receptor, the β subunit of F_1-ATPase (Berger et al. 2002; Park et al. 2004), while the indirect pathways involve serotonin, CCK, and melanocortin pathways.

16.14.1 The β-Subunit of F1-ATPase as a Receptor for Enterostatin

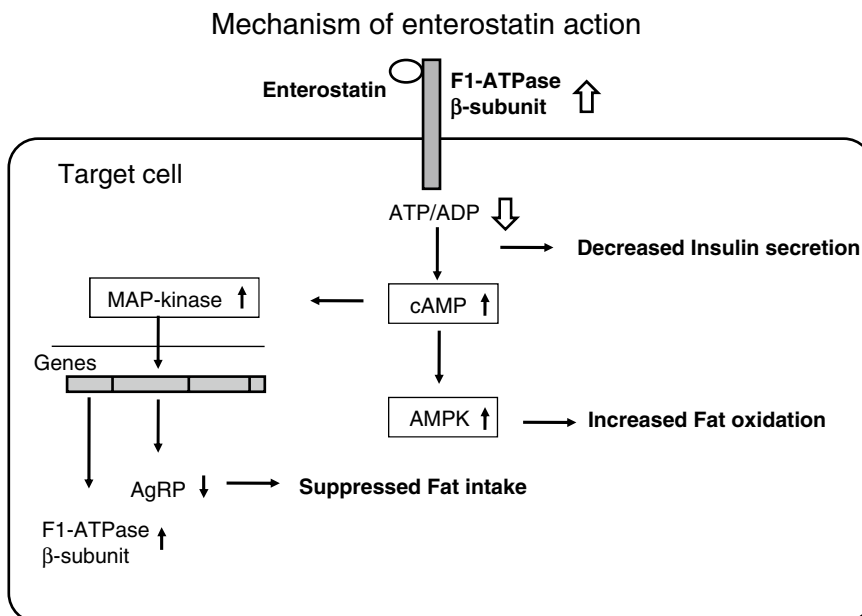
Using purified rat membranes Berger et al. (2002) was able to demonstrate a specific binding of enterostatin to a 60 kDa protein, which was sequenced through Malditof analysis and found to be the β-subunit of F_1-ATPase (Fig. 16.6). There was also a change in intracellular ATP/ADP concentrations by enterostatin, which may be important to modulate intracellular signaling in response to enterostatin. The identification of the β-subunit of F_1-ATPase as a receptor for enterostatin was confirmed by Park et al. (2004) who established the binding constant to be 1.7×10^{-7} M using surface plasmon resonance technique. Using an aqueous two-phase system, the binding between enterostatin and its receptor was found to be equal to 1.5×10^{-7}M (Berger et al. 2004). The identification of the enterostatin receptor (β-subunit of F_1-ATPase) in the plasma membranes of liver cells as well as in amygdala was an important finding (Park et al. 2004). The enterostatin receptor was also localized in INS-1 cells, where enterostatin caused a threefold upregulation of the expression of the receptor (β-subunit of F_1-ATPase) in the plasma membrane (Lindqvist et al. 2008) (Fig. 16.6). Likewise, fatty acids were found to stimulate the expression of the β-subunit of F_1-ATPase in the plasma membrane (Lindqvist et al. 2008). The fact that fat components like fatty acids cause an increased expression of the enterostatin receptor may explain the need to feed animals high-fat diets before they respond to enterostatin (Lin and York 1998b). High-fat diets are known to increase the expression of procolipase/enterostatin. Thus high-fat diets cause an increased expression, both of enterostatin and its receptor (Fig. 16.6).


Fig. 16.6 The intracellular mechanisms for enterostatin. Enterostatin binds to its receptor, the β-subunit of F_1-ATPase. This causes a perturbation of ATP/ADP formation, which in turn activates cAMP, AMPkinase, and MAPkinase. The inhibition of insulin secretion occurs following a reduced ATP or cAMP, whereas an increased AMPkinase is responsible for the increased fat oxidation. Activation of MAPkinase suppresses the expression of the hunger hormone AgRP, leading to suppressed fat intake. Enterostatin induces the expression of its own receptor, the β-subunit of F_1-ATPase in the plasma membrane. High-fat diet induces both enterostatin and its receptor to express satiety

The identity and targeting of F1-ATPase β-subunit in the plasma membrane and not as expected in the mitochondria as part of the ATPsynthase complex is not a unique phenomenon of enterostatin action. There are in fact several reports on the presence of the F1-ATPase β-subunit in the plasma membranes of a variety of cell types, including adipocytes, hepatocytes, and various tumor cell lines (Champagne et al. 2006) and the targeting of various signals to this protein. In the plasma membrane, the F1-ATPase β-subunit is probably complexed with other subunits than when present in the mitochondria. Different functions have been described. The targeting of enterostatin to the F1-ATPase β-subunit in the plasma membrane seems a possible mechanism for enterostatin to affect various cellular processes (Fig. 16.6).

16.14.2 The Interaction with the Serotonin System

Serotonin has been described as a signal specifically related to satiety for fat (Halford and Blundell 2000).With the construction of a three-choice diet of fat–carbohydrate–protein, it was demonstrated that fenfluramine, which raises serotonin levels, reduced fat intake from 61% to 47% compared to saline treatment. This reduction occurred both in fat- and carbohydrate-preferring rats, thus independent of the mechanism involved in dietary preferences (Smith et al. 1998). Thus serotonin signaling was investigated for its possible role in transmission of the enterostatin effect.

Enterostatin was infused into the amygdala to reduce fat intake (Lin and York 2004). In the presence of a serotonin receptor antagonist (5HT1b), the response of enterostatin was completely abolished (Lin and York 2004). Since enterostatin does not interact directly with a serotonin receptor, the mechanism of action could involve the ability of enterostatin to release serotonin (Koizumi and Kimura 2002) (Fig.16.5). Serotonin was released after enterostatin infusion into the lateral hypothalamic area, reaching a maximum 40 min after enterostatin administration.

16.14.3 The Interaction with the CCK-System

Another component that is important for the enterostatin response is the presence of CCK-A receptors (Lin et al. 2003) (Fig. 16.5). CCK is released by dietary fat reaching the intestine and reduces food intake through a CCK-A receptor. CCK causes a reduction in meal size and is dependent on afferent vagal nerves from the gastrointestinal tract to hypothalamic and extrahypothalamic forebrain regions to reduce food intake in a similar way as enterostatin. The interaction of enterostatin with the CCK-induced signaling is based on studies using the OLEFTA rat, which lacks CCK-A receptors (Lin et al. 2003). This rat was found to be unresponsive to enterostatin in contrast to the control LETO rat, where fat intake was reduced by 23% after enterostatin administration. Further support for the involvement of CCK-A receptor was the observation that lorglumide, a receptor antagonist specific for CCK-A receptor, totally abolished the enterostatin effect (Lin et al. 2003). There was however no binding of enterostatin to the CCK-A receptor, neither peripherally nor centrally. There are therefore several possibilities for the explanation of the enterostatin dependence on the CCK-system.

Since enterostatin is released and localized to mucosal layers in the intestine, one possible scenario is the influence of enterostatin on CCK-A-receptors present on vagal afferent neurons from the gastrointestinal tract to the brain and higher centers. This is further supported by the fact that vagal afferent neurons are necessary for the mediation of the reduction in fat intake by enterostatin (Tian et al. 1994).

Another possibility is the release of CCK by enterostatin. There are many similarities between the peripheral action of CCK and enterostatin; they both work through vagal afferent nerves, they both inhibit gastric emptying, they both decrease meal size, they are both fat-specific. The effect of enterostatin to suppress food intake during a longer period than CCK could be explained by a continued release of CCK in response to enterostatin. In Sprague-Dawley rat, where procolipase levels were raised through administration of plant thylakoids (Albertsson et al. 2007), there was also a strong release of CCK suggesting a parallel release between CCK and enterostatin, although the order of release is not known.

16.14.4 The Interaction with the Melanocortin System

The third pathway for enterostatin is the melanocortin pathway. The melanocortin system consists of the hunger hormone agouti-related peptide (AgRP) and the satiety signal melanocyte-stimulating hormone (α-MSH), both of which interact with the melanocortin receptors 3 and 4 to affect food intake. Several lines of evidence support AgRP as a hunger signal specifically stimulating fat intake. In a two-choice paradigm between high-fat and low-fat food, AgRP significantly enhanced high-fat (41 energy percent) food intake during the 4 h following an injection into the third ventricle, whereas low-fat (11 energy percent) food intake was not affected (Hagan et al. 2001). The fact that such a preference for fat also occurred in animals with chronic overexpression of agouti-protein was supported by the finding that the agouti mice (Ay/a), when given a three-choice diet between fat, protein, and carbohydrates, chose to eat fat thus inducing an important weight gain (Koegler et al. 1999). With this background information, experiments were carried out to find out if the melanocortin pathway was involved in mediating the action of enterostatin (Lin et al. 2007).

A first discovery was that food intake was not affected by intracerebroventricular injection of enterostatin into melanocortin receptor 4 (MC4R) knock-out mice, whereas food intake was reduced in wild-type mice by approximately 25% (Lin et al. 2007). Following this result, the receptor antagonist SHU9119 was injected to wild-type mice and essentially abolished the inhibitory effect of enterostatin on food intake. Thus it was concluded that the melanocortin pathway is involved in the mechanism of enterostatin in suppressing fat intake (Lin et al. 2007). Further experiments demonstrated that enterostatin decreased the expression of AgRP in the amygdala and in the hypothalamus (Lin et al. 2007). Since AgRP stimulates fat intake, this inhibition could explain a decreased fat intake by enterostatin. However, the immediate suppression of food intake by enterostatin cannot be explained by a changed gene expression. A likely hypothesis is the release of serotonin, which in turn can activate or release the melanocyte-stimulating hormone (α-MSH) to suppress food intake. It was indeed found that enterostatin caused an increased expression of the satiety hormone melanocyte-stimulating hormone (α-MSH) and an increased release in the arcuate nucleus (Lin et al. 2007). Thus, one possible mechanism for the suppression of fat intake by enterostatin is the release of melanocyte-stimulating hormone (α-MSH), which centrally interacts with its receptor to promote satiety.

16.15 Intracellular Mechanisms Mediating the Enterostatin Effect

Intracellular enterostatin has been found to activate different pathways depending on cell type and intracellular events (Table 16.6).

Regarding the inhibition of insulin secretion enterostatin was found to act through cyclic AMP (cAMP). Thus enterostatin caused a decreased production of intracellular cyclic AMP, after the islet

cells had been stimulated with an opiate kappa agonist (U50 488) (Ookuma and York 1998). The changes in cAMP content of the cells were parallel with changes in insulin release. Berger et al. (2002) suggested that the inhibition of insulin secretion observed in INS-1 cells was due to a perturbed ATP production and increased thermogenesis, ATP being important to stimulate insulin secretion. The expression of the F1-ATPase receptor in the plasma membrane of INS-1 cells was induced by enterostatin, suggesting a feed-forward type of modulation (Lindqvist et al. 2008) (Fig. 16.6).

Regarding the stimulation of fatty acid oxidation in myocytes enterostatin was demonstrated to act through AMP-activated kinase (AMPK) (Fig. 16.6) (Lin et al. 2006). AMPK is recognized to have a central role in regulating energy balance between anabolic and catabolic pathways (Ruderman and Prentki 2004). When activated, AMPK leads to increased fatty acid oxidation and glucose transport in muscle as well as decreased fatty acid synthesis and gluconeogenesis. Enterostatin caused a phosphorylation and subsequent activation of AMPK, which is in agreement with an activation of energy metabolism to recruit energy from energy stores while food intake is suppressed (Lin et al. 2006) (Fig. 16.5).

The regulation of AgRP expression by enterostatin was studied in GT1-7 murine hypothalamic neuronal cells in culture, where enterostatin caused a reduced expression after 1 h of incubation (Park et al. 2009). The mechanism for this effect was found to be under the control of cyclic AMP and MAP kinase ERK pathways (Park et al. 2009). Enterostatin was found to initially increase cAMP levels, the downstream intracellular event being an increased activation of MAPkinase pERK pathway. The activation of the MAPkinase way was found to correlate to a decreased expression of AgRP expression (Fig. 16.6). The GT1-7 cells were shown to possess the F1-ATPase ß subunit protein, the enterostatin receptor, in the plasma membrane, where it was associated with lipid rafts. It was hence suggested that a perturbation of the ATP/ADP could be responsible for the raised cAMP concentration and the following intracellular events.

In the study to understand the mechanism for the anti-angiogenic effect of enterostatin, HepG2 cells were incubated in the absence of glucose, which induced an activation of AMP kinase (Park et al. 2008). In this situation, enterostatin reduced the levels of AMPkinase (Park et al. 2008). This reduction of AMPkinase in turn caused a down-regulation of angiogenic factors like the VEGF (vascular endothelial growth factor), hence explaining the anti-angiogenic effect of enterostatin. Thus enterostatin could either stimulate or reduce the activity of AMPkinase, depending on the energy state of the cell, suggesting enterostatin to have a modulatory role.

16.16 Enterostatin Stimulates Energy Expenditure

Several satiety hormones raise energy expenditure and thermogenesis of which enterostatin is one example (Table 16.5). Chronic injection of enterostatin either intracerebroventricularly (icv) or peripherally caused a greater weight loss than could be accounted for by the reduction of food intake (Lin et al. 1997; Berger et al. 2002). Additionally, enterostatin was found to enhance sympathetic activation of brown adipose tissue (Nagase et al. 1997). One explanation for the increased thermogenesis was an enhanced expression of uncoupling protein 1 in brown adipose tissue in mice fed a high-fat diet, leading to increased heat production (Rippe et al. 2000). The increased energy expenditure served to achieve energy balance during high-fat feeding. The increased expression of uncoupling protein 2 in the stomach by enterostatin (Rippe et al. 2000) probably does not produce heat, but may regulate oxidative stress.

In INS-1 cells enterostatin was found to increase heat production as well as oxygen consumption (Berger et al. 2002), an effect believed to occur through an interaction with the β-subunit of F1-ATPase. The stimulation of energy expenditure by enterostatin could occur through a central or a peripheral pathway.

16.17 Enterostatin as an Endogenous Regulator of Fat Intake

The question of whether enterostatin is an endogenous regulator of fat intake is answered by the fact that the receptor antagonist beta-casomorphin has the ability to increase fat intake (Lin et al. 1998; Berger et al. 2002). There are also studies demonstrating an increased food intake after intracerebroventricular administration of enterostatin antibodies (D.A. York, unpublished). Voluntary fat intake in rodents was demonstrated to be inversely related to the amount of procolipase/enterostatin (Okada et al. 1992) suggesting that endogenous enterostatin regulates fat intake. There are hence various arguments for the statement that enterostatin is an endogenous regulator or modulator of fat intake under normal conditions.

16.18 Regulation of Enterostatin Synthesis and Release

The regulation of enterostatin synthesis and release is summarized in Table 16.3. A couple of hormones like the gastric inhibitory stimulating peptide (GIP) specifically stimulate the synthesis of the pancreatic procolipase, the precursor for enterostatin. This may be one factor mediating the high-fat-diet-induced synthesis of enterostatin, since GIP is released by dietary fat. Another powerful releaser of pancreatic lipase and procolipase and hence of enterostatin is CCK, which stimulates both synthesis and secretion. Leptin has however no effect on enterostatin release. A couple of important metabolic hormones inhibit the synthesis or release of enterostatin/procolipase, like insulin and glucocorticoid hormone. Peripheral insulin acts to promote energy storage and the utilization of carbohydrate as energy substrate, whereas enterostatin is more involved in the utilization of fat as energy substrate. It is therefore not surprising that enterostatin and insulin mutually inhibit each other. The glucocorticoid hormone has a complex role of stimulating the use of carbohydrate as energy substrate and translocating fat as energy store from peripheral adipose tissue to central adipose tissue. The suppression of colipase/enterostatin expression by glucocorticoids may promote such a fat redistribution.

High-fat diets have in several studies been shown to increase the synthesis of procolipase/enterostatin (Table 16.3). It is important to note that sucrose alone and sucrose/high-fat diets fail to simulate enterostatin production (Table 16.3). This may be the consequence of an increased release of insulin, which acts to suppress procolipase synthesis. The stimulated expression of enterostatin by high-fat diets may explain why "pure" high-fat diets are satiating, whereas high-fat/sucrose diets promote overeating. That dietary protein stimulates procolipase/enterostatin synthesis may appear surprising (Table 16.3). One interpretation is that high-fat and high-protein diets often are linked, whereas low-fat diets more often are combined with high-carbohydrate diets.

16.19 Enterostatin Effects in Man

Since the discovery of enterostatin there have been a couple of human studies on the effect of enterostatin on appetite regulation (Rossner et al. 1995; Kovacs et al. 2003). In these experiments, enterostatin were injected as single shots, either intravenously or orally. There has been no visible effect on eating but a documented suppressed hunger.

We have recently performed experiments where the endogenous levels of enterostatin/colipase were found to be elevated through the administration of thylakoids in the food (Albertsson et al. 2007;

Kohnke et al. 2009b) (Table 16.3). Thylakoids are membranes from green leaves that interact with fat digestion by binding both to the fat droplets as well as to the lipase/colipase complex in this way reducing the rate of fat digestion (Albertsson et al. 2007). In humans, the addition of thylakoids to a meal promoted satiety signaling with a release of CCK during 6 h after eating, whereas a control meal induced a CCK signaling only during 3–4 h (Kohnke et al. 2009a). At the same time, insulin levels were reduced (Kohnke et al. 2009a). These experiments hence indicate that endogenous levels of enterostatin are important for the suppression of appetite and the promotion of satiety and that induction of elevated *endogenous* levels of enterostatin is a better way of achieving appetite control than infusion of the peptide. It is important to note that enterostatin targets both appetite-regulating sites to promote satiety and metabolic sites to reduce insulin levels, blood cholesterol, and blood tria-cylglycerol levels. Targeting pancreatic lipase by Xenical to reduce fat digestion fails to promote CCK-signaling and enterostatin/procolipase expression (Mei et al. 2006) (Table 16.3).

16.20   Applications to Other Areas of Health and Disease

Appetite regulation regarding fat intake is important to know in the face of the obesity epidemia, which is linked to a high dietary fat intake in combination with sucrose. Since the satiety for fat is impaired by the presence of sucrose as evidences by the study of enterostatin, diet programs should be careful to restrict fat and sucrose intake, and in particular to separate these two macronutrients to different meals and occasions. The importance of a memory-enhancing effect by enterostatin suggests that areas of aging and mental health are closely related to this field.

Summary Points

- Enterostatin is a pentapeptide
- Is released from pancreatic procolipase during fat digestion
- Suppresses fat intake
- Acts both peripherally and centrally
- Acts in short-term and long-term treatment
- Enterostatin is a gut–brain peptide
- Is produced in the stomach, small intestine, and brain
- Is present in the circulating blood postprandially
- Passes blood–brain-barrier
- Is produced in hypothalamic nuclei and amygdala
- Enterostatin synthesis/release is increased by high-fat food
- Is stimulated by dietary protein
- Is inhibited by dietary sucrose even in the presence of high-fat food
- Is stimulated by the gastrointestinal hormone GIP
- Is inhibited by insulin
- Enterostatin receptor is the β-subunit of F_1-ATPase
- The receptor is localized in the plasma membrane of various cells
- The receptor expression is stimulated by enterostatin and by fatty acids
- Intracellular targets are cAMP, AMPkinase, and MAPkinase

- Gene expression of the hunger hormone AgRP is suppressed
- Enterostatin reduces insulin secretion
- Reduces plasma cholesterol levels
- Stimulates fatty acid oxidation in myocytes
- Increases thermogenesis
- Stimulates memory
- Enterostatin releases serotonin
- Acts through CCK-dependent pathways
- Acts through vagal afferents
- Acts as an opiate-antagonist
- Enterostatin knockout mice have increased serum cholesterol levels
- Induction of enterostatin production produces body weight control in rodents
- Induction of enterostatin production in human produces satiety signals
- Endogenous release of enterostatin – a necessary strategy to produce satiety

---

Key terms

Enterostatin: Peptide which promotes satiety for fat and the utilization of fat as energy substrate.
Procolipase: The precursor from of enterostatin and colipase.
Colipase: A pancreatic protein that acts together with pancreatic lipase to hydrolyze dietary fat especially triacylglycerol in the intestine.
Amygdala: A nucleus in the brain that expresses reward.
Hypothalamus: A brain region where homeostatic mechanisms are expressed to give balance. This includes appetite, body weight, and body temperature.
Melanocortin pathways: Intracellular pathways that express hunger and satiety linked to the melanocortin system, containing two key hormones, AgRP, a hunger hormone, and MSH, a satiety hormone.
Thermogenesis: Production of heat during metabolic events.
F1-ATPase β subunit: Receptor for enterostatin located in the plasma membrane of liver cells, insulin-producing cells, and cells in amygdala that mediates the effects of enterostatin.
AMPkinase: Intracellular enzyme that is activated by enterostatin through its receptor to stimulate the utilization of energy, for instance fat oxidation.
Serotonin: A reward molecule produced centrally and in the gastrointestinal tract to promote stability and satiety.

Chapter 17
The Paradoxical Role of Glucose-Dependent Insulinotropic Polypeptide (GIP) in Diet and Eating Behaviour in Health and Disease

L.R. Ranganath and J. Pinkney

Abbreviations

GIP	Gastric inhibitory polypeptide or glucose-dependent insulinotropic polypeptide
GIPR	Glucose-dependent insulinotropic polypeptide receptor
B-cell	Pancreatic insulin secreting cell
GIT	Gastro-intestinal tract
GLP-1	Glucagon-like peptide-1
T2D	Type 2 diabetes mellitus
K-cell	GIP secreting intestinal cell
DPP IV	Dipeptidyl peptidase IV
MUFA	Monounsaturated fatty acid
SFA	Saturated fatty acid
PUFA	Polyunstaturated fatty acid
EE	Energy expenditure
A-cell	Pancreatic glucagon secreting cell
D-cell	Pancreatic somatostatin secreting cell
SGLT 1 transporters	Sodium-dependent glucose transporter 1
GIPR-/-mice	GIP receptor gene knockout mice

17.1 Introduction

The gastrointestinal tract (GIT) is the organ responsible for the digestion and absorption of ingested nutrients prior to metabolism and storage. Enzymes and hormones produced in the gut enable these processes to occur efficiently. Obesity and diabetes, twin disorders of nutrient intake and metabolism, have assumed major importance, and the role of the GIT in these processes is being re-examined. In particular, two intestinal hormones known as "incretins", glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide 1 (GLP-1), have become important areas of research. Although GIP was the first incretin to be discovered, there has been greater progress in the understanding

of GLP-1 leading to its therapeutic application in type 2 diabetes mellitus (T2D) (Meier et al. 2002). Therefore, the present chapter will instead address the basic and clinical science of GIP and its potential role in human health and disease. The focus of this brief review is on its most important clinical application – the treatment of obesity and T2D, conditions brought about by an imbalance between energy intake and energy expenditure and characterised by insulin resistance and progressive failure of insulin secretion.

17.2 History of GIP

A rise in glucose concentrations in arterial blood perfusing pancreatic B-cell leads to insulin release that in turn restores euglycaemia. The observation that oral rather than intravenous glucose administration resulted in greater insulin secretion confirmed the existence of a connection between the intestinal tract and endocrine pancreas (McIntyre et al. 1964). These studies established that although the arterial blood glucose concentration was a stimulus for insulin secretion, factors that were termed "incretins" released from the gut in response to glucose absorption, which were found subsequently to include GIP and GLP-1 (Brown & Dryburgh, 1971), sensitised the pancreatic B-cell to glucose, and reduced the threshold for release of insulin. The concept of the 'entero-insular' axis was thus born (Fig. 17.1). The first incretin to be discovered was GIP but its significance in gut biology has been overshadowed by rapid advances in the understanding of GLP-1. There continues to be debate about the relative importance of the insulinotropic and other physiological effects of these two incretin hormones.

17.2.1 Incretin concept

The recognition that insulin secretion is different when the same amount of glucose is given orally or intravenously led to the description of the 'incretin' effect (Fig. 17.2). The incretin effect can be calculated under conditions where similar plasma glucose concentrations are produced by oral and controlled intravenous glucose administration (Fig.17.3). Using this approach, it has been estimated that the incretin effect accounts for 70% of insulin secretion in health and half that in T2D (Nauck et al. 1986). Several criteria have to be fulfilled for a hormone to be called an incretin: (a) The hormone should be
Fig. 17.1 The entero-insular axis Ingested nutrients, especially carbohydrates, lead to secretion of insulin from the B-cell by a combination of direct nutrient stimulation as well as neural and endocrine mechanisms (Brown & Dryburgh, 1971)
Fig. 17.2 The incretin effectWhen glucose is administered orally or intravenously, the difference in insulin responses evoked was described as the incretin effect as indicated by the figure (McIntyre et al. 1964)

Fig. 17.3 The quantitation of incretin effect (as %)When glucose is administered orally or intravenously to produce quantitatively similar plasma glucose concentrations, the insulin responses evoked can be used to calculate the incretin effect as indicated by the figure (Nauck et al. 1986)

released in response to oral nutrient ingestion, especially glucose, and (b) it should reach physiological concentrations in vivo that cause insulin release. GLP-1 and GIP are the only currently known incretins. A further property of these incretins that make them attractive as potential therapeutic agents in diabetes is that insulin secretion in response to these peptide hormones ceases when euglycaemia is achieved, thereby minimising the risk of hypoglycaemia. Lastly, the incretin effect appears not only to be due to increased secretion but also decreased hepatic insulin extraction in humans (Shuster et al. 1988).

17.3 Biology of GIP (Table 17.1)

17.3.1 GIP producing cells

GIP is secreted by enterochromaffin K-cells of the proximal intestine (Fehmann et al. 1995). K-cells, which are 'open' to the lumen, are found in greatest density in the proximal intestine. GIP is secreted in response to activation of adenylate cyclase, potassium-mediated membrane depolarisation and

Table 17.1 GIP versus GLP-1 basic science

	GIP	GLP-1
Structure	42 Aminoacids MW 4984	30/31 aminoacids MW 3298
Cell of origin	K cell	L cell
	Duodenum	lleum
	Jejunum	Colon
Circulating half-life (minutes)	<5	<5
Degradation	DPP IV enzyme	DPP IV enzyme
Insulin secretion to hormone in health	Increased	Increased
Insulin secretion to hormone in T2D	Impaired	Retained to nearly normal
Effect on B-Cell mass	Increased	Increased
Gastric emptying	No effect	Delayed
Secretion in T2D	Decreased	Decreased
Insulin sensitivity	Unchanged	Probably Improved
Food intake	?Increased	Decreased

This table lists key facts of GIP including how they relate to carbohydrate and lipid metabolism in health and disease. A comparison with the other major incretin GLP-1 is shown. GLP-1: glucagon-like peptide-1. GIP:glucose-dependent insulinotropic polypepide. T2D: type 2 diabetes mellitus.

rise in intracellular calcium concentrations in the K-cell. In addition to GIP, some K-cells produce additional hormones such as xenin (Althage et al. 2008). K-cells are known to be glucose-sensing cells but much remains to be learned about their physiology. A better understanding of K-cell biology could open the way to the development of new treatments to augment endogenous incretin secretion (Gribble, 2008).

17.3.2 GIP Gene and peptide

The GIP gene is located on chromosome 17, and has 6 exons and 5 introns spanning 10 kb. The gene codes for a pro-GIP protein of 153 amino acids (Fehmann et al. 1995), and this is processed by pro-hormone convertase 1/3 resulting in the production of one main product - active GIP (1–42). Although GIP was initially described as being present in a range of different molecular sizes, there is so far no evidence for the existence of more than one physiologically active form of GIP. The amino-acid sequence of GIP is shown in Fig. 17.4. Both the N-terminus and the central region of the molecule are required for the biological activity of GIP (Fehmann et al. 1995).

17.3.3 Assays for GIP

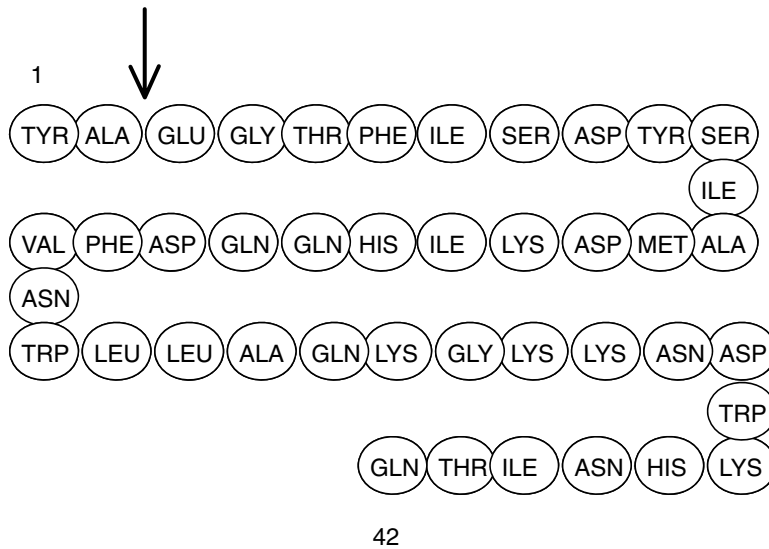
Most assays for GIP are not specific for the biologically active form since they detect all circulating GIP immunoreactivity. This has given rise to contradictory results in the GIP literature and investigators need to be aware of this issue. Furthermore, the relative amounts of 1–42 and 3–42 forms vary in the fasting and postprandial states, although the 1–42 biologically active form accounts for around 35% of measured immunoreactivity.


Fig. 17.4 Amino acid sequences of GIPAmino acid sequences of active GIP (1–42) is shown in the accompanying cartoon. The site of cleavage by enzyme DPP IV is shown by an arrow (Fehmann et al. 1995)

17.3.4 GIP receptors

The GIP receptor (GIPR) is a member of the B-family of G protein-coupled receptors, possessing seven membrane-spanning domains, and that also includes receptors for VIP, glucagon and secretin. The post-receptor pathways in the B-cell include modulation of adenyl cyclase, Ca(2+)-independent phospholipase A2, protein kinase (PK) A and PKB, as well as the Mek1/2-Erk1/2 and p38 MAP kinase (McIntosh et al. 2009). The GIP receptor in the rat is a 455 amino acid protein with molecular weight 52,000 daltons. Other than in pancreatic B-cells, GIP receptors are found on gastric parietal cells, in the duodenum, jejunum, adrenal glands, adipose tissue, pituitary gland and in the brain (Fehmann et al. 1995). The biological function of GIP receptors has been established in some but not all of these tissues. A GIP receptor knockout mouse has been produced (GIPR-/-), which exhibits higher blood glucose levels and impaired initial insulin response after oral glucose load. This suggests that a defect of GIP signalling might contribute to the pathogenesis of diabetes (Miyawaki et al. 1999). Interestingly, high-fat diets in GIPR-/- worsen glycaemic responses after mixed meals, further suggesting that a defect in GIP might contribute to the onset of diabetes.

17.3.5 Kinetics of GIP secretion

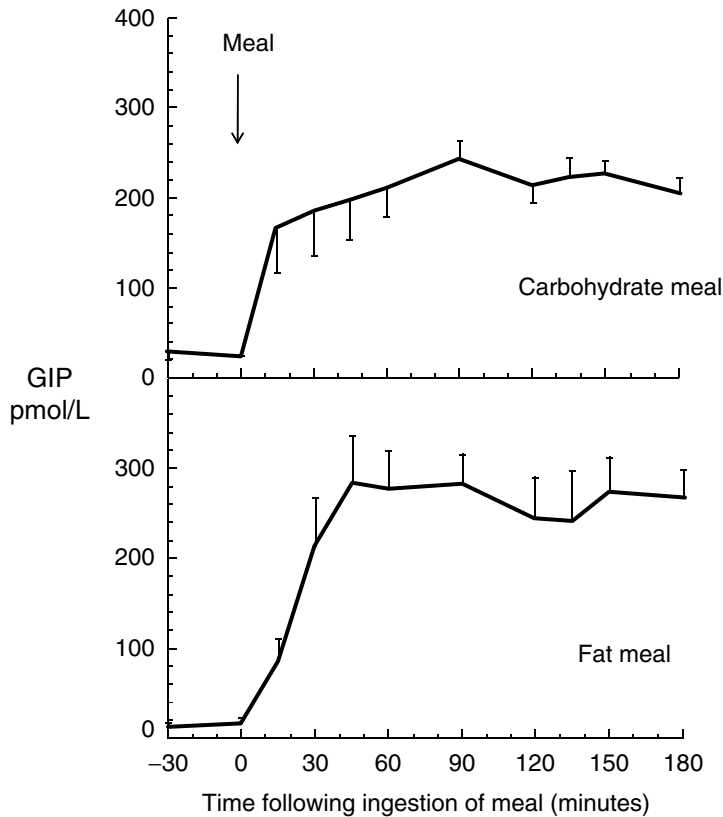
Circulating GIP concentrations rise within 15 minutes of ingestion of nutrients, as a result of direct nutrient stimulation of proximally situated K-cells. The plasma concentration of GIP peaks at around 250 pM within 30–45 minutes of ingestion of nutrients, and returns to basal values by 2–4 hours (Fig. 17.5) (Ranganath et al. 2001). Circulating GIP concentrations are at their lowest in the fasting state, but once feeding begins during daytime, concentrations of GIP do not return to fasting levels late until midnight (Elliott et al. 1993). Various luminal and non-luminal factors modulate GIP secretion. Serum triglycerides tend to parallel GIP levels throughout the day, suggesting that lipid rather than carbohydrate has the dominant influence on GIP secretion.


Fig. 17.5 Single meal GIP responses to oral carbohydrate and fat in 6 lean subjects (Mean ± SEM). Circulating GIP concentrations are low in the fasting state increasing rapidly upon ingestion of liquid carbohydrate or fat reaching near-peak concentrations by 30 to 60 minutes. Little difference is seen in GIP responses between carbohydrate and fat meal in lean subjects (Ranganath et al. 2001)

17.3.6 Degradation of GIP

The aminopeptidase, dipeptidyl peptidase IV (DPP IV), found in the endothelium of the local capillary bed within the intestinal wall, is important for the initial inactivation of GIP. Cleavage by DPP IV generates an inactive N-terminally truncated metabolite, GIP (3–42), which is a major circulating form. Subsequently, the peptides may be degraded by other enzymes and extracted in an organ-specific manner. Intact GIP, initially carried in the portal blood, is inactivated by hepatic DPP IV before further degradation by peripheral tissues. The kidney is important for the final elimination of these metabolites (McIntosh et al. 2009; Deacon, 2004). There is uncertainty whether GIP metabolites affect the action of intact GIP. An antagonistic role at the GIP receptor was initially proposed for (3–42) form but has not been convincingly demonstrated (Deacon, 2004).

17.3.7 Regulation of GIP secretion

Ingestion of nutrients leads to release of GIP from K-cells; carbohydrate and fat macronutrients are the main stimuli and appear nearly equal in their ability to stimulate GIP secretion. Only carbohydrate-mediated GIP secretion leads to insulin secretion whereas this is not the case for fat- and

protein-mediated GIP secretion. Actual absorption of nutrient, and not merely its presence within the intestinal lumen, is required for release of GIP from the K-cell. The GIP secretory response is abolished by the blockade of glucose absorption by phlorizin or chylomicron formation with pluronic L81 (Marks V. GIP – The obesity hormone. In: Current Approaches Obesity et al. 1988; Shimotoyodome et al. 2009). Other nutrient-derived extracellular substances such as meat hydrolysate, glyceraldehyde, and methylpyruvate increase GIP release from a cell line (Li & Wice, 2005). The rate of nutrient entry into the small intestine determined by gastric emptying may further modulate secretion of GIP. Rapid gastric emptying as occurs in post-gastrectomy dumping syndrome causes marked increase in GIP secretion (Gebhard et al. 2001). The physical state of the meal may also play an important role in modulating endocrine and metabolic responses to food since homogenised meals induced a higher GIP response (Peracchi et al. 2000). Functional foods containing cyclodextrin starch, guar gum and xanthan gum that decreased the glycaemic response and delayed gastric emptying also decreased the postprandial GIP responses (Nunes & Malmlof 1992). The influence of the individual nutrient factors is considered in greater detail in the next section.

A series of local and systemic neuroendocrine factors also influence GIP secretion. Enteric neurons stimulate GIP release in vivo through the action of neuropeptides such as bombesin (Li & Wice, 2005), although there continues to be debate about the importance of the neural regulation of GIP secretion. It has been observed that increased GIP secretion occurs in GLP-1 -/- mice (Pederson et al. 1998), raising the possibility that insulin or GLP-1 may influence GIP secretion. Apart from intestinal luminal factors, systemic factors also modulate GIP secretion. Pancreatic glucagon (Ranganath et al. 1999), predominantly present during the fasting state, suppresses the secretion of GIP.

17.3.8 Dietary carbohydrate

Actively absorbed sugars such as glucose and galactose stimulate GIP secretion (Marks V. GIP – The obesity hormone. In: Current Approaches Obesity et al. 1988). Phlorizin blocks active transport of glucose across the intestine and prevents GIP secretion. Food deprivation causes a decrease in GIP synthesis and secretion (Higashimoto et al. 1995). The effect of sucrose on GIP secretion is uncertain, with some suggesting no increase (Flatt et al. 1990) and others reporting a substantial increase (Mazzaferri et al. 1984). Inhibition of sucrose breakdown by alpha-glucosidase inhibitors decreased meal-related GIP secretion (Ranganath et al. 1998). Preventing breakdown of complex carbohydrates by amylase inhibition also decreased GIP secretion (Boivin et al. 1988). Modest variations in the initial rate of duodenal glucose entry may have profound effects on subsequent glycemic, insulin, and incretin responses (O'Donovan et al. 2004). Overall the indications are that normal carbohydrate digestion and absorption of glucose in the gut are required for GIP secretion.

17.3.9 Dietary fat

The role of fat ingestion in the regulation of postprandial blood glucose and insulin levels has received far less attention than carbohydrate intake, which has been assumed to be the dominant influence (Shimotoyodome et al. 2009). Long, but not short or medium chain fatty acids are at least as powerful stimuli of GIP secretion than equimolar amounts of carbohydrate. Triglycerides are normally converted to long chain fatty acids and monoglycerides prior to absorption in the bowel, and are also a powerful stimulus for GIP release (Marks V. GIP – The obesity hormone. In: Current Approaches Obesity et al. 1988). There is evidence, at least in animals, that dietary triglyceride augments glucose-induced insulin secretion via gut-derived GIP, while diacylglycerol reduces GIP

secretion, and therefore the insulin response (Shimotoyodome et al. 2009). Pluronic L-81, which inhibits chylomicron formation in the small intestine, reduces GIP secretion. Similarly, fat malabsorption, either due to pancreatic exocrine failure or action of the lipase inhibitor (Orlistat), is associated with impaired GIP secretion. Altogether, this evidence suggests that digestion and absorption of dietary triglycerides are required for normal GIP secretion.

The influence of different types of dietary triglyceride on GIP secretion has received much attention. Diets rich in MUFA improve glucose tolerance, and this might involve increased GIP secretion (Thomsen et al. 1999). Diets enriched with polyunsaturated fatty acids (PUFA) also augment insulin secretion and post-heparin LPL activity, but these effects appear to be independent of changes in GIP (Lardinois et al. 1987). GIP concentrations have been shown to be relatively lower in response to ingestion of fish oil, compared to other fats such as cocoa butter (SFA), olive oil (MUFA) or corn oil (PUFA). The dietary ratio of PUFA/SFA may therefore influence the postprandial GIP response (Musso et al. 2009). In another study, similar GIP responses were observed with MUFA (olive oil) and PUFA (corn oil), but lower responses were observed with SFA (cocoa butter) (Lardinois et al. 1988). These findings suggest that both the degree of saturation of fatty acids in triglycerides and source of the individual triglyceride has different effects on GIP secretion. Lastly, bile is important in the absorption of dietary fat and it is no surprise that intraluminal bile acid administration in dogs influences fat-stimulated GIP release (Takahashi et al. 1996).

17.3.10 Dietary protein and amino acids

In contrast to the influences of carbohydrate and fat, most studies suggest that dietary protein appears to have only a minor effect on GIP secretion. After protein ingestion, the early GIP response correlates with the insulin but not glucagon response, suggesting that early GIP secretion after protein ingestion may be have a role in islet hormone secretion. Postprandial increase in amino acid concentrations interact with increased glucose during mixed meal consumption and leads to GIP-mediated insulin secretion.

There are differences between individual aminoacids in their ability to increase GIP secretion. Tryptophan administration results in increased secretion of GIP and glucagon (Tsiolakis & Marks, 1984). In animals, the aminoacids arginine, cysteine, and histidine increased secretion of GIP and insulin. In contrast, threonine had no effect , while alanine, hydroxyproline and lysine all increased GIP but not insulin secretion (Flatt et al. 1991). These results suggest that a range of essential and nonessential neutral and basic amino acids can stimulate the release of GIP. However, as with protein consumption, GIP made only a modest contribution to the stimulation of insulin secretion following administration of amino acids in the presence of glucose (Flatt et al. 1991).

17.3.11 Miscellaneous influences on GIP secretion

When consumed with a mixed meal ethanol decreases the incretin levels in the early postprandial period and aggravates postprandial lipemia in type 2 diabetic patients (Dalgaard et al. 2004). There are contradictory reports with regard to fasting, some studies suggesting no change in GIP secretion while others observed increased responses. Insulin-induced hypoglycemia has been shown to result in a modest increase in GIP secretion (Jorde et al. 1981).

Geographical differences in GIP has been described since Southern Europeans show higher dietary GIP and insulin responses that may provide an explanation for attenuated postprandial triacylglycerol and apolipoprotein B-48 responses in this group (Jackson et al. 2000).

17.3.12 Eating behaviour

Humans are periodic feeders and energy consumption usually occurs in a social context. Therefore eating behaviour, influenced by the social context, is important in health and disease. It has been suggested that smaller and more frequent meals may be associated with better health, whereas large and more erratic meals increase the risks of obesity and diabetes. Fewer but larger daily meals have been shown to result in increased levels of GIP (Jones et al. 1995) and conversely more frequent meals was associated with decreased GIP levels (Jones et al. 1993). It has been suggested that larger meal sizes and meals with high caloric value that are associated with exaggerated GIP responses and increased rates of gastric emptying, may partly account for the apparent associations of health with meal size and frequency (Ebert & Creutzfeldt, 1989). The association between meal size and GIP response suggests the existence of rapid mechanisms of adaptation of the GIP-producing cells to the incoming load (Beck et al. 1984). It has been suggested that the incretin defect in type 2 diabetes might be overcome by ingesting a larger meal; however, in practice this is not a realistic option since calorie restriction and weight loss are major priorities in patient management.

17.3.13 Satiety/hunger

Food intake in humans is influenced by a complex interaction of biological factors and social context. Satiety and hunger are influenced by short and long term afferent information about ingested and stored nutrients received from the gastrointestinal tract, liver and adipose tissue. This information reaches the brain through both neural and blood borne routes – and is mediated by nutrient and endocrine signals. Control of energy intake is tightly coupled to control of energy expenditure such that there is usually a reciprocal relationship between energy intake and energy expenditure (EE). Since GIP concentrations increase rapidly following food intake it has been suggested that the postprandial GIP response may be an important regulator of short-term appetite. However, there is little information on the effect of GIP on human energy balance (Daousi et al. 2009). In a recent study involving infusion of synthetic GIP, we observed a trend for healthy subjects to report higher hunger scores and a reduction in EE, whereas these parameters remained unchanged in people with T2DM (Daousi et al. 2009). If confirmed, these findings could suggest that resistance to GIP in T2D may be more widespread and not merely confined to the pancreatic B-cell. It may also suggest, if confirmed, that such GIP resistance by decreasing hunger may limit food intake and protect against obesity and diabetes.

17.4 Effects of GIP (Fig. 17.6)

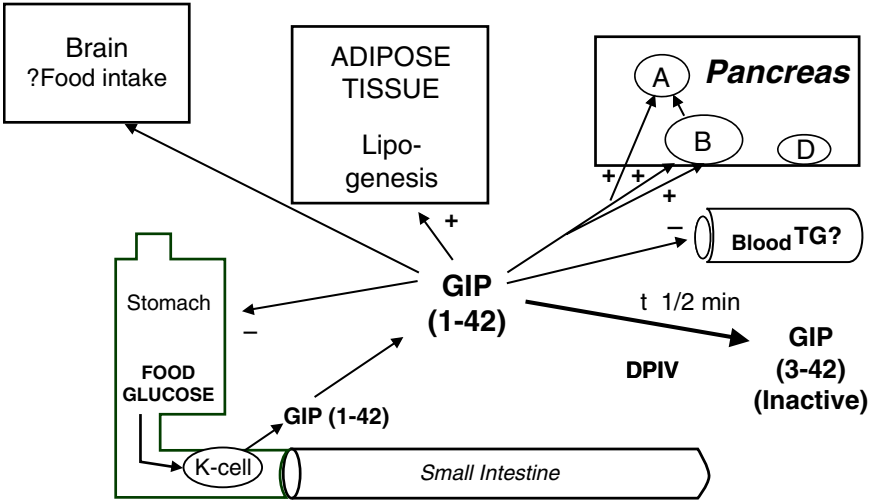
Insulin secretion: An important physiological property of GIP is its ability to promote insulin secretion in a glucose-dependent manner, without inducing hypoglycaemia (Byrne et al. 1998; Wideman & Kieffer, 2004). Glucose entry into B-cell results in formation of ATP which phosphorylates potassium (K)-channels in the cell membrane leading to their closure, in turn triggering calcium entry into cell and exocytosis of vesicular insulin. GIP acts on the pancreatic B-cell by binding to a specific receptor that is coupled to glucose entry and metabolism. c-AMP mediated GIP post receptor events either potentiate the phosphorylation of K-channels and therefore cellular calcium influx and/or directly increase intracellular calcium concentrations leading to insulin release (Fig. 17.7). A GIP


Fig. 17.6 Pancreatic and Extra-pancreatic effects of circulating GIP. GIP after secretion has a number of biological effects in health that are shown in this cartoon (+ = increase; - = decrease)
Fig. 17.7 Interplay of glucose and incretins (here GIP is depicted) on the pancreatic B-cell.The entry and metabolism of glucose generates ATP. Phosphorylation of K-channels by ATP is potentiated by GIP mediated c-AMP protein kinases allows increased calcium entry and subsequent insulin release. C-AMP dependent phopsphoinostiol pathways appear to be involved in maintaining B-cell mass by effects on apoptosis and cell division (Byrne et al. 1998; Wideman & Kieffer, 2004)

knockout mouse was found to exhibit impaired glucose tolerance (Miyawaki et al. 1999), consistent with the idea that GIP signalling is required for optimal prandial insulin secretion.

B-cells mass: GIP has a trophic effect on B-cells both in terms of enhancing the magnitude of insulin secretion as well as increasing their number. GIP regulates cell proliferation and survival and in the pancreatic islets leads to expansion of cell mass by stimulating B-cell proliferation and induction of islet neogenesis as well as by inhibiting apoptosis (Wideman & Kieffer, 2004). GIP also promotes cell differentiation, from exocrine ductal cells or immature islet progenitors, toward a more differentiated B-cell phenotype (Wideman & Kieffer, 2004; McIntosh et al. 2009).

Glucagon secretion: It is currently unclear whether GIP influences glucagon secretion or action. There are no receptors for GIP on the A-cell in the pancreatic islets, and.glucagon secretion has been found to be both increased (Meier et al. 2003) and unchanged (Ahrén et al. 1991) in response to GIP. Although GIP receptors have been found on D-cells, their function is unclear. Given that the insulin/glucagon ratio is an important determinant of glucose and fat metabolism, it is plausible that GIP interacts directly or indirectly with all the major endocrine cells of the islets, to influence glucose and lipid metabolism.

Stomach: The binding of GIP to gastric parietal cells inhibits H+ production at supra-physiological concentrations in humans. In fact, this was the first property of GIP to be recognized, giving rise to its initial name - gastric inhibitory polypeptide - before the more important insulinotropic property was identified (Brown & Dryburgh, 1971). There is no evidence that GIP affects gastric emptying. However, in animal studies, acid instillation into the stomach increases GIP expression in duodenal mucosa (Wolfe et al. 2000).

Liver: There is no evidence for expression of GIP receptors in the liver or that GIP alters hepatic metabolism directly. The evidence that GIP alters the hepatic extraction of insulin is mixed, some observing (Hanks et al. 1984) and others failing to observe such an effect (Rudovich et al. 2004). Unlike GLP-1, which increases insulin and decreases glucagon secretion, affecting hepatic carbohydrate metabolism, GIP secretion appears to have less of a beneficial effect on the insulin/glucagon ratio.

Intestine: The intestine not only produces and secretes GIP but is also subjected to the effects of GIP. Recently, GIP has been shown to increase absorption of glucose in the small intestine by stimulating SGLT 1 transporters (Singh et al. 2008). Physiological concentrations of GIP do not alter gut motility. Enterocyte insulin resistance have been noted in insulin resistant diabetic states and altered lipid metabolism has been described in the enterocyte under these conditions; an altered enterocyte lipid handling including chylomicron assembly and secretion has been postulated. The role of GIP in small intestine metabolism, an area that is clearly important, is currently not fully understood (Hsieh et al. 2008).

Adipose tissue: In vivo, the release of insulin by GIP and the consequent suppression of free fatty acid release is probably an important action for adipose tissue. GIP has been found to be associated with circulating lipoprotein levels, and it also stimulates lipoprotein lipase, thus promoting triglyceride deposition in adipose tissue. In animals, exogenous and endogenous GIP is able to lower the plasma triglyceride response to a fat load (Ebert et al. 1991). An overactive enteroinsular axis has been suggested to play a key role in the accretion of fat (Marks V. GIP – The obesity hormone. In: Current Approaches Obesity et al. 1988) since GIP has been reported to (a) stimulate fatty acid synthesis, (b) enhance insulin-stimulated incorporation of fatty acids into triglycerides, (c) increase insulin receptor affinity, and (d) increase sensitivity of insulin-stimulated glucose transport. The mechanism of action of GIP-induced effects on adipocytes may have an indirect component through insulin, although the presence of GIP receptors on adipocytes suggests there may also be direct effects (Fehmann et al. 1995). Biological effects of adipocyte GIPR stimulation include an alteration in adipokine secretion, including changes in resistin and adiponectin (Naitoh et al. 2008).

Brain: GIP is a member of the VIP/PACAP/secretin family and is also synthesised in the brain (Nyberg et al. 2005). GIP immunoreactivity has been observed in and around neurones in several areas such as the olfactory bulb, hippocampus, cerebellum, cerebral cortex, amygdala, substantia nigra, and lateral septal nucleus as well as in several nuclei in the thalamus, hypothalamus and brainstem suggesting a function either as a neurotransmitter or neuromodulator (Nyberg et al. 2007). In addition to local brain synthesis, the VIP/PACAP/secretin family members are also released into blood from peripheral sites, especially the gut, circulating in the bloodstream and accessing the brain through the blood brain barrier at several sites (Dogrukol-Ak et al. 2004). Therefore, GIP produced peripherally can access and bind to various regions of the brain.

Receptors for GIP are also present in the brain (Ding et al. 2006) allowing specific interaction and biological effects. This therefore suggests that conditions exist for GIP to modulate brain structure and function. Although very little is known about the effect of GIP on the brain in humans at the moment, in rat brain GIP has been shown to modulate neuronal proliferation (Nyberg et al. 2005), reverse the effects of beta-amyloid fragments on synaptic plasticity (Gault & Hölscher, 2008), and increase locomotor behaviour (Ding et al. 2006).

Interestingly, type 2 diabetes has been identified as a risk factor for Alzheimer's disease and incretin biology is altered in this disease. GIP may therefore be capable of protecting and reversing the detrimental effects that beta-amyloid fragments have on synaptic plasticity (Gault & Hölscher, 2008). The use of GIP and its enzyme-resistant analogues show potential as novel treatment for preventing neurodegenerative disease including those secondary to diabetes.

Eyes: Eyes are developmentally derived from the forebrain. GIP peptide and receptor are also expressed in the eyes (Cho et al. 2002). In animal studies GIP expression has been shown to be strongly up regulated in the epithelial cells of the lens in experimental cataract models (Nakajima et al. 2002). In animal studies there has been a demonstration of GIP and GIP receptor in the retina and their up-regulation in streptozotocin-induced diabetes model (Cho et al. 2002), suggesting a possible role in diabetic retinopathy.

17.5 Application of GIP to disease states (Table 17.2)

Diabetes mellitus: The possible role of GLP-1 in the treatment of type 2 diabetes is being investigated by clinical trials. GIP secretion in T2D has had variable reports, some suggesting no change, some suggesting an increase and others a decrease. Administration of GIP did not augment insulin secretion or restore euglycaemia in type 2 diabetes, providing evidence for resistance to the peptide (Nauck et al. 1986). However, inhibition of the K(ATP) channels of the diabetic B-cell using sulphonylureas appears to restore insulin response to GIP thus overcoming the B-cell resistance to GIP

Table 17.2 Summary of role of GIP in Diabetes and Obesity

1. GIP is an important incretin hormone to maintain euglycaemia in health
2. Resistance to GIP occurs in T2D at the B-cell and may play a part in insulin secretion failure in T2D
3. Current thinking suggests that GIP may be more important in lipid storage and metabolism
4. Antagonists to GIPR in animals such as mice decreases lipid storage, body fat stores and also paradoxically improves glucose tolerance preventing diabetes
5. Both pro-GIP and anti-GIP strategies have been proposed in the treatment of obesity and diabetes

This table lists key facts of GIP including how they relate to carbohydrate and lipid metabolism in obesity and diabetes. GIP:glucose-dependent insulinotropic polypepide. T2D: type 2 diabetes mellitus

(Aaboe et al. 2009). GIP, like GLP-1, cannot be given orally due to degradation in the gut; interest in GIP as a treatment of type 2 diabetes has therefore been slow to develop. Inhibitors of the enzyme that degrades GIP, DPPIV enzyme, are increasingly being used in the treatment of type 2 diabetes and have the virtue of oral administration. Significant increase in postprandial GIP concentrations, along with GLP-1, occurs after DPP IV inhibition along with improvement in insulin secretion and glycaemic control; how much of the beneficial effect of DPP IV inhibition is due to GIP is unclear. The long term safety of DPP IV inhibition is unknown since it is not only bioactive GIP and GLP-1 which circulate for longer but a number of other endogenous peptides as well (Doupis & Veves, 2008).

Studies on alteration in GIP secretion in prediabetic states show a mixed picture, some suggesting no change such as those with low birth weight , and others showing a decrease such as in first-degree relatives of patients with T2D pointing to an early, possibly genetic defect . A reduced hepatic insulin extraction in response to GIP may compensate for reduced insulin secretion in normal-weight and normal glucose tolerant first-degree relatives of T2D patients (Rudovich et al. 2004). The foregoing discussion would appear to suggest that re-establishing the biological actions of GIP is beneficial and should be goal of therapy in T2D. Indeed some long acting analogues of GIP enhance insulin release and decrease glucose in vivo in a commonly used animal model of T2D (O'Harte et al. 2000). Also, GIPR-/- mice have higher blood glucose levels with impaired initial insulin response after oral glucose load, suggesting that a defect of GIP in the entero-insular axis may contribute to the pathogenesis of diabetes (Miyawaki et al. 1999). High-fat diets in GIPR-/- worsen glycaemic responses after mixed meals further suggesting that a defect in GIP may contribute to the pathogenesis of diabetes .

In view of the foregoing discussions of the phenotypes of the GIP-/- and GIPR-/- mice, which appear to be more diabetes prone, it is paradoxical that there is evidence suggesting that abolishing the effect of GIP might be beneficial in T2D. For example, active immunisation against GIP has been shown to improve blood glucose control in an animal model of obesity/diabetes (Irwin et al. 2009). Since GIP appears to play a role in lipid physiology, and elevated levels of GIP have been associated with obesity (Marks V. GIP – The obesity hormone. In: Current Approaches Obesity et al. 1988), antagonising GIP action has been proposed as a therapeutic strategy for obesity. This concept has recently been reinforced by the observation that GIP receptor knock-out mice are protected from high-fat diet-induced obesity (Miyawaki et al. 2002). However, eliminating the effect of endogenous GIP may at the same time impair postprandial insulin secretion, thereby disturbing glucose homeostasis. Therefore, therapeutic strategies based on either augmenting or antagonising GIP action are far from being established alternatives for the future therapy of T2D or obesity.

Bariatric surgery: Bariatric surgery is associated with a rapid improvement in glucose tolerance long before weight changes occur. It is hypothesized that endocrine and metabolic factors are altered by the surgery leading to the observed beneficial effects. Laparoscopic gastric banding leads to weight loss and metabolic improvement but does not change GIP responses (Shak et al. 2008).

However when the proximal bowel is excluded by Roux-en-Y gastric bypass and the biliopancreatic diversion leading to the early arrival of a meal in the terminal ileum, GIP and GLP-1 responses are increased and has been postulated to account for the metabolic benefits post-surgery (Patriti et al. 2004; Laferrere et al. 2008); such improvement is very early after surgery (Laferrere et al. 2008). The place of GIP in obesity surgery remains to be clarified.

Obesity: Obesity occurs as a mismatch between energy intake and energy expenditure. Excess calorie intake, easier to achieve by consuming more calorie dense fatty foods, is clearly an important factor in obesity. Since we are experiencing an epidemic of obesity (and consequently diabetes), a better understanding of pathophysiology of obesity, including the role of food intake and appetite,

and the development of effective treatments are urgently needed. Appetite signals including those arising in the brain may be important in modulating food intake. There are few studies that have examined the effect of GIP originating in the periphery, such as the gut, on the brain and appetite (Daousi et al. 2009). Unlike GLP-1 administration that has been associated with long term weight loss, no such studies have been undertaken with GIP or a GIP antagonist.

Experimental obesity can be produced in animals by feeding them 'confectionary style' or 'cafeteria' diets; such diets differ in composition (high fat) but not total energy (Marks V. GIP – The obesity hormone. In: Current Approaches Obesity et al. 1988). Such high-fat diet induced obesity has become an important investigative model. GIP production and secretion are induced by high fat diets in such models. Human studies employing high fat intake also show hypersecretion of GIP or hypergGIPaemia and the loss of normal inhibitory effect of insulin upon fat-stimulated GIP release (Marks V. GIP – The obesity hormone. In: Current Approaches Obesity et al. 1988). This led investigators to postulate a model of obesity due to excess GIP action more than 20 years ago (Marks V. GIP – The obesity hormone. In: Current Approaches Obesity et al. 1988). Experiments using knockout mice suggest that the lack of the GIP receptor prevents diet-induced and high-fat induced obesity, preserves insulin sensitivity, lowered respiratory quotient (by burning fat as the preferred energy substrate) and increased energy expenditure due to increased locomotor activity (Miyawaki et al. 2002; Hansotia et al. 2007). Aging is associated with increased fat mass and decreased lean mass, and knocking out GIP receptor in mice can prevent the development of aging-associated insulin resistance through body composition changes (Yamada et al. 2007). Obesity and its metabolic consequences, induced by ovariectomy in mice, can be prevented by GIP-receptor knockout (Isken et al. 2008). The evidence presented so far has lead to an intriguing hypothesis that ablation of GIP receptor actions may prevent obesity and therefore diabetes. In this regard several groups but especially Flatt and colleagues (Green & Flatt, 2007) have generated a number of GIP analogues that can be tested and is shown in Table 17.3. In the ob/ob mouse early administration of the GIP receptor antagonist (Pro3)GIP prevented the development of diabetes and related abnormalities, thus suggesting that sustained GIP receptor antagonism is a viable approach (Irwin et al. 2007). Even in non-genetic obesity such as high-fat and cafeteria diets fed mice, GIP receptor antagonism both using (Pro(3))GIP and longer acting (Pro(3))GIP[mPEG] decreased body weight, circulating plasma insulin levels and improved glucose tolerance (Gault et al. 2007).

Paradoxically, there is evidence however that GIP *agonists* are beneficial in glucose and lipid metabolism. In mice N-AcGIP(LysPAL37), a longer acting agonist of GIPR, improved glucose tolerance due to enhancement of pancreatic beta cell glucose responsiveness and insulin

Table 17.3 GIP modulation – approaches in therapy

K-Cell secretogogues	Experimental; under development
DPP IV Inhibitors	Sitaliptin, Vildaliptin, ?others
GIP Agonist analogues N-terminal modified	N-AcGIP
Mid-acylated GIP	N-AcGIP(Lys[37]PAL) GIP(Lys[37]PAL)
C-terminal modified	(GIP[mPEG]) D- Ala(2)-GIP or DA-GIP
GIP Antagonist analogues	(Pro3)GIP (Pro3)GIPLys16PAL

This table lists key facts of approaches to GIP therapy in obesity and T2D. For details of analogues consult references in accompanying bibliography (Green & Flatt, 2007; Irwin et al. 2007; Gault et al. 2007; Irwin et al. 2006a; Irwin et al. 2006b; Kerr et al. 2009)

secretion by long term activation of GIPR (Irwin et al. 2006a). Other GIPR agonists such as N-AcGIP (N-terminal modified GIP), as well as mid-GIP acylated molecules such as GIP(Lys(37)PAL) and N-AcGIP(Lys(37)PAL), induced insulin release, improved insulin sensitivity, showed no evidence of GIP-receptor desensitization, increased islet number and islet size; upon administration to diabetic ob/ob mice, body weight, food intake and circulating glucagon were unaltered (Irwin et al. 2006b). In mice prolonged activation of the GIP receptor with GIP[mPEG] counters aspects of impaired beta-cell function and age-related glucose intolerance (Kerr et al. 2009).

We cannot fully know at the moment whether a clinical approach to obesity and therefore to diabetes should focus on pro-GIP or anti-GIP strategies. Whether these paradoxically opposite properties of GIP analogues are due to differences in duration of action at the GIPR is not clear. This is not a unique situation since chronically elevated parathyroid hormone in primary hyperparathyroidism leads to bone destruction while intermittent PTH administration leads to bone formation. There are also well known examples of major species differences in endocrine regulators, and so it is by no means assured that the physiology of GIP in humans is the same as in mice.

Summary

- GIP is an intestinal hormone with an important role in maintenance of B-cell function and mass in health
- In type 2 diabetes, resistance to GIP at the B-cell appears to hinder a therapeutic role for the peptide
- GIP promotes triacylyglycerol accumulation is adipose tissue and behaves as an obesity hormone
- Blockade of GIP receptor has been shown in animals has been shown to decrease and prevent high-fat induced obesity and it's complications
- Further research is urgently required to clarify whether pro-GIP or anti-GIP approaches should be employed in obesity and diabetes

---

Key Terms

GIP: A hormone secreted by small intestinal cells having multiple biological effects in the body

GIPR: The receptor that mediates the biological actions of glucose-dependent insulinotropic polypeptide receptor

K-cell: The small intestinal GIP secreting cell present in greatest density in proximal small bowel

DPP IV: The enzyme that degrades incretins including GIP as well as a host of other biological molecules and is mainly responsible for the very short half life

GIP-/- mice: A mouse model where the gene for GIP has been deleted to allow a study of the consequences of lack of biological GIP hormone

GIPR -/- mice: A mouse where the gene for GIP receptor has been deleted to allow a study of the consequences of lack of biological GIP activity

Chapter 18
The Relationship between the IGF System, Nutrition, and Behavior

Moira S. Lewitt

Abbreviations

IGF	Insulin-like growth factor
IGF1R	Type 1 insulin-like growth factor receptor
IGFBP	Insulin-like growth factor-binding protein
GH	Growth hormone
GHR	Growth hormone receptor
ALS	Acid-labile subunit of the IGFBP-3 ternary complex
kDa	kilodalton
TNF-α	Tumor necrosis factor-alpha

Key Terms

Insulin-like growth factors: IGF-I and IGF-II are ~7 kDa proteins that are ubiquitously expressed, have widespread tissue actions that are regulated by the IGFBPs.

IGFBPs: Family of six proteins with high affinity for IGF-I and IGF-II that have stimulatory or inhibitory effects on IGF actions, depending on the cell milieu, e.g., limited proteolysis by IGFBP proteases, interaction with other proteins in the cell matrix, or on the cell surface.

"Free" IGFs: Those IGFs that are unbound or readily released from binary complexes with IGFBPs, and therefore available to act on target cells.

Endocrine actions of IGFs: IGF effects on cells in tissues distant to where the IGF was produced, with transport via the circulation.

Paracrine/autocrine actions of IGFs: IGF effects in the local tissue environment on cells of the same or different type to those producing the IGFs.

Proinflammatory cytokines: Cytokines produced by activated immune cells and involved in mediating inflammatory effects, e.g., TNF-α.

Plasticity: Ability of brain structure and/or function to adapt to environmental change.

18.1 Introduction

Although the insulin-like growth factor (IGF) system appears overwhelming in its complexity, its relationship to nutrition has emerged as a key to understanding its role in health and disease. The responses of this system to acute and chronic changes in nutrient availability in turn have a metabolic impact on many cell types. The actions of this system on specific areas of brain, and the changes observed in a variety of cognitive disorders, suggest an important role for the IGF system in learning, memory, and behavior.

This chapter will describe the IGF system, with a particular focus on its relationship to nutrition, and its functional role in brain. Evidence of a central role for IGFs and nutrition in the cognitive dysfunction of aging and cytokine-induced sickness behavior will be highlighted, and the potential contribution to other areas of health and disease will also be addressed. In the concluding remarks, challenges and recommendations for future research will be made.

18.2 The IGF System and Nutrition

The IGFs (IGF-I and IGF-II) are members of an evolutionarily ancient superfamily of proteins that include insulin and relaxin (Claeys et al. 2002). Ubiquitously expressed, IGFs have paracrine/autocrine actions, in addition to endocrine roles on cell growth and metabolism which are distinct from and complement those of insulin (Le Roith et al. 2001; Clemmons 2006). The spectrum of activity is dependent on the tissue distribution and level of expression of their receptors (the type 1 IGF receptor (IGF1R), insulin receptor, and hybrids of these receptors), on postreceptor signaling, including cross talk with other growth factor signaling pathways, and on interactions with a family of six high affinity IGF-binding proteins (IGFBPs). Differences in receptor affinity and signaling, and the ability of IGFs to bind to IGFBPs distinguishes their metabolic roles from those of insulin.

An overview of the IGF system in the circulation and peripheral tissues is illustrated in Fig. 18.1. IGFs in the circulation exist mainly in a ternary complex with two other proteins, IGFBP-3, and the acid-labile subunit (ALS). This form has a high molecular mass (150 kDa) which is retained in the circulation, thereby limiting the availability of the IGFs (~7 kDa) to the peripheral tissues. The unbound fraction of IGFs and binary complexes with IGFBP-1 to -6 in the circulation are readily available to the peripheral tissues, where IGFs and IGFBPs are also secreted locally. In this review, those IGFs that are unbound or readily released from binary complexes and therefore available to target cells are collectively referred to as "free" IGFs. IGFBPs are key regulators of the activity of IGFs at the tissue level, with both inhibitory and stimulatory effects observed depending on the cell milieu (Firth and Baxter 2002). A number of IGFBP proteases have been described which generate IGFBP fragments with reduced IGF affinity.

Growth hormone (GH) stimulates IGF-I expression peripherally, and IGF-I reaching the pituitary has an inhibitory effect on GH secretion (Fig. 18.2). Nutrition, in the form of total energy and protein consumption, is also an important regulator of serum IGF-I, directly and through stimulation of insulin production. The other proteins of the ternary complex, IGFBP-3 and ALS, are also increased by GH and nutrition, thus stabilizing IGF-I in the circulation and making it a useful clinical marker of GH secretion and nutritional status. GH also has direct, IGF-I-independent, effects on tissue. For example, GH has a direct effect to increase peripheral insulin resistance, while IGF-I has an insulin-sensitizing role (Clemmons 2006). Less is known about the regulation and roles of IGF-II; however, its higher affinity for insulin receptors than IGF-I (Pandini et al. 2002) suggests that it may have a special role in nutrition.
Fig. 18.1 Overview of the IGF system in the circulation and peripheral tissues. The figure illustrates the major proteins involved in the IGF system, including IGF-I and IGF-II, six IGF-binding proteins (*IGFBPs*), the high molecular mass ternary complex of IGFs, IGFBP-3 and the acid-labile subunit (*ALS*) which is retained in the circulation, and IGFBP proteases which have effects in the tissues. IGFs regulate cellular growth and metabolism by interacting with specific receptors on the cell surface
Fig. 18.2 The endocrine IGF system and brain under conditions of normal nutritional intake. The liver has a central role in producing the IGF-I that reaches the circulation, along with IGFBP-3 and the acid-labile subunit (*ALS*), under the stimulation of GH and nutrition. Insulin also stimulates IGF-I, IGFBP-3 and ALS, but inhibits IGFBP-1 production. Under these conditions, appropriate concentrations of IGFs are available to the peripheral tissues, including the brain, where IGF-I activity is known to influence cognitive function and behavior
Fig. 18.3 The endocrine IGF system and brain under conditions of excessive food consumption. In obesity, increased portal insulin concentrations suppress IGFBP-1 levels, which increase "free" IGF availability to the peripheral tissues, including the pituitary, where there is feedback inhibition of GH secretion. In the metabolic syndrome, there are many other factors, including chronic inflammation, which may have an impact on the activity of IGF-I in brain

In contrast to the IGFBP-3 ternary complex, which acts as a long-term storage pool of IGFs in the circulation, IGFBP-1 has a short-term nutritional role. Also produced in liver, IGFBP-1 is inhibited by insulin and stimulated by several factors including glucagon and cytokines. The patterns of regulation in the circulation together with its effect, to increase blood glucose, suggest that it indeed has a dynamic role to counter-regulate the availability of IGFs for glucose homeostasis (Lewitt and Baxter 1991; Lewitt et al. 1991). It has been proposed that low IGFBP-1 concentrations are responsible for the increase in "free" IGF-I levels in obesity (Frystyk et al. 1995), which in turn have a negative feedback effect on GH secretion in this condition (Attia et al. 1998). This is illustrated in Fig. 18.3. In contrast, under conditions of reduced calorie and protein intake, shown in Fig. 18.4, decreases in the complex of IGF-I, IGFBP-3, and ALS, along with increases in IGFBP-1, result in reduced "free" IGF-I and increases in pituitary GH production. Under these conditions of malnutrition there is resistance to GH action in peripheral tissues that further reduces production of IGF-I. Total IGF-I and fasting IGFBP-1 concentrations are useful clinical markers of nutritional status (Lewitt and Baxter 1991).

18.3 The IGF System in Brain

The IGF system has a well-established role in the growth and development of the central nervous system (Russo et al. 2005; Åberg et al. 2006) and there is evidence that it continues to have important effects throughout life. Adult brain can regenerate following injury to various regions, including the
Fig. 18.4 The endocrine IGF system and brain under conditions of reduced nutritional intake. In starvation or malnutrition, decreased portal insulin and increased IGFBP-1 secretion, along with GH resistance and reduced total production of IGF-I, result in reduced "free" IGF-I and increases in pituitary GH production. One can speculate that reduced IGF-I activity in brain may have an impact on cognitive function and behavior

cerebral cortex, and IGFs are of particular therapeutic interest in this context (Russo et al. 2005). It is now emerging that the IGF system is involved in normal cognition. Growth hormone receptors, IGF-I and IGF1R are expressed in the proliferative zones of the adult brain, and IGF-I can stimulate adult hippocampal neurogenesis and may be involved in synaptic plasticity (Åberg et al. 2006; Fernandez et al. 2007; Llorens-Martin et al. 2009). IGFs also maintain normal brain function through effects on nonneuronal cells, such as glial cells and blood vessel endothelial cells. It has been shown that IGF-I is involved in regulating the transport of proteins across the blood-brain barrier (Carro et al. 2002).

The relative roles of the brain paracrine/autocrine IGF system and of systemically derived (endocrine) IGFs, which can cross the blood-brain barrier (Reinhardt and Bondy 1994), are yet to be established. Ames dwarf mice, despite being deficient in endocrine IGF-I, have increased hippocampal neurogenesis and local IGF-I expression (Sun et al. 2006), suggesting that the paracrine/autocrine IGF system is of primary importance. Mice with a forebrain-specific IGF-I deletion, however, are reported to have few brain changes (Davila et al. 2007); while mice with a liver-specific IGF-I deletion and markedly low circulating IGF-I levels have reduced adult hippocampal neurogenesis, which is restored by systemic IGF-I administration (Trejo et al. 2008). Increasing the complexity of the brain IGF system, a variant of IGF-I, which is truncated by three amino acids (des(1-3)IGF-I), has been purified from brain tissue (Sara et al. 1993). While its role is not yet clear, this variant has reduced affinity for IGFBPs and is likely to have higher biological activity than normal IGF-I. The cleaved *N*-terminal tripeptide may have its own neuroprotective actions (Sizonenko et al. 2001). The role of IGFBPs also needs to be considered, and these are differentially expressed in brain, with IGFBP-5 being selectively expressed near IGF-I producing neurons (Bondy and Lee 1993).

18.4 IGFs and Behavior

There is now a body of evidence supporting a role for peripheral IGF-I in behavior in humans and in animals (Table 18.1). Patients with GH deficiency, and therefore reduced IGF-I levels, have reduced cognitive performance, which may be ameliorated during GH replacement (Falleti et al. 2006). A meta-analysis in the "healthy elderly" supports the conclusion that there is a relationship between IGF-I levels and cognitive function (Arwert et al. 2005). Unfortunately, there was no correction for the confounding of age in this study. However another study which made an adjustment for age, reported an association between "free" IGF-I levels and cognitive performance in older individuals living in the community (Landi et al. 2007). In younger adults, aged 20–44 years, a relationship between IGF-I and factors representing psychological well-being has been demonstrated (Undén et al. 2002). A correlation between the increases in IGF-I levels in response to a

Table 18.1 Studies of the relationship between the GH/IGF system and behavior or cognitive function

	Study population	Aspect of GH/IGF system	Outcome	Reference
Human				
	Meta-analyses of studies in the healthy elderly	Serum IGF-I levels	Relationship with cognitive function	Arwert et al. 2005
	Meta-analyses of studies of adults with GH deficiency	GH-deficient, compared to controls	Associated with reduced cognitive function	Falleti et al. 2006
	Older community-living adults	Serum "free" IGF-I and IGFBP-3	Relationship with cognitive function	Landi et al. 2007
	Centenarians	Serum IGF-I levels	Lower IGF-I associated with higher prevalence of dementia	Arai et al. 2001
	Younger adults	Serum IGF-I levels	Relationship with well-being	Undén et al. 2002
	Older adults	IGF-I response to nutritional supplement	Relationship with mood and memory	Arwert et al. 2003
	Postmenopausal women	IGF-I treatment	No effect on cognitive function	Friedlander et al. 2001
Rodent				
	Mice	Treatment with IGF-I or IGFBP inhibitor	Antidepressant and anxiolytic behavior	Malberg et al. 2007
	Exercising mice	Low circulating IGF-I levels (liver-specific IGF-I knockout)	Resistance to effect of exercise on learning and anxiety	Trejo et al. 2008
	Exercising rats	IGF-I treatment	Antidepressant-like behavior	Duman et al. 2009
	Aging rats	IGF-I treatment	Some reversal of emotional reactivity	Markowska et al. 1998
	Diabetic rats	IGF-I treatment	Prevention of deficit in learning/memory	Lupien et al. 2003
	Mice given cytokines centrally	IGF-I treatment	Attenuation of sickness behavior	Bluthé et al. 2006

This table presents human and rodent studies that address the role of the IGF system in behavior or cognitive function. The study population, the main aspect of the IGF system studied, and relevant outcomes in terms of behavior or cognitive function are summarized

nutritional supplement, and mood and memory parameters has been reported (Arwert et al. 2003). There has been one study of the effect of exogenous IGF-I on normal cognitive functioning in humans, showing no effect on memory in healthy postmenopausal women (Friedlander et al. 2001). Several studies have reported the effects of IGF-I treatment in rodents and reported antidepressant-like or anxiolytic effects (see Table 18.1).

18.5   The Role of IGFs and Nutrition in the Cognitive Dysfunction of Aging

A fall in IGF-I and a decline in cognitive function are both part of the normal aging process. Although the fall in IGF-I with age reflects the decline in GH concentrations, there may be an additional effect of reduced nutritional intake (Arai et al. 2001; Lewitt and Hall 2005). To what extent is the IGF system directly responsible for coincident age-related cognitive decline? In rats, IGF-I ameliorates age-related behavioral deficits (Markowska et al. 1998) and the decline in hippocampal neurogenesis (Lichtenwalner et al. 2001). Alzheimer's disease occurs on this background of normal aging, and it is now recognized that impaired insulin and IGF signaling play a central role in the pathophysiology of that disease (de la Monte 2009). Changes in expression of IGFs as well as insulin, IGF1R and insulin receptors, and intracellular signaling molecules are seen in Alzheimer's disease (Rivera et al. 2005; Steen et al. 2005). The recognition that brain insulin deficiency and resistance may be the cause of neuronal cell death has resulted in the terms "type 3 diabetes" and "brain diabetes" being coined (Hoyer 2004; Steen et al. 2005; de la Monte 2009). Centenarians with lower serum IGF-I levels have higher prevalence of dementia (Arai et al. 2001). The observation that IGF-I reduces brain amyloid-β levels raises the possibility that targeting this system may be a therapeutic approach in Alzheimer's disease (Carro et al. 2002). It is well established that reduced IGF-I signaling and dietary restriction are intricately connected and are associated with longevity (Narasimhan et al. 2009), highlighting that the benefits of increasing IGF-I activity to improve cognitive function needs to be weighed against the potential risks. Many tumor cell types express IGF1R and there is interest in targeting this receptor in the management of cancer (Clemmons 2007). Thus, the risk of increased tumor growth should also be considered if endocrine IGF activity is increased to improve brain function.

18.6   Role of IGFs in Cytokine-Induced Disturbances in Behavior and Cognition

Chronic activation of the immune system may be involved in the pathophysiology of altered mental function in a number of disorders (Elenkov et al. 2005). The syndrome of cytokine-induced sickness behavior, with its attendant symptoms of loss of appetite and fatigue, is a common manifestation of infection and malignancy (O'Connor et al. 2008). The IGF and cytokine signaling pathways represent an interface of the endocrine and immune systems. Cytokines are implicated in causing IGF resistance in peripheral tissues by a variety of mechanisms, and it has been proposed that the central effects of inflammation may also act in part by abrogating IGF function. Treatment with IGF-I attenuates the sickness behavior of mice given intracerebroventricular injections of TNF-α (Bluthé et al. 2006). In that study, IGF-I was delivered centrally, along with the cytokine. Peripheral IGF-I administration in mice also reduces the sickness behavior induced by activated immune responses with peripheral lipopolysaccharide (O'Connor et al. 2008).

18.7 Applications to Other Areas of Health and Disease

The observation that the inflammatory mediators can induce IGF resistance and that IGF-I may reduce cytokine-induced behavioral changes has implications for other diseases that are associated with an increased prevalence of depression. There are a variety of such disorders which are now recognized to have underlying chronic inflammation, including obesity and diabetes (Elenkov et al. 2005). Nutritional factors and insulin resistance and/or deficiency also contribute to reduced IGF-I concentrations that are seen in obesity and diabetes. Treatment with IGF-I has been shown to prevent cognitive impairment in diabetic rats (Lupien et al. 2003).

It has been suggested that depressive syndromes should themselves be considered neuroinflammatory in type and relabeled metabolic syndrome type II (McIntyre et al. 2007). It has been shown that antidepressant treatment is associated with a twofold increase in IGF-I protein expression in rat hippocampus (Khawaja et al. 2004) and that antidepressant-induced neural plasticity depends on peripheral IGF-I uptake (Chen and Russo-Neustadt 2007). Nervous pointer dogs, which are a model of panic disorder and severe anxiety, have lower IGF concentrations than normal pointer dogs, and the degree of fearfulness correlates inversely with the IGF-I levels (Uhde et al. 1992). The role of IGFBPs is yet to be fully explored. One study has shown that subjects with bipolar disorders have reduced IGFBP-2 expression in the prefrontal cortex (Bezchlibnyk et al. 2007).

It is now recognized that physical activity has an important influence on brain plasticity (Llorens-Martin et al. 2009). Exercise improves depression in humans and in animal models, and there is a growing body of evidence that this effect on the brain is mediated at least in part by uptake of peripheral IGF-I (Chen and Russo-Neustadt 2007; Trejo et al. 2008; Duman et al. 2009).

Individuals with anorexia nervosa have decreased IGF-I and increased IGFBP-1 levels in the circulation. Although this is expected to decrease brain IGF availability, in this situation it is difficult to unravel the relative roles of nutrition and the IGF system on the behavior disturbance. The observation that the IGF system changes are reversible with refeeding (Counts et al. 1992) suggests that they are markers of the nutritional state and are not involved in the etiology of the disease.

18.8 Conclusions, Challenges, and Recommendations

The IGF system and insulin have distinct but complementary roles in growth and metabolism. There is a growing evidence base supporting a role for both in brain, in neurogenesis, and in functional plasticity, with effects on cognitive function and behavior. Human and rodent studies that address these roles of the IGF system are summarized in Table 18.1, the multiplicity of factors regulating IGF availability in brain is illustrated in Fig. 18.5, and the key features of the IGF system underpinning its relationship to nutrition and behavior are shown in Table 18.2. Further knowledge of the IGF system and nutrition in relation to behavior is a key to understanding how the body integrates somatic and cognitive functioning.

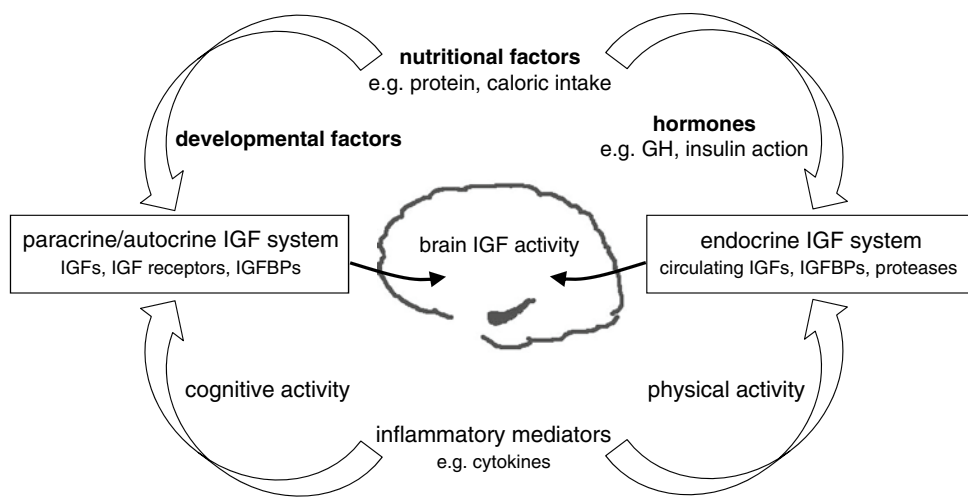
IGF-I is a pleiotropic signal; it modulates cell growth and survival, metabolism, cerebral blood flow, transport of proteins across the blood-brain barrier, and the action of other growth factors and neurotransmitters. One of the research challenges is to fully characterize these pathways, to determine the unique roles of truncated des(1–3)IGF-I and its *N*-terminal tripeptide, and the IGFBPs, and to define the relative importance of the endocrine versus paracrine/autocrine in brain function. In undertaking this, it is impossible to separate a study of the role of nutrition, with its impact on regulation of the IGF system and because of the important effects of IGFs on metabolism.


Fig. 18.5 Factors which may impact brain IGF availability for cognitive function and behavior.The figure summarizes some of the factors influencing IGF activity in brain. Some, such as developmental factors and cognitive activity, have the greatest impact on the paracrine/autocrine IGF system. Inflammatory cytokines have effects both centrally and peripherally. The effects of nutrition and hormonal factors on the endocrine IGF system are well established, but these may also have direct on the brain IGFs and receptors signaling that are yet to be documented. Similarly, there may be a central effect of physical activity in addition to its well-documented action to increase availability of peripheral IGF-I to brain

Table 18.2 Key features of the IGF system

1. The insulin-like growth factors (IGF-I and IGF-II) are proteins that are structurally and functionally related to insulin. In addition to insulin-like, metabolic roles, they have effects on cell growth and survival.
2. The IGFs are widely expressed and have effects on cells in the local environment (paracrine/autocrine actions), as well as in distant tissues after transport via the circulation (endocrine actions).
3. The endocrine IGF system is growth hormone-dependent.
4. A family of six high affinity IGF-binding proteins (IGFBPs) are key regulators of the IGF actions on cells. One of these, IGFBP-1, has an important role in nutrition, by inhibiting the effect of IGFs on glucose homeostasis.
5. Good nutrition and physical activity are important for normal function of the IGF system.
6. The IGF system (paracrine/autocrine and endocrine IGFs and IGFBPs) is involved in normal brain development and function throughout life.
7. There is a fall in IGF-I with age which reflects the decline in growth hormone, with an additional effect of reduced nutritional intake.
8. The IGF system mediates some of the effects of disease on learning, memory and behavior.
9. When considering the use of IGF-I as a therapy, the positive effects of the IGF system on metabolism need to be weighed against the potential effects to promote abnormal cell growth (e.g., cancer).

This table lists the key features of the IGF system that underpin its relationship with nutrition and behavior

A sedentary lifestyle underlies the pandemic of obesity, diabetes, and depression, and it is now known that the impact of exercise on cognitive function is linked to its effect on peripheral IGF-I availability. It is well established that serum IGF-I and IGFBP-1 are useful markers of general nutritional status. Future work should focus on the best type of exercise and on the specific nutritional requirements for an appropriate concentration of each of these at each stage of life, in order to develop guidelines for health promotion and disease prevention. It is now recognized that this may have also an impact on the health of offspring and future generations (Pembrey 2002). High IGF activity is associated with reduced longevity and with progression of some tumors. While exogenous

IGF-I is therefore not recommended in otherwise healthy individuals, the challenge for the future is to target relevant tissues for treating disorders of learning, memory, and behavior, such as those associated with aging and depression.

Summary Points

- IGFs have paracrine/autocrine and endocrine roles in growth and metabolism.
- IGFBPs are key regulators of tissue IGF activity, and may inhibit or stimulate IGF action depending on the IGFBP and the cell milieu.
- Serum IGF-I and IGFBP-1 are useful markers of metabolic status, with low total IGF-I and high fasting IGFBP-1 concentrations indicating poor nutrition.
- IGFs are neuroprotective; and also stimulate hippocampal neurogenesis and plasticity, and have important effects on learning, memory, and behavior throughout life in health and disease.
- The relative roles of the paracrine/autocrine and endocrine IGF system in brain are yet to be established.
- The fall in IGF-I may contribute to the decline in cognitive function with aging and is a background for the development of Alzheimer's disease in predisposed individuals.
- Proinflammatory cytokines cause IGF resistance, which may contribute to disturbances in behavior and cognition.
- The effects of physical activity on cognitive function are mediated in part by endocrine IGF-I.
- Further knowledge of the IGF system and nutrition in relation to behavior may be a key to understanding the integration of somatic and cognitive functioning.

Chapter 19
Leptin and the CNS

Jenni Harvey

Abbreviations

4-AP	4-Aminopyridine
β-amyloid	Beta amyloid
AD	Alzheimer's disease.
AMPA	α-Amino-3-hydroxy-5-methylisoxazole-4-propionic acid
ARC	Arcuate nucleus
BK	Large conductance Ca^{2+}-activated K^+ channel.
CNS	Central nervous system
CSF	Cerebrospinal fluid
D-AP5	D-Amino-5-phosphonopentanoic acid
DMH	Dorsomedial nucleus
ERK	Extracellular signal regulated kinase
EPSC	Excitatory postsynaptic current
GABA	Gamma-aminobutyric acid
ICV	Intracerebroventricular
IPSC	Inhibitory postsynaptic current.
IRS	Insulin receptor substrate
JAK	Janus tyrosine kinase
K_{ATP}	ATP-sensitive K^+ channel
LTD	Long-term depression
LTP	Long-term potentiation
MAPK	Mitogen-activated protein kinase.
NMDA	N-methyl-d-aspartate
NPY	Neuropeptide Y
ObR	Leptin receptor
PI 3-kinase	Phosphoinositide 3-kinase
PKC	Protein kinase C
POMC	Proopiomelanocortin
$PtdIns(4,5)P_2$	Phosphatidylinositol-4,5-bisphosphate.
$PtdIns(3,4,5,)P_3$	Phosphatidylinositol-3,4,5-trisphosphate

Sos	Son-of-sevenless
STAT	Signal transducer and activator of transcription
STP	Short-term potentiation
TEA	Tetraethylammonia
VMH	Ventromedial nucleus

19.1 Introduction

It is known that a physiological system exists that homeostatically regulates body weight. Kennedy first proposed that the amount of energy stored in adipose mass was a balance between calorie intake and energy expenditure. Later, Hervey (1958) formulated the idea of a circulating satiety factor. This concept was supported by parabiosis studies he carried out and the discovery of natural recessive mutations in the obese (*ob*) and diabetes (*db*) genes, which resulted in obesity in mice (Ingalls et al. 1950). The subsequent cloning of the *ob* and *db* genes confirmed the role of these genetic loci in the regulation of energy balance. Injection of leptin into leptin-deficient or wild-type mice was shown to evoke a significant reduction in food intake and body weight (Halaas et al. 1995). Thus, the product of the *ob* gene was given the name leptin (from the Greek, *leptos* meaning thin).

19.2 Leptin

Leptin, the product of the obese (*ob*) gene, is made predominantly by white adipose tissue and once released it circulates in the plasma as a 16 kDa protein in amounts proportional to body fat (Maffei et al. 1995). The obese gene product displays a high degree of homology amongst different species. Leptin also displays a very similar structure to other cytokines and it contains an intra-chain disulphide bond that is pivotal for biological activity.

In mice, mutations in the *ob* gene result in early onset obesity. In leptin-deficient *ob/ob* mice, the substitution of a cysteine with a threonine residue causes synthesis of a truncated leptin protein that is not secreted. In another leptin-deficient mouse strain (*ob²ʲ/ob²ʲ*) synthesis of ob mRNA is stopped by insertion of a transposon in the first intron of the *ob* gene. As well as displaying leptin deficiency, both these mutant mice have morbid obesity, hypothermia and hyperphagia. In contrast, mutations in the *ob* gene are extremely rare in humans. Morbid obesity due to *ob* gene mutations was first reported in two children from a Pakistani family. In these cases, a truncated form of leptin that is targeted for proteosomal degradation was synthesized after deletion of a single guanine nucleotide in codon 133. Members of a Turkish family have also been identified as having morbid obesity associated with a missense mutation in codon 105, which results in the production of an abnormal nonsecretory form of leptin. The rarity of *ob* gene mutations in humans indicates that genetic abnormalities are unlikely to be the major cause of obesity in humans (Table 19.1).

19.2.1 Sites of Leptin Expression

It was initially thought that adipose tissue was the only site of leptin expression. However numerous studies have demonstrated that leptin is widely expressed in many other peripheral tissues including skeletal muscle, gastric mucosa as well as placental and mammary tissues. The expression of leptin

Table 19.1 Key facts of leptin

1. Leptin is a hormone, consisting of 167 amino acids that circulates in the blood and can enter the brain
2. Leptin and its receptors are expressed widely in the brain, suggesting that leptin is a pleiotropic hormone that regulates numerous CNS functions
3. Leptin is an important regulator of food intake and body weight via its actions in the hypothalamus
4. Leptin is a potential cognitive enhancer as it facilitates the cellular events underlying hippocampal-dependent learning and memory
5. Leptin is implicated is various CNS-driven disease as dysfunctions in the leptin system have been linked to neurodegenerative disorders and neuropsychological diseases

in the periphery is influenced by various external factors. For instance, in placenta, glucocorticoids and insulin stimulate expression of leptin (Mise et al. 1998). In the CNS, leptin mRNA, *ob* protein and leptin immunoreactivity have been detected in many brain regions including hippocampus, cortex, and cerebellum (Morash et al. 1999). In addition, the subcellular localization of leptin varies between different neuronal populations. One example of this occurs in the hippocampus as leptin labeling is evident in nuclear and perinuclear regions in the dentate gyrus, whereas labeling is restricted to the nucleus in the CA2 region (Ur et al. 2002). It is also feasible that leptin may be released or made from specific neurons. Indeed, recent studies have demonstrated net efflux of leptin into the internal jugular vein indicating that there is substantial production and secretion of leptin from the brain (Eikelis et al. 2006).

19.3 Leptin Receptor

The leptin receptor (ObR) was first isolated from the choroid plexus by expression cloning techniques (Tartaglia et al. 1995). ObR is encoded by the diabetes (*db*) gene and at least six isoforms (termed ObRa-f) are generated by alternate splicing of the *db* gene. All the isoforms, except ObRe, are membrane spanning receptors that have either short (30–40 residues) or long (302 residues) intracellular domains. ObRb is the main signaling isoform, whereas the short isoforms have limited signaling capacity. ObRe is a distinct isoform as it lacks a transmembrane region and it is thought to bind and transport leptin in the plasma.

In rodents, mutations in the leptin receptor result in leptin insensitivity, early onset obesity, hyperphagia and various neuroendocrine abnormalities (Halaas et al. 1995). In *db/db* mice, a truncated form of ObRb that is unable to stimulate JAK-STAT signaling is produced, whereas there is normal expression of the other splice variants. In fa/fa rats, a single-point mutation in the extracellular domain of all six leptin receptor isoforms occurs, resulting in reduced affinity of the receptor for leptin and attenuated leptin-driven signaling capacity (da Silva et al. 1998). Leptin receptor mutations have been identified in humans, but these are extremely rare. Three sisters from a Kabilian family were the first reported human cases with leptin receptor mutations (Clément et al. 1998). In these individuals, a point mutation in the splice donor site of exon 16 resulted in truncated leptin receptors that lacked both transmembrane and intracellular domains (Fig. 19.1).

19.3.1 Leptin Receptor Expression in the CNS

The hypothalamus is the main target for leptin in the CNS, with respect to regulating food intake and body weight. In rodents, high levels of leptin receptor mRNA and protein are expressed in various hypothalamic nuclei associated with energy homeostasis including the ventromedial hypothalamus
Fig. 19.1 Leptin receptor isoforms. Schematic representation of the six leptin receptor isoforms. ObRb, the long isoform, has an extended C-terminal region that contains the various tyrosine residues required for leptin-driven signaling. The short isoforms, ObRa, ObRc, ObRd, and ObRf, have shorter C-terminal regions, which are thought to limit their signaling capacity. ObRe is a distinct leptin receptor isoform that has no transmembrane region. It is thought to act as a carrier for leptin in the plasma

(VMH), arcuate nucleus (ARC) and dorsomedial hypothalamus (DMH) (Schwartz et al. 1996; Hâkansson et al. 1998). High levels of leptin receptor expression also occur in the hypothalamus of humans (Savioz et al. 1997). In addition to the hypothalamus, high levels of leptin receptor immunoreactivity and mRNA have been detected in numerous other brain regions including the hippocampus, cortex, thalamus, cerebellum, and brain stem (Harvey 2007b). The CA1/CA3 and dentate gyrus regions of the hippocampus display widespread expression of leptin receptor mRNA and immunoreactivity. Expression of leptin receptor mRNA in the hippocampal formation is influenced by fasting (Lin and Huang 1997). The expression of leptin receptors outwith hypothalamic brain regions suggests that in addition to regulating energy balance, leptin plays a more fundamental modulatory role in the CNS. In support of this, leptin mRNA and protein are also highly expressed in numerous brain regions, suggesting that leptin may be made and released locally within the CNS. It is not yet known if centrally derived leptin fulfills the criteria of being a neurotransmitter (or a co-transmitter); however, leptin originating from peripheral sources can still function in the brain. Indeed, intraperitoneal injection of leptin influences glucocorticoid expression in the hippocampus (Proulx et al. 2001).

19.4 Leptin Receptor Signaling

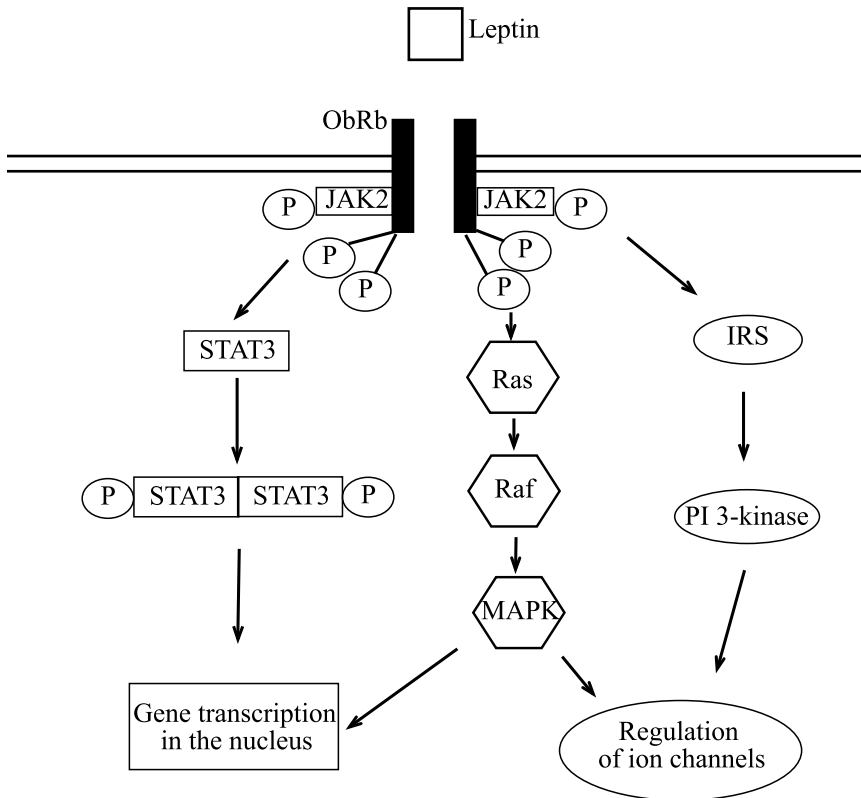
Leptin receptors are members of the class I cytokine receptor superfamily, which includes interleukin 6 and leukemia-inhibitory factor receptors. Like other cytokines, leptin binding to ObR results in the activation of janus tyrosine kinases (JAKs), in particular JAK2 (Baumann et al. 1996). The activation of JAK2 results in its association with specific domains within the C-terminal region of the receptor which in turn promotes trans-phosphorylation of JAK2 and subsequent phosphorylation of tyrosine residues on ObR. This series of events enables recruitment and activation of various


Fig. 19.2 Leptin receptor signaling in neurons. Schematic representation of the key signaling pathways activated by the long leptin receptor isoform in neurons. Following leptin binding to ObRb, tyrosine residues are phosphorylated which results in the association with and activation of JAK2. Subsequently activated JAK2 recruits various signaling molecules including STAT3, IRS proteins and PI 3-kinase and the MAPK signaling cascade. Leptin receptor activation of these pathways results in gene transcriptional changes as well as the regulation of various ion channels

downstream signaling pathways including the STAT (signal transduction and activators of transcription) family of transcription factors, insulin receptor substrate (IRS) proteins, phospho-inositide 3-kinase (PI 3-kinase) and mitogen-activated protein kinase (MAPK) (Fig. 19.2).

19.4.1 STAT3

ObRb is the only isoform that contains the various motifs within its intracellular domain required for activation of STATs. It has been shown that one tyrosine residue (Y1138) in particular enables STAT3 binding, which results in STAT3 dimerization and translocation to the nucleus. Although ObRb activation leads to tyrosine phosphorylation of STAT1, STAT3, and STAT5 in vitro systems, activation of only STAT3 occurs in the hypothalamus following intravenous administration of leptin in vivo. Following STAT3 activation a number of immediate early genes are stimulated such as c-fos and c-jun (Bjorbaek et al. 1998). Furthermore, STAT3 signaling is required for leptin regulation of energy balance as gene-targeted disruption of ObRb-STAT3 signaling in mice results in hyperphagia and obesity (Bates et al. 2003).

19.4.2 PI 3-Kinase

As well as promoting gene transcriptional changes via the JAK-STAT pathway, leptin can also evoke more rapid biological effects by stimulating divergent signaling pathways. In hypothalamic glucose-responsive neurons and insulinoma cells, leptin activates ATP-sensitive K^+ (K_{ATP}) channels via rapid activation of a PI 3-kinase-driven signaling cascade (Spanswick et al. 1997; Harvey et al. 2000a). PI 3-kinase is also implicated in leptin-driven attenuation of food intake as PI 3-kinase inhibitors prevent the anorectic effects of leptin (Niswender et al. 2001). In hippocampal neurons, PI 3-kinase is also a key component of leptin receptor–dependent signaling (Harvey 2007a). One of the main functions of PI 3-kinase is to promote phosphorylation of phosphoinositides on the 3-position, resulting primarily in $PtdIns(3,4,5,)P_3$. Numerous studies have shown a link between the actin cytoskeleton and the lipid products of PI 3-kinase, as the activity of many cytoskeletal proteins is dependent on the levels of $PtdIns(4,5)P_2$ or $PtdIns(3,4,5,)P_3$. The ability of leptin to activate K_{ATP} channels in insulinoma cells is prevented by actin filament stabilization, thereby indicating a functional role for the actin cytoskeleton in the actions of leptin (Harvey et al. 2000a). Leptin application also evokes rapid disassembly of actin filaments, via stimulation of a PI 3-kinase-driven pathway in insulinoma cells. It is known that PI 3-kinase also possesses serine kinase activity and PI 3-kinase has been shown to interact with AGC serine kinases, Tec tyrosine kinases and Rho GTPases. In pancreatic beta cells and hepatocytes leptin activates cyclic nucleotide phosphodiesterase 3B downstream of PI 3-kinase. Furthermore, the PI 3-kinase-cyclic nucleotide phosphodiesterase 3B pathway is implicated in the regulation of food intake and body weight by leptin as ICV administration of selective inhibitors of cyclic nucleotide phosphodiesterase 3B prevent the anorexigenic effects of leptin (Zhao et al. 2002).

19.4.3 Ras-Raf-MAPK

Leptin is also capable of rapidly stimulating the Ras-Raf-MAPK signaling cascade. Leptin receptor–driven activation of this pathway involves tyrosine phosphorylation of Src homology collagen (Shc), an adapter protein, which interacts with Grb2 and subsequently recruits Sos (son-of-sevenless) exchange protein to the plasma membrane. This in turn enables activation of Ras, which then stimulates the step-wise activation of Raf, MEK, and ERK. Leptin receptor activation of this pathway has been observed in many peripheral cell types including rat peradipocytes, porcine chromaffin, and insulinoma cell lines. There is also growing evidence of leptin receptor coupling to MAPK signaling in neurons (Shanley et al. 2001; Morikawa et al. 2004).

19.5 Leptin Transport to the Brain

It is now well established that leptin enters the brain via saturable transport across the blood brain barrier (Banks et al. 1996). Brain microvessels express high levels of the short leptin receptor isoforms, which are capable of binding and internalizing leptin. Impairments in the transport of leptin across the blood brain barrier develop at the same time as obesity in rodents and this can be reversed by modest reductions in weight (Banks and Farrell 2003). The blood-to-brain transport of leptin is also regulated by numerous factors including triglycerides and epinephrine. There is also evidence that leptin transport to the brain may occur via the cerebrospinal fluid (CSF). Indeed, the key site for CSF production, the choroid plexus, expresses high levels of the short leptin receptor isoform, ObRa, which could mediate leptin transport from the blood to the CSF. Leptin may also reach hypothalamic sites via diffusion

as the predominant leptin-target neurons in the hypothalamus are situated extremely close to the median eminence. It is also feasible that leptin is made and released locally in the CNS as there is widespread expression of leptin mRNA and immunoreactivity in the CNS (Morash et al. 1999; Ur et al. 2002).

19.6 Modulation of Hippocampal Function by Leptin

19.6.1 Leptin Regulation of Hippocampal Excitability

19.6.1.1 Leptin Activates BK Channels

A number of studies have shown that leptin inhibits peripheral insulinoma cells (Harvey et al. 1997) and central hypothalamic, nucleus solitarius dorsal motor nucleus neurons ((Spanswick et al. 1997); Williams et al. 2007) via activation of ATP-sensitive potassium (K_{ATP}) channels. In contrast, however, the ability of leptin to inhibit hippocampal CA1 neurons is mediated by the activation of large conductance calcium activated potassium (BK) and not K_{ATP}, channels (Shanley et al. 2002a). Indeed, the leptin-dependent membrane hyperpolarization and increased K^+ conductance in hippocampal neurons were blocked by TEA, but not the sulphonylurea, tolbutamide. Additionally, leptin increased the activity of native BK single channels in hippocampal cultures; an effect that was prevented by the selective BK channel inhibitor, charybdotoxin. BK channels are known to consist of a pore-forming α subunit (*Slo*) either with or without a modulatory β subunit (Toro et al. 1998). Studies in HEK29 cells expressing recombinant BK channels (either h*Slo* or h*Slo*β1) together with the leptin receptor demonstrated that the application of leptin resulted in a rapid increase in BK channel activity. This suggested that expression of β subunits was not required for the effects of leptin. Moreover, the effects of leptin were blocked by charybdotoxin at concentrations that preferentially inhibit BK channels consisting of only α subunits (Fig. 19.3).

19.6.1.2 Role of PI 3-Kinase

In a manner similar to its effects on hypothalamic K_{ATP} channels, leptin-dependent activation of hippocampal BK channels is mediated by a PI 3-kinase-driven process (Shanley et al. 2002b). Recent studies have examined further the nature of the signaling events occurring downstream of PI 3-kinase, that couple leptin receptors to stimulation of BK channels. Agents that promote actin filament stablization inhibit BK channel activation by leptin indicating that disruption of the actin cytoskeleton plays a key role in this process (O'Malley et al. 2005). Indeed, actin filament disrupters such as cytochalasin D mimicked the effects of leptin on single hippocampal BK channels. Leptin receptor activation also results in a rapid and localized PI 3-kinase-dependent increase in the synaptic levels of phosphatidylinositol-3,4,5-trisphosphate (PtdIns(3,4,5)P$_3$), which in turn promotes actin filament depolymerization. Ultimately this series of events causes BK channel activation and subsequent clustering at hippocampal synapses.

19.6.1.3 Leptin Has Anticonvulsant Activity

Neuronal BK channel activity is known to be tightly regulated by voltage and the levels of intracellular Ca^{2+} (Latorre 1989). Hippocampal BK channels also underlie the fast after hyperpolarization which is responsible for action potential repolarization. Thus, BK channels are thought to play an
Fig. 19.3 Activation of BK channels on hippocampal neurons by leptin. Binding of leptin to its receptor (ObRb) promotes the activation of PI 3-kinase, which leads to the conversion of PtdIns(4,5)P_2 into PtdIns(3,4,5)P_3. This lipid intermediate induces alterations in the actin cytoskeletal architecture such that actin filaments (F-actin) are disassembled into globular actin (G-actin). Leptin-driven disruption of actin filaments provokes BK channel opening and also translocation of BK channel to hippocampal synapses

important role in regulating action potential firing rates and the patterns of burst firing. Thus it is conceivable that leptin, by regulating BK channel activity, influences hippocampal excitability. Indeed, leptin significantly attenuates epileptiform-like activity in two distinct models of epilepsy, via a process involving BK channel activation (Shanley et al. 2002b). Thus, in an Mg^{2+}-free hippocampal culture model of epilepsy, leptin reduced the enhanced global levels of intracellular Ca^{2+}, in a rapid and reversible manner. The effects of leptin were mirrored by application of NS 1619, a specific BK channel activator and prevented by exposure to BK channel antagonists, indicating the involvement of BK channels. Leptin also reduced the frequency of interictal firing in hippocampal slices exposed to Mg^{2+}-free conditions. The antiepileptic effects of leptin were absent in Zucker *fa/fa*, but not Zucker lean, rats indicating that leptin receptor activation was required for this process (Shanley et al. 2002b). Recent studies indicate that leptin has antiepileptic properties in other hippocampal models of epilepsy (4-AP, pentylenetetrazole; Xu et al. 2008). Moreover, pentylenetetrazole is reported to induce more severe seizures than normal in leptin-deficient (*ob/ob*) mice (Erbayat-Altay et al. 2008). The ability of leptin to regulate neuronal excitability is not confined to the hippocampus as direct administration of leptin reduces the frequency of spikes in hypothalamic neurons (Takahashi and Cone 2005). Contrastingly, leptin is reported to have pro-convulsant activity as this hormone increases the frequency of epileptic discharges in a penicillin model of epilepsy in the somatomoter cortex. This suggests that there may be regional differences in the regulation of neuronal excitability by leptin.

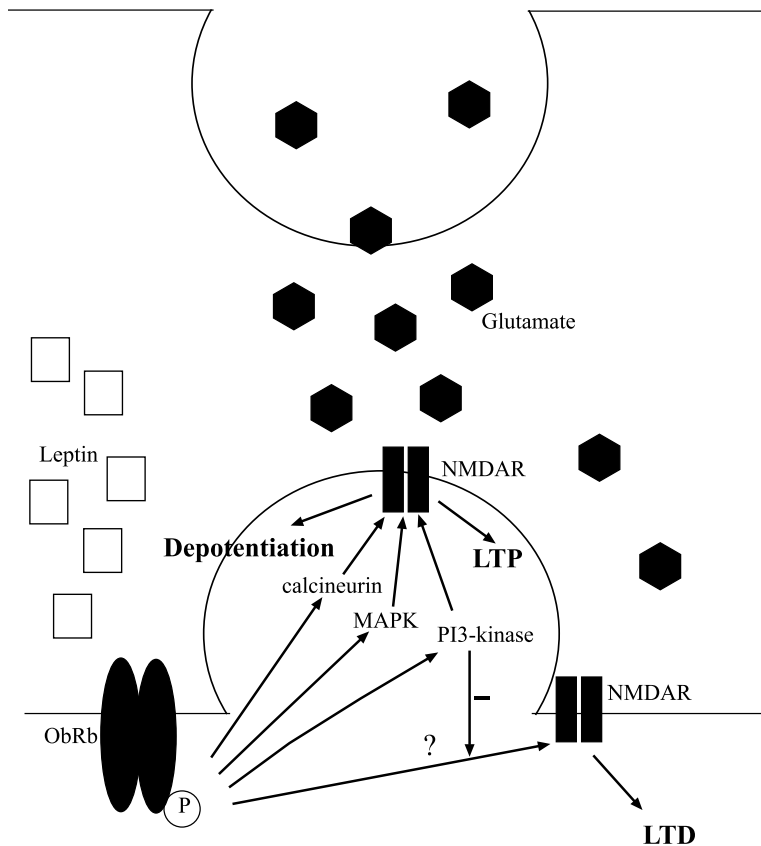
In addition to regulating hippocampal excitability via modulation of neuronal potassium channel function, recent studies indicate that under hyper-excitable conditions, leptin evokes a novel form of NMDA receptor–dependent long-term depression (LTD; (Durakoglugil et al. 2005); This aspect will be discussed in greater detail in Sect. 19.6.2.2). The capacity of leptin to persistently alter the strength of hippocampal excitatory synaptic transmission under such conditions indicates that both synaptic and non-synaptic mechanisms contribute to the regulation of hippocampal excitability by leptin.


Fig. 19.4 Leptin modulates various forms of activity-dependent hippocampal synaptic plasticity. Schematic representation of the different forms of hippocampal synaptic transmission that are regulated by leptin. Following binding of leptin to the leptin receptor divergent signaling cascades are activated. Activation of MAPK and PI 3-kinase-driven signaling leads to facilitation of NMDA receptor-mediated synaptic transmission, which in turn promotes facilitation of hippocampal LTP. Under conditions of enhanced excitability leptin evokes a novel form of NMDA receptor-dependent de novo LTD. In contrast to leptin-driven facilitation of LTP, leptin-induced LTD is negatively regulated by PI 3-kinase. Activation of leptin receptors in the CA1 region of the hippocampus, also results in the reversal of established LTP (depotentiation); a process that is also NMDA receptor dependent and is mediated by calcineurin

Interestingly, divergent signaling pathways underlie these processes as a PI 3-kinase-dependent event mediates leptin activation of BK channels, whereas leptin-induced LTD is negatively regulated by PI 3-kinase (Fig. 19.4).

19.6.2 *Leptin Modulation of Hippocampal Excitatory Synaptic Function*

19.6.2.1 Leptin Facilitates NMDA Receptor–Dependent LTP

It is well documented that the hippocampal formation plays a key role in learning and memory processes and one form of synaptic plasticity, long-term potentiation (LTP) is thought to be a cellular correlate of certain forms of learning and memory and habituation. In the CA1 region of the hippocampus, activity-dependent NMDA receptor–dependent LTP contributes to spatial learning and memory.

Evidence is growing that hippocampal synaptic plasticity can be modulated by various hormones, including leptin. Indeed, rodents that are insensitive to leptin (*db/db* mice; *fa/fa* rats) display significant impairments in hippocampal LTP and LTD as well as impaired spatial memory (Li et al. 2002). Administration of leptin directly into the hippocampus results in the facilitation of synaptic plasticity (Wayner et al. 2004) and it enhances performance in specific hippocampal-dependent learning tasks (Farr et al. 2006). At hippocampal CA1 synapses, leptin promotes conversion of short-term potentiation (STP) into LTP, via enhancing NMDA receptor function (Shanley et al. 2001). Studies in acute hippocampal slices and cultured neurons demonstrated that activation of PI 3-kinase and MAPK (ERK) was required for facilitation of NMDA receptor function by leptin (Shanley et al. 2001). Leptin also enhanced the amplitude, but not the kinetics of NMDA-evoked currents in *Xenopus* oocytes expressing recombinant NMDA (NR1A, NR2A) receptors. This effect of leptin was observed following application of maximal, as well as submaximal concentrations of NMDA suggesting that leptin increased the numbers of NMDA receptors expressed at the cell membrane (Harvey et al. 2008).

19.6.2.2 Leptin Induces a Novel Form of Hippocampal De Novo LTD

It is well established that hippocampal synapses can, in addition to LTP, support activity-dependent reductions in the strength of excitatory synaptic transmission. Long-term depression (LTD) of excitatory synaptic transmission is a persistent weakening of synaptic strength that is involved in learning and memory processes. Moreover, heterosynaptic forms of de novo LTD and depotentiation are thought to enhance the computational flexibility of synaptic networks, which in turn is likely to increase network storage capacity. Two main forms of LTD exist in the mammalian CNS, which are evoked by the synaptic activation of NMDA and metabotropic receptors, respectively (Massey and Bashir 2007). However recent studies have shown that a number of hormones and growth factors have the ability to induce distinct forms of hippocampal LTD. For instance insulin can induce an NMDA receptor–dependent form of LTD at CA1 synapses that is mediated by activation of a PI 3-kinase/PKC coupled pathway (Huang et al. 2004). Under conditions of enhanced excitability (evoked by removal of Mg^{2+} or blockade of $GABA_A$ receptors), leptin can also induce a persistent reduction in the efficacy of excitatory synaptic transmission (LTD; Durakoglugil et al. 2005). Like insulin-induced LTD, the ability of leptin to induced LTD requires the synaptic activation of NMDA receptors as leptin-induced LTD was inhibited by the competitive NMDA receptor antagonist, D-AP5. Contrastingly, metabotropic glutamate receptor antagonists failed to influence the induction or maintenance phases of leptin-induced LTD, indicating that this form of LTD is independent of metabotropic glutamate receptor activation. However, leptin-induced LTD does involve similar expression mechanisms to activity-dependent LTD, as low-frequency stimulation (LFS)-induced LTD occluded leptin-induced LTD, whereas LFS depressed synaptic transmission even after leptin-induced LTD (Durakoglugil et al. 2005). Indeed, like LFS-induced LTD, leptin-induced LTD has a postsynaptic locus of expression as the persistent synaptic depression induced by leptin was not associated with any change in the paired pulse facilitation ratio. In addition, the signaling pathways mediating leptin-induced LTD have been examined. In contrast to the ability of leptin to facilitate hippocampal LTP (Shanley et al. 2001), PI 3-kinase inhibitors enhanced the level of synaptic depression induced by leptin, suggesting that this process is negatively regulated by PI 3-kinase. Protein phosphatases also appear to negatively regulate leptin-induced LTD as inhibition of protein phosphatases 1/2A, but not protein phosphatase 2B, enhanced the magnitude of leptin-induced LTD (Durakoglugil et al. 2005). Several lines of evidence indicate that internalization of AMPA receptors play a pivotal role in mediating activity-dependent forms of hippocampal LTD (Collingridge et al. 2004). Indeed, LFS-induced LTD is associated with endocytosis of GluR2-containing AMPA receptor subunits (Ahmadian et al. 2004). Insulin-induced

LTD is also accompanied by a reduction in the cell surface expression of GluR2 subunits (Ahmadian et al. 2004). However, it still remains to be determined if changes in AMPA receptor trafficking underlie leptin-induced LTD.

19.6.2.3   Leptin Depotentiates Hippocampal CA1 Synapses

Characteristics of Leptin-induced Depotentiation

Recent studies indicate that leptin can also reverse (depotentiate) LTP at hippocampal CA1 synapses (Moult et al. 2009). Thus, application of leptin to hippocampal slices 10–30 min after the induction of LTP resulted in a depression of synaptic transmission to baseline levels (pre-LTP). In contrast, when leptin was applied at later time points after LTP induction, it failed to influence the magnitude of potentiated synapses. This suggests that the ability of leptin to depotentiate hippocampal CA1 synapses occurs within a specific time window. It is known that synaptic plasticity is greatly influenced by prior synaptic activity (known as metaplasticity). Thus, the inability of leptin to depress synaptic transmission when applied 50 min after LTP induction suggests that physiological or biochemical alterations have occurred at the potentiated synapses that have rendered them leptin-insensitive. However the nature of such changes remains to be determined. The ability of leptin to depotentiate hippocampal synapses is concentration-dependent as at 25 and 50 nM concentrations leptin readily reversed LTP, whereas application of 10 nM leptin failed to influence LTP. Leptin-induced depotentiation is also expressed postsynaptically as leptin-induced depotentiation was not accompanied by any change in the paired pulse facilitation ratio or on the coefficient of variation. In a manner analogous to leptin' effects on other forms of synaptic plasticity, leptin-induced depotentiation was NMDA receptor–dependent as exposure to the competitive NMDA receptor antagonist, D-AP5, blocked the effects of leptin. Previous studies have demonstrated that LFS-induced depotentiation involves internalization of AMPA receptors. Endocytosis of synaptic AMPA receptors also underlies depotentiation of hippocampal synapses by metabotropic glutamate receptors or neuregulin. Similarly, the ability of leptin to depotentiate synapses was associated with internalization of GluR2-containing AMPA receptors. Thus, the reversal of potentiated synapses by leptin was accompanied by a reduction in the rectification of synaptic AMPA receptors. Moreover, application of the selective inhibitor of GluR2-lacking AMPA receptor, philanthotoxin, to potentiated synapses mirrored leptin-induced depotentiation. This indicates that leptin-induced depotentiation involves a reduction in the density of GluR2-lacking AMPA receptors at hippocampal CA1 synapses.

Role of NMDA Receptors

Several lines of evidence indicate that de novo LTD and depotentiation are distinct forms of hippocampal synaptic plasticity. For instance, robust NMDA receptor–dependent de novo LTD is observed in calcineurin Aα-knockout mice, whereas activity-dependent depotentiation is absent (Zhuo et al. 1999). Leptin-induced depotentiation and leptin-induced de novo LTD also appear to be a distinct phenomenon as these processes involve the activation of divergent signaling cascades. Thus, inhibitors of calcineurin prevented leptin-induced depotentiation, whereas calcineurin plays no role in leptin-induced LTD (Moult et al. 2009). Evidence is growing that molecularly distinct NMDA receptors underlie different forms of hippocampal synaptic plasticity. Thus NR2B-containing NMDA receptors are implicated in de novo LTD and NR2A-containing NMDA receptors underlie LFS-induced depotentiation. It is also known that depotentiation and de novo LTD results in the

activation of divergent signaling cascades, which in turn leads to dephosphorylation of different sites on GluR1. Thus it has been proposed that the activation of molecularly distinct NMDA receptors triggers the activation of divergent signaling molecules, which in turn underlies different forms of activity-dependent hippocampal synaptic plasticity. In view of this, it is possible that leptin is capable of inducing depotentiation and de novo LTD by activating molecularly distinct NMDA receptors. It is thought that depotentiation of synapses is a process that leads to resetting of potentiated synapses, which is likely to enhance the probability of subsequent generation of LTP. Thus the ability of leptin to depotentiate synapses may indirectly increase the likelihood of LTP induction, which would in turn enhance the effectiveness of information storage in the network.

19.6.2.4 Leptin Promotes Structural Plasticity of Hippocampal Dendrites

Numerous studies support the idea that structural changes contribute to activity-dependent synaptic plasticity in the mammalian CNS. Indeed it is well documented that alterations in dendritic morphology as well as changes in spine density occur following hippocampal LTP (Yuste and Bonhoeffer 2001). Several reports have indicated that growth factors and hormones can promote structural changes in dendrites and spines that enable additional refining of synapses during activity-dependent synaptic plasticity. Similarly, application of leptin to cultured hippocampal neurons evokes rapid (within minutes) changes in the motility and density of dendritic filopodia (O'Malley et al. 2005). This process requires ongoing synaptic transmission as it is blocked by inhibition of action potential driven synaptic transmission with tetrodotoxin. Additionally, the synaptic activation of NMDA receptors is likely to be pivotal for leptin-induced dendritic morphogenesis as the effects of leptin were prevented by blockade of NMDA receptors, but not following inhibition of either AMPA receptors or NR2B-containing NMDA receptors. The leptin-induced alterations in dendritic morphology were associated with the formation of new synapses as increases in synaptic labeling were apparent around 15 min after dendritic morphogenesis (O'Malley et al. 2007). Previous studies have shown that MAPK activation plays an important role in the structural plasticity changes. For example activation of NMDA receptors in hippocampal neurons leads to increases in both MAPK activity and the density of dendritic spines (Goldin and Segal 2003). Similarly, the leptin-driven structural changes involve a MAPK (ERK)-dependent process as inhibitors of MAPK, but not PI 3-kinase block the effects of leptin.

19.6.3 Modulation of Fast Inhibitory Synaptic Transmission by Leptin

In addition to regulating excitatory synaptic transmission, recent studies have shown that leptin also has the capacity to regulate fast inhibitory synaptic transmission mediated by $GABA_A$ receptors in the mammalian CNS. Indeed, application of leptin results in attenuation of $GABA_A$ receptor-mediated synaptic transmission onto proopiomelanocortin (POMC) but not neuropeptide Y (NPY) neurons in the hypothalamus (Cowley et al. 2001; Munzberg et al. 2007). This suggests that leptin is likely to act on presynaptic terminals to reduce the release of GABA onto POMC neurons. Consistent with this possibility, GABAergic inhibitory tone onto POMC neurons is significantly enhanced in leptin-deficient *ob/ob* mice (Pinto et al. 2004). But there is limited information about cellular and molecular basis for the regulation of fast inhibitory synaptic transmission by leptin. However, a recent study by (Solovyova et al. 2009) examined the effects of leptin on $GABA_A$ receptor–mediated inhibitory postsynaptic potentials (IPSCs) onto hippocampal CA1 pyramidal cells. In this study, application of

leptin resulted in a rapid increase in the amplitude of evoked IPSCs and this effect was readily reversed on washout of leptin. Furthermore on prolonged washout of leptin a further reduction in IPSC amplitude was observed that persisted for the duration of recordings. The leptin-dependent enhancement of evoked IPSCs was not associated with any change in the paired pulse ratio or coefficient of variation, but it was paralleled by increases in both the frequency and amplitude of miniature IPSCs (mIPSCs). Furthermore, leptin enhanced postsynaptic currents induced by the $GABA_A$ receptor agonist, muscimol. Together these data indicate that facilitation of fast inhibitory synaptic transmission by leptin involves a postsynaptic mechanism. In support of this, postsynaptic dialysis with inhibitors of PI 3-kinase or Akt prevented the increase in eIPSC amplitude by leptin, indicating mediation by a PI 3-kinase/Akt-dependent process. In contrast the persistent depression induced by leptin (I-LTD) was unaffected by postsynaptic inhibition of PI 3-kinase/Akt indicating that the cellular mechanisms underlying this process are distinct from those responsible for the rapid facilitation of fast inhibitory synaptic transmission induced by leptin. However, leptin-induced I-LTD is also expressed postsynaptically as this effect of leptin was not accompanied by any change in paired pulse ratio or coefficient of variation.

Our previous studies have demonstrated that leptin regulates hippocampal neuron excitability by direct activation of BK channels expressed on pyramidal neurons (Shanley et al. 2002a, b). It is also well established that fast inhibitory synaptic transmission in the CNS plays an important role in regulating neuronal excitability. Thus, leptin is also likely to regulate hippocampal neuron excitability indirectly by modulating the inhibitory drive onto hippocampal CA1 pyramidal neurons. In addition to directly influencing neuronal excitability, alterations in GABAergine tone can also indirectly regulate the induction of synaptic plasticity at excitatory synapses. Thus hippocampal LTP induction is facilitated by $GABA_A$ receptor antagonists (Wigstrom and Gustafsson 1985); an action attributed to $GABA_A$ receptor-mediated regulation of postsynaptic depolarization. Changes in neuronal excitability also accompany hippocampal LTP as there is an increase in the ability of excitatory postsynaptic potentials to fire an action potential after LTP. This phenomenon is known as the E-S coupling component of LTP. Moreover, E-S coupling involves persistent reductions in $GABA_A$ receptor-mediated inhibitory drive (Abraham et al. 1987). Thus, leptin, via its ability to evoke a persistent attenuation of inhibitory tone onto CA1 pyramidal cells, may in turn facilitate the induction of LTP at this synapse (Fig. 19.5).

19.7 The Role of Leptin in Other Areas of Health and Disease

19.7.1 Leptin and its Role in Neurodegeneration

In western societies, life expectancy in steadily increasing and as a consequence more people are suffering from age-related neurodegenerative disorders such as Alzheimer's disease (AD). Evidence is growing that diet and lifestyle are key factors influencing the risk of developing neurodegenerative disorders. Moreover metabolic imbalance is a common feature of such diseases. Numerous studies indicate that dysregulation of metabolic systems are associated with AD. Indeed, dysfunctional neuronal insulin-driven signaling is linked to AD pathology. Recent studies have linked leptin to neurodegeneration as AD patients display markedly reduced levels of circulating leptin (Power et al. 2001). In transgenic murine models of AD that have enhanced levels of β-amyloid, leptin levels are also reduced. Moreover administration of leptin to these murine AD models leads to reductions in the CNS levels of β-amyloid (Fewlass et al. 2004). Furthermore, leptin improves memory in a

Fig. 19.5 Leptin modulates diverse neuronal functions. Schematic representation of the predominant neuronal functions that are regulated by leptin. Leptin derived from adipocytes enters the brain by saturable transport across the blood brain barrier. Within the hypothalamus, leptin acts in the arcuate nucleus to signal satiety. Leptin also plays an important role in regulating thermogenesis and reproductive function via its actions in the hypothalamus. Leptin is also capable of reaching other brain regions at physiologically relevant concentrations. In the hippocampal CA1 region, leptin plays a role in learning and memory processes by enhancing NMDA receptor function and modulating various forms of activity-dependent synaptic plasticity. Defects in the leptin system have also recently been linked to neurodegenerative disorders such as Alzheimer's disease. Leptin also regulates hippocampal neuron excitability by modulating BK channel activity; a process that may play a role in the antiepileptic properties of leptin. The excitability of other neuronal populations including cortical, hypothalamic and nucleus tractus solitarius are also controlled by this hormone. Leptin has also been shown to protect cerebellar, cortical, and hippocampal neurons from various toxic insults. Other brain regions have been shown to play a role in controlling feeding behavior including nucleus tractus solitarius (NTS) and ventral tegmental area (VTA). Leptin receptors have been detected in these regions and leptin influences food intake via its actions in NTS and VTA neurons

murine model of β-amyloid-induced toxicity, and recent studies indicate that leptin reduces tau hyperphosphorylation in neuronal cells. These findings suggest not only that leptin dysfunction contributes to AD pathology but also that leptin may be a potential therapeutic target in the treatment of AD. However, a greater understanding of the cellular and molecular basis for leptin dysfunction in the pathology of AD is still required for progression in this field.

19.7.2 Leptin is a Novel Antidepressant

Depression is currently the most prevalent mental illness with around 20% of the population suffering from this condition worldwide. However a significant proportion of depressed patients are unresponsive to currently available antidepressant therapies that are predominantly monoamine-based drugs. However recent studies indicate that the hormone leptin may be a novel antidepressant (Lu 2007) and the leptin system may offer a possible alternative target for the generation of novel antidepressant therapies in the future. Indeed, rats exposed to chronic stress display significant reductions in circulating leptin levels (Lu et al. 2006), and this occurs independently of alterations in body weight. Systemic administration of leptin mimics the effects of antidepressant agents such that in chronically stressed rats, leptin reversed the deficits in rewarding behavior. The antidepressant effects of leptin are likely to be mediated by leptin receptors located in the hippocampal formation as direct administration of leptin into the hippocampus resulted in antidepressant effects in the forced swim test. In contrast administration of leptin into the hypothalamus failed to influence forced swim behavior. Thus these findings indicate that leptin is a potent antidepressant agent in a number of rodent models that mirror certain behavioral aspects of human depression. However, there is limited information about the role of leptin in human depression. Two studies have reported raised circulating leptin levels in depressed patients, whereas other studies have linked attenuated plasma leptin levels to patients with major depression (Lu 2007). Although the efficacy of leptin as an antidepressant has not been assessed clinically, it is tempting to speculate that depressed patients displaying low leptin levels may be a suitable target group for leptin therapy.

Summary Points

- Leptin, the product of the ob gene is a circulating hormone.
- Leptin mediates its biological actions by activating leptin receptors.
- Leptin receptors are widely expressed in the brain.
- Leptin plays a key role in the hypothalamic regulation of energy homeostasis.
- Leptin modulates hippocampal synaptic transmission and synaptic plasticity.
- Leptin regulates hippocampal neuron excitability.
- Leptin is implicated in CNS-driven disease including neurodegenerative and neuropsychological disorders.

Definitions

Synaptic plasticity: A persistent, activity-driven alteration in the strength of synaptic transmission that is thought to be the cellular basis for information storage in the brain.
Long-term potentiation; A persistent activity-dependent increase in the efficacy of synaptic transmission.
Long-term depression: A long-lasting and activity-dependent reduction in the strength of synaptic transmission.
Structural plasticity: Dynamic modifications that occur in brain structures such as dendrites and synapses, that are thought to contribute to activity-dependent changes in synaptic efficacy.
Metaplasticity: A persistent change in the physiological or biochemical characteristics of a chemical synapse that in turn alters the plastic properties of that synapse.

Chapter 20
Oxytocin and Appetite

Céline Caquineau and Gareth Leng

Abbreviations

AgRP	Agouti-related protein
AP	Area postrema
ARC	Arcuate nucleus
CCK	Cholecystokinin
CNS	Central nervous system
ER	Endoplasmic reticulum
Icv	Intracerebroventicular
Ins (1,4,5)P$_3$	Inositol-1,4,5-triphosphate
InsP$_3$R	Inositol-1,4,5-triphosphate receptor
Ip	Intraperitoneal
Iv	Intravenous
MC4R	Melanocortin receptor 4
α-MSH	Alpha-melanocyte stimulating hormone
NPY	Neuropeptide Y
NTS	Nucleus of the solitary tract
OC	Optic chiasm
OTR	Oxytocin receptor
PLC	Phospholipase C
Ptdlns(4,5)P$_2$	Phosphatidylinositol-4,5-biphosphate
POMC	Proopiomelanocortin
PVN	Paraventricular nucleus
RP	Reserve pool
RPP	Readily releasable pool
Sim1	Single-minded 1
SON	Supraoptic nucleus
VMN	Ventromedial nucleus of the hypothalamus
3V	Third ventricle

20.1 Anatomy of the Oxytocin Systems

Oxytocin is synthesized in the hypothalamus by neurons of the supraoptic nucleus (SON) and paraventricular nucleus (PVN); the PVN contains both large (magnocellular) and smaller (parvocellular) oxytocin neurons, while the SON contains only magnocellular neurons (Fig. 20.1). Axons from the magnocellular neurons project to the posterior pituitary gland, where oxytocin stored in vesicles within neurosecretory nerve endings. Oxytocin stored in these nerve endings is secreted into the blood circulation following calcium-dependent exocytosis, triggered by neuronal electrical activity. There are small additional sources of systemic oxytocin from peripheral sources, but the concentration of oxytocin in the blood essentially mirrors the electrical activity of magnocellular neurons in the hypothalamus. The blood-brain barrier prevents most of the oxytocin that is secreted into the blood from penetrating into the brain, but oxytocin is also secreted centrally, and acts at numerous
Fig. 20.1 The oxytocin system. (**a, b**) Coronal section of the rat hypothalamus. Oxytocin cells and fibers are immunostained with fluorescent red. Oxytocin is synthesized in the hypothalamus by neurones in the supraoptic nucleus (*SON*) and paraventricular nucleus (*PVN*) (**a**). While the PVN contains magnocellular and parvocellular oxytocin neurons, the SON only contains magnocellular oxytocin neurons (**b**). Axons from magnocellular neurons project to the posterior pituitary gland, where oxytocin stored in vesicles can be secreted into the blood. Axons from parvocellular oxytocin neurons project within the central nervous system (*CNS*) to many areas including the hypothalamus, the brainstem and spinal cord. Oxytocin can also be released centrally from the soma and dendrites of the magnocellular neurons. (**c, d**). Expression of Fos, the protein product of the immediate–early gene c-*fos*, in the SON of a hungry rat (**c**) and of a recently fed rat (**d**). There is very little Fos in the SON in the hungry rat, but after a meal, most SON cells are very active (See Johnstone et al. 2006). *OC* Optic chiasm, *3V* Third ventricle

sites in the brain and spinal cord. Axons from parvocellular oxytocin neurons project extensively to the brainstem and spinal cord, and these neurons are regulated independently of the magnocellular neurons. Oxytocin can also be released centrally from the soma and dendrites of the magnocellular neurons and this release can also be regulated independently of peripheral secretion. Thus oxytocin in the brain derives from two separate sources which can be regulated independently of each other, and independently of peripheral secretion (see Ludwig and Leng 2006).

Oxytocin acts through high affinity G-protein coupled receptors, which are widely distributed both at the periphery and within the brain (see Gimpl et al. 2008). Some of these brain areas that contain oxytocin receptors are densely innervated by parvocellular axon terminals, but others aren't, and there is generally no correlation between the abundance of oxytocin receptors and the density of innervation by oxytocin fibers. The parvocellular oxytocin cells of the PVN project mainly to the caudal brainstem, in particular to the NTS and to the spinal cord. In many other areas, including the ventromedial nucleus of the hypothalamus (VMN), oxytocin receptors are abundant and functional, but there are few, if any, oxytocin-containing fibers (see Leng et al. 2008). Thus the central effects of oxytocin depend more on where its receptors are located rather than where the parvocellular neurons project to. Oxytocin that is released in the brain has a relatively long half-life, meaning that oxytocin released within the brain acts more like a "brain hormone" than like a conventional neurotransmitter, diffusing to sometimes distant sites to exert its effects (see Leng and Ludwig 2006).

20.2 Classical Roles of Oxytocin

Oxytocin is important for parturition in mammals. In the rat, an increase in uterine production of prostaglandins toward the end of pregnancy leads to a fall in the production of ovarian progesterone, and one result of this is that the expression of oxytocin receptors is increased in both the myometrium and endometrium. The uterus thus becomes extremely sensitive to oxytocin, which acts directly on the myometrium to promote uterine contractions and indirectly by stimulating further prostaglandin production. Signals from the contracting uterus and cervix are transmitted via the brainstem back to the oxytocin cells, whose activation leads to a further increase in oxytocin secretion, completing a positive-feedback loop. During parturition, large pulses of oxytocin secretion are superimposed on an elevated background secretion, and each birth is associated with one of these pulses, which are triggered by brief and intense bursts of electrical activity of the oxytocin neurons. Oxytocin is thus important in normal parturition, although oxytocin-deficient transgenic mice ("oxytocin knock-out mice") will still give birth; in these mice, prostaglandins replace oxytocin actions and initiate uterine contractions and parturition (see Russell and Leng. 1998; Russell et al. 2003).

However, the only indispensable physiological role for oxytocin is the milk-ejection reflex (Fig. 20.2). The sucking of a baby at one breast causes milk to be let-down as a reflex, and this reflex is not "local" to the breast being suckled but happens in both; it is mediated by the suckling-induced release of oxytocin from the pituitary gland. Without oxytocin there is no significant milk let-down in any mammal, and pups of oxytocin knock-out mice will starve although milk is available. During suckling, sensory receptors in the skin overlying the mammary gland are activated, leading to the activation of spinal nerves, which project indirectly to the oxytocin neurons to induce oxytocin secretion. This reflex, first described in the rat, is one of the most spectacular of physiological reflexes. When hungry pups suckle at the nipples of their mother, all of the magnocellular oxytocin cells, in near synchrony, discharge a brief burst of action potentials every 5–10 min. This burst, which lasts just a few seconds at most, results in a pulse of oxytocin secretion that causes an abrupt rise in intramammary pressure and milk let-down; when oxytocin reaches the mammary gland,

Electrical activity –the milk-ejection reflex
Fig. 20.2 The milk-ejection reflex. During suckling, magnocellular oxytocin neurons in the supraoptic nucleus (*SON*) and paraventricular nucleus (*PVN*) display intense bursts of electrical activity every few minutes; an example of one of these bursts (From Dyball and Leng 1986) is shown at *top right*. These bursts induce oxytocin secretion from both dendrites and axon terminals in the posterior pituitary gland. The dendritic oxytocin release acts back on the oxytocin cells to mobilize intracellular calcium release, an important element in maintaining the reflex. Secretion from the nerve endings enters the blood and reaches the mammary gland, where pulses of oxytocin elicit abrupt rises in intramammary pressure, signaling milk let-down. Oxytocin given centrally in very small amounts will facilitate this reflex, leading to large repeated bursts of activity and subsequent milk let-down. The oxytocin that is released from dendrites subsequently diffuses to act at other brain sites to facilitate maternal behavior

it stimulates the contraction of myoepithelium cells surrounding the alveoli of the mammary gland, inducing milk let-down from these cells to the collecting duct of the mammary gland. Oxytocin released within the brain plays a key role in this reflex; suckling causes large amounts of oxytocin to be released from the dendrites of magnocellular oxytocin neurons, which depolarizes them, and triggers Ca^{2+} release from intracellular stores, and one result of this is to stimulate even more oxytocin release. Very low doses of oxytocin injected directly into the brain (i.c.v.) will facilitate this suckling-induced reflex, milk-ejection bursts are more frequent and more intense; oxytocin antagonists have the opposite effect; they block the reflex (see Leng and Ludwig 2006).

The milk-ejection reflex requires oxytocin secretion to be pulsatile; continuous secretion of oxytocin quickly desensitizes the mammary gland and thus inhibits the milk let-down. The frequency and intensity of milk-ejection bursts in the rat depend on the intensity of suckling – they are proportional to the number of pups suckling. A lactating rat spends many hours of each day nursing her pups, but many other species feed their young only intermittently: rabbits for instance, suckle their young just once a day, and each suckling episode results in just a single milk-ejection reflex. In the pig, the piglets suckle frequently, but for only about 10 min at a time, resulting in a single milk-ejection reflex, after which the piglets detach from the nipples. Thus, in most mammalian species, the reflex comprises a large abrupt pulse of oxytocin release that is triggered with a delay after the onset of suckling. The reflex can also be conditioned – in humans, the cry of a hungry infant can trigger milk let-down, and it can also be easily disrupted by stress and anxiety. In some species, including the rat, the milk-ejection reflex only occurs during periods of slow-wave sleep.

In contrast, many marsupial mammals secrete mesotocin rather than oxytocin from the posterior pituitary gland. Mesotocin differs from oxytocin by only a single amino acid, and appears to be a neutral mutation, as it is fully active at oxytocin receptors. Marsupial mammals display a sophisticated pattern of lactation to allow the nourishment of a neonate that at birth is almost embryonic in form. Milk production is confined to the mammary gland to which the neonate attaches, the volume of milk produced increases and the composition changes during lactation, and evacuation of the pouch leads to the birth of the next young and the development of a second lactation in parallel to the previous one. Thus, at any one time, the kangaroo may support a young neonate permanently attached to one mammary gland in the pouch that receives a dilute milk low in fat and protein but high in carbohydrates, and a lively juvenile intermittently suckling at another, that receives a more concentrated milk higher in protein and fat content (Brennan et al. 2007). The nipples can stretch to an extraordinary degree, allowing the young to feed from almost any position in the pouch and avoiding the danger of accidental detachment of the neonate during maternal grooming or by the activity of the juvenile. In early lactation, the very small pouch young evoke intermittent release of small pulses of mesotocin, enough to induce milk let-down in the gland to which they are attached but not enough to affect the other, less sensitive glands. The juvenile, when it suckles, evokes a much larger reflex secretion which is effective at the "older" gland resulting in a large milk let-down at that gland and, incidentally, giving the neonate an additional meal.

20.3 Oxytocin and Behaviors

In recent years, it became clear that oxytocin receptors are present in many parts of the brain, and that oxytocin acts centrally in the regulation of several behaviors such as pair bonding, maternal care, maternal aggression, stress coping behavior and sexual behavior (see Insel and Young 2001; Ferguson et al. 2002; Carter 2003 for reviews). Oxytocin stimulates maternal motivation toward the offspring and also facilitates the attachment of the infant toward its mother. In rats, oxytocin facilitates the onset of maternal care by overcoming the mother's avoidance behavior toward the neonates and by stimulating nurturing behaviors (Pederson et al. 1982). In sheep, oxytocin is responsible for the selectivity of maternal care that a ewe develops toward her own lamb, leading to rejecting any alien lambs (Keverne and Kendrick 1992). In rats and sheep, these maternal behaviors are initiated by the process of parturition, by the oxytocin that is released within the brain. However, mice are spontaneously maternal, and oxytocin knock-out mice present normal nurturing behaviors. Oxytocin also facilitates the learning processes that allow the pups to recognize its mother olfactory cues and influences the vocalization that a pup produces to signal its isolation to its mother. The involvement of oxytocin in pair bonding has been elegantly described using the prairie and montane voles. Prairie voles are monogamous and

form pair bonds after mating. In female prairie voles, central oxytocin facilitates the formation of pair bonds even in the absence of mating. By contrast, montane voles are polygamous and oxytocin fails to induce pair bonding. This species difference reflects a difference in receptor expression; oxytocin receptors in the prairie vole are densely expressed in brain areas associated with reward such as the nucleus accumbens and caudate putamen, but are almost absent from the same areas in the montane vole (Lim et al. 2004).

The plasma concentration of oxytocin increases during mating in rats and during orgasm in humans. Systemic injections of oxytocin facilitate male sexual behavior by reducing the number of intromissions required to reach ejaculation in rats and rabbits, but oxytocin also has a role in the central regulation of sexual behaviors. When injected into the hypothalamus, oxytocin potently induces penile erection in rats, rabbits, and monkeys, and it increases sexual receptivity and facilitate lordosis in female rats in an estrogen–progesterone-dependent manner (Schumacher et al. 1989). Oxytocin cells in the SON and PVN are activated during penile erection, and expression of the immediate–early gene c-*fos* (a marker of neuronal activity) in oxytocin neurons in the PVN is increased during mating (Witt and Insel 1994). Oxytocin is released in the PVN of male rats during mating and also in the presence of an inaccessible receptive female, suggesting that it has a role in sexual motivation as well as performance (Waldherr and Neumann 2007)

20.3.1 Oxytocin and Feeding Behavior

Central oxytocin is a potent satiety factor; peripheral injections of oxytocin do not affect feeding in rats, but central injections of oxytocin or oxytocin agonists inhibit feeding, including in fasted rats; and these effects can be prevented by an oxytocin antagonist. In mice, the expression of oxytocin mRNA in the hypothalamus is reduced after fasting and restored after refeeding (Kublaoui et al. 2008).

The parvocellular oxytocin neurons of the PVN have a clear role in feeding (see Douglas et al. 2007; Leng et al. 2007). Many of these neurons densely project to the NTS, and conversely, the NTS is the source of dense projections to the SON and PVN. The NTS receives inputs from gastric vagal afferents; these mediate signals from the gut arising as a result of gastric distension and of the effects of peptides released during feeding, including especially the gut peptide cholecystokinin (CCK). Conversely, the NTS is the source of a descending efferent vagal regulation of gastric reflexes that control the flow of food through the gut. In rats, stimuli that increase oxytocin release peripherally are generally accompanied by a reduction in food intake – dehydration, for example, which is a potent stimulus for oxytocin secretion as well as for vasopressin secretion, is accompanied by a profound depression of appetite. Such dehydration-induced anorexia is attenuated in oxytocin knock-out mice, while consumption of solutions that contain NaCl is enhanced. This is not solely attributable to any specific effect on sodium appetite, as oxytocin-deficient mice will also overconsume palatable sucrose solutions, and both sweet and non-sweet carbohydrate solutions (see Leng et al. 2007 for references).

While mice lacking oxytocin appear generally normal in body weight, male (but not female) mice lacking the oxytocin receptor (OTR-KO) mice) have an overt, though mild, late-onset obesity, being slightly heavier than wild-type mice; OTR-KO mice eat significantly more at each meal than wild-type mice, although the meal frequency per day is not significantly different (Takayanagi et al. 2008). As some parvocellular oxytocin neurons in the PVN project polysynaptically to brown adipose tissue, it is possible that oxytocin is involved in peripheral regulation of energy metabolism. When OTR-KO mice are placed in a cold environment (5°C), their body temperature decreases by more than wild-type mice, so a reduced energy consumption might contribute to the late-onset obesity.

Oxytocin deficiency also contributes to the hyperphagia seen in *Sim1*$^{+/-}$ mice. Single-minded 1 (*Sim1*) is one of the six genes implicated in human monogenic obesity and encodes for nuclear

transcription factors (Hung et al. 2007), and is expressed in the PVN and SON and at other sites in the hypothalamus. *Sim1* knock-out mice die shortly after birth and present developmental malfunction of the neurons in the SON, PVN, and anterior periventricular nucleus. Heterozygous *Sim1*[+/−] mice present a phenotype of hyperphagic obesity, increased linear growth and enhanced sensitivity to diet-induced obesity (Holder 2004; Michaud et al. 2001). Oxytocin mRNA expression is reduced in the hypothalamus of *Sim1*[+/−] mice in both magnocellular and parvocellular oxytocin neurons (Kublaoui et al. 2008). Central injection of oxytocin receptor antagonist amplified the hyperphagia seen in *Sim1*[+/−] mice whereas repeated central injections of oxytocin led to a reduction in weight gain in *Sim1*[+/−] mice.

20.4 Oxytocin and Satiety Signaling

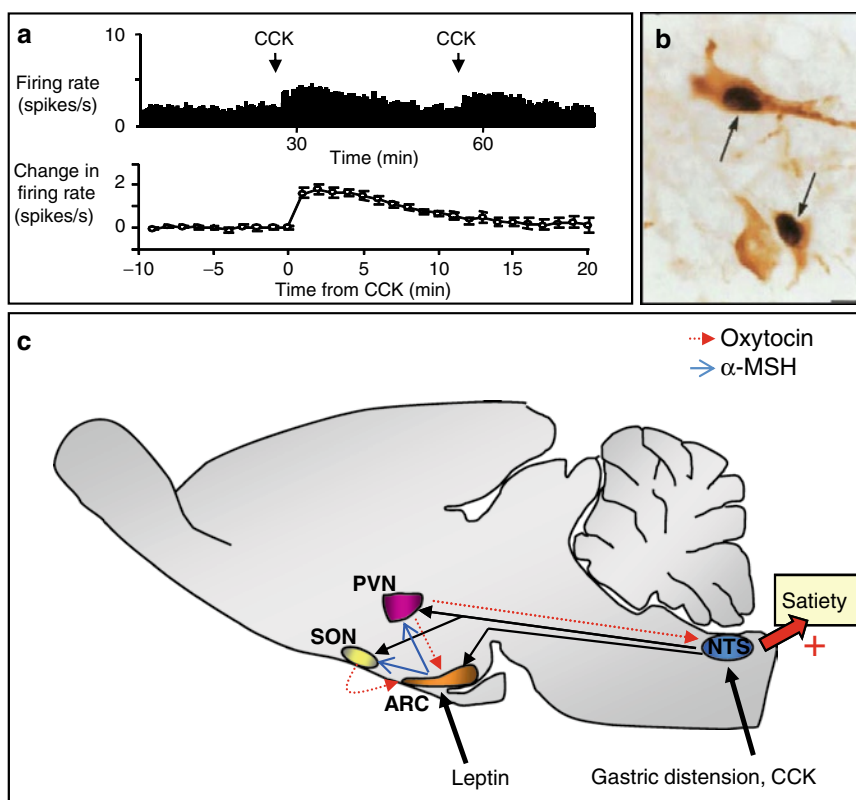
The regulation of food intake depends upon a dynamic balance between "hunger" signals and "satiety" signals arising from the periphery. During feeding, gastric distension and factors released in the stomach mediate satiety by activating afferent vagal neurons that project to the caudal brainstem (Fig. 20.3). Cholecytokinin (CCK) is one important satiety factor that regulates the amount


Fig. 20.3 Oxytocin satiety signaling pathways. (**a**) Cholecystokinin (*CCK*) increases the firing rate of oxytocin cells. (**b**) Oxytocin fibers in the nucleus tractus solitarii (*NTS*), immunostained in fluorescent red. (**c**) Oxytocin is involved in the complex neural network that regulates food intake. Gastric distension and satiety signals such as CCK and leptin activate the release of oxytocin into the brain which then enhances the mediation of satiety. *ARC* arcuate nucleus, *AP* area postrema

of food consumed during a meal. CCK released from the gut during eating acts via CCK-A receptors that are located on the nerve endings of gastric vagal afferent nerves. Via this pathway, peripheral injections of CCK activate neurons in the NTS in the causal brainstem, which project to the SON and PVN, activating both parvocellular and magnocellular oxytocin neurons. As a result of the activation of the magnocellular oxytocin neurons, CCK causes a large amount of oxytocin to be secreted from the posterior pituitary into the systemic circulation. This oxytocin acts on the heart to induce the secretion of atrial natriuretic peptide, which in turn acts at the kidney to promote natriuresis (sodium excretion) as a homeostatic regulatory response to compensate for salt intake that accompanies feeding (Gutkowska et al. 1997); in some species, including the rat, this indirect natriuretic action of oxytocin is supplemented by a direct natriuretic action mediated by oxytocin receptors expressed in the kidney. The parvocellular oxytocin neurons of the PVN that are activated during food intake project back to the NTS; oxytocin released from these parvocellular nerve endings acts on oxytocin receptors, which are present at a high density in the NTS, to activate a descending vagal efferent pathway, which regulates the passage of food through the gut (Blevins et al. 2003). Oxytocin may also have a direct effect on gastric motility, and reduced postprandial secretion of oxytocin has been reported in patients with delayed gastric emptying (Borg et al. 2009). Oxytocin antagonists have also been reported to slow gastric emptying in healthy humans (Ohlsson et al. 2006).

The sensitivity of the hypothalamus and brainstem to signals derived from the gut is modulated by peripheral signals reflecting the status of the body's energy stores, and especially by leptin. Leptin is an anorectic hormone secreted mainly from adipocytes; its plasma concentration increases with feeding and decreases with fasting. When injected centrally, leptin reduces food intake and increases the number of NTS neurons that express c-*fos* after peripheral administration of CCK, and during fasting, leptin deficiency reduces the satiety effect of CCK. There is evidence that oxytocin contributes to the effects of leptin. Leptin induces an increase in c-*fos* expression in the parvocellular oxytocin neurons that project to the NTS. Furthermore, a central injection of an oxytocin receptor antagonist followed by a central leptin and a peripheral CCK injection reduces the potentiating effect of leptin on the satiety action of CCK. This suggests that parvocellular oxytocin neurons activated by leptin act as a relay between the hypothalamus and the NTS to enhance NTS neurons sensitivity to increase their sensitivity to meal-related satiety signals (Blevins et al. 2004). Leptin not only influence oxytocin releases, it also modulates oxytocin expression. This has been supported by an elegant study using laser microdissection and microarray hybridization that showed that the reduction of oxytocin gene expression in the PVN seen in fasted rats can be reversed by peripheral injection of leptin (Tung et al. 2008).

Although considerable evidence supports the role of central oxytocin as a potent satiety factor, the precise neuronal source of oxytocin is still uncertain. Because axons from magnocellular neurons project to the posterior pituitary, the possible central role of these neurons was disregarded in favor of the centrally projecting parvocellular oxytocin neurons. Oxytocin released from parvocellular neurons is undoubtedly involved in the regulation of food intake, by providing a local source of oxytocin in the NTS. However, the major source of oxytocin in the hypothalamus is the magnocellular neurons (Ludwig and Leng 2006). Magnocellular oxytocin neurons are clearly strongly activated during feeding; c-*fos* expression in the SON is markedly increased after food intake in rats (Johnstone et al. 2006) and in the ewe (Chaillou et al. 2000). Gastric distension and systemic injection of CCK both increase c-*fos* expression in magnocellular neurons and induce oxytocin secretion into the bloodstream. Magnocellular oxytocin neurons are also affected by many other factors regulating appetite; for example, they densely express leptin receptors (Håkansson and Meister 1998), and they are powerfully regulated by alpha-melanocyte-stimulating hormone (α-MSH), one of the most potent satiety factors known (Sabatier et al. 2003).

20.5 Magnocellular Oxytocin Neurons and α-MSH

The anorexigenic factor α-MSH is a peptide product of the proopiomelanocortin (POMC) prohormone. Centrally, it is produced in neurons in the dorsomedial hypothalamus and in the arcuate nucleus (ARC) of the hypothalamus. α-MSH actions are primarily mediated via MC4 receptors which are widely distributed throughout the CNS. Central injections of α-MSH inhibit food intake, and mutations in the POMC gene or in the MC4 receptor gene lead to obesity associated with hyperphagia; in humans, mutations of the MC4 receptor gene are the most common monogenic identified cause of early-onset of obesity, suggesting that α-MSH is critical in the regulation of food intake. Within the arcuate nucleus, POMC neurons are innervated by neurons-secreting neuropeptide Y (NPY), a potent orexigenic factor. NPY neurons also produce an endogenous antagonist of the MC4 receptors, the agouti-related protein (AgRP), whose overexpression in the hypothalamus leads to hyperphagia, reduced energy expenditure and obesity (Lu et al. 1994). POMC neurons are also inhibited by the "hunger" signal ghrelin (a large peptide secreted from the empty stomach) both directly and indirectly via the NPY neurons that ghrelin has been shown to excite. Leptin stimulates POMC neurons to release α-MSH directly and indirectly via inhibiting NPY neurons; it also modulates the expression of the processing enzymes responsible for the cleavage of POMC into α-MSH, thus regulating α-MSH synthesis and availability for release.

Oxytocin and α-MSH have remarkably similar behavioral effects. They are both potent satiety factors and they are also both potent stimulator of sexual motivation and performance in rats and humans (Wessells et al. 2000). When injected into the PVN or NTS, α-MSH, and MC4 receptors agonist strongly inhibit food intake, just as oxytocin does. Magnocellular oxytocin neurons express MC4 receptors, and α-MSH-containing fibers innervate both the SON and PVN (Mountjoy et al. 1994). Like for oxytocin, hypothalamic melanocortin signaling is impaired in *Sim1*[+/−] mice (Wisse and Schwartz 2003). It has been suggested that Sim1 intervenes in the regulation of body weight by modulating MC4 receptors signaling in the PVN (Holder 2004). A subset of PVN *Sim1* neurons expresses oxytocin but also MC4 receptors, suggesting that α-MSH signaling is mediated via oxytocin whose expression depends upon Sim1 (Kublaoui et al. 2008).

Central injection of α-MSH induces strong expression of c-*fos* in both the PVN and SON, but more in magnocellular oxytocin neurons than in parvocellular oxytocin neurons (Caquineau et al. 2006). While central injection of α-MSH or MC4 receptor agonist inhibits the electrical activity of magnocellular oxytocin neurons and does not stimulate oxytocin release into the blood circulation, it potently stimulates release of oxytocin from neuronal dendrites. Thus, α-MSH stimulates *central* release of oxytocin rather than peripheral secretion, and this central release originates from dendrites of magnocellular oxytocin neurons rather than the axon terminals of parvocellular neurons (see Sabatier 2006 for review).

20.6 Dendritic Oxytocin Release and Its Significance in the Regulation of Food Intake

The dendrites are those processes of a neuron that receive most of a neuron's synaptic input, and until recently were assumed to have a merely passive role in collating these signals. The only output of a neuron was equally assumed to be neurotransmitters released at axonal nerve endings as a result of electrical activity in the form of action potentials transmitted along the axons. As far as neuropeptides are concerned, however, both of these assumptions are false. Many neurons make and release

one or more neuropeptides as well as conventional neurotransmitters, but the peptides are not packaged in the same vesicles as the neurotransmitters are. Conventional neurotransmitters, like glutamate and GABA, are packaged in small synaptic vesicles that are targeted specifically to synapses. Peptides are packaged in much larger vesicles that are, in generally uniformly distributed throughout the cytosol of a neuron; accordingly, because the dendrites of most neurons comprise 80–90% of the cytosolic volume, most peptides in the brain are packaged in large dense core vesicles that are mainly located within dendrites, and this is true in particular of oxytocin in the hypothalamus.

The secretion of oxytocin from axon terminals is regulated by neuronal electrical activity: depolarization induced by an action potential cause an increase in voltage-gated calcium entry into the nerve terminals, leading to exocytosis of oxytocin-containing vesicles. By contrast, vesicle exocytosis in dendrites of magnocellular neurons is not only triggered by the entry of extracellular calcium but can also be triggered by a mobilization of calcium from endoplasmic reticulum (ER) stores. The mobilization of calcium from ER stores results from the activation of G protein–coupled receptors and related second messenger Phospholipase C (PLC)-inositol-triphosphate pathways, and these pathways can be activated independently from electrical activity – in particular, α-MSH stimulates dendritic oxytocin release by mobilizing intracellular calcium stores while at the same time inhibiting neuronal electrical activity (see Ludwig and Leng 2006). In parallel with stimulating exocytosis, the increase in intracellular calcium can also induce a redistribution of the remaining vesicles in the dendrite into a readily releasable pool; this very important mechanism enhances the availability of oxytocin-containing vesicles to future putative electrical triggers. This preparation for future release of oxytocin, or "priming," lasts for at least 90 min, and so engenders a reconfiguration of the local oxytocin circuitry, opening new routes of communication between neurons (see Ludwig and Leng 2006)

In many brain areas, the content of oxytocin in extracellular fluid is much higher than would be expected by local release from the sparse axon terminals, so it is likely that oxytocin acts as a neurohormone by diffusing through the extracellular fluid from the magnocellular neurons that release it in abundance from their dendrites (Leng and Ludwig 2006).

20.7 The Ventromedial Nucleus of the Hypothalamus

The VMN is one important target for central oxytocin release; it expresses oxytocin receptors densely, but contains few if any oxytocin-containing fibers. The VMN is a large heterogeneous nucleus that can be subdivided into dorsomedial, central, and ventrolateral regions based on the expression of transcription factors, receptors, and neuropeptides (Fig. 20.4). The ventrolateral region is mainly responsible for the facilitation of lordosis behavior in female rats, whereas the dorsal VMN has been known as a satiety center since 1940, when it was first reported that rats with lesions of the VMN display a "voracious" appetite. One interesting subpopulation of VMN neurons, which delineates the more dorsal and central regions, expresses the nuclear receptor steroidogenic factor-1 (SF1); mutations of SF1 are linked to obesity and type-2 diabetes in humans. Leptin excites SF1 neurons in vitro, and the actions of leptin in the VMN help to resist diet-induced obesity. Another population of VMN neurons is involved in glucose homeostasis, and these glucoreceptor neurons are also activated by leptin in vivo. The dorsomedial VMN projects to the bed nucleus of the stria terminalis, the nucleus accumbens, and the medial prefrontal cortex, and also sends strong excitatory inputs to POMC neurons in the arcuate nucleus; this connection is dynamically regulated by nutritional state, as it is weakened by fasting (see Leng et al. 2007 for references).

In the rat brain, the VMN is one of the regions that contain the highest densities of oxytocin-binding sites and oxytocin receptor mRNA expression, with particularly intense labeling in the
Fig. 20.4 The ventromedial nucleus of the hypothalamus (*VMN*) and oxytocin. (**a**, **b**) Oxytocin fibers immunostained with fluorescent red in coronal section of a rat brain. Although the VMN is rich in oxytocin receptors it is barely innervated by oxytocin fibers (**b**). (**c**) Leptin released from the body's fat stores activates the release of alpha-melanocyte stimulating hormone (*α-MSH*) from POMC neurons in the arcuate nucleus (*ARC*) these neurons project densely to the supraoptic nucleus (*SON*) and paraventricular nucleus (*PVN*). In the SON and PVN, α-MSH acts on magnocellular oxytocin neurons via MC4 receptors to stimulate the dendritic release of oxytocin. Oxytocin then diffuses to the satiety center VMN, which expresses oxytocin receptors in great abundance, to reduce appetite. *MC4R* melanocortin receptor 4, *OC* optic chiasm, *OTR* oxytocin receptor, *POMC* proopiomelanocortin neurones. Scale bar:200μm

ventrolateral VMN, and these receptors have been confirmed as functional by electrophysiological studies. The abundance of functional oxytocin receptors on VMN neurons contrasts strikingly with the absence there of oxytocin-containing fibers. The VMN contains very few fibers that show any immunoreactivity for oxytocin (Fig. 20.2), and it is not known whether the few oxytocin fibers there are "stray" axons or dendrites of magnocellular neurons, or come from parvocellular neurons of the PVN. By marked contrast, the region ventrolateral to the VMN is densely permeated by oxytocin-containing axons of magnocellular neurons on their way from the PVN and SON to the neurohypophysis. The magnocellular neuronal axons do not have any collateral branches in this region, so give rise to no conventional nerve endings and synapses. This does not however mean that no oxytocin is released from these axons; oxytocin vesicles can be released from any part of a neuron in which they are present, even including undilated axons; the likelihood of a vesicle being released appears to depend solely on how close it is to the cell plasma membrane. Axons contain relatively few vesicles that are close to the plasma membrane, and far fewer in total than are contained in dendrites, but nevertheless, might be a functionally significant source of oxytocin in the region adjacent to the VMN. So far, there is no evidence of any synaptic innervation of VMN neurons by parvocellular oxytocin neurons of the PVN. Thus it is not clear whether the most important source of oxytocin for the VMN is the nearby axons of magnocellular neurons, from which small amounts are released in response to electrical activity propagated down the axons, or the more distant dendrites, from which more oxytocin is released by stimuli that can be independent of electrical activity.

20.7.1 Interactions Between Appetite for Food and Appetite for Sex

Feeding behavior and sexual behavior are mutually exclusive goal-orientated behaviors: they are both initiated with a drive, a drive to find food or to seek sexual contact. Their regulation involves a complex network of hormonal and neuronal actions to ensure the display of appropriate behavior

Table 20.1 Key features of oxytocin

1. Oxytocin is a peptide hormone secreted from the posterior pituitary gland
2. It is secreted into the systemic circulation from the nerve endings of large neurons whose cell bodies lie in the hypothalamus
3. Oxytocin is secreted into the blood in response to suckling, and is *essential* for milk let-down
4. It is also secreted during parturition, when it promotes the progress of parturition, and it is secreted during sexual activity
5. Oxytocin is also released in the brain, where it affects many behaviors. This central release is governed independently of peripheral secretion
6. Oxytocin release in the brain promotes maternal, social and sexual behaviors, while inhibiting feeding behaviors
7. Oxytocin does not cross the blood-brain barrier, so peripheral administration of oxytocin does not have these behavioral effects

This table lists the key features of oxytocin

according to the physiological needs of each individual. Many factors that regulate feeding also affect sexual behavior and reciprocally, many factors that regulate sexual behavior also regulate feeding. For instance: orexins, neuropeptides that stimulate food intake, also increase sexual arousal and performance in male rats (Gulia et al. 2003); NPY, a potent appetite stimulator, inhibits sexual behavior in sexually experienced male rats (Poggioli et al. 1990); central injection of leptin restores copulatory behavior in streptozotocin-induced diabetic male rats (Saito et al. 2004); dopamine, a crucial factor in the regulation of sexual behavior involved in both sexual motivation and sexual performance (e.g., Hull et al. 1995), also plays a role in the drive for food (e.g., Wang et al. 2002); and analogs of the satiety factor α-MSH induce penile erection in rats and in men with psychogenic erectile dysfunction (e.g., Wessells et al. 2000; Martin et al. 2002).

When male rats are hungry, their sexual behavior is impaired; they are slower to mate than normal; the drive for sex competes with the drive for food in hungry rats, and is thus responsive to the animal's nutritional status. Central injections of MC4 receptor antagonist also impair sexual behavior in male rats, and this action is accompanied by a reduction in c-*fos* expression in magnocellular oxytocin neurons, suggesting that the effects of the antagonist on sexual behavior involve a suppression of oxytocin release in the brain (Caquineau et al. 2006). The need for a coherent organization of feeding and sexual behaviors implies that the competing drives for food and for a sexual partner must be reciprocally regulated. This is likely to involve central mechanisms coordinating a switch in motivation, or a transfer from one drive to another according to physiological and nutritional needs. In part, this fundamental switch in motivational behaviors seems to be regulated by the hypothalamic actions of α-MSH, mediated in part by oxytocin (Table 20.1).

20.7.2 Applications to Other Areas in Health and Disease

As oxytocin in mammals is indispensable for successful reproduction in mammals by virtue of its essential role in nurture of the young, it is unsurprising that few genetic defects of oxytocin systems have been recognized in human populations, One exception is Prader–Willi syndrome, a rare genetic disorder arising from the loss of paternally inherited genes on chromosome 15q11–13, leading to life-threatening insatiable hunger and obesity from early childhood, through developmental hypothalamic defects. The PVN from humans with this syndrome shows a 42% reduction in the number of parvocellular oxytocin neurons (see Goldstone 2006).

There has been recent speculation that autism may be linked to dysregulation of central oxytocin release, but this has yet to be clearly established. Oxytocin is used clinically to promote the progress of labor, and antagonists are used in some cases to prevent threatened preterm labor (Zingg and Laporte 2003).

Summary Points

- Oxytocin secreted from the posterior pituitary gland is essential for milk let-down in response to suckling.
- Oxytocin released in the brain is important for maternal behaviors essential for nurturing the offspring.
- Oxytocin released in the brain is also a potent satiety factor.
- Both parvocellular and magnocellular oxytocin neurones are involved in the regulation of feeding behavior.
- Oxytocin neurons are regulated by signals from the gut and from fat stores, and they interact with the central neuropeptide signaling pathways that regulate food intake.
- Oxytocin acts as a neurohormone. Oxytocin released from dendrites of magnocellular oxytocin neurones diffuses to distant targets areas such as the VMN to inhibit food intake and modulate behaviors.

Definitions

Dendrite: A branched projection of a neuron where synaptic inputs are integrated and processed to generate action potentials. Dendrites can also release neuroactive substances including neurotransmitters and neuropeptides that regulate the cell of origin as well as neighboring cells.

Magnocellular neuron: A large neuroendocrine neuron of the supraoptic nuclei and paraventricular nuclei of the hypothalamus that projects to the posterior pituitary gland.

Parvocellular neuron: A centrally projecting neuron of the paraventricular nucleus.

c-*fos*: An immediate–early gene encoding a transcription factor (Fos) whose expression is stimulated by a variety of cellular stimuli. It is commonly used as a marker of neuronal activation.

Neurohormone: A chemical messenger secreted from one group of neurons that acts on another distant group of neurons.

"knock-out" mice: Transgenic mice with an engineered inactivation of a particular gene; oxytocin knock-out mice do not synthesize oxytocin.

Hypothalamus: Complex brain area that regulates many important homeostatic neuroendocrine functions; different regions of the hypothalamus regulate, among many things, body temperature, hunger, plasma volume and electrolyte balance, stress responses, metabolism and growth, release of hormones from many glands, especially the pituitary gland, sex drive, sleep, circadian rhythms, and thirst

Chapter 21
The Role of Apolipoprotein APO A-IV in Eating Behavior and Diet

Giuseppe Derosa and Sibilla Anna Teresa Salvadeo

Abbreviations

TC	Total cholesterol
HDL	High-density lipoproteins
LDL	Low-density lipoproteins
Tg	Triglyceride; triglycerides
Apo A-IV	Apolipoprotein A-IV
PYY	Peptide Y
NPY	Neuropeptide Y
HNF-4	Hepatocyte nuclear factor 4
PGC-1	Peroxisome proliferator-activated receptor gamma co-activator 1
BMI	Body mass index
CCK	Cholecystokinin
LCAT	Cholesterol acyl transferase
OFLT	Oral fat load test
AUC	Area under curve
POMC	Pro-opiomelanocortin
ABCA 1	ATP binding cassette transporter 1
CETP	Cholesteryl ester transfer protein

21.1 Introduction

Apolipoprotein A-IV was discovered over 22 years ago, but its physiological features were not clearly defined until recently (Table 21.1). Apolipoprotein A-IV has been studied both in rodents and humans, even if the major part of information comes from experiments in animals. In animals, apo A-IV is secreted both in the intestine and the liver, the former being the major organ responsible of circulating apo A-IV. In humans, apo A-IV is produced in the small intestine only. The first data about a relation between apo A-IV and lipid metabolism were published between late 1970s and 1980s (Dvorin et al. 1988).

Fig. 21.1 Proteins associated with chylomicrons in rats and humans. *ARP* Apolipoprotein E (Reproduced from Bisgaier et al. 1987)
In 1990 Hayashi et al. demonstrated that stimulation of apo A-IV production, induced by lipid feeding, is followed by formation of chylomicrons (Hayashi et al. 1990).

Subsequently, many studies were conducted sustaining a role of apo A-IV in lipoproteins metabolism (Goldberg et al. 1990; Stein et al. 1986) even if no direct evidences are available about similar effects of apolipoproteins in vivo. Recent studies have evaluated the genetic expression of apo A-IV and its effects on other lipoproteins metabolism (Li et al. 2008).

There are evidences that apo A-IV exerts a protective action against atherosclerosis in mice (Vergnes et al. 2000). These effects are more evident when highly atherogenic conditions, such as hyperlipidemia and high-fat diet, are present, while no significant results have been observed in the few studies that examined apo A-IV antiatherogenic actions under physiological conditions.

The main purpose of this chapter is to elucidate the role of apo A-IV in food intake regulation and diet according to recent findings. Moreover, recent studies have shown a protective action of apo A-IV against atherosclerosis in humans (Kronenberg et al. 2000) and this has stimulated increasing interest of researchers in this field.

So far, a series of physiological studies supporting the role of apo A-IV in the regulation of food intake in animals and humans have been published (Fujimoto et al. 1992) and new evidences are available about the role of apo A-IV on the regulation of food intake in particular populations, such as diabetic patients.

21.2 Apolipoprotein A-IV

21.2.1 Biochemical Features

Apolipoprotein A-IV is a 46-kDa glycoprotein containing 6% carbohydrate and 376 amino acid residues. It is coded by a gene located on chromosome 11q and clustered with apo A-I and apo C-III. Apo A-IV contains a 14 peptide repeat with the potential of forming amphipathic α-helices and is primarily incorporated into the surface of nascent chylomicrons and high-density lipoproteins (HDL), with a small percentage of very-low-density lipoproteins (VLDL). In circulating blood, active exchange occurs between chylomicrons and HDL particles, the former providing apo A-IV and the latter donating apo C-II and apo E (Ghiselli et al. 1986). Moreover, apo A-IV has been found in the lipoprotein-free plasma fraction. Some studies have demonstrated that apo A-IV α-helices are not amphipathic enough to penetrate lipid monolayers, so that the interaction between apo A-IV and lipoproteins results very labile (Saito et al. 2004). Apo A-IV is secreted by enterocytes in association with Tg-rich lipoproteins (chylomicrons). In humans, apo A-IV is synthesized by small intestine only (Gordon et al. 1984) (Fig. 21.1).

Many genetic variants of apo A-IV have been identified (Table 21.2): two common, apo A-IV-1 and apo A-IV-2, and two rare alleles are characteristic of Caucasian populations. Population screening

Table 21.2 Alleles of apolipoprotein A-IV

Alleles	Populations
Apo A-IV-1	Common in Caucasian populations (0.91)
Apo A-IV-2	Common in Western Countries populations, completely absent in Japanese population (0.07–0.09)
Apo A-IV-0	Rare
Apo A-IV-3	Rare
Apo A-IV-5	Rare, found in US Black population
Apo A-IV-6	Rare
Apo A-IV-7	Common in Nigerian populations

According to these data, apo A-IV-2 allele is a Caucasian marker and the different phenotypes observed are is due to variable degrees of Caucasian admixture. The detection of the apo A-IV-5 allele in Black People from Nigeria and the USA indicates that this is a marker unique to blacks, since no example of this variant allele has been reported in other population groups. If these differences are able to explain different metabolic features between races is still unknown (Sepehrnia et al. 1988)

has estimated that an allele frequency of 0.91 features the major allele apo A-IV-1. One in seven Americans seems heterozygous for the apo A-IV-2 allele, which is completely absent in Japanese population. Data from many studies report a relationship between apo A-IV polymorphism and interindividual variability in plasma lipid concentrations, glucose levels, and body mass index (BMI) (Ehnholm et al. 1994; Hanis et al. 1991).

Recent observations demonstrated that apo A-IV-2 allele delays the postprandial clearance of Tg-rich lipoproteins (Hockey et al. 2001). Discrepancies between results of the different studies in this field are still unexplained, even if an interaction between apo A-IV gene and different diets has been hypothesized.

21.2.2 Regulation of Apolipoprotein A-IV

21.2.2.1 Nutritional Status

Both in animal models and humans, apo A-IV concentration increases following fat-feeding. Malabsorption studies confirm the role of intestinal Tg in regulating apo A-IV concentration. Low levels of apo A-IV have been detected in a variety of pathological states of malabsorption, such as abetalipoproteinemia, hypobetalipoproteinemia, chronic pancreatitis, malabsorptive syndromes, and in total parenteral nutrition (Bisgaier et al 1983; Weinberg et al 1983; Koga et al. 1985; Sherman et al 1988).

Few and controversial data are available about the effects of short- and medium-chain fatty acids on apo A-IV, while long-chain fatty acids have been demonstrated to elicit significant effect on apo A-IV. Furthermore, little attention has been paid to the possible effects of cholesterol on intestinal apo A-IV biogenesis in humans. Up to date, the hypothesis retained is that cholesterol consumption increases hepatic apo A-IV mRNA in the postprandial state, and some authors suggest a chronic fat-induced adaptation of apo A-IV (Kalogeris et al 2001).

Apo A-IV has been found to be associated to Tg-rich lipoproteins and HDL particles in plasma (Lagrost et al. 1989). Moreover, apo A-IV plays a role in the metabolism of both Tg-rich lipoproteins and HDL and modulates the activation of lipoprotein lipase in the presence of apo C-II (Goldberg et al. 1990). A recent study has shown that a dietary intervention occurring later in life is able to prevent cardiovascular decline by affecting apo A-IV and apo C-III levels in rats (Araki et al 2004). Apo A-IV has been clearly demonstrated to play a potentially important role in reverse cholesterol transport, by stimulating the activity of cholesterol acyl transferase (LCAT), a regulatory enzyme of HDL (Duverger et al. 1994).

Furthermore, apo A-IV increases cholesterol efflux from adipose cells (Steinmetz et al. 1990) and participates in HDL particles conversion by cholesteryl ester transfer protein (CETP) (Barter et al. 1988). Apo A-IV can modulate CETP-mediated transfer of cholesteryl esters between HDL and low-density lipoproteins (LDL) fractions, exhibits labile reversible binding to HDL 3 (Weinberg et al. 1992; Gambert et al. 1988) and helps to maintain optimal surface pressure for CETP activity (Weinberg et al. 1992) (Table 21.3 and Fig. 21.2).

Apolipoprotein A-IV gene polymorphism is supposed to be involved in the response to change in the percentage of dietary fats. To our knowledge, only three studies have examined this problem. In a study by Waggemans et al. the polymorphism by itself seemed to produce no effects on response to dietary intervention (Weggemans et al. 2000).

In a second study by Ostos et al., Apo A-IV-2 allele was associated with hyperresponsivity to fat during the postprandial period. Other investigators approached the role of apo A-IV polymorphism

Table 21.3 Main factors with regulatory effects on apo A-IV

Regulation	Hypothalamus	Intestine	Unsolved issues
Lipid absorption	↑ synthesis ↑ secretion	↑ synthesis ↑ secretion	Stimulation by different type of Tg; Mechanism underlying apo A-IV expression in hypothalamus
Circadian rhythms	–	Secretion increased just before feeding and peaked midway through the dark period. Integrity of enterohepatic circulation is necessary for circadian rhythm.	More studies are needed to understand relation between this pattern, lymphatic Tg, cholesterol, and phospholipids output
Leptin	–	↓ apo A-IV transcript levels	Apparent auto-regulation of apo A-IV may be related to elevation in circulating leptin levels
Pancreatic polypeptide family	NPY: ICV infusion increases apo A-IV	PYY: simulates jejunal apo A-IV synthesis and secretion, probably acting via vagus nerve NPY: ICV infusion does not provide increase of jejunal apo A-IV.	NPY effects of jejunal synthesis of apo A-IV
Diet	Apo A-IV ↓ by food deprivation ↑ by lipid feeding	Apo A-IV synthesis and secretion become less responsive to lipid feeding following the chronic consumption of high-fat diet.	Mechanisms that induce this "chronic adaptation" to lipid ingestion are still unexplained.
Apolipoproetin A-IV antibodies	ICV infusion ↑ lipid feeding ↓ hypothalamic apo A-IV mRNA levels	–	Mechanism that induce reduction of apo A-IV mRNA after local infusion of antiserum are still unexplained

ICV intra-cerebroventricular, *PPY* peptide YY, *NPY* neuropeptide Y

in the interindividual variability in reduction of blood lipids, body weight, and cardiovascular risk. Heilborn et al. assessed the effects of an energy-restricted diet for 12 weeks on weight loss and plasma lipids according to apo A-IV genotype in 186 overweight/obese patients. Among participants, a significant increase in HDL was observed in apo A-IV-1/1 subjects, while apo A-IV-2 was associated to increase in HDL. In this study, apo A-IV genotype was not associated to changes in total cholesterol (TC), Tg, and LDL. The authors concluded that apo A-IV genotype might be related to the efficacy of body weight control in reduction of CV (Heilbronn et al. 2000).

Furthermore, the apolipoprotein gene cluster APOA1/C3/A4/A5 probably plays a role in the development of abnormalities in Tg and HDL in nondiabetic population. Recent data indicate that the variability in APOA1/C3/A4/A5 gene cluster may affect Tg and HDL levels in women with type 2 diabetes (Qi et al. 2007). Few studies are available that provide direct demonstration of a relation between Tg concentrations and apo A-IV in humans (Fig. 21.3).
Fig. 21.2 Interactions between apo A-IV and other lipoproteins in lipid metabolism. *ABC1* ATP binding cassette transporter 1, *HDL* high density lipoproteins, *LCAT* cholesterol acyl transferase, *CETP* cholesteryl ester transfer protein, *CE* cholesteryl ester; The activation of LCAT by apo A-IV promotes esterification of cholesterol, which converts discoidal particles to spherical HDL. Apolipoprotein A-IV stimulates lipoprotein lipase activity. Apolipoprotein A-IV enhances the transfer of Tg and CE between lipoproteins by CETP (Reproduced from Stan et al. 2003)

Fig. 21.3 Plasma Tg and apo A-IV during OFLT in humans. Plasma apo A-IV increased after OFLT. After 8 h, apo A-IV levels were significantly higher than basal values ($p < 0.0001$), while Tg had returned nearly to basal values (Verges et al. 2001)
The influence of a high-glucose diet on apo A-IV has been examined in a study by Strobl et al. who determined the effects of a fish oil-rich and a sucrose-rich diet on apo A-IV gene transcription and nuclear and total cellular apo A-IV mRNA abundance in the liver of genetically obese, hyperlipoproteinemic *Zucker rats* and their lean littermates. The sucrose-rich diet increased apo A-IV gene expression twofold in both lean and obese rats. According to results obtained in this study, genetic obesity probably alters the response of hepatic apo A-IV gene expression to a lipid-lowering diet, rich in fish oil, by a mechanism affecting transcriptional regulation (Strobl et al. 1993).

Recent data indicate a modulation of apo A-IV levels by glycemic status. Higher apo A-IV levels have been found in insulin-dependent diabetic patients (independently of Tg or HDL levels) and were closely related to glycemic control (Attia et al. 1997). In addition, there is demonstration that mRNA levels of apo A-IV increase in the liver of rats treated with insulin (Evert et al. 2003).

Results obtained by Hanniman et al. suggest that hepatic and ileal apo A-IV gene expression are induced by fasting in a glucocorticoid-dependent manner. In this study, apo A-IV concentration increase was induced in two established mouse models of diabetes. Despite the requirement for glucocorticoids, analysis of the mouse and human apo A-IV promoters indicated a direct regulatory role of Hepatocyte Nuclear Factor 4 (HNF-4) and peroxisome proliferator-activated receptor gamma coactivator 1 (PGC-1). Although HNF-4 and PGC-1 are necessary for the induction of apo A-IV during fasting and diabetes, these data suggest a more complex and highly conserved in vivo mechanism for regulation of apo A-IV during times of nutritional and/or metabolic stress (Hanniman et al. 2006).

21.2.2.2 Pancreatobiliary Secretion

Studies in animals show that variation of the intestinal availability of bile acids may affect the regulation of apo A-IV synthesis (Sonoyama et al. 1994). Some authors assume that apo A-IV gene expression requires participation of pancreatic output in addition to biliary secretion (Felgines et al. 1994).

The mechanisms underlying the coordinate effects of bile and pancreatic exogenous secretion on apo A-IV regulation remain to be determined.

21.2.2.3 Hormones

Evidences of the existence of hormonal regulation of apo A-IV come from studies in animals. A particular relation between apo A-IV concentration and development has been observed. In rats, apo A-IV is higher in the neonatal period, while, during the adulthood, rat liver apo A-IV mRNA might be stimulated by thyroid hormones and hydrocortisone and suppressed by ethinyl estradiol and *n*-proptylthiouracil, which interfere with the endogenous synthesis of thyroid hormone. Interestingly, the same treatments have no effects on apo A-IV gene expression in the intestine, thus supporting the hypothesis of a different regulation of apo A-IV in the liver and the intestine. In cultured rat hepatocytes, insulin and glucagon inhibit the production of apo A-IV in a dose-dependent manner and dexamethasone stimulates its synthesis and secretion into the media (Huchida et al. 1991).

Another strong hormonal modulator of apo A-IV synthesis is peptide tyrosine, produced by the endocrine cells and released in the ileum and the colon after nutrients ingestion (Table 21.3) (Hill et al. 1991).

21.3 The Role of Apo A-IV in Regulation of Food Intake

Apoliporpotein A-IV was first described in the 1970s and since 1990s amounting data have been collected sustaining a role of this protein in satiety regulation and food intake behavior.

In 1993, Fujimoto et al. showed that intra-cerebrovascular administration of apo A-IV significantly inhibited food intake in a dose-dependent manner and stopped the action of endogenous apo A-IV locally (Fujimoto et al. 1993a).

In 2001, Liu et al. demonstrated that apo A-IV is synthesized also in hypothalamus, which is the organ that regulates satiety and food intake in rats, and postulated that apo A-IV gene expression might be modulated by food deprivation and lipid refeeding (Liu et al. 2001).

Recently, Shen et al. elegantly described, for the first time, a detailed distribution of apo A-IV-containing cells in rat brain areas, which are involved in the regulation of energy homeostasis (Table 21.4 and Figs. 21.4 and 21.5).

Interestingly, apo A-IV immunoreactive cells were found in the arcuate and ventromedial hypothalamic nuclei with less staining in cells of paraventricular and dorsomedial nuclei. Arcuate nucleus cells release a number of neuropeptides, such as NPY and pro-opiomelanocortin (POMC), and are a primary target for leptin, a food-intake regulatory hormone produced by adipose tissue. In a recent study, apo A-IV in the arcuate nucleus is mainly localized in neurons and apo A-IV was found in around 23% of neurons containing POMC. In the same study, injection of apo A-IV in 48-h fasted rats reversed reduction of POMC induced by fasting (Shen et al. 2008).

Apolipoprotein A-IV probably exerts an anorexic effect through interaction with arcuate nucleus. Intravenous administration of apo A-IV affects POMC mRNA expression only in fasted rats and not

Table 21.4 Characterization of apolipoprotein A-IV in brain areas involved in energy homeostasis (Shen et al. 2008)

Previous evidences	• Apo A-IV is synthesized in the hypothalamus
	• Apo A-IV plays an important role in the control of food intake
	• ICV administration of apo A-IV significantly inhibits food intake in a dose-dependent manner and blocks the action of endogenous apo A-IV locally
	• Hypothalamus expresses the Apo A-IV gene and expression is reduced by food deprivation and restored by lipid refeeding
Materials and methods	• Animals: adult male Sprague-Dawley rats divided into four groups (ad libitum fed and 46 h fasting).
	• Double staining of immunohistochemistry
	• Intravenously administration of 125I-labeled recombinant rat apo A-IV and subsequent determination of its uptake in the brain
Statistical analysis	• Two-way ANOVA followed by Turkey's test was used for analysis of gene mRNA levels
	• Multiple time regression analysis was used for calculation of unidirection influx constant from blood to brain
Purpose	• To describe distribution of apo A-IV in the brain areas involved in energy homeostasis;
	• To asses if apo A-IV in the brain comes from blood circulation.
Results	• Apo A-IV immunoreactivity:
	ARC[a]
	PVN[b]
	DMH[c]
	VMH[a]
	LHA[c]
	NTS[d]
	• Circulating apo A-IV does not cross the brain barrier.
Conclusions	• Apo A-IV is produced by neuronal cells and probably exerts its anorexic function by interacting with catabolic regulatory neuropeptides

ICV intra-cerebroventricular, *ARC* arcuate nucleus, *PVN* paraventricular nucleus, *DMH* dorsomedial nucleus, *LHA* lateral hypothalamic area, *nts* nucleus of solitary tract
[a]High density
[b]Moderate density
[c]No nuclear signal
Fig. 21.4 Distribution of apo A-IV in ARC of rats. *ARC* arcuate nucleus, *3V* third ventricule (Reproduced from Shen et al. 2008)
Fig. 21.5 Apolipoprotein A-IV is partially co-localized with POMC in the ARC. Co-localization of apo A-IV and POMC in ARC (Reproduced from Shen et al. 2008)

in ad libitum fed rats. Even if the anorexic effect of apo A-IV is still unclear, these results provide a morphological support to the hypothesis of a direct effect of apo A-IV on melanocortin signaling, which plays a key role in animals' ingestive behavior (Woods et al. 1998) regulation in hypothalamus (Shen et al. 2008) (Fig. 21.6).

Results of this study appear consistent with previous data sustaining a regulation of apo A-IV gene expression by NPY and lipids in rats and a synergistic interaction between apo A-IV and melanocortin system. All these observations strongly support a role of this apolipoprotein in arcuate nucleus and its associated neural circuits (Liu et al. 2003; Gotoh et al. 2006).

A still unsolved issue concerns the possible effect of circulating apo A-IV, produced in the intestine and in the liver, on nutritional behavior. No studies exist that directly demonstrated that apo A-IV is able to cross the blood-brain barrier, even if Fujimoto et al. have reported an increase in cerebrospinal fluid concentration of apo A-IV after lipid administration in rats (Fujimoto et al. 1993b). According to available evidences, apo A-IV in the brain appears locally synthesized (Liu et al. 2001). Again, in Shen et al.'s study, leptin, which had been demonstrated to stimulate apo A-IV synthesis and secretion from neurons in hypothalamus, appeared able to cross the blood-brain barrier (Shen et al. 2007) (Fig. 21.7).

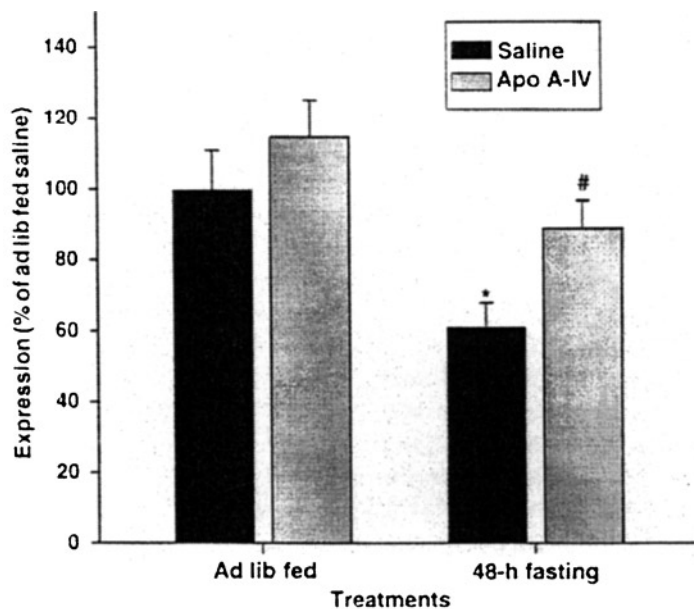
Fig. 21.6 Apolipoprotein A-IV reverses the reduction of POMC mRNA induced by fasting in animals. After 48-h fasting POMC levels were significantly reduced, but this reduction was reversed by iv administration of apo A-IV (Reproduced from Shen et al. 2008). Saline: control solution; *POMC* pro-opi-omelanocortin, *iv* intravenous


Fig. 21.7 Circulating apo A-IV does not cross the brain barrier. On *x* axis: time of exposure of animals. On *y* axis: the ratio of brain to serum over time for recombinant ^{125}I-labeled apo A-IV and ^{99}Tc-albumin. The slope of lines reflects the rate of entry which was not significantly different between apo A-IV and albumin. This was the first experimental demonstration that apo A-IV found in the brain does not come from circulating blood (Reproduced from Shen et al. 2008)
Among the different apolipoproteins assembled in gastrointestinal tract, only apo A-IV synthesis and secretion in highly stimulated, till two- to threefold, by fat absorption (Fukagawa et al. 1994). Synthesis and secretion of this apolipoprotein in intestine is regulated by circadian rhythm, bile secretion, and peptides produced in the distal tract of small intestine (Kalogeris et al. 1998).

Fujimoto et al. firstly suggested that apo A-IV might be a circulating signal released by the small intestine in response to fat feeding, and a mediator of the anorexic effect of a lipid meal (Fujimoto et al. 1992).

Further studies confirmed these findings and better described the physiological effects of acute administration of fat: according to results obtained by Rodriguez et al. in 1997, increase in plasma

Table 21.5 Increase of plasma apo A-IV levels is a marker of abnormal postprandial lipemia: a study in normoponderal and obese subjects (Verges et al. 2001)

Previous evidences	Apo A-IV is elevated in hypetriglyceridemic patients
Materials and methods	Subjects: 16 normotriglyceridemic, normally glucose tolerant android obese subjects and 30 normal weight controls
Statistical analysis	• The AUC was calculated by trapezoidal methods
	• Means were compared between two groups by Student's unpaired *t*-test and between several groups by ANOVA
	• nonparametric Mann-Whitney *U*-test when men and women were analyzed separately
	• χ^2 was used to compare frequency between controls and obese subjects
	• Multiple linear regression analyses were performed for significant independent predictors of postprandial lipemia parameters and independent predictors of fasting plasma apo A-IV levels
Purposes	To determine plasma apo A-IV and postprandial Tg levels after an OFLT
Results	• Obese patients showed increased apo A-IV levels both at fast ($p < 0.05$) and during OFLT ($p < 0.05$)
	• Fasting plasma apo A-IV significantly correlated with AUC of plasma Tg ($p < 0.001$), AUC of chylomicron Tg ($p < 0.01$) and AUC of non-chylomicron Tg ($p < 0.001$)
Conclusions	A strong link exists between fasting apo A-IV and postprandial Tg metabolism

OFLT oral fat load test, *Tg* triglycerides, *AUC* area under curve

levels of apo A-IV in response to a lipid meal was sufficiently quick and extended to produce satiety (Table 21.5) (Rodriguez et al. 1997).

The role of apo A-IV in long-term food intake control is supported by several evidences: first, intravenous administration of apo A-IV decreases food intake in rats (Fujimoto et al. 1993b); second, a link exists between food assumption and circadian rhythms of serum and lymph apo A-IV levels (Fukagawa et al. 1994), that appear independent of dietary restriction; third, intestinal production of apo A-IV is regulated by leptin and insulin (Woods et al. 1998), two hormones that play a key role in energy homeostasis.

Chronic consumption of a high-fat diet induces stimulation of apo A-IV synthesis and increases expression of apo A-IV mRNA levels in the jejunum. Probably, apo A-IV affects gastrointestinal motility and gastric acid secretion (Glatzle et al. 2004).

In humans, chronic consumption of a high-fat diet increases apo A-IV levels, but only at the beginning (i.e., during the first week) of dietary modification. These results also appear consistent with the hypothesis that apo A-IV might be subjected to a rapidly acting auto-regulatory mechanism (Weinberg et al. 1990).

Recent findings in rodents show that chronic consumption of a high-fat diet significantly reduces apo A-IV mRNA levels and the response of apo A-IV gene expression to dietary lipids in the hypothalamus (Liu et al. 2004).

21.4 Apolipoprotein A-IV and Obesity

Plasma apo A-IV levels are increased in human obesity and apo A-IV polymorphism appears associated to the extent of obesity. Lingenhel et al. have determined the effects of weight loss on plasma apo A-IV in obese adolescents and examined the relation of apo A-IV with the degree of obesity in

a longitudinal intervention study of a low-fat hypocaloric diet conducted in a dietary camp. Apolipoprotein A-IV levels before and after weight reduction and changes in plasma apo A-IV were not independently related to relative BMI, weight loss, or plasma leptin levels. Plasma apo A-IV concentration markedly decreased in overweight adolescents undergoing short-term weight reduction. The decrease was not directly related to the degree of weight loss and the mechanisms of this reduction remain to be clarified (Lingenhel et al. 2004).

In experimental studies, leptin-deficient obese (ob/ob) had reduced hypothalamic apo A-IV mRNA levels while intra-gastric infusion of a lipid emulsion significantly stimulated hypothalamic apo A-IV gene expression in lean controls, but not in obese mice with leptin deficiency. Centrally administered leptin raised the reduced apo A-IV gene expression induced by fasting. These results suggest that leptin and apo A-IV might have synergistic effects in reducing food intake. More studies are needed to investigate the mechanisms underlying obesity and/or augmented calories consumption, the differential influence of central and peripheral apo A-IV expression in animals and the relation between leptin and the responsivity of brain cells to apo A-IV (Shen et al. 2007).

With most of the required reagents available, e.g., the apo A-IV knockout and transgenic animals and apo A-IV antibodies, the next few years should bring considerable new information on the function of apo A-IV. Apolipoprotein A-IV and cholecystokinin (CCK) are peptides that act both peripherally and centrally to reduce food intake. Lo et al. examined the effects of intraperitoneal administered bolus doses of recombinant apo A-IV, CCK-8, and a combination of subthreshold doses of apo AIV and CCK on 4-h food intake in rats that were fasted overnight. Subthreshold single doses of apo A-IV (50 μg/kg) or CCK (0.06 μg/kg) alone had no effect on food intake. However, when the same doses of apo A-IV and CCK were administered together, the combination produced a significant inhibition of food intake and duration of the effect was longer than that caused by the administration of either apo A-IV or CCK alone. The satiation effect produced by CCK-8 + apo A-IV resulted attenuated by lorglumide, a CCK-1 receptor antagonist. Authors concluded that, whereas the intraperitoneal administration of doses of either recombinant apo A-IV or CCK, at or above threshold levels, reduces food intake, the coadministration of subthreshold doses of the two peptides induces significant effect on satiety probably acting via CCK-1 receptor (Lo et al. 2007).

Systemic or central administration of apo A-IV reduces food intake and body weight of rats and administration of apo A-IV antibodies has the opposite effect. Because both intestinal and hypothalamic apo A-IV are regulated by absorption of lipid but not by carbohydrate, this peptide may be an important link between short- and long-term regulators of body fat (Fujimoto et al. 1993b.)

21.5 Apolipoprotein A-IV: Applications to Other Areas of Health

21.5.1 Apolipoprotein A-IV as a Target for Pharmacological Therapy in Obesity

Actually, few studies have examined a possible role of apo A-IV as a marker of efficacy of pharmacological treatment of obesity. In a recent study by Guo et al., 17 Chinese medicinal herbs, traditionally used to treat obesity, have been tested for their potential effect on apo A-IV expression and Tg formation on intestinal cell line Caco-2/TC7 (Guo et al. 2009).

Among apolipoproteins, apo A-IV resulted as the most affected by gastric by-pass as demonstrated in a recent study by Culnan et al. This interesting observation is consistent with the effects of

Table 21.6 Apolipoprotein A-IV and pharmacological therapies that affect metabolism

Drugs	Authors	Results
Fibrates	Liu et al. (2009)	Apolipoprotein A-IV has been proposed as a possible marker of individual response to fibrates
Herbal medications	Guo et al. (2009)	17 traditional Chinese medical herbs were tested for their potentiality to increase apo A-IV and Tg
Thiazolidinediones	–	No data available
Metformin	–	No data available
Sibutramine	–	No data available
Orlistat	–	No data available
Rimonabant	–	No data available

apo A-IV on satiety and with the fact that patients undergoing bariatric surgery commonly experience an augmented sensation of satiety. Since apo A-IV is mainly expressed in the duodenum and in the first tract of the small intestine, which are by-passed by this surgical procedure, other factors were examined by authors. In this field, many open issues are still unsolved, and more studies are needed to define the role of changes in apo A-IV after surgery (Culnan et al. 2008).

To our knowledge, no studies are available that directly examined changes in apo A-IV levels after administration of commonly used antiobesity drugs such as orlistat and sibutramine.

There are recent findings sustaining a direct relation between apo A-IV and postprandial hypertriglyceridemia, that is an established cardiovascular risk factor in humans (Verges et al. 2001). Apolipoprotein A-IV expression is one of the mechanisms underlying decrease of Tg and elevation of HDL observed with PPAR-α agonist treatment (Nagasawa et al. 2009). Some authors suggest that genetic variants of APOA1/C3/A4/A5 gene cluster may be useful markers to predict response to a lipid-lowering therapy with fenofibrate. Further studies to replicate and to confirm these results are warranted (Liu et al. 2009) (Table 21.6).

Key Points

- Apolipoprotein A-IV is produced in the small intestine and the liver in rodents and only in the small intestine in humans. Recently apo A-IV has been detected also in the hypothalamus of experimental animals, and its concentration in brain cells is influenced by food deprivation.
- Apolipoprotein A-IV is involved in lipid metabolism.
- Apolipoprotein A-IV plays a role in lipoproteins metabolism even if this issue has been better studied in experimental animals.
- Apolipoprotein A-IV secretion and concentration are regulated by hormones, circadian rhythms, food, and particularly by lipids intake.
- Amounting evidences are available sustaining a key role of apo A-IV in regulation of food intake and satiety.
- An anti-atherogenic role of apo A-IV has been suggested according to the results of recent experimental studies.

Chapter 22
Brain Histamine Affects Eating and Drinking Behaviours

Leonardo Munari and Maria Beatrice Passani

Abbreviations

2-AG	2-Arachidonoylglicerol
ADH	Antidiuretic hormone
BAT	Brown adipose tissue
cGMP	Cyclic guanosine monophosphate
CNS	Central nervous system
FEO	Food-entrainable oscillator
GABA	Gamma-aminobutyric acid
GLP-1	Glucagon-like peptide 1
LH	Lateral hypothalamus
NAcc	Nucleus accumbens
PVN	Paraventricular nucleus
TMN	Tuberomammillary nucleus
TRH	Thyrotropin releasing hormon
Ucp-1	Uncoupling protein 1
VLPO	Ventrolateral preoptic area
VMH	Ventromedial hypothalamus

22.1 Introduction

In the early 1980s two major discoveries convinced the scientific community of the existence of a central histaminergic system and contributed to the understanding of its many functions. Immunohistochemical studies demonstrated the localization of histaminergic neurones in the tubero-mammillary nuclei of the posterior hypothalamus with projections to almost all parts of the brain (Panula et al. 1984; Watanabe et al. 1984), and pharmacological studies proved the existence of a novel histaminergic autoreceptor, the H_3 receptor (Arrang et al. 1983). A plethora of neuro-pharmacological and behavioural studies ensued and it soon became clear that brain histamine affects a variety of homeostatic regulatory functions such as circadian rhythms, neuroendocrine secretion,

food intake, body weight and drinking. Furthermore, it was soon proven that histamine-containing neurones constitute a major wake-promoting system because their terminals influence neuronal excitability in distinct brain regions. Wakefulness is a prerequisite for learning and memorising salient events, but there is ample evidence that the histaminergic system affects cognitive functions per se. These observations are relevant for feeding behaviour, both for food searching and food consumption, as the ability to remember the context associated with food availability or the palatability of the food eaten provides a clear adaptive advantage to animal foraging. Hence, brain histamine does not only provide a satiety signal released during eating that might integrate postprandial messages conveyed from peripheral tissues (e.g. leptin), but it is important in setting up circadian homeostatic functions that create the expectations for a meal and coordinate food searching strategies. In other words, evidence indicates that histaminergic neurones control both the appetitive, or food searching, behaviour and the consummatory phases of feeding. However, very few experiments have dealt with this issue. The association of histamine with feeding behaviour became clear when it was observed that antidepressants and antipsychotics stimulate appetite and induce weight gain and that these drugs are potent H_1 receptor blockers. Indeed, early studies showed that intracerebral injections of histamine depressed the feeding behaviour of rats (Clineschmidt and Lotti 1973), while microinjections of the histaminergic H_1 receptor antagonists in the ventromedial hypothalamus (VMH) elicit feeding. Recent observations, though, indicate that histamine release during feeding is better interpreted in the context of appetitive rather than the consummatory phase of feeding behaviour (Meynard et al. 2005).

We now know that brain histamine is involved in feeding physiology by modulating the release of neurotransmitters and hormones that drive or inhibit feeding (Toftegaard et al. 2003). In addition, to exert their orexigenic or anorexigenic effects, hormones and peptides require an intact histaminergic system. Hence, in addition to having an effect on food intake, brain histamine regulates body weight by modulating peripheral energy metabolism in rodents. Also, compulsive eating in *anorexia nervosa*, bulimia, or binge-eating syndrome likely relates to histamine effects on brain reward systems and learning circuits and their dysfunction in addiction.

22.2 Histamine as a Central Neurotransmitter

Like the other biogenic amine neurotransmitter systems (noradrenaline, dopamine and serotonin), the somata of histamine-containing neurones are localised in a discrete brain region in the posterior hypothalamus, the tuberomammillary nuclei (TMN; Fig. 22.1). Histaminergic neurones project throughout the brain, including the VMH and the infralimbic cortex, two brain regions involved in different aspects of feeding behaviour. Histaminergic neurones appear a rather homogenous cell group and for a long time they have been thought of as a regulatory network for whole brain activity through diffuse and overlapping projections (Kohler et al. 1985) (Inagaki et al. 1990). Recent evidence, though, shows that histaminergic neurones are not homogenous, as only subgroups respond to different types of stress (Miklos and Kovacs 2003) or *hypercapnic* loading (Haxhiu et al. 2001). Neuroanatomical studies have shown differences in size and shape, in the complement of intracellular components such as histamine vescicular monoamine transporter, neurotransmitters like gamma-aminobutyric acid (GABA) or galanin (Kukko-Lukjanov and Panula 2003), and in their sensitivity to GABA (Sergeeva et al. 2002). Anatomical experiments did not demonstrate a topographical mapping of histaminergic projections as it is the case, for instance, for the dopaminergic system, but recent findings demonstrated that the histaminergic system is organized into distinct functional circuits that may contribute to the diverse roles played by brain histamine in feeding homeostasis, arousal and procognitive effects (Giannoni et al. 2009).
Fig. 22.1 Sagittal, schematic representation of the rat histaminergic systems. The somata of histaminergic neurons are located in the posterior hypothalamus, in the tuberomammillary nucleus (*TMN*). Histaminergic fibers project to the whole brain. *CX* cerebral cortex, *OB* olfactory bulb, *LS* lateral sulcus, *VDB* ventral diagonal band, *MD* mediodorsal nucleus, *AH* amygdalo-hippocampal area, *SOX* supraoptic chiasm, *VMH* ventral medial hypothalamus, *CG* cingulate gyrus, *DR* dorsal raphe, *Cer* cerebellum, *Pn* peduncular nucleus, *CC* corpus callosum, *Hip* hippocampus

Hypothalamic histamine neurones receive inputs from the cortex, the septum and other hypothalamic areas. The infralimbic, frontal cortex provides the principle cortical input to the TMN (Wouterlood et al. 1987) and lesion studies demonstrated that the activation of this pathway is important to determine the behavioural arousal that accompanies the appetitive behaviour in rats (Valdés et al. 2006).

22.3 Histamine and Wakefulness

The histaminergic neurones in the TMN are *pacemakers*, they fire at a slow regular rate that can vary depending on the behavioural state (Haas and Panula 2003). Direct recordings of these neurones in freely moving cats indicate that their activity is high during waking and attention, and low or absent during sleep (Lin et al. 1994). The inhibition during sleep is thought to be mediated mainly by GABA innervation from the ventrolateral preoptic area (VLPO) a brain region that shows high activity during slow-wave sleep. Indeed, the histaminergic system is part of a neuronal organization that regulates biological rhythms, integrating the inputs and the activity of wake-promoting systems (reviewed in Haas et al. 2008). Together with the cholinergic, serotonergic, adrenergic and orexinergic cells, histaminergic neurones form a wake-promoting system named the ascending arousal system, where each cell group contributes in a unique way to the onset or maintenance of wakefulness. Histamine regulates the sleep-wake cycle through projections to the suprachiasmatic nucleus, the centre of the biological clock and contributes to cortical activation and wakefulness by activating cholinergic corticopetal neurones originating in the basal forebrain (Lin et al. 1994). TMN neurones also excite cholinergic cells in the mesopontine tegmentum that project to the thalamus and hypothalamus, which in turn affect cortical excitability (Lin et al. 1996). More precisely, the activity of histaminergic neurones plays an important role, not so much in the induction of wakefulness *per se*, but in the maintenance of the high level of vigilance necessary for cognitive processes. Conversely, cessation of their activity seems to be important in both the initiation and maintenance of sleep (Takahashi et al. 2006) (Table 22.3).

The importance of histaminergic neurones in maintaining the brain in a wake state when challenged by environmental demands was demonstrated in mice lacking either histidine decarboxylase (the histamine synthesizing enzyme) (Parmentier et al. 2002) or the histamine H_1 receptor (Parmentier et al. 2006). Indeed, the abolition of histamine synthesis or one of its effector mechanisms impairs the cortical electroencephalogram and deteriorates both sleep and waking quality, thus causing somnolence and behavioural deficits. Histamine is also involved in regulating the maintenance of the circadian rhythm. Histamine deficiency leads to a lowered activity level, disrupts circadian rhythm of the clock genes *mPer1* and *mPer2* expression in the neocortex and striatum, but not in the circadian pacemaker suprachiasmatic nucleus, suggesting that histamine modulates the output behaviour of the circadian pacemaker (Abe et al. 2004). Furthermore, the activity of histaminergic cells is important for maintaining a high level of arousal during demanding tasks such as food searching (Meynard et al. 2005). Thus, the histaminergic system is a good candidate to link the sleep-wake cycle and feeding habits. Indeed, reversible depletion of brain histamine enhances food-associated locomotor activity only in the circadian phase during which histamine is high (reviewed in Haas et al. 2008). These observations are relevant to understanding feeding disorders in humans, as several studies demonstrated that disruption of the circadian rhythm of feeding behaviour often accompanies obesity in animal models and in patients.

22.4 Histamine and Cognition

It is known that manipulation of the histaminergic central system during several learning paradigms modifies animal behaviour; however, the results are often contradictory, as both facilitatory and inhibitory effects of histamine on memory have been described (Passani et al. 2004). This is not too surprising, as memory is a complex process that consists of related, but dissociable events, involving distinct brain regions activated to different degrees and at different times to elaborate disparate learning situations. The specificity of action of histamine depends on the localization of histaminergic receptor subtypes, the brain region and the nature of the cognitive task involved, and the activation of specific intracellular pathways. Hence, activation of selected histaminergic circuits may be important to consolidate temporal and spatial information associated with food availability and consumption and to coordinate appetitive and consummatory behaviours.

22.5 Histamine in Feeding and Energy Metabolism

The participation of the histaminergic system in regulating food intake has been known for many years (Fig. 22.2). Early studies showed that treatments increasing histamine availability in the central nervous system (CNS) of rats and mice suppressed food intake, in contrast administration of compounds that decreased central histamine increased food consumption. Brain histamine not only affects food intake, but studies in rodents showed that it apparently regulates body weight and adiposity by modulating peripheral energy. One of the markers of energy expenditure is *Uncoupling protein 1* (Ucp1) in brown adipose tissue (BAT), the expression of which is regulated by humoral and neuronal factors. The central administration of histamine or H_1 receptor agonist increases the expression levels of BAT Ucp1 mRNA in rodents, the central administration of histamine or the H_3
Fig. 22.2 Schematic drawing of the hypothesized action of hypothalamic histamine neurons in feeding behaviour. Glucagon-like protein-1 (*GLP-1*) regulates histamine neurons in the TMN via GLP-1 receptors expressed on CRH neurons and histamine suppresses food intake via H1-receptors expressed on feeding-related neurones in the PVN and the VMH. Leptin stimulates histamine neurons via leptin receptors (Ob-Rs) expressed on GLP-1 and CRH neurons. *HA* histamine, *H1r* histamine H1 receptor, *NTS* nucleus of the solitary tract, *PVN* paraventricular nucleus, *TMN* tuberomammilary nucleus, *VMH* ventromedial hypothalamic nucleus

receptor antagonist thioperamide increases the lipolytic response in rodents white adipose tissue and pretreatment with a β-receptor antagonist, blocks the thioperamide-induced response suggesting that the effect is mediated by sympathetic nerves that innervate white adipose tissue (reviewed in Masaki and Yoshimatsu 2006). Brain histamine also inhibits the development of obesity in both diet-induced and *db*/*db* obese mice (Masaki and Yoshimatsu 2006). These mice are hyperleptinemic, develop obesity and severe type 2 diabetes partly due to a functional defect in a leptin receptor. Hence, all these findings support the notion that the histaminergic system regulates adiposity by affecting both food intake and energy expenditure in rodents. Another site implicated in food intake is the mesencephalic trigeminal nucleus, as mastication activates histaminergic neurones (Sakata et al. 2003) that in turn suppress food intake through H_1 receptor activation in the paraventricular nucleus (PVN) and VMH.

22.6 Histaminergic Receptors

As a neurotransmitter, histamine interacts with four known receptor subtypes each of which has been sequentially cloned (Fig. 22.3). Histamine receptors H_1, H_2, H_3, are densely expressed in the brain. The expression of the fourth histaminergic receptor (H_4, which was initially described only in peripheral tissues such as the bone marrow and leukocytes) is restricted to some regions in the rat brain, such as the cerebellum (Strakhova et al. 2009). The histaminergic receptors differ in their signal transduction pathways, CNS distribution, and function and pharmacological properties of their
Fig. 22.3 Histamine-mediated transmission and cellular mechanisms involved in arousal and feeding behaviour. Activation of histamine H1 or H2 receptors increases cell activity and excitability by decreasing the background K+ leakage current (IKL) or the after hyperpolarization current (IAHP) or by increasing the hyperpolarization-activated cation current (IH). H3 auto- and heteroreceptors are involved in arousal and feeding behaviour regulation by modulating the release or synthesis of histamine and other neurotransmitters. Histamine also interacts with the H4 receptor that was recently found to be expressed in the brain. *AC* adenylyl cyclase, *HDC* histidine decaborxylase (Modified from Passani et al. 2004)

agonists and antagonists. Histamine excites neurones in most brain regions through H_1 receptors and selective H_1 agonists stimulate vigilance and alertness, in contrast to the all-too-well-known sedative effects of centrally acting H_1 receptor antagonists.

The H_1 and H_3 receptors are important for regulating feeding, whereas the H_2 receptor does not have any effect. The H_1 receptor transduction signal is typical of and convergent with that of other $G\alpha q/11$ protein-coupled receptors including activation of phospholipase C. Other effector pathways of the H_1 receptor include production of arachidonic acid, nitric oxide, and cyclic guanosine monophosphate (cGMP) via pertussis toxin–sensitive Gi/Go protein-mediated activation of phospholipase A2, $[Ca^{2+}]_i$-dependent nitric oxide synthase, and nitric oxide–dependent guanylate cyclase, respectively. The H_1 receptor activates AMP-kinase, a checkpoint in the control of energy metabolism and food intake (reviewed in Haas et al. 2008). When postsynaptic H_1 receptors are activated within the VMH, food intake is inhibited, whereas H_1 receptor antagonists block this effect. Indeed, orexigenic atypical antipsychotic drugs stimulate hypothalamic AMP-kinase pathways potently, reverse the action of the anorexigenic hormone leptin and these effects require the activation of H_1 receptors (Kim et al. 2007). Hence the weight gain induced by atypical neuroleptics requires the integrity of the brain histaminergic system. Unfortunately, no CNS penetrating nor CNS selective H_1 receptors agonists are currently available, that would have anti-obesity effects. Infact, from a therapeutic perspective, the challenge exists of identifying potent H_1 receptor agonists to be delivered selectively to the CNS without activating peripheral H_1 sites that could lead to severe cardiovascular, respiratory, or gastrointestinal side effects.

H_3 receptors are located on histaminergic and other cell somata, dendrites and axons, where they provide negative feedback to restrict histamine synthesis and release, and the release of other transmitters, such as serotonin, acetylcholine and noradrenaline, some of which have important roles in appetite or mood (e.g. serotonin). Blockade of H_3 autoreceptors enhances CNS histamine release from histaminergic neurones and several preclinical studies indicate that H_3 receptor antagonists causes changes in food consumption and body weight (Hancock and Brune 2005). Hence, a proposed alternative strategy to H_1 activation to treat obesity is afforded by the blockade of H_3 receptors, provided the effects of presynaptic, H_3 heteroreceptor activation and ensuing enhancement of various neurotransmitters do not interfere (but see below). The cloning and functional expression of the H_3 receptor paved the way to the discovery of several splice variants and signal transduction mechanisms, and a variety of H_3 *receptor isoforms* from several species that show differential CNS expression has been reported (Drutel et al. 2001). Stimulation of the H_3 receptor activates several intracellular pathways including $G_{i/o}$-dependent inhibition of adenylate cyclase, activation of the antiapoptotic Akt/GSK-3β pathway (Mariottini et al. 2009), activation of phospholipase A_2, as well as inhibition of the Na^+/H^+ exchanger, and of K^+-induced Ca^{2+} mobilization (Leurs et al. 2005). Splice variants of the H_3 receptor may couple preferentially to different signal transduction pathways and have varying distribution within the CNS (Drutel et al. 2001). H_3 receptors are constitutively active, which implies that antagonists of H_3 receptors may also function as inverse agonists to alter the basal state of the receptor and uncouple constitutive receptor-G-protein interactions. To add to their complexity, H_3 receptors exhibit different pharmacological characteristics at multiple levels.

22.7 Is Hypothalamic H_1 Receptor Activation a Satiety Signal?

Remarkably consistent evidence supports a role of brain histamine in food intake and energy metabolism. In rodents' CNS, activation of H_1 receptors regulates the diurnal rhythm of feeding and modulates peripheral energy metabolism (Table 22.1). The preferential site of histamine-mediated suppression of food intake in the mammalian brain is likely the VMH, a prominent satiety centre. When postsynaptic H_1 receptors are activated within the VMH food intake is inhibited and H_1 receptor antagonists block this effect. On the other hand, microinfusions of H_1 antihistamines into the VMH, but not other hypothalamic nuclei such as the PVN or lateral hypothalamus (LH), elicit feeding responses and increases both meal size and duration (Fukagawa et al. 1989). In accordance to pharmacological manipulation of the H_1 receptors, genetically modified mice that do not express H_1 receptors exhibit an increase in daily food consumption and visceral adiposity (Masaki et al. 2004). In humans, atypical antipsychotics such as olanzapine stimulate appetite most probably through H_1 receptor signalling, although relatively few studies in humans have been carried out to unequivocally establish a relationship between food consumption and H_1 receptors activation.

22.8 H_3 Receptors and Feeding Behaviour: Controversial Findings

The growing interest in the histaminergic H_3 receptor as a potential target to develop anti-obesity drugs, stems from the unavailability of selective H_1 receptor agonists devoid of peripheral action. As already mentioned, the use of compounds that enhance histamine release from nerve terminals such as H_3 receptor antagonists, may afford an effective therapeutic alternative. The role of H_3

Table 22.1 Activation of histaminergic receptors regulates the diurnal rhythm of feeding and modulates peripheral energy metabolism

Drug	Class	Effect	Reference
Histamine and H_1 agonist	HA agonist	Increases expression levels of BAT *Ucp 1* mRNA in rodents (marker of energy expenditure)	Masaki and Yoshimatsu (2006)
Mepyramine	H_1 antagonist	Increases food intake and decreases water intake	Magrani et al. (2004)
Chlorpheniramine	H_1 antagonist	Increases food intake and decreases water intake (light phase)	
Chlorpheniramine	H_1 antagonist	Elicites feeding behaviour, increases deambulation. No effect on water intake	Fukagawa et al. (1989)
Prometazine		Elicites feeding behaviour	
Mepyramine		Elicites feeding behaviour	
Chlorpheniramine	H_1 antagonist	Bilateral injections into VMH elicit feeding behaviour; Bilateral injection into LH; no effect; Bilateral injection into PVN; no effect	Sakata et al. (1988)
Thioperamide	H_3 antagonist	Decreases food intake and does not affect water intake (dark phase)	Doi et al. (1994)
Immepip	H_3 agonist	Elicits feeding behaviour	Chiba et al. (2009)

The brain histaminergic system modulates food consumption and energy metabolism. The table lists some of the seminal papers that demonstrated the role of brain histamine controlling food intake and drinking

receptor ligands in the treatment of metabolic diseases, though, is still unclear as results from different studies are inconsistent, which is understandable in sight of the above mentioned complexity of the H_3 receptor.

Most experimental observations in rodents seem to agree that blockade of brain H_3 receptors is beneficial in decreasing energy intake, body weight and plasma triglycerides (Hancock and Brune 2005) (Table 22.1). Indeed, several studies have shown that H_3 receptor antagonists increase histamine release from the hypothalamus and reduce energy intake in normal and leptin-resistant mice with diet induced obesity (Ishizuka et al. 2008). In addition, the administration of H_1 receptor antagonists attenuates the feeding suppression induced by H_3 antagonists (Hancock and Brune 2005).

Not all data, though, support an appetite-suppressant effect of H_3 receptor blockade. A recent report showed that in diet-induced obese mice, an H_3 receptor agonist suppresses food intake and decreases body weight, presumably with a mechanism independent of histamine release modulation (Yoshimoto et al. 2006). Also, H_3-receptor-deficient mice manifest disrupted regulation of body weight, energy expenditure and food intake. H_3 receptor deletion produced obese hyperphagic mice with reduced energy expenditure, which resembles the phenotype of H_1-receptor-deficient mice (Takahashi et al. 2002). Why then, does deletion of the H_3 receptor induce hyperphagia with reduced energy expenditure in mice? One possible explanation hypothesised by the authors is that a concomitant downregulation of the H_1 receptor in the hypothalamus of H_3-receptor-deficient mice leads to hyperphagia and obesity. It is clear that the effects of H_3 receptors modulators on food consumption and metabolism are more complex and not only mediated by histamine release, but they are regulated

through a variety of receptors and neurotransmitters and may be responsible for the discrepancies described above.

Given the substantial differences of the preclinical outcome, considerable experimental effort remains necessary to prove the so far unclear concept of H_3 receptor antagonists in the treatment of obesity and weight gain. Certainly, the general profile of the more recently synthesized H_3 receptor ligands suggest that they may offer clinical advantages over currently used drugs or those used in the past for treating obesity. Considering the abuse and addiction of amphetamines for instance, H_3 receptor antagonists lack stimulant and sensitization properties (Fox et al. 2003) and tend to show a gradual and prolonged decrease in body weight in contrast to the rapid and often quickly waning effect of other anti-obesity drugs. In this regard, clinical trials phase II with H_3 receptor antagonists are underway for the treatment of other neurological pathologies, namely, narcolepsy and photo-induced epilepsy.

22.9 The Relationship Between Histamine and Some Peptides That Control Feeding Behaviour

Several peptides function as satiety or hunger signalling molecules in the hypothalamus. These hypothalamic systems that regulate energy balance and food intake have a prominent role in the development of obesity. Peptides such as orexin/hypocretin, leptin, glucagon-like peptide 1 (GLP-1) and thyrotropin releasing hormone (TRH), exert their orexigenic or anorexigenic effect through, at least in part, the histaminergic system (Table 22.2).

Orexin/hypocretin-containing neurones intermingle partially with histaminergic neurones in the posterior hypothalamus and together they represent a functional entity. Orexinergic neurones maintain wakefulness, particularly in the context of metabolic challenges, and presumably are responsible for preventing unwanted frequent transitions between behavioural states (Saper et al. 2005). There is a close and reciprocal anatomical connection between histaminergic and orexin neurones and orexin strongly excites TMN neurones (Eriksson et al. 2001). Perfusion of orexin A into rats TMN increases wakefulness (Huang et al. 2001) and stimulates food intake (Jørgensen et al. 2005), effects that depend on an intact histaminergic neuronal system and seems to involve a mechanism mediated by

Table 22.2 The relationship between histamine and some peptides that control feeding behaviour

Peptide	Class	Effect	Reference
TRH (thyrotropin-releasing hormone)	Anorexigenic hormone	Decreases food intake	Gotoh et al. (2007)
Orexin-A	Orexigenic peptide	Increases histamine release	Huang et al. (2001) and Jørgensen et al. (2005)
Ghrelin	Orexigenic peptide	Increases food intake Stimulates food intake	
Glucagon-like peptide-1 (GLP-1)	Anorexigenic peptide	i.c.v. injection of GLP-1 decreases food intake and increases histamine content into TMN	Gotoh et al. (2005)
Leptin	Adipocyte-derived peptide	Decreases food intake and decreases hypothalamic histamine content	Toftegaard et al. (2003)

The table lists some of the seminal papers that demonstrated the role of brain histamine in mediating the orexigenic and anorexigenic effect of some hormones

Table 22.3 Key features of histamine

1. Brain histamine regulates the circadian wake-sleep cycle in concert with other neurotransmitter systems, maintains the brain in a vigilant state, controls feeding homeostasis and cognitive processes.
2. As a neurotransmitter, histamine interacts with four known receptor subtypes each of which has been sequentially cloned and is expressed in the brain.
3. Activation of the histaminergic H_1 receptor subtype regulates the diurnal rhythm of feeding and modulates peripheral energy metabolism.
4. In humans, antihistamine drugs used to treat allergies block the H_1 receptors and have a sedative effect.
5. Atypical antipsychotics have sedative effects and stimulate appetite most probably through H_1 receptor signalling.
6. Brain histamine also regulates diuresis with mechanisms independent of food intake regulation.
7. Currently, no histaminergic compounds have entered clinical trials to regulate feeding disorders. Preclinical studies though are providing promising results that may soon lead to the therapeutic applications of brain penetrating histaminergic ligands.

This table lists the key facts of brain histamine and its relevance in controlling homeostatic functions such as sleep, arousal, feeding and drinking behaviours

Table 22.4 Key features of circadian rhythms

1. A circadian rhythm is defined as the cyclical 24-h period of animal biological activity.
2. The circadian cycle is controlled by a region of the brain known as the hypothalamus, which is the master centre for integrating rhythmic information and establishing sleep patterns.
3. A hypothalamic region receives signals about light and dark from the eye.
4. During the wakeful hours, mental and physical functions are most active.
5. During sleep, voluntary muscle activities almost disappear and there is a decrease in metabolic rate, respiration, heart rate, body temperature and blood pressure.
6. The circadian cycle can alter the effectiveness of some drugs. The administration of hormonal drugs, for instance, must follow the natural circadian rhythm of hormone production.

This table lists the key facts of circadian rhythms

H_1-receptor. In contrast to various other genetically modified mice, H_1 receptor knock-out mice have lower orexin levels (Table 22.4).

The interaction between the histaminergic and orexinergic systems is of clinical relevance, as orexin deficiency causes *narcolepsy*, which combines sudden loss of muscle tone with maintenance of environmental awareness. In this pathological condition, histamine neurones are the only monoaminergic cells of the ascending arousal system to remain active during cataplegic attacks in narcoleptic orexin-2 receptor-deficient dogs, suggesting that activity in histamine cell groups is strongly linked to forebrain arousal, rather than motoractivity (John et al. 2004).

Leptin provides a satiety signal linking peripheral adiposity levels to the regulation of energy homeostasis in the brain. Leptin affects feeding behaviour partially by activating histamine-containing neurones and H_1 receptors. Indeed, the administration of α-fluoromethylhistidine, an inhibitor of histidine decarboxylase, the histamine synthesising enzyme, in rats and mice decreases the leptin-induced suppression of food intake (Yoshimatsu et al. 1999). Also, in H_1 receptor–deficient mice leptin-induced hypofagia is diminished, and leptin deficient, *ob/ob* mice have lower histamine turn over (Yoshimatsu et al. 1999).

TRH is secreted by neurones in the PVN, it suppresses food intake, directly activates the majority of TMN neurones (Parmentier et al. 2009) and increases histamine turnover (Gotoh et al. 2007). In food-deprived, H_1-receptor knock-out mice and histamine-depleted rats, TRH-induced suppression of feeding is significantly attenuated (Gotoh et al. 2007).

Glucagon-like peptide 1 is produced by and released from intestinal L-cells in response to dietary fat and carbohydrate and is also expressed in the nucleus of solitary tract and ventrolateral medulla

of the brainstem. GLP-1 reduces food intake by inhibiting gastric emptying, increasing satiety through central actions and by suppressing glucagon release. Hypothalamic neuronal histamine partially mediates the GLP-1-induced suppression of feeding behaviour, as its anorexigenic effects are blunted by pharmacological or genetic loss of H_1 receptors function (Gotoh et al. 2005).

All together, these observations further prove the intricacy of the histaminergic system as a regulator of food intake, and energy metabolism, as both orexigenic and anorexigenic effects of endogenous molecules appear to necessitate the integrity of the histaminergic system.

22.10 Histamine, Endocannabinoids and Feeding Behaviour

There is convincing evidence that both exogenous and endogenous cannabinoids such as anandamide and 2-arachidonoylglicerol (2-AG) stimulate feeding. Their action is mediated by activation of CB1 receptors distributed in all brain areas and peripheral tissues involved in the control of energy intake, including the hypothalamus and nucleus accumbens (NAcc; reviewed in Matias et al. 2006). This effect is of therapeutic relevance, as cannabinoid agonists are currently used to alleviate anorexia and nausea in AIDS patients.

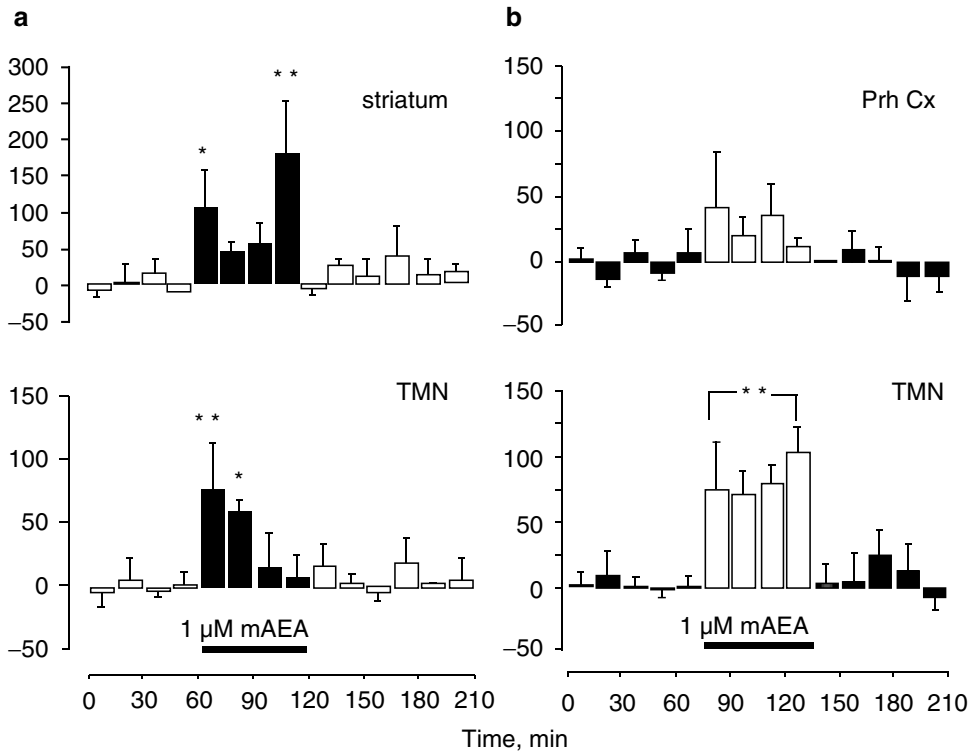
It has been suggested that brain endocannabinoids control energy balance both in the appetitive phase, increasing the incentive to find food, and during the consummatory phase, increasing appetite, but the mechanisms involved remain to be elucidated. Recent evidence indicates that both the *mesolimbic reward* mechanism and the homeostatic hypothalamic nuclei are involved in these two aspects of feeding behaviour. Endocannabinoid levels vary in the hypothalamus and limbic forebrain with different nutritional manipulations, with levels being the highest with food deprivation and lowest during food consumption (Kirkham et al. 2002). Furthermore, either 2-AG injections in the shell of the NAcc (Kirkham et al. 2002), or anandamide administration into the VMH-induce hyperfagia (Jamshidi and Taylor 2001). In some aspect, the histaminergic and endocannabinoid systems seem to be regulated in an opposing fashion: for instance, systemic administration of leptin that signals to the hypothalamus the nutritional state and reduces food intake, facilitates histamine release from the hypothalamus (Morimoto et al. 1999), whereas it downregulates endocannabinoids levels in the same region (DiMarzo et al. 2001). Furthermore, concentrations of hypothalamic histamine and tele-methylhistamine, a major histamine metabolite, are significantly lower in obese (*ob*/*ob*) and diabetic (*db*/*db*) mice, and fatty (*fa*/*fa*) rats, leptin-deficient and leptin-receptor-defective animals, respectively, relative to lean littermates (Itateyama et al. 2003). On the other hand, defective leptin signalling is associated with elevated hypothalamic levels of enocannabinoids in obese *db*/*db* and *ob*/*ob* mice and Zucker rats. In conclusion, for both histamine and endocannabinoids the mechanisms involved in regulating food intake are not fully understood and nothing is known about the temporal and causal relationship between these two systems in controlling feeding behaviour. We recently began to address these questions studying the effect of systemic and intra-hypothalamic administration of selective CB1 receptor agonists on histamine release from several brain regions of the rat brain, with the double-probe microdialysis technique in freely moving rats (Cenni et al. 2006). Unexpectedly, CB1 receptor agonists increase histamine release in some, but not all areas tested (Fig. 22.4). The question arises then, if and where in the brain the endocannabinoids and the histaminergic system interact and whether these interactions are involved in feeding behaviour. Understanding in what circumstances endocannabinoids are released and activate histaminergic cells may provide interesting hints to develop new therapeutic strategies in the treatment, for instance, of food intake disorders.


Fig. 22.4 Effect of intra TMN administration of the CB1 receptor agonist mAEA in different brain regions of freely moving animals. Results obtained from double-probe microdialysis experiments in freely moving rats. (**a**) Administration of the CB1 receptor agonist mAEA into TMN significantly increased histamine content in both the TMN and the striatum. In contrast (**b**), mAEA perfused into TMN increased the local release of histamine, but did not histamine release in the Prh Cx. ** $p < 0.01$, *p < 0.05 relative to basal level; ANOVA and Dunnett's post hoc test. *mAEA* R(+)-methanandamide, *Prh Cx* perirhinal cortex, *TMN* tuberomammilary nucleus (Modified from Passani et al. 2007)

22.11 Anticipatory and Consummatory Phases of Feeding Behaviour

The observations presented so far make it clear that histamine controls heterogeneous aspects of feeding and, presumably, histamine drives food intake by increasing the arousal state of the animal (Valdés et al. 2005). Secondary to arousing the animal, brain histamine seems to coordinate satiety and the consolidation of temporal information associated with food consumption. Infact, nowadays it is generally accepted that histamine does more than only mediating satiety. Recently, it has become clear that food-anticipatory activity exhibits the characteristics of a circadian rhythm, although determining the anatomic location of the food-entrainable oscillator (FEO) has been very difficult.

Histamine drives feeding anticipating arousal, an important actor in the FEO, and is probably involved in numerous other feeding-related processes such as temperature and locomotion changes. In fact, while the effects of the histaminergic system in the modulation of the consummatory phase of feeding have been shown to be robust although sometimes contradictory, the role of histamine in the appetitive phase and underlying behavioural mechanisms remains unclear. The appetitive phase of motivated behaviours has distinctive preparatory physiological changes, such as increases in behavioural arousal (Pfaff et al. 2002) and core temperature (Valdés et al. 2005). Therefore, the histaminergic system is a good candidate to promote arousal during the appetitive state. Indeed, histamine-containing neurones are the only aminergic cells related to arousal that become active in

anticipation of an upcoming meal, as rats rendered motivated for food by 24-h fasting and enticed with food that they cannot obtain, show a significant increase in the early gene marker of activated neurones *c-Fos* immunoreactivity in the TMN, much earlier than in other brain regions (Meynard et al. 2005). Recent reports demonstrated that the infralimbic cortex that receives visceral information and coordinates motivated behaviour (Hok et al. 2005), and the TMN are activated in a coordinated temporal way during the appetitive responses to food enticing (Valdés et al. 2006).

Histamine neurones may participate in the appetitive aspects of feeding also modulating reward processes involved in the motivation to feed. The shell of the nucleus NAcc (a reward related brain area) receives a dense histaminergic innervation and local administration of histamine into the NAcc enhances dopamine release (Galosi et al. 2001). The role of histamine in reward-related processes, though, is controversial, as both inhibitory and facilitatory effects have been described (Hasenöhrl et al. 2001; Wagner et al. 1993), and nothing is known on the role of this pathway during feeding behaviour.

22.12 Histamine and Fluid Intake

The role of histamine in diuresis has been extensively studied with mechanisms independent of food intake regulation and has been reviewed extensively elsewhere (Haas et al. 2008). Injection of histamine into the cerebral ventricles or into several hypothalamic sites elicits drinking in rats and evokes antidiuresis (Leibowitz 1973). This effect is mediated by activation of H_1 receptors that stimulates neurones in the supraoptic nucleus to release the antidiuretic hormone (ADH) (Knigge et al. 1999). The release of ADH causes antidiuresis and renal sympathetic activation. In addition, AVP release is stimulated indirectly via histamine-induced local release of norepinephrine (Bealer and Abell 1995). Prolonged (24 or 48 h) dehydration increases synthesis and release of histamine in the hypothalamus (Kjaer et al. 1995). Pharmacological blockade of histamine synthesis, activation of presynaptic H_3 autoreceptors, or antagonism of postsynaptic H_1 receptors and H_2 receptors strongly depress dehydration-induced vasopressin release (Kjaer et al. 1995). Indeed, acute functional blockade of central H_3 receptors is often demonstrated by blocking the *dipsogenia* response to selective H_3 receptors agonists (Fox et al. 2005).

22.13 Concluding Remarks

Our knowledge of the functional roles of brain histamine is far from complete. It is clear that the hypothalamic histamine neurones are involved in basic brain and body functions linking behavioural state and biological rhythms with vegetative and endocrine control of body weight and temperature. For as much as it may seem that the role of the histaminergic system is redundant in modulating the sleep–wake cycle, it is becoming clear that histamine in the brain finely orchestrates diverse aspects of behavioural responses that require an aroused state. Histamine plays a major not only in many homoeostatic mechanisms, among which the regulation of energy expenditure, but also in higher integrative brain functions. Novelty-induced attention and arousal are of major importance for adaptation to changing environments by comparing new information with the recollection of past events. This has a major impact on feeding behaviour, as histamine supposedly drives food intake by increasing the arousal state of the animal, and secondary to arousing the animal, it coordinates satiety and the consolidation of temporal information associated with food consumption. Augmented

histamine release is also an indicator of stress and disrupting the spatiotemporal specificity of histamine release may contribute to maladaptive behavioural responses.

In conclusion, the all-too-long-neglected histaminergic system is raising interest in the scientific community in light of its role in enabling the organism to cope with environmental challenges and novelty, and in the physiology and pathophysiology of central nervous disorders, among which dysfunctions of metabolism and feeding behaviour.

22.14 Applications to Other Areas of Health and Disease

The control that histamine exerts on appetite, feeding rhythms and energy metabolism may be relevant in eating disorders and metabolic syndromes. Compulsive eating, anorexia, bulimia may relate to maladaptive effects of the histaminergic system on brain reward systems and learning circuits that may lead to addictive behaviour.

Changes in brain histamine release may also accompany cardiovascular dysfunction and hypertension linked to metabolic syndromes or obesity, as brain histamine regulates fluid balance, adiposity and energy metabolism.

Summary Points

- Histamine as a central neurotransmitter
- Histamine is a neurotransmitter that alters central nervous system functions in both behavioural and homeostatic contexts through activation of four receptor subtypes. Histaminergic neurones are organized into distinct functional circuits that may contribute to the diverse roles played by brain histamine in feeding homeostasis, arousal and procognitive effects.
- Histamine and wakefulness
- The histaminergic system is part of a wake-promoting system named ascending arousal system. The activity of histaminergic neurones plays an important role, not so much in the induction of wakefulness per se, but in the maintenance of the high level of vigilance necessary for cognitive processes and feeding behaviour.
- Histamine and cognition
- Manipulation of the histaminergic system during several learning paradigms modifies animal behaviour. Activation of selected histaminergic circuits may be important to consolidate temporal and spatial information associated with food availability and consumption and to coordinate appetitive and consummatory behaviours.
- Histamine in feeding and energy metabolism
- Plenty and consistent evidence supports a role of brain histamine in controls food intake and appetite. Activation of H_1 receptors in the ventral hypothalamus provides a satiety signal, whereas compounds that decrease central histamine increase food consumption. Brain histamine also regulates body weight and adiposity and energy expenditure.
- H_3 receptors and feeding behaviour: controversial findings
- The role of H3 receptor ligands in the treatment of metabolic diseases is still unclear and results from different studies are inconsistent. The growing interest in the H_3 receptor as a potential target to develop anti-obesity drugs stems from observations that H_3 receptor antagonists lack stimulant

and sensitization properties and tend to show a gradual and prolonged decrease in body weight in contrast to the rapid and often quickly waning effect of other anti-obesity drugs.
- The relationship between histamine and peptides that control feeding behaviour
- Several peptides function as satiety or hunger signalling molecules in the hypothalamus. Peptides such as orexin/hypocretin, leptin, glucagon-like peptide 1 (GLP-1), thyrotropin releasing hormone (TRH), exert their orexigenic or anorexigenic effect through, at least in part, the histaminergic system.
- Histamine, endocannabinoids and feeding behaviour
- The histaminergic and endocannabinoid systems seem regulated food intake in opposing fashion, but the mechanisms involved in regulating food intake are not fully understood. Understanding the relationship between histaminergic and endocannabinoid systems may provide interesting hints to develop new therapeutic strategies in the treatment of food intake disorders.
- Histamine regulates both anticipatory and consummatory phases of feeding behaviour
- Histamine controls heterogeneous aspects of feeding. Presumably, histamine drives food intake by increasing the arousal state of the animal -and coordinates satiety and the consolidation of temporal information associated with food consumption. This may be relevant to understand dysfunctions of metabolism and feeding behaviour.
- Histamine and fluid intake and balance
- The role of histamine in diuresis has been extensively studied with mechanisms independent of food intake regulation.

Key Terms

Dipsogenia: A metabolic disorder characterized by intense thirst and excessive urination.

Hypercapnia: (from the Greek *hyper* = 'above' and *kapnos* = 'smoke'), also known as hyper-carbia, is a condition of above-normal carbon dioxide (CO_2) in the blood.

Mesolimbic system: Is one of the dopaminergic pathways in the brain. Dopaminergic fibers originate in the ventral tegmental area of the midbrain and project to the limbic system. It is known to be involved in modulating behavioural responses to stimuli that activate feelings of reward (motivation) and reinforcement.

Narcolepsy: Is a chronic sleep disorder. The condition is characterized by excessive daytime sleepiness in which a person experiences extreme fatigue and may fall asleep at inappropriate times, such as whilst at work or at school. A narcoleptic will most probably experience disturbed nocturnal sleep and also abnormal daytime sleep pattern, which is often confused with insomnia.

Pacemakers: 'natural pacemakers' are cells that create rhythmical impulses. A classical example is the cardiac cells that directly control the heart rate.

Receptor isoform: Any of several different forms of the same receptor. Different forms of a protein may be produced from related genes, or may arise from the same gene by alternative splicing.

Uncoupling protein 1 (Ucp-1): Also called thermogenin, is an uncoupling protein found in the mitochondria of brown adipose tissue (BAT). It is used to generate heat by non-shivering thermogenesis. Non-shivering thermogenesis is the primary means of heat generation in hibernating mammals and in human infants.

23.1 Introduction

Adipose tissue is an endocrine organ affecting a wide variety of functions, including the regulation, and dysregulation, of metabolism, and reproduction (Ahima and Lazar 2008; Catalan et al. 2009). The prototypical adipose-tissue-derived hormone remains leptin, but proteomic analysis of the adipocyte secretome revealed almost 100 proteins, or *adipokines*, that behave as secretory molecules released from adipose tissue (Trayhurn and Wood 2004; Halberg et al. 2008). Further evidence for the adipocyte's complexity comes from a recent in-depth analysis of the *total* adipocyte proteome, using mass spectrometry and bioinformatics, that identified 3,287 proteins (Adachi et al. 2007). It remains unclear whether the adipocyte is the primary site of production of adipokines, or whether other adipose cell types act in concert with adipocytes. Nevertheless, adipokines function as hormones as well as autocrine/paracrine factors in a complex signaling network (Breitling 2009) that includes the immune response (e.g., interleukins, tumor necrosis factor alpha (TNF-α)); control of metabolism (e.g., leptin, resistin, visfatin); regulation of the extracellular matrix (e.g., cathepsin S, matrix metalloproteases); and various other complex pathways via, for example, nerve growth factor (NGF), angiotensinogen, and fibroblast growth factor. Also, because fat deposits are interspersed with many tissues throughout the body (e.g., liver, muscle, heart, bone marrrow) they may function as "miniorgans" with specific paracrine effects (Halberg et al. 2008). Also, given the overwhelming complexity of the adipocyte proteome, it remains possible that these different sites might employ distinct signaling arrays.

For leptin at least, the brain is perhaps the most studied target system (Ahima and Antwi 2008). Leptin receptors are widely distributed in the rodent and human brain, and this led us to hypothesize that many of these – with the exception of those in the basal hypothalamus – would be accessible *only* to a brain-derived ligand, if not leptin of brain origin. We subsequently demonstrated that leptin mRNA was detectable within the rat brain, and leptin immunoreactivity could be co-localized to neurons. Further studies revealed that leptin mRNA was also readily detectable in human, guinea pig, hamster, sheep, pig, and fish brain, and in human neuroblastoma and rat glioblastoma cells (Wilkinson et al. 2007). In the mouse, Lim et al. reported a marked induction of leptin mRNA in injured spinal cord (Lim et al. 2009). Investigations in vivo demonstrated that leptin was also secreted from the human brain (Eikelis and Esler 2005). Several other adipokines, such as resistin, adiponectin, and fasting-induced adipose factor (FIAF), are also expressed in the central nervous system where they function as *cephalokines*. We believe that they exist as components of a unique circuitry able to fine tune the feedback effects of peripherally derived adipokines via their cognate receptors not only in the control of energy balance (Wilkinson et al. 2007) but perhaps in cognitive function as well (see Harvey; this volume, Sect. 1.3).

We have now extended our original hypothesis – *that adipokines would be expressed in brain cells* – to include the possibility that the converse is also true, i.e., *peptides previously assumed to be brain- or hypothalamic-specific should be expressed in adipose tissue*. In fact, gene expression profiling of human fat revealed several transcripts that are associated with hypothalamic function, including those for neuropeptide Y (NPY), corticotrophin releasing factor (CRF), melanin concentrating hormone (MCH), and orexin (Yang et al. 2003; Gomez-Ambrosi et al. 2004). There is also evidence that adipose tissue expresses receptors for NPY, angiotensin II, and orexin, implicating local (autocrine) or paracrine feedback loops (Yang et al. 2003). This chapter will outline the evidence that adipose tissue should be considered as a local source of neuropeptides, which may also function as adipokines.

In the first section, we focus on *kiss1* expression and outline our evidence that this gene, currently a worldwide research focus in the hypothalamic control of reproduction, is expressed and regulated in rodent and human adipose tissue. We will then describe other neuropeptide/adipokine candidates, including NGF, NPY, prolactin, and a product of the renin-angiotensin system, angiotensin II.

23.2 *Kiss1* Gene Expression in Adipose Tissue

Kiss1, originally identified as a metastasis suppressor gene, encodes a 145 amino acid precursor that is cleaved to a family of peptides known as kisspeptins. Kisspeptins appear to be the natural ligands of the orphan G-protein coupled receptor 54 (GPR54), and the *kiss1*/kisspeptin network is a fundamental gatekeeper of the reproductive system (Roa et al. 2008). For example, loss-of-function mutations in human *gpr54* are associated with absence of puberty and hypogonadotrophic hypogonadism. Further, hypothalamic *kiss1* expression is regulated by sex hormones and decreased by food restriction (Smith 2008; Castellano et al. 2009). Since the hypothalamic-pituitary-gonadal axis is crucially dependent on sufficient energy stores such as adipose tissue (Wade et al. 1996), the sensitivity of *kiss1* expression to food restriction provides a plausible link between negative energy balance and infertility. This observation led us to speculate that kisspeptins may also exert biological effects outside of the brain. *Kiss1* and *gpr54* mRNA were detected in several peripheral sites, including pituitary, pancreas, ovary, and placenta (Horikoshi et al. 2003; Castellano et al. 2006; Hauge-Evans et al. 2006; Brown et al. 2008; Richard et al. 2009), and was recently demonstrated in hypothalamic GT1–7 neurons in tissue culture (Quaynor et al. 2007). Therefore, kisspeptins could act as autocrine/paracrine signals in these peripheral sites.

Using hypothalamic tissue as a positive control, we demonstrated that a *kiss1* gene transcript was readily detectable in rat adipose tissue (Brown et al. 2008). Previous work by Muir et al. confirmed the presence of *gpr 54* mRNA in human fat tissue (Muir et al. 2001), and we determined that rat adipose tissue also expresses this gene (Brown et al. unpublished data). In subsequent experiments we showed that adipose *kiss1* mRNA levels were *increased* severalfold by food restriction (Fig. 23.1). Additional studies in obese rat models also revealed abnormal adipose *kiss1* expression and regulation. For example, *kiss1* mRNA levels were significantly *reduced* in fat tissue from rats fed a high-fat diet, and in fat from the obese *fa/fa* rat (Brown et al. 2008). In contrast, in rats made obese with dihydrotestosterone treatment (Manneras et al. 2007), adipose *kiss1* expression was e*levated* 8-fold (Fig. 23.2). Note that *kiss1* mRNA levels were significantly *reduced* in hypothalamic tissue from the same rats, suggesting that *kiss1* expression is differentially regulated in these two tissue sites.

Our data indicate that *kiss1* gene expression in rat fat tissue is under metabolic and hormonal control, and raise several questions regarding a physiological or pathological role for adipose-derived kisspeptins. For example: (a) are kisspeptins secreted from adipose tissue? (b) in which adipose tissue cell type(s) is the gene expressed? (c) how is *kiss1* expression regulated ? (d) how do adipose tissue cells respond to stimulation with kisspeptins via the GPR54 receptor? (e) is *kiss1* expressed in human adipose tissue? (f) given that high levels of kisspeptins were detected in the circulation (Horikoshi et al. 2003; Katagiri et al. 2009), what would be the purpose of adipose tissue GPR54 receptors being exposed to both circulating (e.g., from the placenta) and locally produced, kisspeptin?

We have made some progress in answering question (e): is *kiss1* expressed in human fat? *Kiss1* mRNA was detectable in female omental fat tissue, and particularly in women with high body mass indices (BMI) (see Fig. 23.3). This observation is not consistent with our data from obese rats, where *kiss1* mRNA levels were reduced in fat, and suggests that an important avenue of investigation should be the possible influence of leptin and insulin on adipose *kiss1* expression. Leptin is known to increase *kiss1* mRNA in murine hypothalamus (Luque et al. 2007). The answers to questions (a)–(d) should be forthcoming from current investigations, but question (f) remains a difficult one. We posed a similar question with respect to circulating leptin, which is expressed in the pituitary gland even though the pituitary is normally exposed to blood-borne leptin (Wilkinson et al. 2007). We speculated that pituitary-derived leptin could tune the local leptin-signaling pathway to maintain

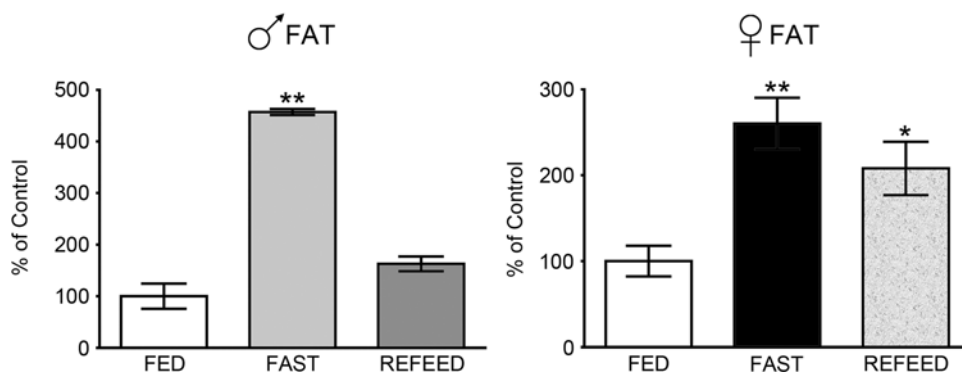
Effect of fasting/refeeding on adipose *Kiss1* expression


Fig. 23.1 Effects of fasting (18 h) and then refeeding (6 h) on *Kiss1* mRNA in visceral fat from male and female rats. *Kiss1* mRNA values were determined by realtime RT-PCR and are expressed as percentage changes compared to control rats fed *ad lib* (mean ± SEM). *$p < 0.05$; **$p < 0.01$ versus fed control values ($n = 5$–6 per group)

The effects of dihydrotestosterone on *Kiss1* expression
Fig. 23.2 *Kiss1* mRNA in adipose and hypothalamic tissue of female rats treated with dihydrotestosterone. Rats were exposed to dihydrotestosterone for 26 days released from subcutaneous pellets according to the method of Manneras et al. (2007). *Kiss1* mRNA values were determined by realtime RT-PCR and are expressed as percentage changes compared to untreated control rats. Values are mean ± SEM ($n = 4$–6 per group). **$p < 0.01$; ***$p < 0.001$

responsiveness, particularly when circulating levels of fat-derived leptin are reduced, for example, during food restriction. A similar concept has been proposed for localized renin-angiotensin systems (see below) and we will illustrate several other examples in this review.

23.3 A Renin-Angiotensin System in Adipose Tissue

Angiotensin II is derived from the proteolytic cleavage of angiotensinogen and is a prototypical *ectopic* neuropeptide. Originally regarded as the effector peptide of a peripheral hormonal system involved in the maintenance of volume and blood pressure homeostasis, organ-based sites of production are now well described (Paul et al. 2006). Brain renin-angiotensin systems, now considered as a model neuro-peptide system particularly in the hypothalamus, may potentially be involved in several pathologies such as stress and depression (Phillips and de Oliveira 2008). Other so-called *tissue renin-angiotensin*
Fig. 23.3 *KISS1* mRNA levels in omental fat obtained from women. *KISS1* mRNA values were determined by real-time RT-PCR and are expressed relative to the value obtained at the lowest BMI (23.8). There is a highly significant correlation ($p < 0.0001$) between *KISS1* expression and BMI. This correlation was not seen in subcutaneous adipose tissue obtained from the same patients (Cockwell, Wilkinson, Bouzayen, Imran and Wilkinson; unpublished data)

systems are reported for adrenal, kidney, and heart (Bader and Ganten 2008), and there is good evidence for a local renin-angiotensin system in adipose tissue that appears to regulate fat growth, metabolism, and adipocyte differentiation (Fowler et al. 2009). Local adipose production of renin occurs independently of circulating renin, and gene expression of all components of the renin-angiotensin system, namely, renin, angiotensin converting enzyme, and the peptide products angiotensinogen and angiotensin I and II, have been identified in adipocytes (Paul et al. 2006). Angiotensinogen gene expression (*agt* mRNA) was also reported to be significantly reduced in adipose tissue from obese rodents (Jones et al. 1997), but increased in obese men (Van Harmelen et al. 2000). Expression of angiotensin II receptor types I and 2 (AT1 and AT2) were also detected in human and rodent adipocytes (Schling et al. 1999; Mallow et al. 2000), suggesting the possibility of autocrine/paracrine interactions. Recent studies by Cassis et al. revealed a differential effect of local angiotensin II production (stimulatory) compared to an *inhibitory* influence of *systemic* angiotensin II (Cassis et al. 2004). This relates directly to the question posed in Sect. 23.2, i.e., what would be the purpose of adipose tissue angiotensin II receptors exposed to both locally produced and circulating, angiotensin II? Cassis et al. (2004) provide one reasonable answer that low, physiological, concentrations of angiotensin II, produced locally by adipocytes, *stimulate* leptin expression and secretion whereas high circulating levels of angiotensin II are inhibitory. An adipose renin-angiotensin system may therefore be a necessary functional component of adipocytes in the presence of low levels of systemic angiotensin II.

Significant progress has been made in confirming the importance of the adipose renin-angiotensin system using transgenic mice in which *agt* expression was specifically modified in adipose tissue (Kim et al. 2006). Figure 23.4 illustrates that a complete knockout of the *angiotensinogen* gene decreased fat mass and lowered blood pressure, whereas *overexpression* of *agt* specifically in adipose tissue in wild-type mice did the opposite, i.e., fat mass and blood pressure were both increased. However, when *agt* was reexpressed *only* in adipose tissue in the *agt* knockouts, fat levels were substantially restored and blood pressure was normalized. Adipokine secretion was also affected; restoration of *agt* expression specifically in adipose tissue increased leptin and resistin secretion, but decreased adiponectin release, when compared to *agt* knockouts. These data imply that locally produced angiotensin II has direct effects on fat mass and adipokine secretion, but also influences blood pressure presumably via secretion into general circulation. Note also that *overexpression* of *agt* in adipose tissue induced hyperinsulinemia and greatly increased leptin secretion. In keeping with these

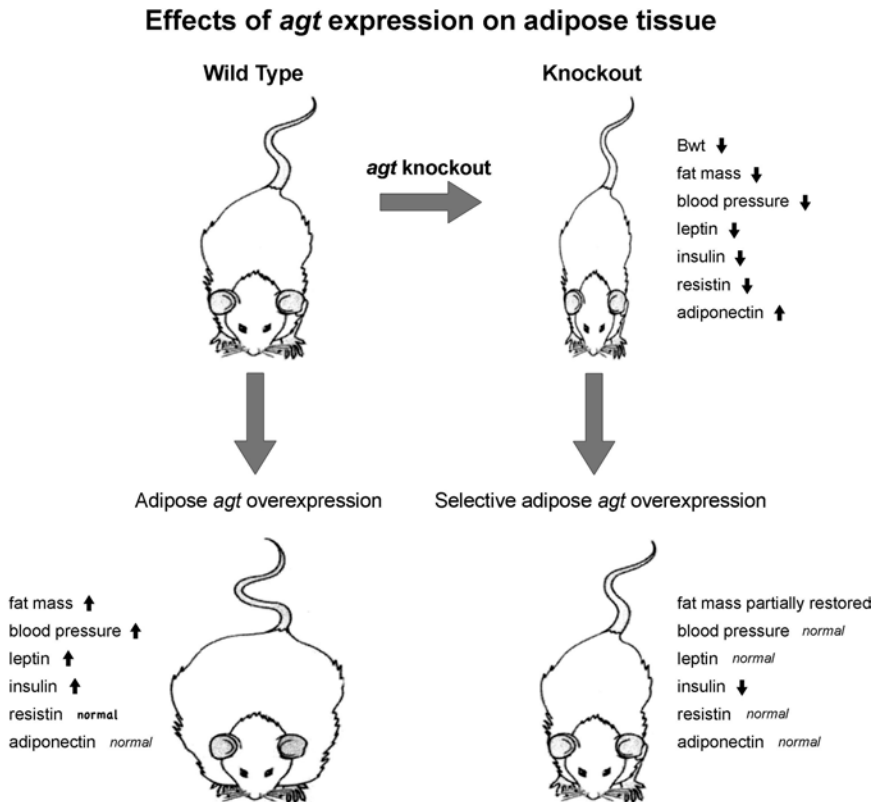
Effects of *agt* expression on adipose tissue


Fig. 23.4 Adipose-specific and endocrine effects of targeted angiotensinogen (*agt*) gene expression. Overexpression of adipose *agt* in wild-type mice produced obesity and increases in blood pressure and insulin levels, whereas in *agt* knockouts the effects were in the opposite direction. Note that targeted expression of *agt* in adipose tissue of *agt* knockouts largely restored these changes to normal (adapted from Massiera et al. 2001)

data, Engeli et al. (2003) suggested a role for the adipose renin-angiotensin system in the development of the metabolic syndrome (Engeli et al. 2003). Also, In attempts to implicate the adipose renin-angiotensin system in the onset of type 2 diabetes, Kohlstedt et al. (2009) reported that angiotensin converting enzyme inhibitors upregulated adiponectin expression in isolated human adipocytes (Kohlstedt et al. 2009). This strongly implicates the involvement of an endogenous, adipose-specific formation of angiotensin II that may contribute to the beneficial effects of angiotensin converting enzyme inhibition in the development of type 2 diabetes.

In summary angiotensin II, a peptide product of an adipose tissue renin-angiotensin system, is a component of adipocyte function that might operate separately, or in conjunction with, the systemic renin-angiotensin system. The evidence obtained so far indicates that this system may be a useful therapeutic target in the treatment of obesity and diabetes.

23.4 Neuropeptide Y as an Adipokine

Neuropeptide Y (NPY) is widely distributed in the central and peripheral nervous systems and is known primarily for its appetite-stimulating effects (Morris 1989), particularly in the arcuate nucleus of the hypothalamus (Kalra and Kalra 2004). The role of NPY in appetite regulation is the subject of

intensive study where it is emerging as a promising target for the development of new anti-obesity drugs (Kamiji and Inui 2007). For instance, centrally injected NPY stimulates food intake whereas NPY inhibition reduces appetite (Kalra et al. 1999). NPY also activates the hypothalamic-pituitary-adrenal axis, another crucial system implicated in the regulation of metabolism and energy balance (Kakui and Kitamura 2007).

Direct effects of NPY on adipocyte function are also well described. Treatment of human subcutaneous adipocytes with recombinant human NPY downregulates leptin expression (Kos et al. 2007), exerts an anti-lipolytic effect (Valet et al. 1990), and promotes the proliferation of pre-adipocytes (Kuo et al. 2007; Yang et al. 2008a). These data led to the hypothesis that NPY would also be expressed in adipose tissue. Supporting evidence for this idea came from gene expression profiling of human omental (visceral) adipose tissue obtained from non-obese female subjects (Yang et al. 2003). Several appetite-regulating genes including melanin concentrating hormone, corticotrophin releasing factor, cholecystokinin and NPY, as well as their corresponding receptors, were expressed in visceral adipose tissue. Kos et al. subsequently reported that NPY was not only expressed, but was also secreted by human adipose tissue (Kos et al. 2007). The coexistence of locally produced NPY and its receptors, implicates an NPY autocrine/paracrine system in adipose tissue function. Kuo et al. (2007) confirmed this view and demonstrated that a combination of stress and a high-fat/sucrose diet induced a marked upregulation of *Npy* and *Npyr2* gene expression in mouse adipose tissue (Kuo et al. 2007). They also showed that in obese *ob/ob* mice, characterized by high glucocorticoid secretion (Edwardson and Hough 1975), subcutaneous fat tissue had very high levels of *Npy* gene expression. The adipogenic NPY/NPYR2 system also exists in nonhuman primate adipose tissue (Kuo et al. 2007).

Polycystic ovary syndrome (PCOS) is also associated with obesity and insulin resistance, and in a recent study Manneras et al. (2007) demonstrated that mesenteric (visceral) adipose tissue expression of NPY in a rat model of PCOS, is higher than that in control rats. Exercise reduced adiposity and normalized ovarian cyclicity and adipose NPY expression. The increase in NPY expression in the obese PCOS rats is consistent with the data of Kuo et al. (2007). However, it is unlikely that stress-induced increases in blood corticosterone levels were responsible since Manneras et al. (2007) reported a decrease in corticosterone in blood. Thus, unlike the model described by Kuo et al. (2007), stress may not be important in elevating adipose NPY expression.

As we have outlined in other sections, a key question is why should adipose tissue produce NPY in the face of systemic and sympathetic neural sources of NPY? Kuo et al. (2007) propose that under stressful and high-fat dietary conditions circulating glucocorticoids enhance local adipose NPY production, which in turn drives the expression of NPYR2 receptors. Such an enhancement of autocrine signaling leads directly to increases in adipogenesis and angiogenesis, producing further growth of adipose tissue. These authors argue that targeting the local NPY/NPYR2 system may be a therapeutic route to drug-induced *liporemodelling*, but this requires further investigation.

23.5 Is Nerve Growth Factor an Adipokine?

Early structural analysis revealed profound similarities between nerve growth factor (NGF) and pro-insulin, and like insulin, NGF was also found to influence cellular metabolism in sympathetic neurons as well as in isolated rat adipocytes (Mukherjee and Mukherjee 1982; Ng and Wong 1985). Thus NGF stimulated lipogenesis and glucose metabolism in isolated rat adipocytes, while simultaneously inhibiting lipolysis, although its effects were less potent than those of insulin (Mukherjee and Mukherjee 1982; Ng and Wong 1985). NGF also induced the expression of vascular endothelial growth factor in 3T3-L1 adipocytes, as well as in brown adipose tissue from transgenic mice

overexpressing NGF (Hansen-Algenstaedt et al. 2006). As expected, the expression of both low-affinity (p75) and high-affinity (Trk A) NGF receptors were also detected in a range of adipose tissue depots as well as in isolated adipocytes and adipocyte cell line models (Nisoli et al. 1996; Peeraully et al. 2004). Thus NGF has the capacity to directly modulate adipocyte gene expression and metabolism. NGF is also expressed and released from adipose tissue, where it appears to modify local adipocyte metabolism and the innervation of adipose tissue by sympathetic nerves, raising important questions about its putative role as an adipokine (Peeraully et al. 2004; Trayhurn and Wood 2004).

NGF mRNA and protein secretion have been detected in a variety of white and brown adipose tissue depots from several species including mice, rats, canines, and humans (Nisoli et al. 1996; Peeraully et al. 2004; Ryan et al. 2008). NGF mRNA was found to be enriched in isolated adipocytes suggesting that fat cells are a major source of adipose tissue-derived NGF (Nisoli et al. 1996; Peeraully et al. 2004). Further, NGF expression was highest in epididymal and peri-renal fat depots, but was also readily detected in subcutaneous and omental depots isolated from mice (Peeraully et al. 2004). Although this tissue-dependent pattern of distribution was not replicated in canines, limited data suggested that NGF gene expression was also higher in omental, rather than subcutaneous, human adipose tissues (Peeraully et al. 2004; Ryan et al. 2008). This tissue-dependent pattern of NGF distribution may account for the varying degree of sympathetic nervous system innervation within the various fat tissue depots (Peeraully et al. 2004). Murine, canine, and human cell cultures also confirmed the direct expression and secretion of NGF from adipocytes. However it was found that NGF regulation was dependent on the degree of differentiation such that NGF expression and secretion was greatest in preadipocytes (Nisoli et al. 1996; Peeraully et al. 2004; Wang et al. 2005; Ryan et al. 2008). Although one of the major roles predicted for adipose-derived NGF is to direct the sympathetic nervous system-dependent innervation of fat (Peeraully et al. 2004), we should not preclude other possible functions, such as mediating local energy metabolism and gene expression. Regulatory studies suggest that NGF may also be involved with the inflammatory processes associated with obesity (Nisoli et al. 1996, 1998; Peeraully et al. 2004; Bullo et al. 2007). Various inflammatory molecules were shown to stimulate the expression of NGF, including tumor necrosis factor alpha and lipopolysaccharide, whereas anti-inflammatory compounds such as rosiglitazone, a peroxisome proliferator-activated receptor gamma (PPARγ) ligand, or dexamethasone were found to have an inhibitory effect on adipocyte NGF mRNA levels (Peeraully et al. 2004; Wang et al. 2005; Ryan et al. 2008). Thus it was not surprising that NGF levels were increased in obese subjects given the recent correlations drawn between obesity and inflammation (Nisoli et al. 1996; Bullo et al. 2007). However other factors may influence the regulation and secretion of NGF, including age and gender. For example, NGF levels increase markedly after birth until around 3 months of age, and decrease thereafter in rats (Nisoli et al. 1998). Although data from humans failed to detect any correlation with age in adults, we do not know what the pattern is like in early life when the sympathetic nervous system is developing (Bullo et al. 2007). However the major question that remains is what is the purpose(s) and role(s) of adipose-derived NGF in all these various processes?

Although it is now evident that adipocytes express NGF, as well as the low (p75) and high-affinity tyrosine kinase receptor A (TrkA) NGF receptors, the precise role(s) of adipose-derived NGF within fat tissue, and within the whole body, remains unknown. Current evidence suggests that locally derived NGF plays a critical role in the sympathetic innervation of adipose tissue, but emerging data also implicates NGF in local inflammatory responses associated with obesity. Further, like other adipose-derived brain peptides, NGF may act locally within fat via autocrine/paracrine pathways in order to control gene expression and adipocyte metabolism, in addition to impacting local tissue function. In summary, this remains an interesting avenue of discovery as attempts are made to

uncover the role(s) of adipose-derived NGF that may ultimately prove to be a unique modulator of adipocyte function, or even bodyweight regulation.

23.6 Prolactin as an Adipokine

Prolactin is a multifunctional pituitary peptide hormone implicated in numerous hormonal, immune, and metabolic functions (Goffin et al. 2002; Ben-Jonathan et al. 2008), and is also expressed, and secreted, in the hypothalamus as a neuropeptide (Torner et al. 2004; Roselli et al. 2008). Ben-Jonathan and coworkers have provided persuasive evidence that prolactin is also an adipokine (Brandebourg et al. 2007). These data are of particular interest because prolactin gene expression in rodent adipose tissue is thought to be negligible, whereas production in human fat and adipocytes is well described (Hugo et al. 2008). It is clear that prolactin is secreted from adipocytes and that pituitary and adipose prolactin proteins are identical. Prolactin receptors were also identified in adipose tissue and considerable evidence exists that circulating prolactin, of *pituitary* origin, participates in adipose tissue function through prolactin receptor signaling. For example, prolactin affects adipogenesis, lipolysis, and release of adipokines such as leptin and interleukin 6 (Hugo et al. 2008). Thus it seems highly likely that locally produced adipose prolactin could serve as an autocrine and/or paracrine factor (Ben-Jonathan et al. 2008).

Explants of visceral, but not subcutaneous, adipose tissue obtained from obese patients secreted high levels of prolactin over several days (Hugo et al. 2008). This was not the case in non-obese explants where elevated secretion from both depots was essentially the same. Adipocyte cultures, derived from mature, non-obese, subcutaneous adipose tissue, also released high levels of prolactin. This suggests that adipocytes might be the primary source of prolactin expression, though this would not exclude contributions from other cell types (e.g., preadipocytes, fibroblasts) which themselves could provide other factors capable of regulating prolactin secretion.

A critical development in these studies followed the establishment of a human adipocyte cell line, LS14, that secretes prolactin along with other prototypical adipokines such as leptin and adiponectin (Hugo et al. 2006). LS14 cells also expressed the prolactin receptor and angiotensinogen (see Sect. 23.3). In general, gene expression profiles appeared similar to those seen in primary adipocytes with the exception of tumor necrosis factor α and interleukin 6, which were markedly downregulated following differentiation. In fact, interleukin 6 mRNA was dose-dependently inhibited by exogenous prolactin. In addition, insulin, but not IGF-1, dose-dependently inhibited both prolactin release and expression. Similar results were obtained from human differentiated primary subcutaneous adipocytes (Hugo et al. 2008). Further investigations into the control of prolactin expression in LS14 cells, especially following treatment with tumor necrosis factor α and β, and forskolin, revealed differences between differentiated and non-differentiated adipocytes. Several drugs that normally increase cyclic adenosine monophosphate (cAMP) levels, such as isoproterenol and epinephrine, successfully elevated prolactin gene expression and prolactin release from preadipocytes (McFarland Mancini et al. 2006). Of particular interest is the recent demonstration that adipocyte prolactin release is regulated by dopamine, just as in the anterior pituitary (Borcherding et al. 2009). These authors demonstrated the presence of dopamine receptor mRNAs in human visceral, subcutaneous and breast adipose tissues, and in mature adipocytes. Moreover, prolactin secretion from adipose explants and differentiated adipocytes was inhibited by dopamine receptor 2 (D2R) and 4 agonists.

In summary, prolactin appears to be an adipokine and its expression and release from adipocytes is regulated by obesity, insulin, and biogenic amines. Prolactin production by adipose tissue might also be depot specific. Progress has been made in delineating some of the signaling pathways, and the role of the prolactin gene promoter, in controlling adipose tissue prolactin release. A fundamental question

remains to be answered: What is the purpose of local prolactin release from adipocytes when adipose tissue is already exposed to high levels of pituitary-derived prolactin in the circulation? Hugo et al. (2008) estimated that adipocyte secretion of prolactin was 4–5 orders of magnitude *lower* than that seen from pituitary gland, implying that adipose contribution to *circulating* prolactin is probably negligible. They also speculated that low levels of prolactin released from adipocytes are likely to be bound by connective tissue heparin sulphate proteoglycans and held in the vicinity of adipocyte prolactin receptors, increasing local concentrations and the likelihood that prolactin acts in a paracrine/autocrine fashion. Further studies are needed to examine possible interactions between adipocyte prolactin expression and other hormones, such as glucocorticoids, that are known to influence glucose metabolism, lipogenesis and lipolysis. Local homeostatic control of adipose prolactin may be important in conditions where pituitary prolactin secretion is low. This would, in turn, imply that pituitary prolactin secretion should be regulated differently to prolactin release from adipocytes. Indeed, at least one notable difference lies in the response to estrogen and progesterone. As noted by Zinger et al., the superdistal prolactin promoter in adipose tissue is unaffected by estrogen and progesterone whereas the proximal promoter in pituitary is stimulated by estrogens (Zinger et al. 2003). On the other hand, dopamine agonists *inhibit* prolactin secretion from adipose tissue just as it is from pituitary gland. The possibility that adipocyte prolactin expression might be specifically targeted for therapeutic purposes in the treatment of obesity and diabetes exists.

23.7 Expression of Atrial Natriuretic Peptide in Adipose Tissue

Atrial natriuretic peptide is another prototypical *ectopic* peptide. Originally discovered as a polypeptide secreted from cardiac muscle cells, it is implicated not only in the control of cardiovascular, renal, endocrine, and skeletal homeostasis (McGrath et al. 2005; Gardner et al. 2007), but is also expressed in several brain sites including cortex and hypothalamus (Wiggins et al. 2003). It is now clear that atrial natriuretic peptide is a physiological regulator of human and primate, but not rodent, adipocyte lipolysis (Sengenes et al. 2002; Lafontan et al. 2008), acting through the atrial natriuretic peptide receptor type A and the guanylyl cyclase/cGMP system (Nishikimi et al. 2009). Garruti and coworkers postulated the presence of atrial natriuretic peptide expression in human fat cells and employed several tissue preparations to confirm this hypothesis. Atrial natriuretic peptide gene expression was observed in visceral and subcutaneous samples of fat tissue obtained from obese patients (Garruti et al. 2007). In addition, they determined that primary human preadipocytes, and an immortal human preadipocyte cell line (*Chub-S7*; derived from human subcutaneous fat tissue), also expressed atrial natriuretic peptide. Immunofluorescence studies employing a specific antiserum for pro-atrial natriuretic peptide revealed the presence of atrial natriuretic peptide-like immunoreactivity in Chub-S7 cells, thus confirming the expression and production of atrial natriuretic peptide protein. Further, using a highly sensitive radioimmunoassay, they demonstrated that Chub-S7 and primary preadipocytes also secreted pro-atrial natriuretic peptide/atrial natriuretic peptide into the culture medium at concentrations similar to those found in the circulation. Since the authors demonstrated the presence of the protease necessary for conversion of pro-atrial natriuretic peptide to atrial natriuretic peptide, they speculated that the secreted protein was probably atrial natriuretic peptide. In preliminary experiments to investigate possible atrial natriuretic peptide-mediated signaling pathways, the PPAR-γ agonist rosiglitazone increased atrial natriuretic peptide secretion from both types of preadipocyte cultures.

As intimated elsewhere for other hormones in this chapter, adipocytes possess an autocrine/paracrine regulatory system involving atrial natriuretic peptide. Further exploration into the significance of this phenomenon is required, and especially to seek an answer to why atrial natriuretic peptide receptors

on adipose cells should be exposed to both systemic and locally produced atrial natriuretic peptide. Intuitively one might suppose that the local atrial natriuretic peptide system could be especially important in situations where cardiac atrial natriuretic peptide secretion is minimal or nonexistent. Also, as described for prolactin (Sect. 23.6), the control of atrial natriuretic peptide gene expression may be different in adipose and cardiac tissue, i.e., in situations where cardiac atrial natriuretic peptide expression is inhibited, the adipose atrial natriuretic peptide gene may be unaffected, so as to preserve local production of atrial natriuretic peptide. Whether this might be therapeutically valuable remains to be determined. This is especially relevant given the known involvement of atrial natriuretic peptide in angiogenesis, an important process that also occurs in adipose tissue (Casco et al. 2002).

23.8 Additional Neuropeptide Gene Transcripts Identified in Adipose Tissue

Table 23.1 lists further examples of neuropeptide gene transcripts in adipose tissue. In general, gene expression was detected by microarray technology or by reverse transcriptase-polymerase chain reaction (RT-PCR). Yang et al. (2003) identified numerous unusual transcripts in adipose tissue, including expression of several peptides normally considered to be hypothalamic neuropeptides, and their receptors. Although these data suggest the existence of additional adipose-derived neuropeptides, a word of caution has been offered by Trayhurn and Wood (2004). These authors, using conventional RT-PCR, were unsuccessful in their search for some of these transcripts. This discrepancy might reflect the different techniques used (i.e., microarray vs RT-PCR) or could be due to different experimental preparations (cultured cells vs rodent tissue). Moreover, Yang et al. (2003) performed additional experiments with in situ hybridization to confirm some of their microarray results. Nevertheless, all of these potential new adipokines require further study in terms of protein identification and whether they are expressed and secreted by adipocytes.

Solid evidence is also available for nesfatin-1 and IGF-1 as potential adipokines. Nesfatin-1 was originally identified as a satiety molecule in rat hypothalamus (Oh et al. 2006) and the protein found in many brain regions (Foo et al. 2008). However, recent studies by Ramanjaneya et al. (2009) provided firm evidence, using RT-PCR and Western blotting, that nesfatin-1 is highly expressed in human and rodent adipose tissue, and nesfatin-1 is secreted from mouse adipocytes in culture during the differentiation of preadipocytes (Ramanjaneya et al. 2009). Adipose gene expression is also upregulated in mouse models of obesity and in mice given a high-fat diet. There is also some evidence that expression of nesfatin-1 is regulated by insulin, dexamethasone, and tumor necrosis factor α, strongly suggesting that nesfatin-1 is a new adipokine.

Insulin-like growth factor 1 (IGF-1) is also a prototypical *ectopic* peptide. Thought of as an endocrine hormone, IGF-1 is secreted predominantly by the liver. However, it is a well-described

Table 23.1 Additional neuropeptide gene transcripts in adipose tissue

brain-derived neurotrophin that acts on central IGF-1 receptors (Aguado et al. 1993; Sonntag et al. 1999). In addition, IGF-1 promotes survival of adipocytes in culture by inhibiting apoptosis, but it is now evident that human adipocytes express and secrete IGF-1 (Fischer-Posovszky et al. 2004). These authors demonstrated that inhibition of the autocrine/paracrine action of IGF-1 dramatically sensitized human fat cells to ligand-induced apoptosis. Thus human adipocytes protect themselves from cell death through an autocrine/paracrine effect of IGF-1. This knowledge offers a potential therapeutic route to a reduction of fat mass.

Chemerin is a newly described adipokine that is also widely expressed in the brain, including the hypothalamus (Goralski et al. 2007; KB Goralski, Personal Communication). The involvement of chemerin in adipocyte function seems to be complex, involving adipogenesis, lipolysis and the inflammatory response that accompanies metabolic stress (MacDougald and Burant 2007).

23.9 Conclusions and Speculations

In little more than a decade, the perceived biological role of adipose tissue has grown in stature from a mere energy storage system to its current acceptance as a complex multifunctional endocrine organ, and fat is now known to secrete multiple adipokines. The present review provides evidence that certain brain and pituitary peptides, such as NPY, NGF, prolactin, and atrial natriuretic peptide, are also expressed and released by adipose tissue. In their paper on adipokines, Trayhurn and Woods (2004) speculated that if such neuropeptides were confirmed as adipokines, then: "the adipocyte is even more remarkable as a secretory cell than currently envisaged; indeed, it would be a veritable powerhouse of neuroendocrine signals." Gene microarray and proteomic analyses indicate that there are likely to be many more adipokines waiting to be discovered. The amazing complexity of cell signaling within adipose tissue suggests that a high degree of redundancy is likely to exist. At present, we can only speculate that the signaling cascades and communication networks present in adipose tissue are required to be sufficiently robust that the loss of individual entities can readily be accommodated. The application of this knowledge to an understanding of adipose physiology, and especially to pathophysiology, might only be achieved through a systems biology approach (Breitling 2009). We can also assume that the integration of multilayered signaling components in adipose tissue, with local and endocrine feedback loops, might constitute site-specific functions of various adipose tissue depots. There is no doubt that there are adipose depot-specific differences in gene expression profiles and that these are modified by, for example, type 2 diabetes (Vidal 2001; Yang et al. 2008b). The *ectopic neuropeptides* discussed in this review could represent an additional signaling device that reflects, or responds to, neuroendocrine activity in the hypothalamic/pituitary system. Schäffler and colleagues have already proposed the existence of "adipotropins"; i.e., circulating pituitary and hypothalamic hormones that act directly on adipocytes via a hypothalamic-pituitary-adipose axis (see Fig. 23.5) (Schaffler et al. 2006). Given that the pituitary hormone prolactin – described by Schaffler et al. (2006) as an adipotropin – is released from adipose tissue (Sect. 23.6), it is possible that other adipotropins, such as growth hormone and vasopressin, could also be expressed there.

A fundamental issue that this review has not satisfactorily confronted is why adipose tissue should possess autocrine signaling devices for secretory products that are already present in the circulation. Put another way, what could be the purpose of prolactin secreted from adipose tissue when this hormone is already present in high concentration in the blood? We posed a similar question with respect to circulating leptin, which is expressed in the pituitary gland even though the
Fig. 23.5 Overview of the possible major contributions of locally derived neuropeptides to adipocyte function. On the *left* of the figure is a partial list of *adipokines*, such as leptin and resistin, that we have termed "classical." These adipokines are secreted into the systemic circulation but may also exert autocrine activity. On the right are some neuropeptides, and their receptors, now found to be produced by adipose tissue, that are commonly regarded to be of brain, or non-adipose, origin. We provide evidence that this latter group has profound autocrine effects on adipocytes, though they are unlikely to contribute to blood levels. *We also illustrate peptide hormone input from several circulating pituitary hormones (*Adipotropins*), as described by Schaffler et al. (2006). At present, there is no evidence that these pituitary hormones are also expressed in adipose tissue

pituitary is normally exposed to systemic leptin (Wilkinson et al. 2007). We speculated that pituitary-derived leptin could "tune" the pituitary-specific leptin signaling pathway to maintain responsiveness, particularly when circulating levels of fat-derived leptin are reduced, for example, during food restriction. A similar concept has been proposed for localized renin-angiotensin systems (see Sect. 23.3), and for adipose *kiss1*/kisspeptin (Sect. 23.2). In the latter case, we noted that *kiss1* gene expression is regulated differently in adipose tissue compared to the hypothalamus, i.e., following food restriction we demonstrated that *kiss1* mRNA was reduced in hypothalamic tissue but increased in fat (Fig. 23.1). Prolactin gene expression is also regulated differently in adipose tissue versus pituitary gland (Sect. 23.6). Finally, we note that there is a logical parallel between what we have termed *ectopic neuropeptides* and the well-described synthesis of steroid hormones in traditional "target" tissues (Schmidt et al. 2008). For example, glucocorticoids, the accepted signaling products of the hypothalamic pituitary adrenal axis, are also synthesized in the immune system where they are hypothesized to play an important role in thymic homeostasis (Pazirandeh et al. 2005). Analogous to the local renin-angiotensin system described in Sect. 23.3, the thymus employs a complete CRF – adrenocorticotropin hormone (ACTH) – cortisol system that Schmidt et al. (2008) describe as a miniature hypothalamic pituitary adrenal "homolog." We suggest that this homolog concept can be profitably applied to probing the function of ectopic adipose neuropeptides. The practical means to do this are available and site-specific gene knockouts, or gene silencing techniques, will provide a clearer understanding of the role of neuropeptides in adipose tissue.

23.10 Application to Other Areas of Health and Disease

Although the study of adipose-derived neuropeptides is in its infancy, it seems likely that in the coming years the potential roles for these atypical neuropeptides in adipose tissue will be uncovered. Although it may be premature to speculate as to the exact purpose of each of these genes within adipocytes, and their potential impacts on health and disease, the evidence presently available has clearly demonstrated that many of these peptides are capable of influencing a variety of adipocyte-specific processes including modifications to energy metabolism through the induction of lipogenesis or lipolysis, as well as impacting adipogenesis. Further, many of these neuropeptides also appear to exert an effect on local gene expression, and that their regulation is tightly associated with both inflammatory (e.g., lipopolysaccharide and interleukin 6) and anti-inflammatory (e.g., PPARγ ligands) suggesting that locally produced neuropeptides may offer an even further layer of control in the complex inflammatory processes that have become firmly associated with obesity. We also speculate that neuropeptide expression and release from adipocytes may contribute to the developmental "tuning" of local energy metabolism and could have lifelong effects on adipocyte function.

The discovery of *ectopic neuropeptides* in adipose tissue not only enhances our understanding of the complex neuroendocrine signaling in adipose tissue, but will perhaps lead to the identification of unique targets for new therapies. For example, bromocriptine, which is traditionally used to treat hyperprolactinemia, is now emerging as a novel treatment for the metabolic syndrome. As we noted in Sect. 23.6, dopamine agonists inhibit the release of prolactin from adipocytes and Kok et al. (2006) report that bromocriptine may stimulate lipolysis in obese women (Kok et al. 2006).

The diversity of these adipokines, and their tissue-specific effects, will also offer an exciting area for developing tissue target-based therapies to avoid undesirable side effects. Needless to say, many avenues of discovery have now been opened, and as further progress and discoveries are made, it seems likely that adipose-derived neuropeptides may be found to impact local development and energy metabolism. Perhaps adipose-derived neuropeptides may even prove to be unique targets that can be harnessed to control and prevent some of the devastating consequences that are now known to be associated with obesity, including the development of cardiovascular disease, diabetes, and perhaps even fertility.

Summary Points

- Adipose tissue is now known to secrete a large number of signaling molecules called *adipokines*.
- We have shown, for the first time, that several of these adipokines are also made in the brain and by pituitary cells. Such neuropeptides are more appropriately termed *cephalokines*.
- We now hypothesize that the converse of this would also be true: that some neuropeptides, normally considered to be of specific brain or pituitary origin, should be expressed in adipose tissue.
- In this chapter, we have outlined fairly solid evidence for gene expression of the following peptide systems, and their receptors, in adipose tissue: *Kiss1*/kisspeptin, renin-angiotensin system/angiotensin II, neuropeptide Y (NPY), nerve growth factor (NGF), prolactin, and atrial natriuretic peptide.
- More limited evidence exists for many other peptides, including IGF-1, nesfatin-1, galanin, orexin, neurotensin, cholecystokinin, and ghrelin.
- Using *kiss1* as an example, we have sought answers to the following questions as a means to establish possible physiological/pathological function(s) to these potential new adipokines:
- Are kisspeptins secreted from adipose tissue?
- In which adipose tissue cell type(s) is the gene expressed (i.e., mature adipocytes versus stromal vascular cells versus stem cells)?

- How is adipose *kiss1* expression regulated?
- How do adipose tissue cells respond to *autocrine* stimulation with kisspeptins via the G protein coupled receptor 54 (GPR54) receptor, which is also present in adipose tissue?
- Is *kiss1* expressed in human adipose tissue?

Given that high levels of kisspeptins (e.g., of placental origin) have been detected in the circulation, what is the purpose of adipose tissue GPR54 receptors being exposed to both circulating, and locally produced, kisspeptin? We believe that one answer to the latter question is to propose that kisspeptin receptor signalling in adipose tissue might be critical in situations in which systemic, *circulating* levels of peptides are very low, for example, during fasting. Indeed, we have shown that adipose and hypothalamic *kiss1* expression is regulated in opposite directions following fasting.

- Following the discovery of leptin, adipose tissue swiftly became accepted as probably the largest endocrine gland. The present chapter further establishes that adipose tissue is capable of secreting a bewilderingly complex array of neuroendocrine as well as adipokine signals.

Definitions

Adipokines: Also known as *adipocytokines*. Proteins secreted from adipocytes in humans and rodents. Act as signaling molecules within adipose tissue or as systemic hormones. *Leptin*, for example, is the best known adipokine. We all secrete leptin from our fat cells, particularly when we eat. Leptin is thought to give us the feeling of being "full," so that we do not eat too much. In some people, the leptin does not work and as a result they become obese. It may be possible one day to target this system with drugs so as to reduce body weight.

Cephalokines: Adipokines that are expressed in the brain and pituitary gland.

Adipose secretome: The entire body of molecules released (secreted) by adipose tissue, including hormones, adipokines, and lipids. *Proteomic* analysis of the secretome would reveal the number of *protein* hormones or messengers released by adipose tissue.

Polymerase chain reaction (PCR): A common laboratory technique used to amplify and detect very small amounts of DNA. Widely used in medical and biological research laboratories for a variety of applications, including functional analysis of genes, the diagnosis of hereditary disease, and the identification of genetic fingerprints (used in forensic sciences and paternity testing).

Neuropeptide: Neuropeptides are usually small proteins found in brain or nerve tissue. They are released, and act as messengers, by different populations of neurons in the mammalian brain.

Autocrine/paracrine: Paracrine signaling is a form of cell signaling in which cells send chemical messages over short distances to other cells that are located close by ("para" = near). An important distinction is made between paracrine and autocrine signaling since autocrine signaling occurs when a cell releases a message that then acts on itself, i.e., acts on the releasing cell.

Microarrays: Microarray technology enables scientists to estimate, in a single experiment, the expression levels of hundreds or thousands of genes within a cell or tissue. With the aid of a computer, *microarray* analysis can generate a profile of gene expression in specific tissues such as fat.

Gene knockout: A *knockout* mouse is one that is genetically engineered so that one or more genes have been disrupted and rendered nonfunctional. These knockout mice are very important because they can be used to find out what would happen if a gene of interest, such as *angiotensinogen*, is disabled. Then, if the mouse's behavior or physiology changes, researchers can arrive at conclusions as to that gene's probable function.

Key Points

- Several neuropeptides, and their associated receptors, are now known to be expressed in adipose tissue. These neuropeptides may also function as adipokines (see Overview: Fig. 5). This list includes, but is not limited to: *kiss1,* the renin-angiotensin system, NPY, NGF, prolactin, and atrial natriuretic peptide.
- Regulation of fat-derived neuropeptides is different than that in the central nervous system, suggesting a unique role in local adipose tissue function.
- Also, because deposits of adipose tissue are interspersed with many tissues throughout the body (e.g., liver; muscle; heart; bone marrow) they may function as "miniorgans" with specific paracrine effects.
- The possibility exists to specifically target adipocyte expression of neuropeptides for therapeutic purposes, for example, in the treatment of obesity, diabetes, and infertility.

Chapter 24
Orexigenic Hypothalamic Peptides Behavior and Feeding

Jon F. Davis, Derrick L. Choi, and Stephen C. Benoit

24.1 Introduction

The primary focus of this chapter is to understand better how peptides produced within hypothalamic nuclei act to influence behavior and feeding. In particular, this chapter will focus on peptides that are "orexigenic" which act to increase feeding behavior.

To date there are two distinct regions within the hypothalamus that produce orexigenic peptides; the Arcuate nucleus (Arc) located in the mediobasal hypothalamus and the lateral hypothalamus (LH) located adjacent to the third ventricle which spans almost the entire length of the hypothalamus. The traditional contention regarding orexigenic peptide function ascribed that peptides produced within the Arc & LH exerted their effects on feeding through acting within local hypothalamic centers, with a major emphasis on the LH. These ideas were borne from observations that administration of orexigenic peptides into the neighboring third ventricle produced robust increases in food intake in addition to altering the activation and gene expression profiles of feeding peptides in the hypothalamus. However, reports over the last decade indicate that orexigenic peptides not only act within hypothalamic centers to regulate food intake but are also capable of affecting feeding through their actions at extra-hypothalamic centers, namely, within the brain's endogenous reward circuitry. This observation not only expanded the complexity of feeding behavior but also indicated that the behavior of feeding itself could be manifested through reward processing. In addition, studies from the field of addiction biology now indicate that orexigenic peptides are also capable of modulating drug taking behavior. Thus, to begin our discussion of how orexigenic peptides regulate behavior and feeding, it is first important to gain an understanding of rewarding behavior and the circuitry which control it.

Rewarding behaviors include three basic functional components: (1) they induce learning, (2) they produce approach and consummatory behavior, and (3) they induce positive emotions regarding the behavior (Dickinson 1994; Shultz 2004). Thus, reward and learning overlap to produce optimal conditions for obtaining a particular goal/reward. In rodents, rewarding behaviors are controlled by the mesocorticolimbic system (Shultz 1998, 2004; Wise 1978), which originates in the ventral mesencepahalon or ventral tegmental area (VTA). Dopaminergic fibers originating in the VTA send dense projections to the nucleus accumbens (Nacc) as well as the medial wall of the Prefrontal

Fig. 24.1 Rat mesolimbic system. Mesolimbic system schematic in the rat adapted from Kauer and Malenka (2007) highlighting the mesolimbic system and its target regions; blue lines indicate glutamatergic projections, red lines indicate dopaminergic projections and green lines indicate orexinergic connections. This figure also highlights the ability of the orexin system, originating in the lateral hypothalamus, to activate ventral tegmental area (*VTA*) neurons and thus activate mesolimbic circuitry

Cortex (mPFC) (Emson and Koob 1978; Fuxe and Hokfelt 1972). The projection of dopamine neurons from the VTA to Nacc comprises the mesolimbic component of this system and the dopamine projection from the VTA to the mPFC make up the mesocortical component of this system. The mPFC along with receiving dopamine input from the VTA sends glutamatergic projections both back to the VTA as well as to the Nacc (Sesack et al. 1989; Sesack and Pickel 1992; Bernedise et al. 1992), thus allowing a cortical interface to be superimposed onto rewarding behaviors. Although it is not the primary focus of this chapter, it should be noted that manipulations of dopamine or glutamate signaling within the mesolimbic system affect many aspects of drug taking including self-administration, relapse, and withdrawal (Fig. 24.1).

Although much of the field of reward neurobiology is focused on unnatural rewards like drugs of abuse, there is now a growing understanding of the novel and shared neural mechanisms involved in natural reward processing like ingestive behaviors (Volkow and Wise 2005). Recently, it was demonstrated that leptin, a well-documented homeostatic regulator of food intake, acts on mesolimbic dopamine neurons in the VTA and regulates reward-related behaviors (Fulton et al. 2006; Hommel et al. 2006). It is believed that the dysregulation of mechanisms like these and the overriding of homeostatic regulators may be significant contributors to the obesity crisis (Berthoud 2004; Volkow and Wise 2005). Food reward behaviors are driven by the hedonic impact and motivational aspects of food intake. On the other hand, they are also very much different from drug reward behaviors in that the reward, food, is a natural necessity for energy homeostasis and survival. The neural mechanisms of food reward are believed to be largely common to those of unnatural rewards, namely, the mesolimbic dopamine pathway (Berridge 1996; Kelley and Berridge 2002; Wise 2004). High-fat food is commonly considered a highly palatable and rewarding food type (Levine et al. 2003) and in many cases, despite metabolic repletion or a state of satiation, animals and humans can still experience high-fat appetite (Zhang et al. 1998; Berthoud et al. 2007). A central hypothesis in addiction biology states that neuroplastic changes as a result of chronic drug use create neuroadaptive changes that further promote the behavior (Nestler 2002). Thus, it is possible that chronic ingestion of high-fat

foods may contribute to adaptations of the central reward pathway to further promote high-fat food reward behaviors and, ultimately, lead to weight gain (Levine et al. 2003). To understand how this might occur, it is important to gain a better understanding of food reward behavior.

24.2 Food Reward

Here we define the term "reward" operationally as behavior reinforced through multiple pairings with rewarding stimuli, i.e. food, or drugs. Food reward in particular can be characterized as a reinforced-learning phenomenon driven by sensory stimulus inputs such that the food elicits positive emotion and is desired independent of homeostatic or metabolic demands (Berthoud 2007). One way reward behavior is modeled in rodents is by using an operant conditioning chamber (Skinner Box) in which a rat can be trained and learn to associate the action of lever-pressing with the acquisition of a reward. The number of lever-presses can be correlated to the animal's motivation or "wanting" of the reward. Evidence to support this correlation in food reward can be seen in the dependence of this behavior on dopamine signaling (Wise and Schwartz 1981). Drug addicts, when attempting to abstain from drug use, often relapse to drug-seeking behavior. This phenomenon is also modeled in a self-administration paradigm, reinstatement following extinction (Shaham et al. 2003), and was first described in Pavlov's original studies, called spontaneous recovery or renewal, using food reinforcements (Pavlov 1928). Recently, studies have "re-adapted" this technique of reinstatement of food reward-seeking in modeling of stress-induced and food-primed relapse to maladaptive eating habits (Nair et al. 2006; Ghitza et al. 2006; 2007). Another model of reward behavior commonly used in studies of reward in drugs of abuse is the conditioned place preference (CPP) paradigm. In this model, a rat is conditioned to associate the environmental cues of its surroundings (unique chamber) with positive reinforcements. A preference to spend more time in a reinforcement-paired chamber is a measure of the rewarding aspects of that reinforcement. Place preference can be acquired in animals conditioned with food rewards (Tzschentke 1998) and is dependent on intact dopamine signaling (Papp 1988). Reinstatement of food-seeking behavior can also be modeled in the CPP procedure (Duarte et al. 2003).

We will now consider, individually, four separate orexigenic hypothalamic peptide systems. Initially, a functional–anatomical description of each neuropeptide system will be discussed. These descriptions will then be followed by a brief description of how each system impacts mesolimbic reward circuitry.

24.3 Neuropeptide Y

Neuropeptide Y (NPY) is a 36 amino acid neuropeptide distributed throughout both the peripheral and central nervous systems. One of the central regions with the highest expression of NPY is the Arcuate nucleus (ARC) of the hypothalamus (Chronwall et al. 1985). NPY is perhaps the best-described anabolic effector peptide in the brain. When injected centrally, NPY is capable of inducing feeding in animals that had been previously sated prior to testing (Clark et al. 1984) suggesting that NPY is a potent meal initiation signal. Although NPY mRNA and peptide are distributed widely throughout the CNS, NPY-containing cell bodies in the ARC are hypothesized to be especially important in the control of food intake (Schwartz et al. 1992). ARC neurons that express NPY directly influence several areas of the brain; however, two major projections to the nearby periventricular nucleus

(PVN) and the lateral hypothalamic area (LHA) have received a significant amount of attention in regard to the regulation of energy balance. For instance, in response to food deprivation, ARC NPYergic neurons respond by synthesizing more NPY mRNA, which is consequently released into the PVN (Kalra et al. 1991; Schwartz et al. 1992) and presumably the LHA as well. Importantly, animals in negative energy balance have low levels of the adiposity hormones insulin and leptin, which normally act to suppress NPY and AgRP expression. Thus, when energy levels are low, this suppression is removed, resulting in elevated NPY mRNA in the ARC. Moreover, local replacement of either insulin or leptin in the vicinity of the ARC normalizes the elevated NPY mRNA in the ARC in fasted animals (Schwartz et al. 1992; Sipols 1992). Hence, the activity of these ARC NPY neurons is under the direct influence of at least two adiposity signals.

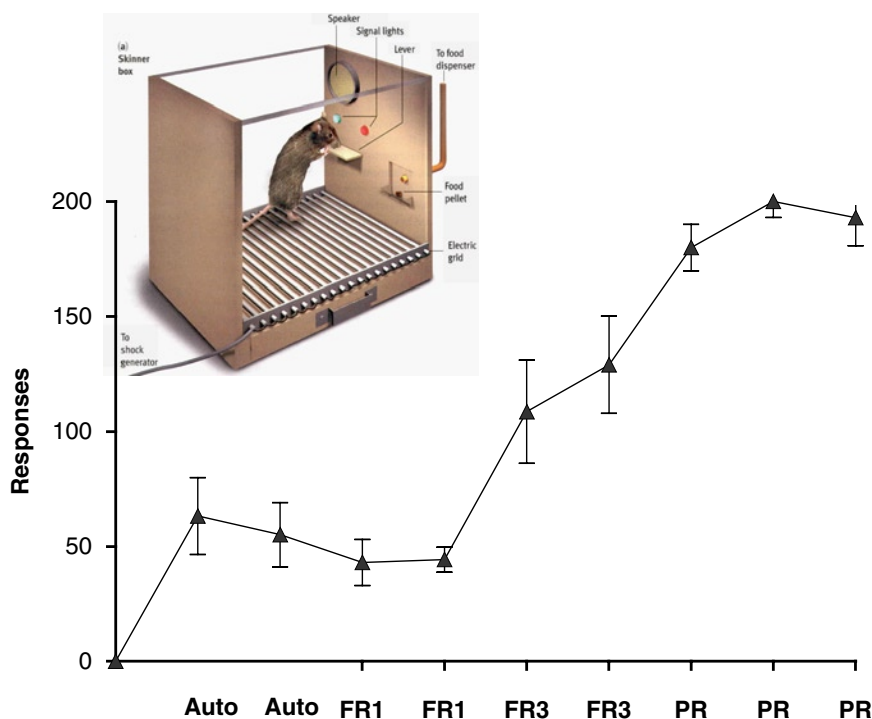
Although NPY has been recognized primarily for its ability to influence energy balance, it is also capable of affecting food reinforcement learning. Progressive ratio (PR) responding is one way to measure an animals ability to work for a given reinforcer (Fig. 24.2). In this model, animals are trained to make an operant response (normal to press a lever) in order to achieve a single reinforcer (normally a food pellet of intravenous injection of a drug). Initially, to achieve a reinforcer the animal is required to make a single response; however, using a PR schedule of reinforcement each subsequent reinforcer requires a higher work requirement. When using this model, animals trained to respond for sucrose pellets will respond at significantly greater rates after receiving a central injection of NPY (Brown et al. 1998), suggesting that in addition to initiating feeding behavior, NPY also modulates an animal's motivation to obtain a food reward. The effect of NPY on operant responding is mediated by NPY's action in the perifornical hypothalamus (PFA) as direct application of NPY into the PFA stimulates PR responding (Fig. 24.3) (Brown et al. 1998). Interestingly, NPY positive neurons are also located within brain reward circuits, and these extra-hypothalamic neuronal populations


Fig. 24.2 Operant responding in the rat. Figure illustrating instrumental fixed and progressive ratio (*PR*) training across time. Figure also illustrates operant training apparatus with auditory and visual cues

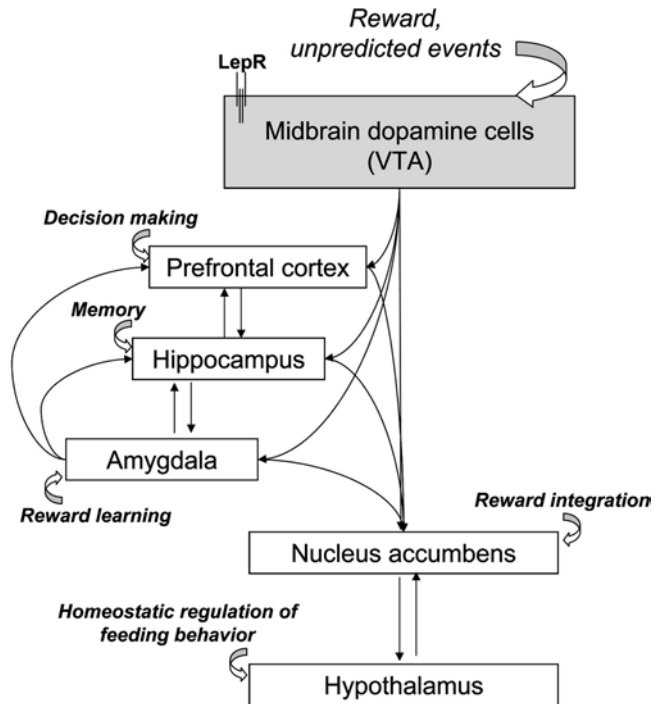
Fig. 24.3 Hypothalamic regulation of food intake. Hypothalamic regulation of food intake figure adapted from Schwartz et al. (1992) illustrating anatomical location of neuropeptide Y/melanocortin neurons, POMC, and orexin neurons. NPY/melanocortin neurons normally promote feeding behavior; however, when energy levels are high, leptin and insulin from the periphery feedback on POMC and melanocortin neurons to negatively regulate feeding behavior
are capable of regulating rewarding behavior. The nucleus accumbens and dorsal striatum are two regions that lie within the brains natural reward circuitry that each contains NPY-positive populations of neurons (Adrian et al. 1993). Importantly, NPY neurons within these regions make neuronal contacts with terminals that express tyrosine hydroxylase (the rate-limiting enzyme for dopamine production) suggesting that once released, NPY may be capable of affecting mesolimbic dopamine tone (Aoki and Pickel 1988). Interestingly, early behavioral pharmacological studies indicated that NPY could impart direct effects on dopaminergic neurocircuitry. For instance, NPY applied directly to the NAcc elicits the formation of a conditioned place preference, an effect that is dependent on intact dopamine signaling (Josselyn and Beninger 1992) suggesting that NPY is capable of effecting rewarding processes through its direct action within mesolimbic neurons. Although it seems plausible that NPY might affect food reinforcement through a similar mechanism, an elegant study by Brown and colleagues (Brown et al. 2000) determined that the effects of NPY on food reinforcement and general reward could be dissociated. In particular, the effect of NPY on food reinforcement is mediated through NPY action on PFA neurons and is dopamine independent, while the effects of NPY on general reward are mediated through both the PFA and NAcc, the later of which is dopamine dependent (Brown et al. 2000). Collectively, these results suggest that NPY is capable of influencing feeding, food-reinforced behavior, and general reward through distinct neural circuits that reside both within and outside the hypothalamus (Fig. 24.4).

24.4 Melanocortins

The hypothalamic melanocortin (MC) system is another central effector system with the ability to exert both positive and negative effects on the control of food intake and energy balance. The evidence for this is multifold: In melanocytes inappropriate expression of agouti-related peptide (AgRP) results in

Fig. 24.4 Regulation of non-homeostatic feeding. This figure adapted from Cota et al. (2006) illustrates the ability of cognitive emotional information processed by the amygdala, hippocampus, and prefrontal cortex as well as reward information processed by the mesolimbic system to interface and override hypothalamic processes that normally mediate homeo-static feeding behavior


antagonism of alpha-melanocyte-stimulating-hormone (α-MSH) signaling. The resulting phenotype is an obese mouse with a yellow coat. This observation led to the hypothesis that ectopic agouti protein antagonizes central MC receptors involved in food intake. As predicted, agouti is an antagonist of these receptors, which were later reported to be localized to the hypothalamus (Lu et al. 1994). Importantly, an endogenous agouti-related peptide (AgRP) was found to be almost exclusively produced in the ARC and to project to the sites of the hypothalamic MC receptors. Additionally, during periods of negative energy balance, expression of AgRP mRNA is increased while expression of POMC, the precursor molecule to α-MSH, is decreased (Mizuno et al. 1999). During positive energy balance on the other hand, expression of POMC mRNA is increased and AgRP is decreased. Further, POMC-containing neurons also have the ability to respond to the adipocyte hormone, leptin (Cheung et al. 1997; Mountjoy and Wong 1997; Seeley et al. 1997). These findings suggest that the hypothalamic MC system is a likely central target of adipose signals and a mediator of their effects on food intake.

The melanocortin system has been studied extensively for its role in the hypothalamic regulation of food intake. This system is unique in that it possesses both an endogenous agonist and an inverse agonist with opposite effects on feeding behavior. Alpha-melanocyte stimulating hormone (α-MSH) and agouti related peptide (AgRP) are the primary effector peptides of the melanocortin system. Increases in α-MSH serve to decrease food intake while increases in AgRP drive food consumption; under basal conditions, the expression of each peptide is regulated by caloric status as they are down-stream targets of the adiposity hormone leptin (Schwartz et al. 2000). Traditionally, these peptides are thought to mediate their effects by binding specifically to the melanocortin-4 receptor (MC4R) within a distributed set of nuclei in the hypothalamus. However, emerging evidence suggests that this system is capable of mediating effects outside the hypothalamus, specifically within the mesolimbic system (Alvaro et al. 1996; 2003; Hsu et al. 2002, 2005).

The yellow mouse has an autosomally transmitted trait resulting from deletion of DNA 3′ of the coding region of the agouti gene which results in ectopic expression of the agouti protein. In melanocytes, this inappropriate

expression results in antagonism of alpha-melanocyte-stimulating-hormone (α-MSH) signaling. The resulting phenotype is a yellow coat. However, the agouti mouse is obese as well as yellow. This observation led to the hypothesis that ectopic agouti protein antagonizes central MC receptors involved in food intake. Indeed, though melanocortins have been known to influence food intake since the 1980s, it was only during the last decade that their receptors were cloned and localized to the hypothalamus, an important CNS site for the control of energy balance. As predicted, agouti is an antagonist of these receptors. Importantly, an endogenous agouti-related peptide (AgRP) was found to be almost exclusively produced in the ARC and to project to the sites of the hypothalamic MC receptors.

Separate from their expression in hypothalamic nuclei, melanocortin receptors (MC3R and MC4R) are also expressed in brain regions that regulate motivated behaviors (Mountjoy et al. 1994; Alvaro et al. 1996; Adan and Gispen 1997). Importantly, pharmacological studies have outlined functional roles for these receptors in the modulation of drug-taking behavior. Specifically, antagonism of these receptors within nucleus accumbens inhibits operant responding for cocaine, while central agonism of this system augments amphetamine-related behaviors (Cabeza de Vaca and Carr 2002; Hsu et al. 2005). In addition, the expression of the MC4R is increased in the striatum after repeated exposure to psychostimulants and mutant mice lacking this particular receptor fail to display a sensitized locomotor response to repeated cocaine administration (Hsu et al. 2002, 2005). Taken together, these results suggest that the MC system is capable of influencing addictive behaviors.

24.5 Orexin

Orexin, a neurotransmitter produced in small neuronal populations of the LH and perifornical area (PFA), is known to regulate arousal, wakefulness, and feeding behaviors (Sakurai 2007). There are two different orexins: orexin-A (33 amino acids) and orexin-B (28 amino acids). Orexin-A can bind to both orexin-1 receptors and orexin-2 receptors (two orexin G-protein–coupled receptor subtypes) while orexin-B has preferential binding affinity for orexin-2 receptors (Sakurai et al. 1998). Both orexin receptors are widely distributed throughout the central nervous system (Marcus et al. 2001). Due to the lack of an effective and commercially available orexin-2 receptor antagonist, orexin-A signaling on orexin-1 receptors is much better characterized. Intracerebroventricular administration of orexin-A increases food intake (Sakurai et al. 1998) and when given a choice, rats will selectively increase intake of a preferred high-fat diet (Clegg et al. 2002). Furthermore, a selective orexin-1 receptor antagonist, SB-334867, is effective in blocking central orexin-A-induced hyperphagia and behavioral satiety (Rodgers et al. 2001). Orexin neurons receive important orexigenic information from NPY/AgRP neurons of the arcuate nucleus and are thought to be "second order" neurons of a hierarchy in the integration processes involved in regulating food intake (Dube et al. 2000; Yamanaka et al. 2000). However, evidence suggests that orexin neurons may also act as "first order" neurons, sensors of metabolic status, that are modulated by circulating leptin, glucose, and ghrelin levels (Cai et al. 1999; Lopez et al. 2000; Toshinai et al. 2003; Burdakov et al. 2005). Orexin neurons most likely take on both first- and second-order neuron roles in integrating intra- and extra-hypothalamic information to affect consummatory behaviors (Fig. 24.5).

Orexin neurons in the LH have very diverse projections in the CNS, and the VTA is one structure that receives input from these neurons (Peyron et al. 1998; Fadel and Deutch 2002). Additionally, VTA neuron populations express both orexin receptor subtypes (Marcus et al. 2001). It was proposed that plasticity in the VTA could be regulated and enhanced by secondary input neuroadaptations from the orexin system (Scammell and Saper 2005; Carr and Kalivas 2006). Indeed, orexinergic projections to the VTA signal specifically on a majority of dopamine neurons, increase dopaminergic neuron firing rates and activate the mesolimbic pathway (Korotkova et al. 2003; Narita et al. 2006).
Fig. 24.5 Functional anatomy of the orexin system in rat. This figure adapted from Harris et al., illustrates the functional anatomical connections of the hypothalamic orexin system in the rat brain and its target regions. Orexin-containing neurons in the lateral hypothalamus (*LH*) are activated in response to food- and drug-related cues and project to limbic regions to mediate food and drug reward. Orexin neurons in the perifornical hypothalamus (*PFA*) are activated by general arousal and project to brainstem nuclei important for autonomic responses
Fig. 24.6 Structural plasticity within a rat mesolimbic neuron. Structural plasticity figure adapted from Nestler (2001) illustrating the ability of mesolimbic neurons to undergo morphological changes in response to repeated activation by abused drugs or food

Importantly, drug-associated cues activate orexin neurons, and central application of orexin-A reinstates drug-seeking behavior (Harris et al. 2005). Similar results were demonstrated using orexin-1 receptor blockade to attenuate operant responding for alcohol and the reinstatement of alcohol- and cocaine-seeking (Boutrel et al. 2005; Lawrence et al. 2006). Moreover, studies in male sexual behavior also suggest a role for orexin in the VTA in natural reward processing (Muschamp et al. 2007). These behavioral implications have set the stage for orexin's role as a functional neuromodulator at the level of the VTA. Furthermore, intra-VTA orexin-1 receptor blockade effectively prevents behavioral sensitization and neurophysiological changes that are typically caused by chronic cocaine use (Borgland et al. 2006). Orexin-A is implicated in lever-pressing for palatable food rewards (Nair et al. 2008; Thorpe et al. 2005) and within the mesolimbic system, is necessary for opioid-induced high fat intake (Zheng et al. 2007). These studies suggest that orexin's effects on reward-related behaviors include not only those of drugs of abuse, but also of natural rewards like food. We hypothesize that orexin neurons may play a critical role in relaying information from the hypothalamus, possibly regarding changes in metabolism and energy status, to extra-hypothalamic areas such as the mesolimbic dopamine pathway to ultimately affect reward-related behaviors (Fig. 24.6).

24.6 Ghrelin

Ghrelin is a 28 amino acid peptide synthesized in both gut and brain that increases food intake (Tschop et al. 2000; Nakazato et al. 2001; Tolle et al. 2002) and gut motility (Masuda et al. 2000). Endogenous ghrelin signals through a seven transmembrane G coupled protein receptor (GHSR) that is present in many brain regions including the hypothalamus, hippocampus, thalamus, and ventral tegmental area (VTA) (Guan et al. 1997; Zigman et al. 2006). Ghrelin is produced in the Arc nucleus of the hypothalamus (Lu et al. 2002) and like other orexigenic hypothalamic peptides, in times of negative energy balance plasma ghrelin levels increase (Tschop et al. 2001) suggesting that ghrelin may act as a meal initiator. Interestingly, plasma ghrelin levels peak before expected meals in both humans and animals (Cummings et al. 2001; Sugino et al. 2002) and drop post prandially (Tschop et al. 2001), suggesting that ghrelin may act as a meal initiation signal. However, one study by Drazen and colleagues suggested that plasma ghrelin increases as a function of meal conditioning rather than being a conditioning factor itself. The implication being pre-prandial rises in plasma ghrelin act to facilitate the consumption, absorption, and metabolism of an expected meal without effecting meal initiation (Drazen et al. 2006). Nevertheless, ghrelin is thought to exert its effects on feeding behavior through activation of NPY and AgRP signaling mechanisms. The evidence for this comes from the observation that NPY/AgRP neurons express ghrelin receptors (Willesen et al. 1999). Furthermore, both NPY and AgRP mRNA levels are increased by ghrelin and NPY/AgRP neurons become activated by central ghrelin administration (Shintani et al. 2001).

However, ghrelin receptors are present in other area of the hypothalamus known to regulate feeding behavior, in particular, the LH. Functional anatomical studies indicate that ghrelin also promotes feeding behavior through activation of LH orexin neurons. A study by Toshinai et al. demonstrated that ghrelin positive axon terminals synapse onto orexin-producing neurons in the LH. In addition, central ghrelin administration induced neuronal activation of LH orexin producing neurons. In the same study, ghrelin-induced feeding was suppressed in animals pretreated with antibodies directed toward orexin A, orexin B, or NPY, suggesting that ghreli's ability to stimulate food intake is achieved through activation of both NPY and orexin signaling (Toshinai et al. 2003).

Apart from its role in stimulating food intake, central ghrelin signaling has also been suggested to act as a "meal preparation" signal. This contention comes from the observation that central ghrelin administration increases glucose utilization in white and brown adipose tissue which resides outside the central nervous system (Theander-Carillo et al. 2006). Additionally, the expression of enzymes associated with fat storage is reduced in ghrelin-deficient mice. When viewed collectively, these data suggest that central ghrelin is capable of modulating peripheral metabolism and that ghrelin may exert these effects on peripheral metabolism prior to meal consumption. Moreover, these data suggest that central ghrelin signaling may be at the top of a neuroendocrine cascade which participates in many aspects of feeding behavior and nutrient storage.

One way in which ghrelin may effect feeding behavior is through its ability to modulate meal anticipation or food-seeking behavior. Ghrelin receptors are present on neurons in the VTA, an area noted for its role in food-seeking behavior. Direct application of ghrlein within the VTA of rodents induces new synapse formation and neuronal activation in dopaminergic neurons. Intra-VTA injection of ghrelin also triggers feeding behavior and increases dopamine turnover in the NAcc (Abizaid et al. 2006). Thus, like many of the other orexigenic peptides discussed in this chapter, ghrelin is also capable of activating brain reward circuitry to promote feeding behavior.

Another way in which ghrelin may affect feeding behavior is through its ability to modulate learned associations after an organism experiences a meal. The primary brain region noted for its ability to modulate memory formation is the hippocampus; ghrelin receptors are present on hippocampal neurons and ghrelin selectively binds its receptors within this region (Diano et al. 2006). Perhaps more importantly, ghrelin acts in the hippocampus to promote new dendritic spine formation, and

prolonged electrical activity. Mutant mice which lack functional ghrelin receptors in the hippocampus display decreased dendritic spines in the CA1 region, a region noted for its role in memory consolidation, as well as spatial learning deficits (Diano et al. 2006). Taken together, these results suggest that ghrelin signaling within the hippocampus is capable of altering learning and potentially the learning associated with meal consumption.

24.7 Applications to Other Areas of Health and Disease

At this point, the ability of orexigenic hypothalamic peptides to affect alternative area of human health will be discussed. This section will focus entirely on the propensity of orexigenic peptides to impact drug addiction, and relapse to addictive drugs.

24.8 Metabolic Status and Drug Intake

For several decades it has been recognized that alterations in metabolic status have dramatic effects on drug taking behavior in animals. In particular, restricting or depriving an animal from feeding augments the reward efficacy as well as the motivation to engage in drug-taking behavior (Bell et al. 1997; Carroll et al. 1984). Since the realization that lateral hypothalamic self-administration (LHSS) was an invaluable model to investigate reward and motivated behaviors, many have speculated that one or more of the peptide systems in the hypothalamus that promote feeding may also impart positive effects on drug taking. Moreover, because many individuals that display disordered eating behavior also abuse drugs, it has been suggested that a common neural mechanism, may contribute to both disordered eating and drug-taking behavior (Kalra et al. 1991). In fact, some have even suggested that a disruption within a hypothalamic neuropeptide system might underlie pathological overfeeding and addictive behaviors (Brown et al. 2000). Over the past decade numerous reports have indicated that apart from promoting feeding behavior, orexigenic hypothalamic neuropeptides can also modulate drug-taking behavior.

24.8.1 NPY and Melanocortins

For example, central replacement of NPY is capable of augmenting the rewarding properties of both opioids and psychostimulants, which are functionally distinct in their method of cellular activation. When delivered into the third ventricle of the brain, NPY increased self-administration of heroin as well as the relapse to heroin in rats that had extinguished heroin taking (Maric et al. 2008). A more recent study from the same group extended these finding by demonstrating that central NPY replacement also augments cocaine self-administration and also the locomotor activating effects of cocaine (Maric et al. 2009). These studies suggest that apart from affecting feeding behavior, and general reward, NPY signaling is also capable of modulating the rewarding properties of recreationally abused drugs. As the NPY and melanocortin system overlap in their anatomical location and both augment feeding behavior, it is perhaps not surprising that melanocortin peptides have also been implicated as regulators of drug-taking behavior.

As mentioned earlier (Sect. 24.4) melanocortin receptors are expressed within mesolimbic circuitry and antagonism of the MC4R within the NAcc with the synthetic antagonist SHU9119 attenuates

self-administration as well as the locomotor activating effects of cocaine (Hsu et al. 2006). Moreover, agonism of the MC system with the synthetic agonist melanotan-II (MTII) augments the rewarding effects of amphetamine (Cabeza de Vaca and Carr 2002) a drug that is very similar to cocaine in regards to its psychostimulant properties. It is important to note here that both antagonism and agonism of the same receptor population seem to have similar effects on psychostimulant taking behavior. This is in contrast to the general notion that peptides that normally stimulate food intake also stimulate drug taking. The synthetic agonist MTII decreases food intake behavior, while the synthetic antagonist/inverse agonist SHU9119 stimulates feeding behavior. It is possible that the differential effects of melanocortin signaling on drug-taking behavior in animals are due to the site of pharmalogical intervention, in this case the NAcc versus central injection which presumably also reaches the NAcc; it is also possible that these effects might be brought about by actions at different receptors (i.e. MC3R vs MC4R). However, at this point, it is unclear how agonism and antagonism of the melanocortin system achieve similar effects in their ability to attenuate drug-taking behavior.

24.8.2 Ghrelin

In the context of metabolic status, the temporal pattern of the hormone ghrelin is unique in that it increases in plasma before scheduled meals but also increases as a result of food deprivation. The ability of ghrelin to increase before a meal, also known as the cephalic response, has been suggested to result from an animals' ability to learn or anticipate their next meal. This "feeding entrainment" is important to consider when investigating the effects of metabolic status on drug taking behavior as it identifies a time in which endogenous levels of orexigenic peptides are elevated. Thus, it is possible that food-entrained hormones such as ghrelin may exert maximal effects on drug-taking behavior when they are naturally elevated before a meal. Although this possibility has not been explored directly, ghrelin has been shown to be capable of altering the rewarding potential of psychostimulants. Systemic administration of ghrelin increases cocaine-induced locomotor activity in rats, and also learned associations with cocaine ingestion as measured by the conditioned place preference model (Wellman et al. 2007; Davis et al. 2007) suggesting that exogenous ghrelin can affect cocaine-related behaviors.

24.8.3 Orexin

As the rate of recidivism is high among drug addicts, gaining a better understanding into the neurobiology of relapse behavior is of utmost importance. Among all of the hypothalamic orexigenic peptides discussed, the orexin system has the potential to make the most significant impact on relapse behavior. In the context of relapse, environmental cues associated with drug-taking behavior are very potent activators of relapse. Although the orexin system was initially recognized for its ability to mediate arousal in animals, orexin neurons in the hypothalamus become activated in response to both food- and drug-related cues. The first evidence of this was reported in 2005 when Harris and colleagues reported that animals trained to expect chocolate and morphine exhibited significant neuronal activation within hypothalamic orexin neurons (Harris et al. 2002). In the same study, exogenous orexin administration reinstated a conditioned place preference for morphine (Harris et al. 2005) suggesting that orexin was capable of mediating both the anticipation and learned associations with opioid drugs. In a more recent report, rats that had previously extinguished operant responding

for cocaine reinstated responding after receiving a direct injection of orexin-2 peptide into the VTA (Wang et al. 2009). A major concept regarding relapse behavior ascribes that the endogenous stress system plays a major role in reinstatement of drug-taking behavior. In this way, the experience of stress or administration of stress hormones (CRH, corticosterone) is sufficient to elicit drug taking in animals that had previously extinguished drug-taking behavior, suggesting that stress alone is a potent activator of relapse behavior. It is important to note here that the ability of orexin to reinstate cocaine-taking behavior is independent from the effects of the stress on reinstatement; the implication of this being that orexin signaling alone within VTA neurons is sufficient to reinstate drug cocaine taking. Collectively, these examples provide evidence that the hypothalamic orexin system is capable of modulating the anticipation of cues associated with previous drug experience as well as the reinstatement of drug-taking behavior.

Summary

In summary, it is apparent that factors originally recognized for their ability to increase feeding behavior are also capable of modulating drug-taking behavior. With the exception of the melanocortin system, most orexigenic peptides impart positive effects on drug ingestion, i.e. they increase the rates of ingestion, or other read outs of drug efficacy such as drug-induced locomotion or conditioning effects of repeated drug exposure. Relapse to drug-taking behavior is a major problem faced by the addiction community and as such factors that affect relapse or reinstatement of drug-taking behavior are useful toward an understanding of the underlying neurobiology contributing to addiction. The orexin system has the capacity to affect anticipation and reinstatement of drug taking behavior, both of which contribute to relapse behavior. In closing, it is possible that metabolic status and the factors that regulate it are more important than ever before in their ability to regulate addictive behaviors.

Definitions

Orexigenic peptides: Peptides that stimulate appetite.
Reward: A specific intuitive drive in animals; utilized in most animal training systems.
Drug relapse: To engage in drug taking after abstinence.
Mesolimbic system: A neural pathway in the brain which links the ventral tegmentum in the midbrain to the nucleus accumbens which is located in the striatum.
Psychostimulant: A stimulant which acts on the nervous system which increases locomotor behavior and in addition to having mood-elevating effects.

Chapter 25
Circadian Neuroendocrine-Immune Aspects of Feeding Behavior: Lessons from Calorie-Restricted or High-Fat-Fed Rats

Ana I. Esquifino and Daniel P. Cardinali

Abbreviations

ACTH	Corticotropin
FSH	Follicle-stimulating hormone
GH	Growth hormone
IFN-γ	Interferon-γ
IL	Interleukin
LH	Luteinizing hormone
MCP-1	Monocyte chemoattractant protein-1
PAI-1	Plasminogen activator inhibitor-1
SCN	Suprachiasmatic nucleus
TNF-α	Tumor necrosis factor-α
TSH	Thyroid-stimulating hormone

25.1 Introduction: Relevance of the Circadian Clock for Neuroimmune Organization

Temporal organization is an important feature of the biological systems and its main function is to facilitate adaptation of the organism to the environment. It is known that the mammalian circadian timing system comprises peripheral oscillators located in almost every cell of the body together with a central rhythm generator located in the hypothalamic suprachiasmatic nucleus (SCN) (Hastings et al. 2003). At the cell level, circadian rhythms are driven by the self-regulatory interaction of a set of genes named clock genes and their protein products.

The light–dark cycle, food, ambient temperature, scents, and social cues have been identified as synchronizers (or "Zeitgebers") in rodents. An entraining agent can actually reset, or phase shift, the internal clock. Depending on when an organism is exposed to such an entraining agent, circadian rhythms can be advanced, delayed, or not shifted at all. Therefore, involved in adjusting the daily activity pattern to the appropriate time of day is a rhythmic variation in the influence of the Zeitgeber

A.I. Esquifino (✉)

Universidad Complutense, 28040 Madrid, Spain
e-mail: pelayos@med.ucm.es

as a resetting factor (Hastings et al. 2003). In humans, light exposure during the first part of the night delays the phase of the cycle; a comparable light change near the end of the night, advances it. At other times during the day light exposure has no phase-shifting influence.

Both the humoral arm and the delayed (cellular) arm of the immune system function in a rhythmic manner. Circadian changes in the circulation of T, B, or natural killer lymphocyte subsets in peripheral blood and in the density of epitope molecules at their surface, which may be related to cell reactivity to antigen exposure, have been reported (Cutolo et al. 2006). Changes in lymphocyte subset populations can depend on the time of day-associated changes in cell proliferation in immunocompetent organs and/or on diurnal modifications in lymphocyte release and traffic among lymphoid organs. Circadian rhythmicity is revealed in circulating cells, lymphocyte metabolism and transformability, circulating hormones and other substances that may exert various actions on different targets of the immune system, cytokines, receptors, and adhesion molecules, cell cycle events in health and cancer, reactions to antigen challenge, and disease etiology and symptoms (Hastings et al. 2003; Cutolo et al. 2006).

It must be noted that the role of SCN in the entrainment of lymphocyte function and in coordinating signals by which circadian information is conveyed to the immune cells remains unsettled. Rhythms in the number of circulating T cells persisted in rats with disrupted circadian output. Similarly, SCN ablation did not affect the 24-h rhythms in cell cycle phase distribution in bone marrow cells (Filipski et al. 2004), suggesting that some rhythms in the immune system are SCN-independent. Rather than a mere rhythm generator for the periphery, the SCN should be envisioned as a transducer for light entrainment. However, there are entrainment signals other than light that may be coordinating the rhythm in natural killer cell function and other immunological parameters like, e.g., feeding.

Several studies have investigated the changes in cytokine levels that occur during the most prominent 24-h cycle in humans, the sleep–wake cycle. Plasma tumor necrosis factor (TNF)-α levels peak during the dark phase of the cycle, and the circadian rhythm of TNF release is disrupted by sleep pathology like obstructive sleep apnea. Plasma interleukin (IL)-1β levels also have a diurnal variation, being highest at the onset of slow sleep. The levels of other cytokines (including IL-2, IL-6, IL-10 and IL-12) and the proliferation of T cells in response to mitogens also change during the 24-h cycle. Although the production of macrophage-related cytokines (such as tumor necrosis factor-α (TNF-α)) increases during sleep (in response to in vitro stimulation), this occurs in parallel with the rise in monocyte numbers in the blood. The production of T-cell-related cytokines (such as IL-2) increases during sleep, independent of migratory changes in T-cell distribution (Pandi-Perumal et al. 2007). All of these observed diurnal changes could be specific to the effects of sleep or associated with the circadian oscillator. To dissociate the effects that result from the sleep–wake cycle from those due to the endogenous circadian oscillator, experimental procedures such as constant routine or forced desynchrony need to be used. At present, there are no reports of studies using these methods to elucidate the effects of sleep on immunity.

Sleep and the immune system share regulatory molecules (Pandi-Perumal et al. 2007). These are involved in both physiological sleep and sleep in the acute-phase response to infection or in chronic inflammation. This supports the view that sleep and the immune system are closely interconnected. It is feasible that sleep influences the immune system through the action of centrally produced cytokines that are regulated during sleep. These endogenous cytokines are known to function through the autonomic nervous system and the neuroendocrine axis, although other pathways might be involved.

In recent years, we examined the circadian disruption of hormone release and immune-related mechanisms in several animal models in which circulating cytokines are increased including calorie restriction and a high-fat diet. Basic rationale for the experimental approach used was that most published studies dealing with hormone or immune changes in the above mentioned situations were performed at single time-points in the 24-h span, an important drawback in view of the circadian

Table 25.1 Summary of changes in circadian rhythms of neuroimmune responses after caloric restriction in rats (Results from Chacon et al. 2004, 2005, 2006; Esquifino et al. 2004b)

24-h rhythms	Amplitude	Acrophase	Mean

nature of hormone release and immune function and on the fact that most manipulations employed disrupt circadian rhythmicity. The results obtained are reviewed below and are summarized in Tables 25.1 and 25.2.

25.2 Circadian Neuroimmune Organization after Caloric Restriction

Homeostasis defines the mechanisms that react to maintain a constant, fixed set point of a physiological variable (reactive homeostasis) as well as those that are active in advance to maintain a set point that itself is rhythmic (predictive homeostasis) (Moore-Ede 1986). This last type of homeostasis evolves

Table 25.2 Summary of changes in circadian rhythms of hormones and adipocytokines in rats fed a high-fat diet (Results from Cano et al. 2008, 2009)

24-h rhythms	Amplitude	Acrophase	Mean

Table 25.3 Circadian neuroendocrine-immune organization in calorie restriction: key points

- Availability of nutrients affects the mechanisms that modulate the circadian variation of pituitary-gonadal axis
- Reduced availability of nutrients is a stressor that affects the circadian variation of pituitary hormones and leptin
- Malnutrition produced by low or absent proteins in diet is linked to increased susceptibility to infection while calorie restriction of rodents by a diet enriched in proteins and low in fat and carbohydrates significantly increases immune responses

as an adaptation to anticipate predictable changes in the environment, such as light and darkness, food availability, temperature, or predator activity, and is the basis of the circadian clock as discussed above.

One of those environmental predictable changes, the scarcity of food, occurs rhythmically in nature every year and can be reproduced in laboratory conditions by calorie restriction (Table 25.3). Experimental calorie restriction (e.g., 25–50% reduction of caloric intake), without deficiency in essential nutrients have been widely employed in this respect (Roth et al. 1999; Masoro 2000).

Under calorie restriction the use of energy is greatly reduced and the basal plasma levels of several hormones are altered. Among them, the hormones of the hypothalamic–pituitary–gonadal axis have been extensively examined.

In a study analyzing the effect of caloric restriction on the 24-h variation of pituitary–testicular function in young male Wistar rats, we submitted animals to a calorie restriction equivalent to 66% of food restriction for 4 weeks starting on day 35 of life (Chacon et al. 2004). Rats were killed at six time intervals around the clock. Mean secretion of prolactin augmented and that of luteinizing hormone (LH) and testosterone decreased in calorie-restricted rats whereas follicle-stimulating hormone (FSH) release remained unchanged. Significant changes in the 24-h secretory pattern of circulating prolactin, LH, and testosterone levels occurred in calorie-restricted rats. These include the appearance of a second maximum of plasma prolactin, the blunting of LH peak and a phase-delayed of testosterone peak. The significant positive correlation between individual LH and testosterone levels found in controls was not longer observed in calorie-restricted rats (Chacon et al. 2004).

Availability of nutrients presumably affects the mechanisms that modulate the circadian variation of pituitary-gonadal axis in growing male rats.

With the aim to assess whether the chronobiological sequels of calorie restriction could be the consequence of stress, we examined the 24-h variations of plasma corticotropin (ACTH), corticosterone, GH, and leptin, and of adrenal corticosterone content (Chacon et al. 2005). Significantly lower ACTH levels were detected in calorie-restricted rats. Plasma corticosterone levels during the light phase of daily cycle (but not in the whole set of six time points throughout the 24-h cycle) were significantly higher in calorie-restricted rats. Time-of-day variations of plasma ACTH and corticosterone attained significance in calorie-restricted rats only, with a maximum toward the end of the resting phase. The daily pattern of adrenal gland corticosterone mirrored that of circulating corticosterone, calorie restriction reducing its levels. Plasma ACTH and corticosterone correlated significantly in controls only. Calorie restriction decreased plasma GH and leptin and distorted their 24-h rhythmicity (Fig. 25.1). Plasma ACTH levels in calorie-restricted rats were lower, and plasma corticosterone levels were higher than those of pair-fed, isolated controls and grouped caged controls (Chacon et al. 2005). The results indicate that a reduced availability of nutrients is a stressor that affects the circadian variation of pituitary hormones and leptin.

Malnutrition produced by low or absence of proteins in diet is linked to increased susceptibility to infection, often associated with severe marasmus or kwashiorkor. In contrast, calorie restriction of adult rats by a diet enriched in proteins and low in fat and carbohydrates only partially affected weight and significantly increased immune responses (Pahlavani 2004). The immunological status of adult rodents fed a calorie-restricted diet is superior to the immunological status of the nonrestricted animals and through this mechanism caloric restriction may retard immunosenescence. Indeed, experimental calorie restriction (e.g., 25–50% reduction of caloric intake), without deficiency in essential nutrients, is a very unique manipulation in slowing the aging process in rodents. To examine this subject, mitogenic responses, lymphocyte subset populations, and interferon (IFN)-γ release were determined in submaxillary lymph nodes at 6 time intervals during the 24 h span (Esquifino et al. 2004b). After caloric restriction, mean values of concanavalin A (Con A) response, lymph node T and CD4$^+$ cell number and CD4$^+$/CD8$^+$ ratio augmented, whereas those of B cell number, IFN-γ release and glutamine and glutamate concentration decreased. Calorie restriction modified 24-h rhythmicity of lymph node mitogenic responses to Con A and lipopolysaccharide (LPS), and of T, T-B, CD4$^+$, and CD4$^+$–CD8$^+$ lymph node cell subsets. It also changed the 24 h pattern of lymph node IFN-γ release. Availability of nutrients presumably affects the mechanisms that modulate the circadian variation of immune responsiveness in growing rats.

In a subsequent experiment the effect of calorie restriction on splenic immune responses was studied (Cano et al. 2006). Calorie-restricted rats showed increased splenic Con A response with peak activity during the activity span. The highest values of T cells occurred in calorie-restricted rats and mean values of splenic CD4$^+$ and CD8$^+$ cells augmented in these animals. It is of interest that these immunological changes correlate with the efficacy of calorie restriction to prevent experimental allergic encephalomyelitis in rats (Esquifino et al. 2004a, 2007). The changes caused by caloric restriction on circadian organization of the neuroimmune response in rats are summarized in Table 25.1.

25.3 Circadian Neuroimmune Organization after Hyperadiposity in High Fat-Fed-Rats

There is a large body of evidence that links feeding regimens and food components with the circadian system (Froy 2007). A high-fat diet, that contributes to insulin resistance, impaired glucose metabolism, type 2 diabetes mellitus, stroke, and coronary artery disease can feed back to influence the
Fig. 25.1 Effect of calorie restriction on 24-h changes in plasma GH and plasma leptin levels in male rats. Calorie-restricted rats had daily access to 7 g of a diet enriched in proteins and low in fat and carbohydrates and water ad libitum for 4 weeks. This calorie restriction was equivalent to a 66% of food restriction. Groups of seven to eight rats were killed by decapitation at six different time intervals throughout a 24-h cycle. Bar indicates scotophase duration. Results are the means ± SEM. Letters indicate the existence of significant differences between time points within each group after a one-way ANOVA followed by Tukey–Kramer´s multiple comparisons test, as follows: [a] $p < 0.05$ versus 13 HALO. [b]$p < 0.01$ versus 9, 13, 17, and 21 HALO. [c]$p < 0.05$ versus 5 HALO. [d]$p < 0.05$ versus 21 HALO, $p < 0.01$ versus 5 HALO. [e]$p < 0.05$ versus 1, 13, 17, and 21 HALO (Reproduced from Chacon et al. 2005. With permission)

biological clock (Yanagihara et al. 2006). This could explain why the circadian oscillation of many hormones involved in metabolism, such as corticosterone, insulin, glucagon, adiponectin, leptin, and ghrelin, becomes disrupted in the development of the metabolic syndrome and obesity (Froy 2007).

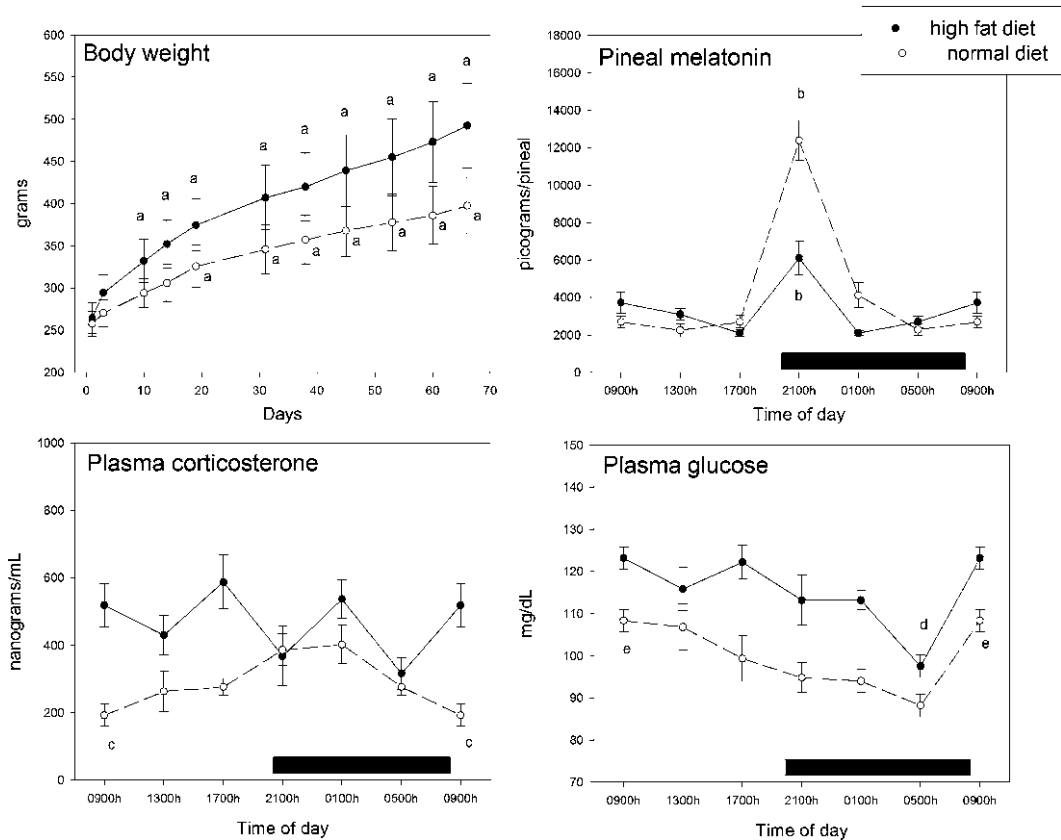
In a recent series of studies we have analyzed the effect of a high-fat diet (35% fat) on 24-h changes circulating prolactin, LH, testosterone, corticosterone, thyroid-stimulating hormone (TSH),


Fig. 25.2 Progression of body weight, and 24-h changes in pineal melatonin content, plasma corticosterone, and glucose levels in Wistar male rats fed with normal or high-fat diet. When body weights of high-fat-fed rats attained values about 20–25% higher than controls (after 66 days of treatment), groups of eight rats were killed by decapitation at six different time intervals throughout a 24-h cycle. Shown are the means ± SEM. [a]$p < 0.01$ versus initial weight; [b]$p < 0.01$ versus the remaining time points; [c]$p < 0.02$ versus 2100 and 0100 h. [d]$p < 0.01$ versus 0900, 1700, and 0100 h, $p < 0.05$ versus 1300 and 2100 h. [e]$p < 0.01$ versus 0100 and 0500 h (one-way ANOVA followed by a Student–Newman–Keuls multiple comparisons test) (Redrawn from Cano et al. 2008. With permission)

and glucose, and pineal melatonin content, in rats fed a high fat diet (Fig. 25.2) (Cano et al. 2008). A significant disruption of the 24-h pattern of plasma TSH, LH and testosterone, and a less prominent disruption of prolactin rhythm were found (Table 25.4). Additionally, high-fat-fed rats showed significantly lower total values of plasma TSH and testosterone and absence of correlation between testosterone and circulating LH levels. Plasma corticosterone levels increased significantly in high-fat-fed rats and their 24-h variation became blunted. In obese animals, a significant hyperglycemia developed, individual plasma glucose values correlating with circulating corticosterone in high-fat-fed rats only. The amplitude of the nocturnal pineal melatonin peak decreased significantly in high-fat fed rats (Fig. 25.2). Altogether the results underlie the significant effects that obesity has on circadian organization of hormone secretion (Cano et al. 2008).

The key involvement of the adrenocortical axis in obesity in animals is well recognized, since most obese animals are hypercorticoid and many of the metabolic and endocrine impairments are normalized or attenuated by adrenalectomy or by preventing glucocorticoid action (Vegiopoulos and Herzig 2007). Indeed, high-fat feeding alters both basal and stress-induced hypothalamic–pituitary–adrenal

Table 25.4 Circadian neuroendocrine-immune organization in hyperadiposity: keypoints

- Circadian oscillation of many hormones involved in metabolism (corticoids, insulin, glucagon, adiponectin, leptin, ghrelin) becomes disrupted in the development of the metabolic syndrome and obesity
- Obese rats show increased circulating levels of leptin and decreased plasma ghrelin, together with signs of insulin resistance
- The increased levels of plasma IL-1, IL-6, TNF-α, and MCP-1 in obese rats indicate the occurrence of a moderate degree of inflammation
- Obesity is associated with a low-grade inflammation of the white adipose tissue that can subsequently lead to insulin resistance, impaired glucose tolerance, and diabetes
- A disruption of the 24-h pattern of TSH, corticosterone, melatonin, LH, and testosterone with absence of correlation between testosterone and circulating LH levels is found in obese rats
- Obesity results in disruption of the inherent transcription, translation, and posttranslational modifications that give the cellular clock its own natural rhythmicity

activity in genetically obese Zucker rats, as well as in other rodent models of obesity (Chen and Wang 2005). A major observation is that the return of ACTH and corticosterone to initial values was delayed, indicating resistance to glucocorticoid feedback. In a study to assess whether dietary fat-induced increase in corticosterone was due to an altered regulation of hypothalamic–pituitary–adrenal axis, rats fed a high-fat diet exhibited significantly elevated levels of plasma ACTH, corticosterone, fatty acid, and glucose before, during, and after the termination of a restraint stress (Tannenbaum et al. 1997).

A high-fat diet contributes to insulin resistance, impaired glucose metabolism, type 2 diabetes mellitus, stroke, and coronary artery disease. As far as glucose metabolism is concerned, dietary fat not only lowers glucose uptake but also stimulates inappropriate glucose production, resulting in elevations in both circulating insulin and glucose (Glueck et al. 1969). High-fat diets decrease the number of insulin receptors in liver, skeletal muscle, and adipose tissue, decrease glucose uptake into skeletal muscle and adipose tissue, and decrease hepatic glycolysis and glycogen synthesis. One of the factors accounting for insulin resistance in high-fat fed animals is the elevation of glucocorticoid production that antagonizes most of insulin's actions. Indeed, the effects of increased glucocorticoid levels mimic those of a high-fat diet, as suggested in our studies by the significant correlation between circulating corticosterone and glucose levels found in high-fat-fed rats only (Cano et al. 2008).

In obese men, sex hormone-binding globulin as well as total testosterone levels are decreased (Winters et al. 2006). The results of Cano et al. (2008) in obese rats indicate a significant decrease of total plasma testosterone levels and a loss of correlation of testosterone with circulating LH levels. Since saturated fatty acid treatment decreases LH-stimulated adenylate cyclase activity and testosterone levels (Gromadzka-Ostrowska et al. 2002) in rat testis, and induces apoptosis of Leydig cells (Lu et al. 2003), the results are compatible with a deleterious effect of high-fat diet on testicular function (Cano et al. 2008). It must be noted, however, that interpretation of the total serum testosterone concentration is problematic because it is related directly to the serum sex hormone-binding globulin concentration. Further studies are needed to assess whether free testosterone are also decreased in high-fat-fed rats. Indeed, an estimate of the serum-free testosterone concentration is frequently advised to better assess the clinical status of the obese patient (Elin and Winters 2004), being decreased in some morbidly obese men only.

Melatonin has a role in energy expenditure and body mass regulation in mammals (Bartness et al. 2002). Daily melatonin administration has been found to inhibit age- and olanzapine-related gain in visceral fat (Rasmussen et al. 2001; Raskind et al. 2006), and to prevent the increase in body fat caused by ovariectomy in rats (Ladizesky et al. 2003; Sanchez-Mateos et al. 2007). In a model of diet-induced obesity, Sprague Dawley rats fed a 39.7% high-fat diet and concomitantly administered with melatonin showed a 50% reduction in body weight increase (Prunet-Marcassus et al. 2003). Melatonin had no effect on plasma insulin level, but it decreased plasma glucose, leptin, and triglyceride

levels significantly. Conversely, in pinealectomized high-fat fed rats, body weight gain and feed efficiency increased, an effect prevented by melatonin treatment (Prunet-Marcassus et al. 2003). These results, together with the significant reduction of melatonin synthesis in high-fat-fed rats described by us (Fig. 25.2), indicate that melatonin can act as a regulator of body weight in this model of obesity and can prevent some of the side effects on glucose homeostasis such as decreased insulin sensitivity.

Reduction in amplitude of circadian rhythms like that reported for melatonin has been attributed to fatness. For example, in rats susceptible to obesity (Osborne-Mendel rats) the amplitude of rhythm of leptin and insulin was about 50% that in rats relatively resistant to obesity (Ishihara et al. 2004). Other 24-h rhythms are affected by high-fat diet in animals. For example, induction of obesity using a high-fat diet in rabbits causes hypertension by suppression of the nocturnal dip in blood pressure and heart rate and elimination of the day–night difference in both parameters (Antic et al. 2001). Diurnal rhythms of blood pressure and heart rate were abolished as early as day 1 of ad libitum high-fat feeding, before significant changes in body weight were evident (Carroll et al. 2005). Thus, food intake by itself appears to be a significant influence on the circadian apparatus (Table 25.2).

Via a number of secreted proteins called adipocytokines including hormones, cytokines, growth factors, complement factors, and matrix proteins, the adipose tissue participates in the regulation of body weight homeostasis, glucose and lipid metabolism, immunity, and inflammation (see for Ref. (Holvoet 2008)). This prompted us to examine whether the significant disruption of 24-h hormonal pattern seen in high-fat fed rats coexists with changes in the daily pattern of several circulating adipocytokines (Cano et al. 2009) (Table 25.2). As expected in high-fat fed rats increased circulating levels of leptin and decreased plasma ghrelin, together with signs of insulin resistance (i.e., hyperglycemia and increased insulin levels). Concomitantly, the increased mean levels of plasma IL-1, IL-6, TNF-α, and MCP-1 suggested the occurrence of a moderate degree of inflammation in high-fat-fed rats. The normal daily pattern of plasma insulin, leptin, ghrelin, adiponectin, TNF-α, and monocyte chemoattractant protein (MCP)-1, and to a lesser extent, that of IL-1 and IL-6, became disrupted in experimentally obese rats (Cano et al. 2009).

There is impressive information indicating that obesity is associated with a low-grade inflammation of the white adipose tissue that can subsequently lead to insulin resistance, impaired glucose tolerance, and diabetes (Waki and Tontonoz 2007; Phillips and Prins 2008). Inflammation in obesity is indicated by increased circulating levels of C-reactive protein and other biological markers of inflammation. The adipose tissue, in obesity, is characterized by an increased production and secretion of inflammatory molecules like TNF-α and IL-6, which may have local and systemic effects. The amounts of TNF-α and IL-6 are positively correlated with body fat and decrease in obese patients after weight loss (Tilg and Moschen 2008). Among the biological actions of TNF-α and IL-6, induction of insulin resistance is paramount; thus, fat cells are both a source of and a target of TNF-α and IL-6. High-fat diets have been shown to produce a significant increase of TNF-α, IL-1, and IL-6 levels (Guest et al. 2008). The increased circulating levels of leptin and insulin and decreased plasma ghrelin reported in high-fat-fed rats (Cano et al. 2009) confirms that excess fat accretion is associated with hyperleptinemia, hyperinsulinemia, and hypoghrelinemia in experimental animals and humans (Guest et al. 2008).

Adiponectin is known to have an important anti-inflammatory and antiatherogenic effect that is apparently mediated by inhibition of inflammatory cytokines, blocking the activation of macrophages and posterior transformation to foam cells Sheng and Yang 2008). Although several studies point out to a decrease in plasma concentration of adiponectin in obesity other results indicate an increase in mean levels of adiponectin in high-fat-fed rats as well as a significant modification in its daily pattern in circulation (Cano et al. 2009) (Table 25.2). Therefore, in dietary-obese rats, a decrease in adiponectin mRNA levels reported in fat does not translate to a parallel decrease in plasma adiponectin concentration.

In the stromovascular (non-adipocyte) fraction of adipose tissue from obese rodents there is an increase in the number of bone marrow–derived macrophages (Weisberg et al. 2003). Indeed, white adipose tissue from obese animals expresses multiple genes usually attributed to macrophages. The mechanism for macrophage recruitment to adipose tissue has not been defined in detail but presumably includes chemotactic molecules like MCP-1, which is synthesized and secreted by preadipocytes and mature adipocytes in diet-induced obese mice (Chen et al. 2005). The results of Cano et al. (2009) indicate that a high-fat diet augments the mean levels of MCP-1 and disrupts its 24-h pattern (Table 25.2). Since MCP-1 impairs insulin-stimulated glucose uptake by cultured adipocytes in vitro (Sartipy and Loskutoff 2003), the increased MCP-1 levels may contribute to the insulin resistance. Collectively, the above discussed observations suggest that a high-fat intake causing insulin resistance and signs of inflammation may disrupt the daily pattern of several hormones and adipocytokines, an indication that obesity has a significant effect on circadian organization of neuroendocrine and immune responses.

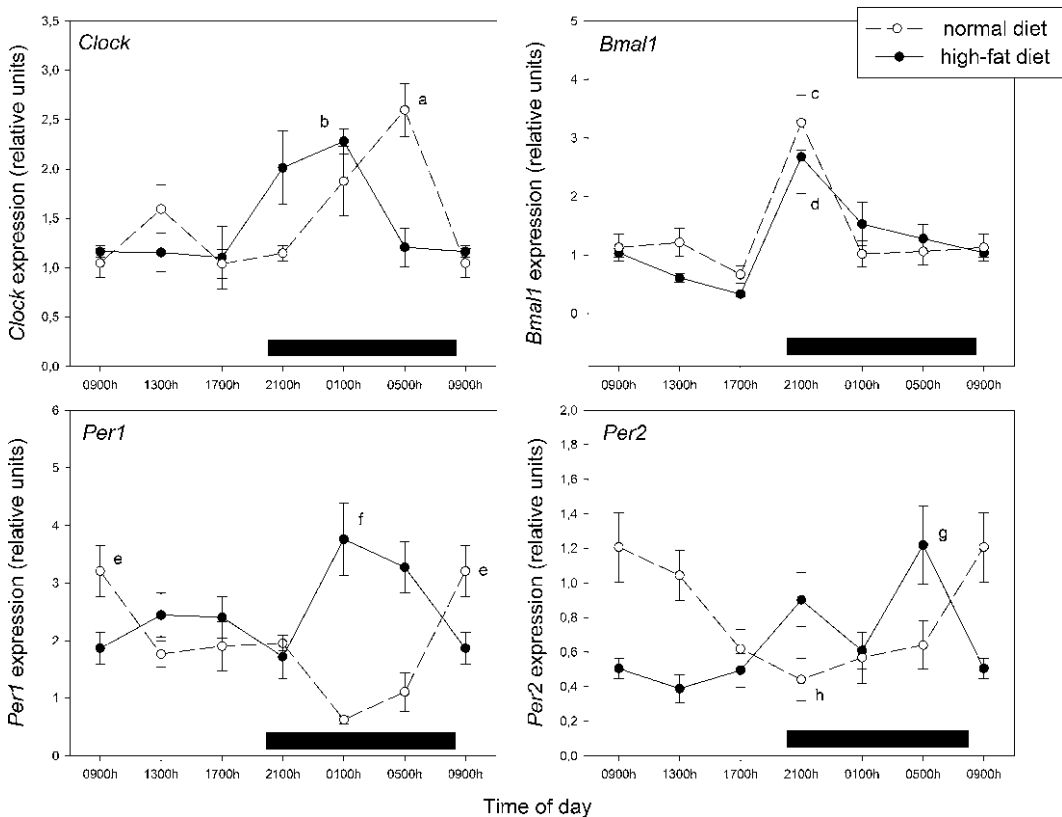
That the high-fat diet did interfere with the circadian signaling regulating gene expression of these enzymes was indicated by clock gene expression changes (Figs. 25.3 and 25.4). At a cellular


Fig. 25.3 Effect of a high-fat diet on 24-h changes in expression of *Clock*, *Bmal1*, *Per1*, and *Per2* genes in the anterior pituitary of rats. When body weight of high-fat-fed rats attained values about 20–25% higher than controls, groups of six to eight rats were killed by decapitation at six different time intervals throughout a 24-h cycle. mRNA levels encoding circadian clock genes were measured as described elsewhere (Cano et al. 2007). Shown are the means ± SEM of mRNA determination as measured by triplicate real-time PCR analyses of RNA samples. Letters denote significant differences in a one-way ANOVA followed by a Bonferroni's multiple comparison test, as follows: [a]$p < 0.05$ versus 0900, 1700, and 2100 h; [b]$p < 0.05$ versus 0900, 1300, and 2100 h; [c]$p < 0.01$ versus all other time points; [d]$p < 0.01$ versus 0900, 1300, and 1700 h; [e]$p < 0.01$ versus 0100 and 0500 h; [f]$p < 0.05$ versus 0900 h; [g]$p < 0.01$ versus 0100, 0900, 1300, and 1700 h; [h]$p < 0.05$ versus 0900 h (Esquifino et al. unpublished results)

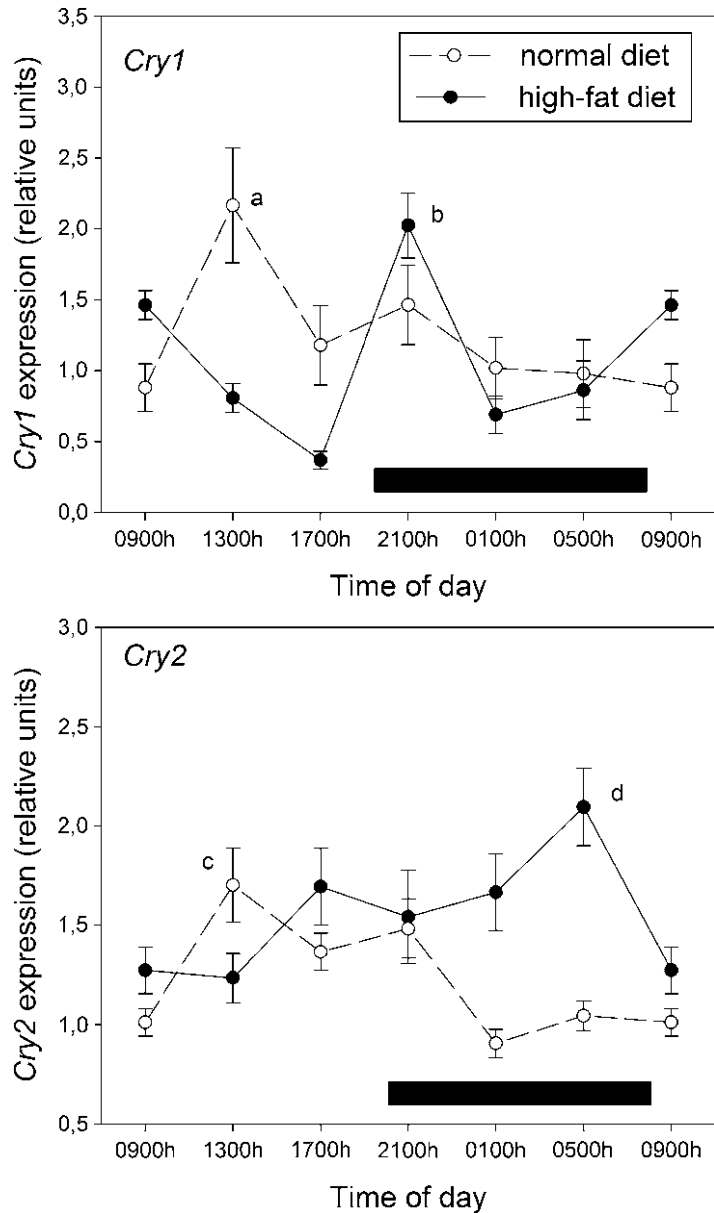
Fig. 25.4 Effect of a high-fat diet on 24-h changes in expression of *Cry1* and *Cry2* in the anterior pituitary of rats. When body weights of high-fat-fed rats attained values about 20–25% higher than controls, groups of six to eight rats were killed by decapitation at six different time intervals throughout a 24-h cycle. mRNA levels encoding circadian clock genes were measured as described elsewhere (Cano et al. 2007). Shown are the means ± SEM of mRNA determination as measured by triplicate real-time PCR analyses of RNA samples. Letters denote significant differences in a one-way ANOVA followed by a Bonferroni's multiple comparison test, as follows: [a]$p < 0.05$ versus 0900 h; [b]$p < 0.01$ versus 1300, 1700, 0100, and 0500 h; [c]$p < 0.05$ versus [d]$p < 0.05$ versus 0900, 0100, and 0500 h (Esquifino et al. unpublished results)


level, circadian rhythms are driven by the self-regulatory interaction of clock genes and their related proteins. Among these *Bmal1*, *Per1*, *Per2*, *Cry1*, *Cry2*, and *Clock* play a major role (Hastings et al. 2003). The heterodimer of the proteins Clock:Bmal1 binds E-box elements at the promoter region of *Per1*, *Per2*, *Cry1*, and *Cry2*, inducing their transcription. Conversely, Per1–2 and Cry1–2 proteins, by interacting with the Clock:Bmal1 heterodimer operate as negative regulators inhibiting their own transcription. Via clock-controlled genes and their downstream effectors, peripheral circadian clock components directly regulate many aspects of cell physiology, such as membrane trafficking, detoxification, nutrient metabolism, and the cell cycle (Hastings et al. 2003).

In the anterior pituitary of rats fed a normal diet the peaks of *Bmal1* and *Per1* and *Per2* expression were in antiphase, *Bmal1* peaking at the beginning of the night and *Per1* and *Per2* peaking about 12 h

later, at the beginning of the light phase. Such a normal relation was reported in several peripheral tissues. Maximal expression of *Cry1* and *Cry2* showed a phase delay of about 4 h as compared to *Per1* or *Per2*.

High-fat-fed rats exhibited a disrupted 24-h rhythmicity of *Clock*, *Per1*, *Per2*, *Cry1*, and *Cry2* expression without affecting the diurnal rhythmicity of *Bmal1*. In particular, *Per1*, *Per2*, *Cry1*, and *Cry2* rhythmicity was almost inverted by the high-fat diet. The results indicate that the inherent transcription, translation, and posttranslational modifications that give the clock its own natural rhythmicity can be severely disrupted in obese rats.

25.4 Conclusions

This review discusses the circadian disruption of hormone release and immune-related mechanisms in the animal models of calorie restriction and hyperadiposity in rats. In every case, the experimental manipulation used perturbed the temporal organization by affecting the shape and amplitude of the rhythm. Further experiments are needed to assess whether the changes in amplitude as well in timing of 24-h rhythms discussed herein can be attributed to an effect on the SCN or to a masking effect on some output(s) of the clock.

25.5 Applications to Other Areas of Health and Disease

Among the innumerable periodic changes that underlie and support the overt circadian physiologic rhythms, the peak values occur in a characteristic sequence over the day ("phase map") in human healthy subjects. Such a sequence and spacing reflects the order and temporal relationships of cause–effect in the normal interactions of the various bodily processes and is very indicative of an organism's health. Most chronic diseases come along with a significant circadian disruption. Medical chronobiology is concerned with the mechanisms of periodic influences on health and disease. Chronopathology is the study of biological rhythms in disease processes and in morbid and mortal events; most medical conditions are affected by circadian rhythms. Chronopharmacology is the discipline that investigates the effects of a drug as a function of biological time. Disruption of amplitude or phase of circadian rhythms by dietary conditions like that discussed in rodents herein can underlie major health problems affecting the developed and the developing world, like the metabolic syndrome.

Summary Points

- Availability of nutrients affects the mechanisms that modulate the circadian variation of pituitary–gonadal axis.
- Malnutrition produced by low or absent proteins in diet is linked to increased susceptibility to infection while calorie restriction of rodents by a diet enriched in proteins and low in fat and carbohydrates significantly increases immune responses.
- Circadian oscillation of many hormones involved in metabolism (corticoids, insulin, glucagon, adiponectin, leptin, ghrelin) as well as of TSH, corticosterone, melatonin, LH, and testosterone becomes disrupted in the development of the metabolic syndrome and obesity.
- Obesity results in disruption of the inherent transcription, translation, and post-translational modifications that give the cellular clock its own natural rhythmicity.

Definitions and Explanations

Circadian: The term "circadian" comes from the Latin circa, "around," and diem or dies, "day," meaning literally "approximately one day."

Zeitgeber: Circadian rhythms are endogenously generated, and can be entrained by external cues, called Zeitgebers, the primary one of which is daylight. An entraining agent can actually reset, or phase shift, the internal clock.

Humoral immunity, delayed (cellular) immunity: Humoral Immunity comprises the aspect of immunity that is mediated by secreted antibodies produced in the cells of the B lymphocyte lineage (B cell). Delayed (cellular) immunity is an immune response that does not involve antibodies or complement but rather involves the activation of macrophages, natural killer cells, antigen-specific cytotoxic T-lymphocytes, and the release of various cytokines in response to an antigen.

Cytokines: Cytokines are a category of signaling molecules that are used extensively in cellular communication. The term cytokine encompasses a large and diverse family of polypeptide regulators that are produced widely throughout the body by cells of diverse embryological origin. Although current terminology refers to cytokines as immunomodulating agents, the differences with hormones are not yet clearly defined.

Adipocytokines: It is a cytokine produced by an adipocyte. The term includes, besides cytokines, hormones like adiponectin, leptin, and resistin.

Chapter 26
Development of Regulation of Food Intake by the Gut and the Brain: Modeling in Animals

Takashi Higuchi and Chuma O. Okere

Abbreviations

AGRP	Agouti-related protein
ARC	Arcuate nucleus
CART	Cocaine-amphetamine-regulated transcript
CCK	Cholecystokinin
DG	Deoxyglucose
DMH	Dorsomedial hypothalamus
DVC	Dorsal vagal complex
LHA	Lateral hypothalamic area
MA	Mercaptoacetate
MC	Melanocortin
NPY	Neuropeptide Y
NTS	Nucleus of the solitary tract
OLETF	Otsuka Long-Evans Tokushima fatty
POMC	Proopiomelanocortin
PVN	Paraventricular nucleus

26.1 Pups Receive Nutrition from the Mother Through Suckling

26.1.1 Suckling and Weaning

The rat offspring is immature at birth and the pups are born blind and deaf, unable to maintain body temperature, or eliminate wastes without maternal stimulation. During the first 2 weeks of postnatal life, milk supply from the mother is the only food for the young pups. Milk contains 60% fat and provides required fatty acids and ketones that are utilized for routine metabolism by the brain. In addition to dependence on food, the pups depend on their mothers for warmth, urination, and

defecation. During this period, for instance, the thermoregulatory mechanisms present in adults that are responsible for increasing heat production when there is a decline in body temperature are immature in the pups. Thermal homeostatic mechanisms mature between P10 and P20 and the pups begin to nibble on solid matter including bedding, feces, and chow around the P16 or P17 postnatal day. The process of weaning proceeds gradually over the next week. These developmental changes are paralleled by a change in diet from one that is high in fat and low in carbohydrate to one that is low in fat and high in carbohydrates during weaning. Concomitant with the process of weaning, the eyes and ears open on P14, just before the pups commence on a robust avid exploration of their environment.

26.2 Suckling: Interaction Between Mother and Pup

26.2.1 Location and Attachment to the Nipple by the Pups

Generally speaking, behavioral interaction between mothers and pups can be described in three phases. The first phase occurs during the first week after birth with the mother being the exclusive initiator of contact with pups. Typically, the maternal behavior during this first phase includes, but is not limited to, the mother dam retrieving the pups to her nest followed by spending 80–90% of her time hovering over her nestled young during the initial days immediately following parturition. By P15, the pups are well insulated with fur and fat and their eyes have opened and are rarely retrieved by the dam. The second phase is characterized by mutually initiated bouts of contact with the pups often leaving the nest to approach the mother. In the third stage of the nursing–suckling relation, the contact is initiated almost exclusively by the infant (Blass and Teicher, 1980).

26.2.2 Lactation and Nipple Attachment

Once contact with the mother is established, the pups locate and attach to a nipple and suckle. In the rat pup, contact elicits a characteristic "rooting" response through which the infant, using swimming-like motions, moves quickly across the mother's body, scanning the surface by moving its head from side to side until the pup contacts a nipple. The pup probes the nipple area, extending its tongue and vigorously licking the nipple until it becomes erect, whereupon the pup suckles and becomes immediately quiescent (Blass and Teicher, 1980). It appears that physicochemical features of the nipple facilitate the attachment of pups. For instance, washing the nipples essentially eliminate attachment, indicating that some substance must coat the rat's nipples in order for pup attachment to occur. Subsequent application of the perfusate to the nipple reinstated suckling in much the same way that painting an extract of pup saliva on washed nipples resulted in full restoration of suckling. Intriguingly, while rat milk does not constitute an effective stimulus for nipple attachment, maternal saliva and amniotic fluid effectively bring about suckling in much the same way as the extract from washed nipples. The effectiveness of maternal saliva and amniotic fluid in enhancing pup nipple attachment is based on the fact that the parturient rat mother, between the births of pups, cleans and licks each newborn and her anogenital

region, both of which are coated with birth fluids. She also licks the nipple region thereby depositing her saliva, now rich with amniotic fluids and serves as a chemoattractant for the pups (Blass and Teicher, 1980).

26.3 Ontogeny of Hunger

Various internal stimuli (for example, stomach distension) that inhibit feeding in adult rats do not affect milk withdrawal until the pups are about 15 days old; this is the age that also marks the transitional point in nipple-attachment latency. The stretch response that is associated with milk letdown is eliminated only when the pups' stomach become so distended by repeated injections of milk that fills up the esophagus (Fig. 26.1). Another distinction between infants and adult ingestion derives from the influence of nutrient in the stomach, which differentially suppresses intake in adults, but does not exert such an effect in the pups (Fig. 26.2).

26.3.1 Attachment Latency

In early studies, the anesthetized, non-lactating dam model was used to investigate the attachment latency in the suckling test in rat pups deprived of the opportunity to suckle. It is known that olfactory cues of the dam play a significant role in the pup attachment to the nipple depending on the age of the pups (Hall and Cramer, 1977). Hence, during the first 12 days of postnatal life, the mean attachment latency for non-deprived rat pups was virtually identical to that of their deprived siblings (Fig. 26.3). However, at about P12–P14, rat pups deprived of suckling continued to exhibit rapid nipple attachment resulting in a lower mean attachment frequency in comparison with the non-deprived pups. Also, between P15 and P25, suckling was still observed in the non-deprived rats, but attachment of the nipple in addition to occurring with longer latencies, appeared to differ quantitatively. During this latter age limit, attachment to the nipple seemed almost casual in that the rats sniffed about the nipple, or they might lick it and then turn away. This overall behavior in non-deprived pups lacked the excitement characteristic of younger pups or their deprived siblings. It is therefore apparent that after the pups attained 25 days of age, liberation from maternal sensory cues seems complete. Consequently, sensory properties of the mother no longer elicited any suckling in the absence of deprivation. In this regard, suckling takes on the characteristics of adult ingestion behavior (Hall and Cramer, 1977). Suckling-deprived pups showed another age-related difference in suckling behavior. Pups 12 days of age and younger, did not leave non-lactating nipple even after 8 h of nonnutritive suckling. Starting at about P15, they shift from nipple to nipple in the absence of milk letdown. This incidence of shifting increased with deprivation and age, reaching its maximum in 21–24-day-old rat pups (Henning et al., 1979).

Cholecystokinin (CCK) is usually a potent modulator of milk ejection. However, the stretch response and milk intake were not affected by CCK until pups were about 2 weeks old: at this age, a 40-unit dose was effective in reducing milk intake (Blass et al., 1979). On the other hand, at 29 days of age, a 20-unit dose of CCK was effective in reducing milk intake in these young rats as was observed in free-feeding adults. In addition, both suckling and the stretch response were voluntarily terminated in older pups. This may be interpreted as indicating that they exhibited grooming, cage exploration, eventual rest, and sleep behaviors typically observed in adult rats at the end of a

Fig. 26.1 Stretch reaction by a pup at the time of milk letdown. A pup is suckling to an anesthetized mother (**a**), when milk-ejection reflex occurs, the pup exhibits characteristic stretch reaction, it pulls strongly against the nipple with its legs outstretched and its back arched (**b**)

meal. Such a sequence of behavioral patterns associated with satiety usually become evident after 15 days of age.

Thus during the first 2 weeks of postnatal life, pups have a basic tendency to suckle, perhaps due to olfactory cues but do not have hunger signals per se. During this time, the mother plays an active role in pup nutrition by retrieving and crouching over them to encourage suckling. A sense of hunger is not necessary during this early stage and attachment to the nipple may be an end in itself since the behavior of rats that have been suckling almost continuously is virtually indistinguishable from that of rat pups
Fig. 26.2 Pattern of weaning as determined by amount of milk and chow present in stomach contents at various developmental ages. Units are percentage by weight of total stomach contents and values are given as means±SE (*n*=5) (Reprinted from Henning et al. 1979. With permission)
Fig. 26.3 Mean latency (±SE) of non-deprived (●) and 22-h deprived (○) rat pups to attach to nipples of their anesthetized mother. A pup's score was taken as the mean of its three 5-min tests. The number of subjects given varied from 22 to 36 at each data point (Reprinted from Hall et al. 1975. With permission)

deprived of suckling for up to 24 h. Moreover, continued attachment to the nipple is apparently not dependent on letdown or amount of milk in the stomach. However, beyond the second week of postnatal life, the pups begin to roam further from their mothers and also start to nibble solid food. During this and later ages, a sense of hunger assumes a more important role as a stimulus that regulates food intake in contrast to the active role of the mother, which ensures adequate nutrition of pups of younger age.

26.4 Suckling Is Not a Prototype of Food Intake Pattern in Adults

26.4.1 Suckling and Independent Ingestion

In order to distinguish the suckling behavior of rat pups from the behaviors initiated by the mother, Hall (1979b) developed a new experimental paradigm with anesthetized mothers and pups with oral catheters. In this paradigm, a thin, polyethylene tube was implanted in the back of the rat pup's mouth through which a bolus of milk could be injected after pup attachment to a nipple. The injection of milk through this tongue cannula triggered the "stretch" response, which occurs naturally when the milk-ejection reflex occurs intermittently at 3–5 min intervals (Lincoln et al. 1973). Using these intraoral catheters, milk was infused into the mouths of pups in warm, moist, testing chambers on P3. Differential behavioral dispositions result depending on the location of oral cannula placement. For instance, when the catheter was placed on top of the tongue toward the rear to the mouth at the position of the teat during sucking, pups swallowed all of the volume of milk infused. Interestingly, the pups continued to withdraw or accept milk until they were no longer able to retain any more milk in their stomach as evidenced by either esophageal milk reflux or pup inability to maintain an appropriate nipple attachment posture (Cramer and Blass 1983). This behavior is a reflexive swallowing resulting from stimulation of the posterior portion of the oral cavity, the last component of the sensorimotor sequence of ingestion (Hall 1979b).

However, placement of the catheter beneath the tongue on the anterior floor of the mouth resulted in ingestion accompanied by active mouth movements in the pups resembling mastication and mandibulation observed in the adult rat during feeding. One major difference from pups with cannula placement in the top of the tongue toward the back of the mouth is that pups with cannula placement beneath the tongue do not ingest all the infused milk. Rather, these pups controlled their milk intake; essentially eating more after deprivation of suckling and refraining from further ingestion of infused milk when gastric volume was about 5% of body weight. This controlled ingestion observed during anterior catheter infusions is called "independent ingestion" because it occurs away from the dam and its oromotor topography differed from that associated with suckling. Another form of independent ingestion is based on the observation that the pups licked from a puddle of milk on the floor of the test chamber (Hall and Bryan 1980). This eliminates the need for a pup to search for milk while retaining the demand that the pup initiate licking and other oral movements required to move milk to the rear of the mouth to elicit swallowing. However, not until P9–P12 do pups consume milk from a spatially restricted source. Therefore, it is a reasonable proposition that independent ingestion, not suckling, may be a developmentally continuous process with adult feeding.

From a behavioral standpoint, certain distinctions can be made between suckling in pups and adult feeding behavior in terms of the physiological control and motor pattern of ingestion. For example, in the normal mother–litter situation, direct control of milk intake does not depend upon the pups altering their nipple-attachment behavior, regardless of whether suckling occurs or not. Rather, it is presumable that pups indirectly regulate intake by the vigor and rhythm of suckling. Hence, any gross or general change in behavioral vigor would have a significant influence on intake within the limits of milk availability determined by the amount of milk provided by the mother. One functional consequence of this fact is that young rats will literally drown at the nipple if provided with unlimited milk supply because young pups do not control intake when suckling. On the contrary, adult rats directly control food intake when feeding.

26.5 Development of Positive and Negative Feedback Control of Independent Ingestion

26.5.1 Positive and Negative Feedback Control

Observations from several studies indicate that post-ingestive stimulation terminated feeding because sham-fed meals were always larger than real-fed meals. The type of diet, duration of food deprivation, and experience with the diet has been suggested to determine the size of animals with sham-fed meal (Smith 2006). The different feeding patterns are under regulation of specific pathways and stimuli. For instance, olfactory and orosensory stimuli exert positive-feedback control of food intake while post-ingestive stimuli produce negative-feedback control of intake. Both orosensory and post-ingestive stimuli act preabsorptively, and stimulate the mucosal surface of the gut from mouth to the end of small intestine (Smith 2006) and may be segregated into positive and negative influences, respectively. While the positive stimuli are conveyed to the nucleus of the solitary tract (NTS) in the medulla by fibers in the cranial nerves, the negative stimuli are transmitted to the NTS by the abdominal vagus nerves. Functionally, the NTS comprises the dorsal vagal complex (DVC) with the dorsal motor nucleus of the vagus and area postrema (Fig. 26.4). Neurons within the DVC receive direct neural input from neurons in the hypothalamus implicated in the control of food intake including the paraventricular nucleus (PVN), lateral hypothalamic area (LHA), dorsomedial hypothalamus
Fig. 26.4 A schematic illustration of the neural connections of the hindbrain dorsal vagal complex (*DVC*) and hormonal inputs to the DVC in the rat. *Ap* area postrema, *Sol* nucleus of the solitary tract (*NTS*); 10 dorsal motor nucleus of the vagus (Reprinted from The Rat Brain in Stereotaxic Coordinates written by Paxinos and Watson 1982 with modification. With permission)

(DMH), and arcuate nucleus (ARC). Several unique features of the DVC make it ideally suited as a brainstem integration and command center for ingestive behavior (Rinaman 2006).

26.5.2 Eating and Drinking

Until the second week of postnatal life, eating and drinking are not differentiated as distinct responses to food and water deprivation. Hence, orosensory stimulation with milk, sucrose, and water are generally adequate orosensory stimuli in the first postnatal week since from P3 to P6, intake of the three respective stimuli are not significantly different after 24 h of deprivation (Hall 1979a). On the contrary, during the later phase of postnatal life, the extent of ingestion is dependent on the duration of nutrient deprivation. Expectedly therefore, more food intake occurs during the independent ingestion phase after 24 h of deprivation than after 1- or 7-h deprivation (Hall 1979b). In terms of functional efficacy to induce ingestion, while dehydration is the critical property that increases food intake during the first postnatal week, adult rats display dehydration anorexia. Similarly, it is hydration, not metabolic or caloric signals, that appears to be the primary modulator of independent intake after a period of deprivation. This preferential efficacy of the influence of hydration on ingestion appears to depend on postnatal evolution given that gastric infusion of isotonic saline or milk during deprivation eliminated the stimulation of intake by deprivation in pups on P6. However, only milk infusions blocked the increased intake in pups on P15 (Phifer et al. 1986). These observations suggest that when deprived of nutrients in early postnatal life, thirst but not hunger is the primary stimulus for increased ingestion by pups.

This conclusion is supported by findings that as early as P2, intracerebroventricular (i.c.v.) injection of angiotensin II induces an intake of both milk and water. It is noteworthy that a preferential intake of a greater amount of water relative to milk, which is the characteristic dipsogenic response to angiotensin II seen in adults, appears on P8. Also, neurochemical modulators of feeding exert different effects during different phases of early postnatal life or development. For example, the orexigenic effect of i.c.v. norepinephrine is believed to appear at P9 and P10; and, at an age when it exerted orexigenic effect in pups feeding away from their dam, norepinephrine had no effects on nipple attachment latencies or on the amount of time spent on the nipple (Ellis et al. 1984). Also, injection of neuropeptide Y (NPY) into the PVN enhanced milk and water intake equally at P2 while at P15, NPY produced a significantly greater enhancement of milk than water intake (Capuano et al., 1993).

In another context, dehydration anorexia does not emerge until after the first 2 weeks of postnatal development (Bruno, 1981), while the inhibitory effect of dehydration on gastric emptying emerges sometime between P11 and P19. This developmental period coincides with that during which plasma hyperosmolality first begins to inhibit independent ingestion (Callahan and Rinaman 1998). Taken together, an early picture of the ontogeny of mechanisms controlling food intake in rat pups suggest that pups possess only rudimentary control over independent ingestions that are related to the hydrational status and not to energy status.

26.5.3 Taste

During the first few days of postnatal life, rat pups can distinguish various chemical solutions and milk from water. Hence, intraoral milk infusions on P1 can serve as a reinforcing stimulus in shaping an operant response (Johanson and Hall, 1980). From P3, pups show discrimination between water and sucrose in their mouthing behavior and general activity, but discrimination of the amount of intake appears from P6. For example, infusions of 5%, 10%, and 20% sucrose during this period of

postnatal life produced equivalent intake in the amounts of the three solutions all of which were significantly more than the intake after water infusion (Hall and Bryan 1981). Later in development by P14, the volume of sucrose ingested was a monotonic linear function of sucrose concentration (Ackerman et al. 1992).

Similarly, intake after infusions of corn oil changed during this period, but these changes occurred later than those in response to sucrose. For instance, by 12–15 days of age, pups responded more to oil emulsions (10% and 30%) than they did to water or emulsifier solution. Interestingly, the corn and mineral oil emulsions were almost as effective as milk but less effective than sucrose (0.3 M) in stimulating ingestion (Ackroff et al., 1990). On P14, emulsions of corn oil produced more intake than infusions of water, but the intake was not a monotonic function of concentration until P21 (Ackerman et al., 1992). The changing potency of corn oil emulsion is due to maturation of the sensitivity of the trigeminal tactile system to texture of viscosity or the maturation and sensitivity of a gustatory system to fatty acids.

26.6 Emergence of the Post-ingestive Inhibition

26.6.1 Gastric Volume

Of all the post-ingestive stimuli that can influence ingestion, gastric volume is sufficient to terminate eating in the first postnatal week, a time when the eating and drinking systems have not been differentiated. For instance, when pyloric noose was open or closed on P6, a gastric preload of milk or saline decreased food intake equally in pups. However, regardless of noose or preload condition, post-ingestive food intake stopped when stomach content reached approximately 6.5% of body weight (Phifer et al. 1986). When gastric fistulas were unplugged after the pups had stopped ingesting milk, additional vigorous ingestion followed with total intakes of up to 20% body weight. Therefore, the signal for termination of intake in young rat pups appears to be controlled exclusively by the level of gastric filling: pregastric signals alone appear insufficient, and postgastric signals appear unnecessary for termination of intake (Phifer et al. 1986).

26.6.2 Hypertonic Preload

In addition to the effect of preload volume, hypertonic preloads of 20% glucose and 20% maltose produce a larger reduction of food intake by pups than isotonic preloads (Weller et al. 1997). This inhibitory effect of 20% glucose on P12 may be unrelated to post-absorptive metabolic effects because a preload of 20% 2-deoxyglucose (2-DG), which is not metabolized, actually decreased glucose utilization and produced equivalent inhibition of intake (Weller et al. 1997). In addition, the magnitude of the reduction of intake by intraperitoneal injection of 20% glucose was much smaller than by gastric preload (Weller et al. 2001). In a separate experiment circumventing intestinal degradation and transport problems, the glucose solution was introduced into the rat's body closer to the circulation; but this route drastically decreased the efficacy of the glucose solution to inhibit intake. This suggests that the nutritive metabolic stimulus of carbohydrate preload may not control post-ingestive intake during preweaning period in the rat. Moreover, hypertonic stimuli in the stomach or small intestine provide inhibitory control of food intake by postnatal day 12.

The mechanism by which the volume of an isotonic preload or hypertonic preload inhibits food intake is unknown, but is most likely through vagal mechanoreceptors transmitting the signal to the

NTS. This derives from findings that CCK1 receptor antagonist devazepide did not inhibit the inhibitory effect of volume and hypertonic preloads (Weller et al. 1997). When the CCK antagonist was administered prior to the test in which no preload was given, food intake did not change in pups tested on P9–P18. This evidence suggests that endogenous CCK does not mediate the post-ingestive negative feedback control of intake of milk in pups of this age.

26.6.3 Nutritive Effect of Fats and Proteins

Compared to a sham-preload treatment, gastric preloads of corn oil inhibited intake on P12 to an equivalent extent as preloads of a similar concentration of nonnutritive mineral oil. Only a few days later, on P15 and P18, corn oil preloads significantly reduced intake more than the mineral oil preloads (Weller et al. 1997). The inhibitory effect of corn oil appeared to be due to its fatty acid components rather than its tactile or textual effects because identical preload of mineral oil produced significantly less inhibition of intake. The gastric preload of corn oil probably inhibited intake by a preabsorptive chemical action related to its component fatty acids. The site of this preabsorptive action is uncertain, but is mediated, at least in part, by the endogenous CCK system. While pretreatment with devazepide did not affect the decreased net intake produced by a nonnutritive fat preload compared to sham preload, this antagonist significantly reduced the intake inhibition of corn oil. This result suggests an attenuation of its differential effect compared to the mineral oil preload (Weller et al. 1997), probably acting at the vagal afferent terminals in the small intestine.

Intragastric or intraduodenal administration of peptones, hydrolysates of proteins, decreases food intake in adult rats. Also, the effects of isotonic or hypertonic gastric preloads of peptones on food intake during an independent ingestion test away from the dam reveal that preloads of isotonic peptone significantly reduced intake more than preloads of isotonic saline on P18, but not on P12 (Weller and Tsitolovskya 2004). Thus, the ability to respond behaviorally to this nutritive stimulus appears to emerge between P12 and P18. This is a similar ontogenic time course as that observed for the inhibition of intake by a preload of corn oil.

26.6.4 CCK

CCK exists in several forms (amino acid chain lengths), all sharing a common identical bioactive C-terminal primary 8-amino-acids long, called CCK-8. Most experiments were performed using this CCK-8. Release of CCK from the upper small intestine by preabsorptive nutrient stimuli is a mechanism for negative feedback control of meal size under physiological conditions. Entry of food into the intestine triggers the release of endogenous CCK by the intestinal mucosa thereby activating CCK-1 receptors located in the abdomen and vagus nerve terminals to transmit satiety signal to the NTS in the hindbrain (Moran and Kinzig, 2004).

It has been reported that CCK reduced the volume of milk ingested during independent feeding as early as P1 without any evidence of aversive behavioral side effects (Robinson et al., 1988). Also CCK inhibited the rate of gastric emptying in P1 and P3 rat pups, and the threshold dosage for this suppression were identical to the threshold for the inhibition of ingestion. Since in P6 rat pups, gastric distention is the only signal inhibiting independent ingestion (Phifer et al. 1986), an aspect of the satiety action of CCK is indirect and derives from the hormone's action on gastric emptying, resulting in gastric distention.

Rinaman and colleagues were the first to investigate the pattern of increased cFos immunoreactivity, an index of neuronal activity, after intraperitoneal CCK injections in neonatal rats. They observed

that CCK increased the numbers of cFos-positive cells in the NTS on P2, but unlike the adult rats, there was no increase in the number of cFos immunoreactive cells in the forebrain (Rinaman et al. 1994). They interpreted the lack of forebrain cFos immunoreactivity in pups on P2 as evidence of immaturity of ascending connections from the hindbrain to the hypothalamus. The caudal brainstem of the adult rat has sufficient neural complexity to process vagal stimulation by peripheral CCK into an inhibitory effect on intake, because peripheral CCK decreased intake in the chronic decerebrated rats (Grill and Smith 1988). That CCK decreased intake on P1 and increased cFos immunoreactive cells in the NTS but not in the forebrain, is evidence that this is also the case in the neonatal rat. On the other hand, CCK did not reduce milk intake by P5 and P10 but was effective in depressing milk intake in P15 and P20 rat pups. Of significant note is that, despite its inhibitory effect on milk intake, CCK never lengthened the latency to attach to the nipple (Blass et al. 1979).

The stimulation of cFos immunoreactive cells in the NTS in pups on P10 and P11 (Blumberg et al. 2006b), and the decrease in food intake produced by the release of endogenous CCK in pups on P9–P12 (Weller et al. 1990) indicate that negative feedback control mechanisms from the small intestine may be functional by the second week by which time the regulatory mechanisms that control nutrient and water intake during independent ingestion have become differentiated. Results from studies using devazepide suggest that CCK-1 receptors appear to mediate a portion of the reduction of food intake produced by corn oil, but not by glucose or peptone in infant rats. However, recent finding that Otsuka Long-Evans Tokushima fatty (OLETF) rats, which do not express CCK-1 receptors, exhibit increased meal size and weight gain as early as P2–P4 (Blumberg et al. 2006a), suggest that the CCK system may have a physiological role in the regulation of food than earlier thought.

26.6.5 Ghrelin

Ghrelin was identified as an endogenous ligand for growth hormone secretogogue receptor, and was later found to have an orexigenic action. Ghrelin is produced mainly in the oxyntic glands of the stomach and is released in response to negative energy balance, such as starvation (Kojima and Kanagawa 2005). Generally, it is accepted that olfactory and orosensory stimuli elicit positive-feedback control of intake while post-ingestive stimuli produce negative-feedback control of intake. Ghrelin is only one endogenous orexigenic substance that is synthesized in the gastrointestinal tract. Similar to the site of action of CCK, the vagus afferent nerve is the major pathway for peripheral signals of ghrelin for starvation (Kojima and Kangawa 2005).

There are not many studies on the role of ghrelin in the control of food intake during preweaning period. It is however known that 8 h of milk restriction significantly decreased and increased the ghrelin concentration in the stomach and the plasma, respectively, in P7 rat pups (Hayashida et al., 2002). It has been reported recently that ghrelin increased independent feeding as early as P10 in pups whereas the increase in milk intake during suckling appeared only after P20. Also, an anti-ghrelin antibody inhibited milk intake on P25 and later, indicating that ghrelin may start regulating food intake from about fourth postnatal week (Piao et al. 2008).

26.7 Development of Controlling Food Intake by Metabolic Signals

Generally speaking, periods of food deprivation result in increased food intake. Among the factors that contribute to this response are cues related to change in energy availability. In adult rats, alterations in the utilization of glucose-derived energy provide a clear stimulus to increase food intake. In P6 pups, nutritive gastric preloads were followed by similar intakes and only changes in hydrational

state caused by distilled water loads appeared to affect food intake. Thus, such young pups appeared to be relatively insensitive to metabolic or caloric signals produced during deprivation. However, by P15, food intake following nutritive preloads was less than intake following nonnutritive preloads (Phifer et al. 1986). Therefore, by P15, behavioral responsiveness to a metabolic signal appears to have emerged or at least began to do so. Studies examining the nature of this metabolic signal first focused on changes in glucose metabolism using 2-DG.

The effects of interfering with glucose utilization or availability using 2-DG, 5-thioglucose, or insulin did not increase independent ingestion until the fourth postnatal week (Houpt and Epstein 1973; Leshem et al. 1990). 2-DG stimulates pups to eat chow but not to suckle (Gisel and Henning 1980). The lack of effect of glucoprivation on independent ingestion in the first 3 weeks of postnatal life is not due to the inability of the preweaning pup to sense glucoprivation, because the hyperglycemic response to glucoprivation occurs as early as P3 (Houpt and Epstein 1973; Leshem et al. 1990). Thus, it is unlikely that the metabolic or caloric signal produced by food deprivation that emerges between P6 and P15 in rat pups is related to changes in availability of glucose utilization.

An alternative possibility is that the signal is related to changes in fat availability or utilization. Changes in fat metabolism were produced by administration of mercaptoacetate (MA), a drug that inhibits mitochondrial acetyl-CoA dehydrogenases resulting in increased food intake over several hours and is accompanied by characteristic changes in circulating energy-related substances such as ketone bodies and free fatty acids in adult rats. In addition, simultaneous blockade of both fat and glucose metabolism produces synergistic effects on food intake, suggesting that these signals are integrated to control food intake.

In tests of consuming diet from the floor of a test container, moderate doses of MA stimulated independent ingestion on P12 and P15. Although MA failed to stimulate independent feeding on P9, its effect to decrease the plasma concentration of beta-hydroxybutyrate (a ketone body) (Swithers 1997), indicates that MA was effective in decreasing fat metabolism at this age. However, results from a recent study appear to contradict this conclusion. For instance, MA failed to stimulate intake of milk on P18 and P21 while higher doses which stimulate intake in adult rats, suppressed milk intake. In addition, MA inhibited chow intake on P18 (Swithers et al. 2004). Hence, it is not clear why MA does not stimulate food intake during preweaning rat pups. This is because by P18, pups initiate food intake independent of the dam and begin to alter the fat composition of their diet from the high-fat milk to a lower fat chow. In adult animals, the effect of MA is influenced by the fat composition of the maintenance diet, with higher fat diets resulting in more profound responses. Thus, while P18 pups still consume a significant percentage of their calories from the mother's milk, the decreasing fat content of the chow may inhibit the response to changes in fatty acid oxidation by MA in preweaning pups.

26.7.1 Leptin

The adipose hormone leptin is an important regulator of energy balance. Leptinergic pathways send signals about nutritional status and energy storage levels to the feeding center in the hypothalamus, through its action on the orexigenic and anorexigenic neuropeptides in the ARC (Schwartz et al. 2000).

There is a surge in plasma levels of leptin during the second postnatal week without a concomitant increase in body fat mass in mice (Ahima et al. 1998). The high level of leptin during the neonatal period is surprising, because this is an important growth phase and it seems counterintuitive to have such a high satiety signal (Fig. 26.5). It is reasonable to conceive the idea that the neonatal pups may be in some form of leptin resistance. This metabolically irrelevant surge of leptin may consequently
Fig. 26.5 Leptin signaling in neonatal life. The plasma leptin levels (*left*) and leptin (*ob*) mRNA expression (*right*) in female mice. Values represent means $\pm$ SE; $n = 5$–10. For ob (leptin) mRNA, values represent arbitrary densitometric units, $P < 0.05$ compared with day 7 (Reprinted from Ahima et al. 1998. With permission)

act as a developmental signal to promote formation of arcuate pathways (Bouret and Simerly 2004) as discussed later.

There are many reports that show that exogenous leptin treatment does not inhibit growth, ingestion, or energy expenditure during the first 2–3 postnatal weeks (Ahima and Hileman 2000; Proulx et al. 2002). While leptin seems to have little effect on food intake during early postnatal period, it affects neuronal activity in the ARC during this phase. Acute peripheral leptin treatment at P10 increased mRNA expression of suppressor of cytokine signaling 3 (a marker of leptin receptor activity) in the ARC, suggesting that the leptin receptors in the ARC are functional (Proulx et al. 2002). The same treatment increased proopiomelanocortin (POMC) mRNA levels, but decreased NPY mRNA levels in the rostral part of the ARC. Chronic leptin treatment (daily, P3–P10) downregulated leptin receptor mRNAs and NPY mRNAs (Proulx et al., 2002). Although there is a report that daily leptin injections from P10 to P17 did not exhibit any change in hypothalamic expression of mRNAs for NPY, agouti-related protein (AGRP), POMC, or cocaine- and amphetamine-regulated transcript (CART) in mice (Ahima and Hileman, 2000), a recent report confirms leptin's effect on neurons in the ARC as early as P6 (Bouret and Simerly, 2004).

26.8 Development of the Hypothalamic Circuit Controlling Food Intake

26.8.1 NPY Neuron

NPY neurons in the ARC are the target of leptin activity and provide a potent orexigenic drive in the brain, as well as energy expenditure (Gehlert, 1999). The NPY neurons in the ARC synthesize AGRP, an endogenous antagonist of anorexigenic melanocortin 3/4 receptors, and is itself a potent orexigenic peptide (Table 26.1). Thus, NPY/AGRP fibers provide a powerful dual orexigenic drive by activating NPY receptors and antagonizing MC3/4 receptors.

Since microinjection of NPY into the PVN as early as P2 can elicit an increase in independent milk intake (Capuano et al. 1993), there is an intact NPY receptor system within the hypothalamus during early postnatal period when NPY neurons in the ARC have not extended their axons to the targets. NPY mRNA expression has been reported to be present within the ARC throughout

Table 26.1 Key features of AGRP

1. AGRP is a potent orexigenic peptide.
2. AGRP was identified from studies of agouti mouse, an autosomal dominant model of genetic obesity character-ized by a yellow coat color and an obese phenotype.
3. AGRP is synthesized in the NPY neuron that exists in the arcuate nucleus (ARC).
4. AGRP binds to melanocortin 3 (MC3) and melanocortin 4 (MC4) receports.
5. AGRP is an endogenous antagonist of anorexigenic melanocortins such as α-melanocyte-stimulating hormone (α-MSH).
6. AGRP causes hyperphasia when administered into the cerebroventricle.
7. AGRP expression is upregulated together with NPY by fasting and leptin deficiency.

postpartum development, with low levels at P1 followed by rapid, progressive increase that peaks at P16 before returning to levels observed in the adult by P30 (Grove et al. 2005). The physiological significance of this increase in NPY mRNA at P16 is not known but may be associated with a stimulation of the drive to eat solid food, possibly due to a change in dietary needs prior to weaning. Another characteristic feature of NPY expression during early postnatal period is its presence in the regions such as the DMH, perifornical region, PVN, and LHA that are not apparent in the adult rats. The reason for this NPY distribution in the neonatal period is not clear. Also, AGRP mRNA is expressed exclusively in the ARC throughout postnatal development, and that it displays a developmental pattern of expression similar to that seen for NPY mRNA in the ARC, with relatively low levels of gene expression observed as early as P2, and high levels by P12 (Grove et al. 2003).

26.8.2 POMC Neuron

The melanocortin system is also an important regulator of food intake and energy balance. The main populations of melanocortin neurons that contain POMC and CART are located within the ARC. Nearly all of the components of the melanocortin system (POMC, AGRP and MC4 receptor) are present in the hypothalamus throughout the postnatal period (Grove et al. 2003). A nonselective melanocortin receptor agonist melanocortin II (MTII) decreased milk intake and increased energy expenditure at P5–P6, P10–P11, and P15–P16. Also, MT II induced cFos activation in the PVN and VMH, but did not increase NPY mRNA in the ARC (Glavas et al., 2007). MT II can inhibit food intake and stimulate energy expenditure as early as P5–P6, before the full development of hypothalamic feeding neurocircuitry. It is noteworthy that MT II inhibited suckling-mediated milk intake as early as P5–P6, a time when food intake is primarily inhibited by gastric filling (Phifer et al. 1986). At least at this time of development, visceral inhibitory signal is able to stimulate melanocortin system.

26.8.3 Development of Leptin-Sensitive Projection Pathways

Using axonal tracer Dil to label axons of the ARC in mice at various postnatal ages, the ontogeny of projections from the ARC was visualized (Bouret and Simerly 2004). The neurons of the ARC do not extend axons to the majority of their target nuclei until the second week of postnatal life. ARC projections extend through the periventricular zone of the hypothalamus to provide inputs to the DMH by P6, followed by inputs to the PVN between P8 and P10. Projections from the ARC to the

LHA appeared on P12 and the pattern of arcuate projections does not achieve their adult-like distribution until P18 (Bouret and Simerly, 2004). Consistent with this idea, peripheral leptin injection induces cFos immunoreactivity in the ARC as early as P6, whereas leptin-induced cFos is not observed in the PVN before P10, or in the LHA before P16. This suggests that this activation by leptin may be due to transneuronal relay of leptin signals originating from the ARC (Bouret and Simerly, 2004). The inability of leptin to affect independent ingestion during the first 3 postnatal weeks may be attributed to the immaturity of the neural pathways from the ARC to the target areas that play important roles in food intake regulation.

26.8.4 Trophic Action of Leptin on Arcuate Neurons

By comparing projection pathways from the ARC in leptin-deficient (ob/ob) and wild-type mouse pups, leptin deficiency was shown to cause a dramatic reduction in the density of axons emanating from the ARC and innervating the DMH, PVN, and LHA (Fig. 26.6) (Bouret et al. 2004). Both NPY/AgRp and POMC projections are affected. Leptin treatment in adult ob/ob mice is largely ineffective in reversing innervation pathways, whereas supplementation during the neonatal period fully restores the density of arcuate projections to that found in wild-type mice (Bouret et al. 2004).

Mice with intrauterine undernutrition, when fed a high-fat diet, develop pronounced weight gain and adiposity. These mice exhibited a premature onset of neonatal leptin surge compared to offspring with intrauterine normal nutrition (Yura et al. 2005). Both offspring with intrauterine undernutrition and neonatally leptin-treated offspring with intrauterine normal nutrition exhibited an impaired response to leptin administration as well as an increased density of nerve terminals
Fig. 26.6 Ontogeny of circuits regulating feeding. Projections from the arcuate nucleus (*ARH*) are immature at birth and appear to innervate the dorsomedial nucleus (*DMH*), paraventricular nucleus (*PVN*), and lateral hypothalamic area (*LHA*) in succession, within distinct temporal domains. The projections from the ARH to the DMH develop rapidly and are established by P6, whereas those to the PVH develop significantly later, with the mature pattern of innervation first apparent between P8 and P10. Projections to the LHA are established by P12. Projections from the brain stem appear developed at birth (Reprinted from Bouret and Simerly 2007. With permission)

containing NPY or CART in the PVN (Yura et al. 2005). These confirmed the importance of the premature leptin surge in the pronounced developmental origins of obesity using ob/ob mice (Yura et al. 2008) and may explain the epidemiological evidence suggesting that intrauterine undernutrition is closely associated with adulthood obesity related to detrimental metabolic sequelae.

26.9 Application to Other Areas of Health and Disease

It is not clear whether there are two types of ingestive behavior (suckling and independent feeding) in human infants. For instance, milk ejection from mother's nipple does not appear to exhibit intermittent bursts of release of milk like that observed in the rat. However, whether a child's suckling is regulated by mechanisms similar to those involved in the development of as drinking behavior in rodents is an interesting question that will await further investigation.

Summary Points

- The volume of milk ingested by rat pups is not under their voluntary regulation, as is the case in adult rats that stop eating when they have had enough food.
- Ingestion of milk by pups independent of the mother's direct influence (independent ingestion) can be experimentally induced in neonatal pups, but this type of feeding behavior naturally does not occur before the weaning begins. Rather, this ingestion is regulated by the pups themselves.
- Eating and drinking are not differentiated in the rat pups in the first postnatal week. During this period, deprivation from their mother stimulates independent ingestion primarily on the basis of dehydration, a shortage of water, which acts to inhibit food intake in adults.
- Hormones secreted from the epithelial cells of the gastrointestinal tract play important roles in the movement of the gastrointestinal tract and secretion of digestive juices. In addition, they also regulate food intake such as CCK and ghrelin discussed in this chapter.
- During the second week after birth, there is dramatic spike in the blood concentration of leptin. This leptin surge may have a role in the facilitation of neuronal development of the hypothalamus, a brain area responsible for food regulation.

Key Terms

Independent injection: This is induced by injecting milk through an implanted cannula into the anterior portion of pup's mouth as early as 1 day after birth and is a good experimental model for studying the development of feeding behavior observed in adult animals.

Milk ejection: Milk secreted from epithelial cells of the mammary gland is expelled by contraction of myoepithelial cells surrounding the alveolus in response to circulating oxytocin.

Arcuate nucleus: A key hypothalamic nucleus responsible for regulating metabolic balance.

Leptin: An important hormone secreted from fat cells and acts within the arcuate nucleus to inhibit appetite.

Preabsorptive inhibition: Ingested food in the stomach or intestine inhibit food intake before being assimilated.

General and Normative Aspects: Neurological

Chapter 27
Dietary Proteins and Satiety-Related Neuronal Pathways in the Brain

Gilles Fromentin, Nicolas Darcel, Catherine Chaumontet, and Daniel Tomé

Abbreviations

BDNF	Brain derived neurotrophic factor
CCK	Cholecystokinin (formerly called pancreozymin), a food intake suppressing peptide hormone released by the gastrointestinal tract during digestion
5-HT	Serotonin
HP	High protein
NP	Normal protein
NTS	Nucleus tractus solitarius
ARC	Arcuate nucleus of the hypothalamus
APC	Anterior piriform cortex
I-cells	A type of enteroendocrine cell found in the mucosal epithelium that lines the lumen of the small intestine. I-cells secrete a wide variety of gut hormones, including cholecystokinin.
PYY	Peptide YY
GLP-1	Glucagon-like peptide 1
IAA	Indispensable amino acid
GC	General control
CNS	Central nervous system
CTA	Conditioned taste aversion
PVN	Paraventricular nucleus
VMN	Ventromedial nucleus
DMN	Dorsomedial nucleus
LH	Lateral hypothalamus
POMC	Proopiomelanocortin
NPY	Neuropeptide Y
AgRP	Agouti-related peptide
αMSH	α Melanocyte stimulating hormone
mTOR	Mammalian target of rapamycin

AMPK   AMP-activated protein kinase
ICV   Intracerebroventricular
ACC   Acetyl-CoA carboxylase

27.1 Introduction

Proteins appear to be the macronutrient that exerts the greatest satiety effect in rats and humans (Latner and Schwartz 1999; Bensaid et al. 2002), ahead of carbohydrates and lipids (Porrini et al. 1997). Moreover, the macronutrient (Latner and Schwartz 1999) composition of a diet is known to influence energy intake, energy metabolism, and long-term changes to body weight and body composition. High-protein diets have been studied extensively for their ability to reduce total energy intake and body weight, and to limit lipid deposition (Jean et al. 2001). These observations are in line with the idea that in addition to total ingested energy, nutrient-specific mechanisms are also involved in inducing satiety and controlling food intake. Several redundant mechanisms, such as the secretion of gut satiety peptides, an increase in energy expenditure or an increase in plasma amino acid levels, are candidate signals for protein-induced satiety (Potier et al. 2009). Dietary proteins are thought to be closely monitored by the central nervous system (CNS), and especially by central structures such as the nucleus tractus solitarius (NTS), hypothalamus, and anterior piriform cortex (APC), regions that control or influence food intake. Since proteins are likely to be monitored in the same regions where satiety is thought to originate, dietary proteins may therefore influence the onset of satiety.

The purpose of this review is thus to consider some aspects of these neuromechanisms that are associated with peripheral and central signaling processes and concern the effects of protein and amino acids on the control of food intake.

27.2 Protein-induced Satiety (High Protein Preload and High-Protein Diet)

> Protein is considered to be a strong inhibitor of food intake in omnivores, displaying the most marked appetite suppressant effects of the three macronutrients. Eating a high-protein diet does not induce a conditioned food aversion but rather experience-enhanced satiety. Moreover the poor palatability of dietary protein is not the principal mechanism causing a reduction in energy intake.

In the short term, and in the context of the preload paradigm, a test-meal was given to subjects after an interval that followed ingestion of the preload. Dietary protein appeared to be a strong appetite inhibitor and suppressed food intake during subsequent meals beyond that which could be accounted for by its energy content alone, both in rats (Trigazis et al. 1997) and humans (Barkeling et al. 1990). Moreover, dietary proteins cause stronger appetite inhibition than carbohydrates. For instance, a gluten load induced a more pronounced depression of food intake than an isocaloric wheat starch load (Bensaid et al. 2002). However, some discrepancies have been shown to originate from physiological status, the duration of eating, and the method of nutrient administration; i.e., oral, intra-gastric, or intravenous (Reid and Hetherington 1997). Moreover, the type of protein can influence the satiating effect, although the mechanism involved remains unclear, it being unlikely that this originates from the presence of certain specific amino acids as precursors of neuromediators, e.g., tryptophan and serotonin, or tyrosine and dopamine (Anderson et al. 1994). Finally, some interactions have been suspected between the satiating effects of the three macronutrients. In order to analyze the

nature of the food intake depression induced by a high-protein (HP) load, one research group performed a meal pattern analysis (Bensaid et al. 2002) of the meal following the load, which suggested that animals were more satiated by protein (at least when loads contained a high level of protein) than by carbohydrate.

In the longer term, the ingestion of a high-protein diet most frequently promotes satiety, facilitates weight loss, and improves body composition. In rats, the consumption of a high-protein diet (55% of energy supplied by proteins) for several days led to both a reduction in cumulative food intake and less weight gain and adiposity than a normal-protein diet (14% of energy supplied by proteins) (Harper and Peters 1989; Jean et al. 2001; Halton and Hu 2004). However, this effect was modulated by the ratio between carbohydrate and fat and by the protein type (total milk protein, whey protein, or beta-lactoglobulin). Indeed, it has been suggested that different protein sources may differently affect satiety in a context of high-protein diets (Pichon et al. 2008).

In order to determine the respective roles of conditioned food aversion, satiety, and palatability, behavioral responses to an HP diet were compared to those observed with a normal-protein diet (Bensaid et al. 2003; L'Heureux-Bouron et al. 2004). Different paradigms were applied, including meal pattern analysis, two-choice testing, flavor testing, a behavioral satiety sequence, and taste reactivity. Only behavioral and food intake parameters were disturbed during the first day on which the animals ate the HP diet, and most of them returned to the control level as early as the second day of this diet. Rats adapted to an HP diet did not acquire a conditioned taste aversion but exhibited satiety and a normal behavioral satiety sequence.

It is possible that the appetite suppressant effect of dietary protein is partially induced by poor palatability. Indeed, the poor palatability of high-protein diets has been documented (McArthur et al. 1993), but its relative importance remains unclear. L'Heureux-Bouron et al. (2004) measured food intake in rats after modifying the composition of their high-protein diets by varying the carbohydrate composition (sucrose/cornstarch) and protein source (soy, gluten, or total milk protein) of these diets. The orosensory properties of the diets were also modified. However, no differences in food intake were observed between the groups of rats studied during the transition phase or after adaptation. More generally, this issue was studied several decades ago by modifying the orosensory properties of experimental foods by the addition of pleasant flavors (citral), unpleasant flavors (eucalyptol) (Le Magnen 1999), or unpleasant substances (e.g., quinine or sucro octa acetate (Kratz et al. 1978)). After a transient decline that was dependent on the substance used, all groups chronically consuming the poorly palatable diets ad libitum ate as much as the control group. This putative poor palatability of dietary protein is probably not the principal mechanism that reduces energy intake, but an initial decrease in HP diet intake appears to result from the poorer palatability of a food, combined with the satiety effect of an HP diet and the interval required for metabolic adaptation to the HP level.

27.3 Proteins, Amino Acids, and Satiety Signaling to the Brain

> The input signals associated with protein and amino acid ingestion originate from visceral and metabolic mechanisms and involve both indirect (signals originating from different parts of the gut, mainly mediated by vagal afferents) and direct information (plasma levels of nutrients, gut peptides, and hormones), recorded by the central nervous system.

Ingested proteins are believed to generate redundant pre- and post-absorptive signals that contribute to controlling gastric kinetics, pancreatic secretions, and food intake. In the brain, two major
Fig. 27.1 Mechanisms responsible for the protein-induced suppression of food intake. Dietary protein is detected as early as in the mouth, via amino acid sensing by taste cells. Gastrointestinal signals are generated in the stomach, duodenum, and ileum via the release of gut hormones that activate peripheral nerves (particularly the vagus nerve). These gut hormones are also carried by the bloodstream and act directly on brain centers such as the area postrema and hypothalamus to suppress food intake. Post absorptive anorectic signals are also generated by the liver. Finally, protein detection may modulate the reward system and reduce the motivation for food

afferent pathways are involved in monitoring proteins and amino acids: the indirect, neuromediated (vagus-mediated/ileal brake) pathway and the direct blood pathway (Potier et al. 2009). The neuro-mediated pathway communicates pre-absorptive and visceral information which is mainly transferred via the vagus nerve that innervates part of the orosensory zone: stomach, duodenum, and liver. Other information is directly monitored in the blood (Fig. 27.1).

27.3.1 Sensory Information

Orosensory information provides animals with valuable information about the nature and quality of food (Nelson et al. 2002). Mammals can recognize and respond to a wide variety of chemical products, including sugars, salts, acids, and a broad range of toxic substances.

According to Zhao et al. (2003), several amino acids taste sweet or delicious (umami) to humans, and are attractive to rodents and other animals. Umami is one of the five basic taste sensations, induced solely and synergistically by free glutamate and 5-mononucleotides. To sense umami, several receptors such as taste receptors (T1R1/T1R3 heterodimer) and metabotrophic glutamate receptors (mGluR1 and mGluR4) can be found in the taste buds on the tongue.

Nelson et al. (2002) identified and characterized another mammalian amino acid taste receptor, T1R1 + 3, which combines the T1R1 and T1R3 G-protein coupled receptors to function as a broadly tuned L-amino-acid sensor; this responds to most of the 20 standard amino acids.

Gustatory detection via taste receptor cells on the tongue and palate is a key process in protein and amino acid signaling to the brain centers that control ingestion and hunger.

27.3.2 Satiation: The Gastrointestinal Regulation of Food Intake

27.3.2.1 Visceral Vagus-mediated Signals

Vagus Nerve

During digestion, both dietary proteins and other macronutrients are detected in the small intestine (this nutrient-specific information acting as a potent anorexigenic signal). This sensory process is dependent upon the action of gut mediators such as cholecystokinin (CCK) or serotonin (5-HT) on vagal afferents which in turn convey peripheral information to the brain in order to influence the control of food intake. The vagus nerve is thus a key element in the pathways controlling ingestion. Although dietary proteins have been shown to activate vagal afferents (Darcel et al. 2005b), the links between protein detection in the intestine and the control of ingestion have not yet been clarified.

Role of Dietary Proteins in Gastric Volume and Stomach Emptying

Powley and Phillips (2004) stated that the prepotent negative feedback from the stomach regarding short-term ingestion is a volumetric signal that is monitored by mechanoreceptor innervation of the stomach assured by multiple vagal branches. An increase in intake volume may participate in a post-prandial increase in stomach distension, causing activation of the vagal afferent fibers associated with reduced gastric kinetics and food intake (Davis 1999). The increase in gastric volume induced by dietary proteins is probably due to an increase in gastric secretions and/or the amount of water drunk. However, L'Heureux-Bouron et al. (2004) showed that eating an HP diet did not induce a marked increase in stomach volume, which might explain the enhanced satiety and decreased food intake triggered by the activation of vagal afferent fibers.

A variation in the rate of gastric emptying can alter the gut peptide response, but may also modify the hormonal response to feeding and hence the rate of ingested nitrogen. According to Mellinkof et al. (1956), ("The aminostatic hypothesis") such modifications to plasma amino acid kinetics may modulate food intake. Boirie et al. (1997) showed differences in gastric emptying as a function of dietary protein type (thus demonstrating the concept of fast and slow proteins). Hall et al. (2003) tried to correlate the concept of fast and slow proteins and an effect on satiety. However, according to Calbet and Holst (2004), caloric density seems to be the main factor determining the rate of gastric emptying, even if at the isocaloric level, dietary factors (that include the volume, osmolarity, viscosity, pH, and nutrient content of the meal) modulate the physiological control of gastric emptying.

Detection of Protein in the Gastrointestinal Wall

Our current understanding of amino acid detection in the intestinal wall is based on two main detection mechanisms: the first involves specialized cells present throughout the gastrointestinal tract (Conigrave et al. 2000; Xu et al. 2008) which carry amino acid receptors on their luminal membranes. These cells initiate a signaling process that results in the release of gut hormones by enteroendocrine cells in the gastrointestinal tract epithelia which act on the vagus nerve to trigger satiation. The second detection process involves epithelial absorptive cells that are able to sense variations in luminal amino acid concentrations via changes in their cellular metabolism. In the same way, these cells initiate a paracrine signaling process that results in the release of gut mediators by enteroendocrine cells. Both of these detection mechanisms are present in the gut (Bezençon et al. 2007), but their contribution to the positive effects of peptide and amino acid intake on energy intake has not been studied.

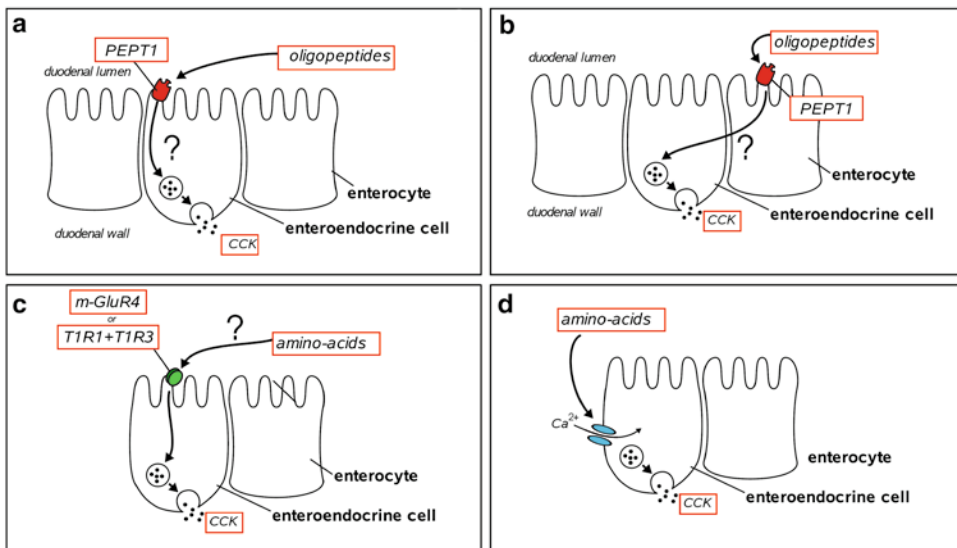
The sensing mechanisms underlying the detection of dietary proteins and their hydrolysates in the intestine is not entirely clear; however, it has been found that proteins and amino acids trigger release of the anorexigenic gastrointestinal hormone CCK (Foltz et al. 2008). Whether other mechanisms are also involved (such as reduced production of the "hunger hormone" ghrelin) remains unknown. The precise mechanism by which dietary protein induces CCK release is unclear, but a recent study showed that the transport peptide PepT1 was necessary to enable CCK release from duodenal I-cells (Darcel et al. 2005b) (Fig. 27.2).


Fig. 27.2 Putative mechanisms for protein detection in the duodenum. Several mechanisms have been proposed regarding the intestinal sensing of dietary proteins. First, it has been shown that the proton-coupled oligopeptide transporter PEPT1 is necessary to detect oligopeptides in the intestinal wall (Darcel et al. 2005a) (**a, b**). However, it is not yet clear whether PEPT1-mediated detection involves cross-talk between enterocytes and enteroendocrine cells (**a**), or whether enteroendocrine cells express PEPT1 and can detect oligopeptides independently of enterocytes. It is also possible that amino acids may be sensed by taste receptors located at the apical side of enteroendocrine cells; e.g., through the heterodimeric T1R1/T1R3 receptor or the mGluR1 or mGluR4 glutamate receptors (Zhao et al. 2003) (**c**). It has also been postulated that amino acids such as phenylalanine may act directly on L-type calcium channels at the basolateral side of the enteroendocrine cells to stimulate the exocytosis of gut hormones (Mangel 1995) (**d**). In addition, recent data have also suggested that additional receptors may be involved in detecting dietary protein, such as the calcium sensing receptor CaSR in the intestine

It is conceivable that other mechanisms are involved, particularly because peptide uptake via PepT1 does not occur in other gastrointestinal compartments such as the stomach. Indeed, it has been hypothesized that protein-induced satiety may be linked to the secretion of gut neuropeptides; candidate mechanisms include either an increased secretion of the anorexigenic gut hormones glucagon-like peptide 1 (GLP-1), CCK, and peptide YY (PYY), or a decreased secretion of the orexigenic gut hormone ghrelin.

27.3.2.2 Ileal Brake

The ileal brake is a feedback mechanism that results in the inhibition of proximal gastrointestinal motility and secretion. Animal and human studies have shown that activation of the ileal brake by local nutrient perfusions increases feelings of satiety and reduces ad libitum food intake (Maljaars et al. 2008). These results point to a potential role for the ileal brake in the regulation of digestion, exerting a direct or indirect impact on eating behavior and satiety. Ileal protein infusions in both humans and animals activate the ileal brake, and differences may exist between different types of protein or amino acids (Meyer et al. 1998).

PYY and GLP-1, two peptide hormones secreted mainly in the lower gut, and particularly the ileum, colon, and rectum, seem to be most relevant to the control of appetite. Interestingly, they are both secreted by the same enteroendocrine cells: L-cells. According to Batterham et al. (2006), a high protein intake induced the greatest release of PYY and the most pronounced satiety in normal-weight and obese human subjects. A long-term augmentation of dietary protein in mice induced elevated plasma PYY levels, and reduced food intake and adiposity. In order to determine directly the role of PYY in mediating the satiating effects of protein, Batterham (Batterham et al. 2006) generated PYY null mice that were selectively resistant to the satiating and weight-reducing effects of protein; these animals developed marked obesity that was reversed by exogenous PYY treatment.

27.3.3 Blood-Mediated Signals of Satiety

Metabolic signals, including an increase in energy expenditure and the production of glucose through gluconeogenesis, have been also hypothesized as signals for protein and amino acids (Potier et al. 2009). It is currently accepted in the literature that in humans, protein stimulates diet-induced thermogenesis to a greater extent than other macronutrients (Westerterp-Plantenga 2008). The de novo synthesis of glucose in the liver from gluconeogenic precursors (including amino acids) is stimulated by an HP diet in the fed state (Azzout-Marniche et al. 2007). This process may be involved in the satiating effect of protein through a modulation of glucose homeostasis and glucose signaling to the brain.

It has been suggested that elevated concentrations of blood or plasma amino acids that cannot be channeled into protein synthesis may serve as a satiety signal for a food intake regulating mechanism and thereby result in depressed food intake (Mellinkoff et al. 1956; Harper and Peters 1989). Elevated plasma amino acid concentrations can be detected directly by a specific area in the hypothalamus. Variations in plasma hormones and free amino acid concentrations can be recorded directly by the central nervous system, mainly through concomitant variations in their intracerebral levels. However, even though histidine and tyrosine are precursors of histamine and dopamine, respectively, Bassil et al. (2007) failed to demonstrate any effect of a diet supplemented with 5% of either histidine or tyrosine on the levels of food intake by Sprague-Dawley rats (Potier et al. 2009).

The neuromediated pathway transfers pre-absorptive and visceral information via the vagus nerve that innervates part of the orosensory zone (stomach, duodenum, and liver). Localized in the brainstem, the NTS is the main projection of the vagus nerve and integrates sensory information from the oropharyngeal, intestinal, and visceral organs. The involvement of vagal afferent pathways in protein sensing and signaling to the brain is supported by results showing that intraduodenal protein activates vagal afferent fibers, and high-protein feeding induces c-Fos expression in neurons within the NTS (Phifer and Berthoud 1998; Darcel et al. 2005a). Faipoux et al. (2008) showed that a reduction in food intake after a high-protein load (versus a normal-protein load) resulted from activation of the noradrenergic neurons related to CCK-induced anorexia. Another study also showed that neurons expressing GLP-1 were not activated, which is consistent with the fact that protein-induced satiety is not associated with aversive behavior or conditioned taste aversion (CTA) (Bensaid et al. 2003).

27.4.2.2 Activation of the Hypothalamus

Peripheral information is further centralized in the hypothalamus, which is critical to the regulation of food intake as it contains a number of discrete neuronal populations or nuclei, including the ARC, the paraventricular nucleus (PVN), the ventromedial nucleus (VMN), the dorsomedial nucleus (DMN), and the lateral hypothalamus area (LH). Energy homeostasis-regulating circuits are found within and connecting these nuclei. In the ARC, proopiomelanocortin (POMC) neuron activation induces a reduction in food intake. These neurons are responsible for the anorectic response induced by circulating leptin (Cowley et al. 2003) through the activation of neurons in the PVN (Balthasar et al. 2005). The activation of POMC neurons is also inseparable from the behavior of another population in the ARC, neuropeptide Y (NPY)/agouti-related peptide (Agrp) neurons, activation of which is potent in increasing food intake and inhibiting POMC neuron activation (Cowley et al. 2001). Indeed, Faipoux et al. (2008) showed that after the ingestion of a high-protein meal, the numbers of double-labeled fos and α-melanocyte stimulating hormone (MSH) (a marker of POMC neuron activation) increased, concomitantly with a reduction in the activation of non-POMC neurons. This result was less pronounced when a high-protein diet had been served for several days (21 days) than in an acute setting. Moreover, because arcuate neurons are mainly POMC or NPY, it could be hypothesized that NPY neurons are less strongly activated after high-protein meals.

27.4.2.3 AMP-Activated Protein Kinase and the Mammalian Target of Rapamycin Are Involved in the Satiety Induced by High-Protein Diets

HP diets, an increase in dietary leucine (Ropelle et al. 2008) or the intra-cerebroventricular (ICV) administration of amino acids (or leucine only) (Cota et al. 2006; Morrison et al. 2007) reduce food intake and body weight. This effect seems to be leucine-specific, because leucine alone exerts the same effect on food intake as a mixture of amino acids (Ropelle et al. 2008). It has been shown that AMP-activated protein kinase (AMPK) and the mammalian target of rapamycin (mTOR) are involved in the satiety induced by high-protein diets (Fig. 27.3).

AMPK is the downstream component of a kinase cascade that acts as a sensor for the cellular energy charge, being activated by an increase in the AMP/ATP ratio. Once activated, AMPK phosphorylates acetyl-CoA carboxylase (ACC) and switches on energy-producing pathways at the expense of energy-depleting processes. Ropelle et al. (2008) showed that both a high-protein
Fig. 27.3 mTOR, AMPK, and GCN2 coordinate adaptation of the metabolic pathways for energy in response to protein intake in the rat. Putative signaling pathways induced in the arcuate nucleus of the hypothalamus by amino acids. The AMP-activated protein kinase (*AMPK*) and the mammalian target of rapamycin (*mTOR*) are involved in the satiety induced by high-protein diets. High-protein diet and ICV leucine administration suppressed AMPK and acetyl-CoA carboxylase (*ACC*) phosphorylations in the rat hypothalamus. In parallel, there has been growing interest in mTOR, an intracellular signaling molecule sensitive to both amino acid and growth factors, which is also described as a metabolic sensor and is able to phosphorylate two regulatory proteins, the p70 ribosomal S6 protein kinase (*p70S6K*) and the eukaryotic initiation factor 4E-binding protein-1 (*4E-BP1*) that stimulates translation initiation. The general control nondepressible 2 kinase (GCN2), which is sensitive to amino acid deprivation, could be also a target for amino-acid signals, GCN2 controls translation via the phosphorylation of eukaryotic initiation factor 2α (*eIF2α*). Nevertheless, there is no evidence that the increase in amino acid concentration decreased the phosphorylation of GCN2 in the hypothalamus. The participation of these pathways on food intake control needs to be clarified

diet and ICV leucine administration suppressed AMPK and ACC phosphorylation in the rat hypothalamus, this being concomitant with a reduced AMP/ATP ratio. In parallel, there has been growing interest in mTOR, an intracellular signaling molecule sensitive to both amino acid and growth factors which is also described as a metabolic sensor. Both a high-protein diet and the ICV administration of free amino acids, or leucine only, led to mTOR activation in the hypothalamus (Cota et al. 2006; Morrison et al. 2007). Moreover, high-protein diets modulate AMPK and

mTOR in the same specific neuronal subsets, the ARC and PVN of the hypothalamus. AMPK and mTOR may have overlapping and reciprocal functions (Cota et al. 2006). Finally, the activation of mTOR and the suppression of AMPK phosphorylation activity seem to modulate hypothalamic neuropeptides: they reduce levels of NPY and Agrp (which are both orexigenic neuropeptides) and increase the expression of POMC, which exerts an anorexigenic effect (Morrison et al. 2007; Ropelle et al. 2008).

27.5 Applications to Other Areas of Health and Disease

The macronutrient composition of a diet is known to influence energy intake, energy metabolism, and long-term changes to body weight and body composition (Potier et al. 2009). Reduced-energy diets are a widely recommended as a noninvasive primary strategy to treat overweight and obese subjects. High-protein diets have been studied extensively for their ability to reduce total energy intake and body weight and to limit lipid deposition. One major criticism advanced regarding evaluations of high-protein, low-carbohydrate, high-fat diets is that their high protein and high fat contents may have adverse effects on health. High-protein diets nevertheless remain popular, suggesting that there are some perceived benefits in the eyes of the public. One such benefit may be the increased satiety arising from the protein in these diets, which aids in ensuring better compliance with a reduced energy diet and/or contributing to a spontaneous reduction in energy intake (Anderson and Moore 2004).

27.6 Conclusion

The protein and amino acid content of a food is a strong determinant of short-term satiety and the amount that will be eaten. Peripheral hormones (CCK, GLP-1, and PYY) have been shown to be involved in the mechanism of short-term protein-induced satiety. Moreover, the fact that the protein source may impact their satiety effect seems to suggest the presence of functional specific peptides that are selectively beneficial. Still at the peripheral level, an increase in energy expenditure and the production of glucose through gluconeogenesis have been also hypothesized as signals for protein-induced satiety. Specific amino acids such as leucine, or other precursors of neuropeptides, can exert an impact on protein-induced satiety thanks to central mechanisms. Several brain regions are indeed involved in the central regulation of food intake, and it has been shown that proteins may affect them by acting in different regions of the brain stem or in the hypothalamus. Other areas that are also involved in the detection of high-protein meals include the area postrema or the lateral hypothalamus with orexin-containing neurons, but their precise roles need to be clarified. Finally, recent findings have suggested that neural components of the gut brain axis display a high potential for neuronal plasticity that is present or could be active in adult subjects. These phenomena may explain the prolonged aspects of diet-induced metabolic and behavioural changes (Table 27.1).

Table 27.1 Key features of neuronal plasticity of the gut brain axis

1. Receptor dynamics
  1.1 Receptor dynamics at the level of the plasma membrane constitute a common modality for neuronal adaptations in response to diet
  1.2 Neurons can down-regulate their activity when subjected to repeated stimulations
  1.3 Chronic stimulation can lead to neuronal desensitization or potentialization via either receptor internalization or changes to de novo receptor expression by vagal afferent neurons
  1.4 Furthermore, receptor profiles (particularly at the level of peripheral sensory terminals) can be influenced by external conditions
2. Neurogenesis
  2.1 Neurogenesis in the brain stem has been shown to occur in adult laboratory animals
  2.2 The presence of neural stem cell progenitors in the brainstem and hypothalamus has been demonstrated, suggesting that newly formed neurons can be included in existing neural networks controlling food intake
  2.3 Very few studies have tried to understand the physiological role of these adult neurogenesis processes, even though they may be of considerable importance to the sustained satiety induced by high-protein diets
3. Neurotrophic factors
  3.1 The brain-derived neurotrophic factor (BDNF) supports the high plasticity potential of the vagus nerve, as this mechanism has been shown to play a role in vagus nerve resection
  3.2 These receptors have been localized in the brainstem at the level of the solitary tract nucleus, but their role in neuronal plasticity remains controversial and has not been studied in detail (Bariohay 2009)

This table lists the key factors of neuronal plasticity including receptor dynamics, neurogenesis, and neurotrophic factors.

Summary Points

- Protein is considered to be a strong inhibitor of food intake in omnivores, displaying the most marked appetite suppressant effects of the three macronutrients.
- Eating a high-protein diet does not induce a conditioned food aversion but rather experience-enhanced satiety.
- The input signals associated with amino acid ingestion originate from visceral and metabolic mechanisms.
- The satiety effect of dietary proteins appears to be mediated by anorexigenic hormones such as CCK, GLP-1, and PYY, there is also evidence that circulating leucine levels may impact food intake.
- In the central nervous system, high-protein diets trigger the activation the nucleus of the solitary tract and the hypothalamus.
- How information arising from the ingestion of dietary protein leads to the control of food intake is a highly complex process that is not yet fully understood.

Definitions and Explanations

Satiety: Satiety is defined as an absence of hunger during the interprandial period, while satiation describes the overall mechanisms that lead to a cessation of eating. It is satiety that delays the start of the next meal and may reduce food consumption the next time there is an opportunity.

Palatability: Palatability is the property of a food product of being acceptable, pleasant to the mouth. Palatability depends to a large extent on food intrinsic properties, in particular on their organoleptic properties or also on macronutrient content.

Conditioned taste aversion (CTA): Conditioned taste aversion is an acquired mechanism allowing a subject to avoid consuming a food when the post-ingestive consequences are remembered as harmful. CTA requires that the subject links one or more orosensory characteristics of the food to unpleasant post-ingestive consequences.

Gut brain axis: Gut brain axis is a multiple signaling system involving the brain and the gastrointestinal tract and playing a key role in metabolic control. The gut brain axis exhibits two major communication modalities: (1) effects may take place directly through action of gut peptide in the brain or (2) through nervous signaling from the gastrointestinal to the brain. The gut-brain axis is involved in a multitude of physiological processes including satiety, food intake, and regulation energy metabolism.

Chapter 28
The Importance of Trace Elements for Neurological Function

Joel G. Anderson and Keith M. Erikson

Keywords Iron • Manganese • Copper • Zinc • Nutritional Deficiency • Neurotransmitters • Neurodegeneration

Abbreviations

Aβ	Amyloid beta protein
AD	Alzheimer's disease
APP	Amyloid precursor protein
BBB	Blood-brain barrier
BCB	Blood cerebral spinal fluid barrier
CNS	Central nervous system
CSF	Cerebrospinal fluid
Ctr-1	Copper transporter-1
DAT	Dopamine transporter
DMT-1	Divalent metal transporter-1
GABA	Gamma-aminobutyric acid
GAT	GABA transporter
ID	Iron deficiency
IRE	Iron response element
IRP	Iron regulatory protein
MNK	Menkes copper ATPase
MRI	Magnetic resonance imaging
NET	Norepinephrine transporter
NMDA	N-methyl-d-aspartate
PD	Parkinson's disease
SOD	Superoxide dismutase
TfR	Transferrin receptor
UTR	Untranslated region
WND	Wilson's copper ATPase
ZnT	Zinc transporter

28.1 Introduction

The essentiality of micronutrients for proper development and function of biological systems has long been recognized. By participating in oxidation-reduction reactions, trace elements play a role in various cellular metabolic processes. However, the dual nature of dietary metals requires that they must be both available to cells and stringently regulated. Disturbances in the homeostasis of these metals can have deleterious effects, specifically in the central nervous system (CNS), resulting in substantial injury to neurons and glia through oxidative damage, in turn leading to neurodegeneration and neurological dysfunction (see Table 28.1). This chapter will focus on iron, manganese, copper, and zinc, essential metals required for numerous important processes in mammalian systems, particularly the CNS (Aschner et al. 2005; Burhans et al. 2005; Arredondo and Núñez 2005; Donnelly et al. 2007).

Iron plays a crucial role as a component of various enzymes and is required for oxidative phosphorylation, nitric oxide metabolism, and oxygen transport (Donnelly et al. 2007). Found throughout the brain, with the highest concentrations in the basal ganglia and the white matter, iron is involved in the synthesis of neurotransmitters and myelin, playing an essential role in neuronal function (Table 28.2) and as a cofactor for a variety of metalloenzymes (Table 28.3) (Beard et al. 1993). As a critical component in dozens of proteins and enzymes, manganese is present in all mammalian tissues and is active in maintaining normal immune function, regulation of blood sugar, and cellular energy, reproduction, digestion, bone growth, defense against free radicals, and blood clotting in concert with vitamin K (Aschner et al. 2005).

Copper is an essential component for a variety of critical enzymes in metabolism, as outlined in Table 28.3. Required for cellular respiration, iron oxidation, and pigment formation, copper also plays a role in neurotransmitter biosynthesis, antioxidant defense, peptide amidation, and connective tissue formation (Madsen and Gitlin 2007). Almost 100 enzymes in mammalian systems require zinc as a cofactor (Table 28.2) (NAS 2002). Zinc is highly abundant in mammalian tissue second only to iron (McCall et al. 2000), and present predominately in the brain (Szewczyk et al. 2008). A major regulator of synaptic transmission and other neuronal processes, zinc is present in the synapse at millimolar concentrations (Donnelly et al. 2007).

28.2 Uptake and Transport of Metals in the Brain

28.2.1 Iron

Iron is widely distributed throughout the various cell types of the CNS, but is particularly abundant in astrocytes, lending credence to the hypothesis that glial cells function in iron storage and regulation (Madsen and Gitlin 2007). The highest concentrations of iron within the brain occur in the basal

Table 28.1 Key facts about trace elements that are important for normal brain functioning

1. The primary essential trace elements that are important for normal brain functioning are iron, manganese, copper, and zinc
2. These trace elements are critical for normal motor control, appetite regulation, learning, memory, mood, and several other neurological functions
3. Brain cells have multiple mechanisms for ensuring adequate trace element availability
4. A lack of these trace elements will cause devastating neurological problems ranging from behavioral to cognitive deficiencies
5. An overload of these trace elements is linked with neurodegenerative diseases (e.g., Parkinson's disease and Alzheimer's disease)

This table lists the key facts about neurologically relevant essential trace elements

Table 28.2 Key brain functions of selected trace elements

Metal	Function
Iron	• Cofactor essential for synthesis of ATP in the brain • Maintains sufficient oxygen levels in the brain as a component of hemoglobin • Functions as a cofactor in the enzymes responsible for the synthesis of biogenic amine neurotransmitters • Critical role in myelinogenesis • Important for packaging, uptake, and degradation of neurotransmitters
Manganese	• Cofactor essential for production of ATP via gluconeogenesis • Antioxidant functions through the action of Mn-SOD • Regulates brain ammonia levels as a component of glutamine synthetase
Copper	• Antioxidant function through the action of Cu/Zn-SOD • Ferroxidase activity as a component of ceruloplasmin and hephaestin • Critical for production of norepinephrine through the action of dopamine β-hydroxylase • Participates in oxidative phosphorylation as a cofactor of cytochrome c oxidase • Plays role in brain development through synaptogenesis
Zinc	• Trace element with the highest intracellular abundance • Involved in protein synthesis • Cofactor in a myriad of enzymes involved in all aspects of metabolism • Regulates synaptic activity and neuronal processes • Critical role in regulation of gene transcription • Important for synaptogenesis and neuronal growth

This table lists the key brain functions attributed to enzymes or processes that depend on the listed trace element. Many functions are related to neurotransmitter biology and chemistry

Table 28.3 Selected metalloenzymes

Metal	Enzyme	Function	Consequences of loss
Iron	Tyrosine hydroxylase	Dopamine synthesis	Dystonia and movement disorders
	Tryptophan hydroxylase	Serotonin synthesis	Anxiety and pulmonary dysfunction
	Xanthine oxidase	Catabolism of purines	Hematuria
	Ribonucleotide reductase	Rate limiting step in DNA synthesis	Embryonic lethality
	Cytochrome P450s	Various metabolic pathways	Altered metabolism, congenital defects, and embryonic lethality
	Catalase	Antioxidant defense	Oxidative damage
Manganese	Glutamine synthetase	Regulation of ammonia levels	Severe brain malformations
	Phosphoenolpyruvate carboxykinase	Gluconeogenesis	Altered ATP synthesis
	Manganese superoxide dismutase	Antioxidant defense	Oxidative damage
Copper	Lysyl oxidase	Crosslink formation in collagen and elastin	Perinatal death
	Peptidylglycine α-amidating monooxygenase	Activation of peptides with α terminal glycine	Embryonic lethality
	Copper/zinc superoxide dismutase	Antioxidant defense	Oxidative damage
	Ceruloplasmin	Ferroxidase	Iron overload, anemia, diabetes, and neurodegeneration
	Hephaestin	Ferroxidase	Impaired iron absorption, anemia
	Dopamine β-hydroxylase	Norepinephrine synthesis	Impaired sympathetic regulation
	Cytochrome c oxidase	Oxidative phosphorylation	Encephalopathy
Zinc	Copper/zinc superoxide dismutase	Antioxidant defense	Oxidative damage
	Alcohol dehydrogenase	Catabolism of alcohol	Decreased retinol utilization
	Carbonic anhydrase	Conversion of carbon dioxide to carbonate	Osteopetrosis

This table highlights key enzymes that are dependent upon the divalent metals for proper functioning. The role of the enzyme as well as the pathologies associated with its dysfunction are listed by column
Fig. 28.1 Basic cellular iron transport. Mechanisms of cellular iron transport within the brain are illustrated, including known transport proteins and pathways. Iron may enter cells via transferrin-mediated transport or via the divalent metal transporter (*DMT-1*). Once inside the cell, iron is stored complexed with ferritin. Iron may be excreted from cells by ferroportin, also known as IREG-1. Iron regulatory proteins such as IRP-1 and IRP-2 bind iron responsive elements (*IRE*) in response to changes in iron homeostasis, influences the transcription of iron transport proteins, such as TfR and DMT-1

ganglia at levels equivalent to those observed in the liver, suggesting that the basal ganglia may act as a region of iron storage and distribution within the brain (for a more thorough review, see Beard et al. 1993). Transferrin, a plasma glycoprotein transporting iron in the periphery, is responsible for the shuttling of iron across the blood-brain barrier (BBB) (Madsen and Gitlin 2007) (Fig. 28.1). The highest levels of transferrin in the brain occur in regions containing more myelin, and in the white matter more so than the gray matter. The synthesis of myelin from fatty acids and cholesterol by oligodendroglia is an iron-dependent process (Beard et al. 1993).

One-third of brain iron is stored as ferritin, which is ten-fold more abundant in the brain than transferrin, mostly in oligodendroglia and microglia. Ferritin is comprised of either a heavy chain, which takes up and releases iron more rapidly and is found predominately in neurons, or a light chain, found mostly in glia (Beard et al. 1993). This implies that within the brain, cell populations regulate iron levels in differing ways. The mature brain gains iron through BBB and the brain-cerebral spinal fluid barrier (BCB) via pathways dependent upon transport by transferrin receptor (TfR) and divalent metal transporter-1 (DMT-1), a transporter of divalent metals present in astrocytes (Siddappa et al. 2003). Expression of both TfR and DMT-1 is regulated by the iron regulatory proteins IRP-1 and IRP-2, cytosolic proteins sensitive to decreases in intracellular iron status. These proteins bind to an iron response element (IRE) on 3′ UTR of TfR and DMT-1 mRNA when intracellular iron is low, increasing the stability of the mRNA and increasing protein expression (Fig. 28.1). The brain has two mechanisms to increase iron delivery to neurons: increasing total brain iron delivery from serum via BBB and BCB and/or increasing the percentage of cells expressing TfR and DMT-1 (Siddappa et al. 2003).

28.2.2 Manganese

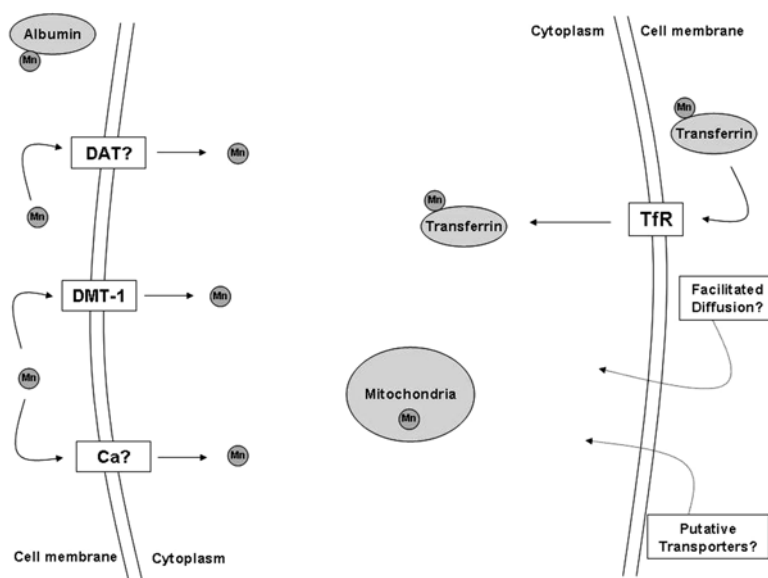
Most brain manganese is found in the iron-rich regions of the basal ganglia. Transport of manganese into the CNS may occur via the blood at the BBB or via cerebral spinal fluid at the BCB (Aschner et al. 2005), with the entry of manganese into the CNS via the BCB increasing with elevated plasma concentrations of manganese (Normandin et al. 2004). Manganese may also enter the brain following inhalation, bypassing the normal systemic regulatory processes and delivering manganese directly to the CNS. This may occur via the olfactory nerve, the epithelia, or a more systemic route through the mucosa (see Erikson et al. 2007 for review of brain manganese transport). In the brain, manganese can migrate to most regions utilizing a variety of mechanisms. Axonal transport of manganese has been demonstrated, as well as the ability of manganese to cross synapses and travel along secondary and tertiary neurons (Aschner et al. 2005). Manganese may also enter neurons and glial cells through calcium channels (Aschner et al. 2005). To date, the precise mechanism of manganese transport in the brain is still unknown and probably consists of more than one primary route. Facilitated diffusion, active transport, and transferrin-dependent transport are all proposed mechanisms of manganese transport across the BBB (Aschner et al. 2005) (Fig. 28.2). A recent study demonstrated that inhibition of DAT inhibits manganese accumulation in the globus pallidus during chronic exposure, suggesting that the DAT may not play a central role in normal manganese transport in the brain, but may become relevant in a toxicological paradigm in terms of manganese exposure (Anderson et al. 2007). Other transporters recently implicated in the manganese transport include the monocarboxylic acid transporter and the organic anion transporter (Crossgrove et al. 2003), as well as the Zrt/Irt-like proteins (ZIP) (He et al. 2006) (Fig. 28.2).


Fig. 28.2 Basic cellular manganese transport. Mechanisms of cellular manganese transport within the brain are illustrated, including known and hypothesized transport proteins and pathways. Manganese may enter cells via transferrin-mediated transport or via the divalent metal transporter DMT-1, though the exact mechanism of manganese absorption is not completely understood and may include facilitated diffusion or other putative transporters, such as the monocarboxylic acid transporter, organic anion transporter, or ZIP transporter. DAT and calcium channels have been shown to allow entry of manganese into the cell. Inside the cell, the mitochondria act as a sink for manganese

28.2.3 Copper

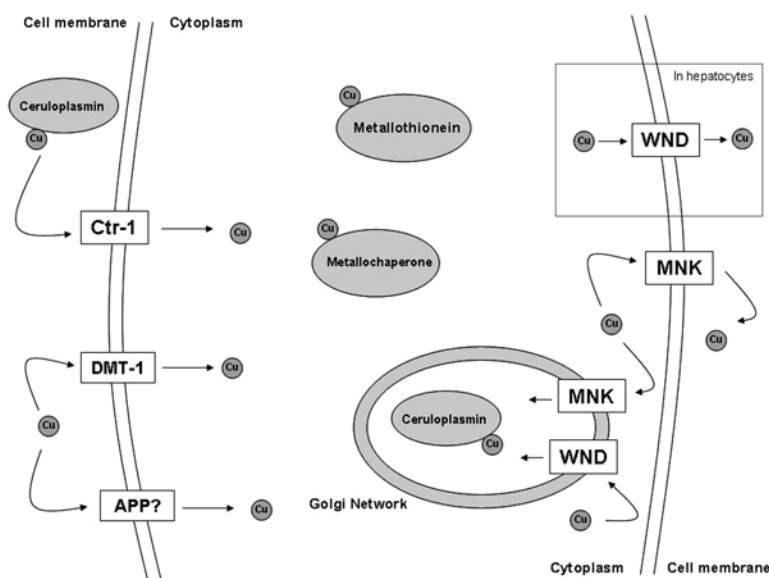
Copper is distributed across most regions of the brain, with the highest levels found in the basal ganglia (Madsen and Gitlin 2007). Transport of copper is dependent upon the oxidation state, with the reduced form of copper being the only form able to be transported (Macreadie 2008). Additionally, metallochaperone proteins, such as Atox1, bind and transport copper to specific locations within the cell in a pathway-specific manner (Fig. 28.3). Since excess and free copper is toxic to cells, sequestration is essential through copper-binding proteins such as metallothionein, a cysteine-rich cytoplasmic protein that chelates copper and is essential to protect against toxicity (Madsen and Gitlin 2007). Two transporting ATPases, Atp7a (MNK) and Atp7b (WND), are the main proteins regulating cellular copper homeostasis (Arredondo and Núñez 2005). MNK excretes copper from most cells when concentrations become too high, while WND performs this function in hepatocytes, excreting copper into the bile. Both transport proteins supply copper for enzymes by shuttling copper into the Golgi (Fig. 28.3). Additionally, in the brain MNK is expressed within specific populations of neurons in several brain regions, including the cerebellum and hippocampus, as well as the BBB endothelium, and facilitates copper movement (Madsen and Gitlin 2007). Copper transporter-1 (Ctr-1) is a plasma membrane protein present on the endothelium of the BBB and essential for early embryonic development (Madsen and Gitlin 2007). Expression of Ctr-1 increases during perinatal copper deficiency (Arredondo and Núñez 2005), suggesting that Ctr-1 transports copper into the brain from the plasma. DMT-1 (Arredondo and Núñez 2005) and amyloid precursor protein (APP) (Macreadie 2008) are also likely copper transporters in the brain (Fig. 28.3).


Fig. 28.3 Basic cellular copper transport. Mechanisms of cellular copper transport within the brain are illustrated, including known and hypothesized transport proteins and pathways. Copper may enter the cell through the copper transporter Ctr-1 or DMT-1. The amyloid precursor protein may act as a copper transport protein as well. Inside the cell, copper is bound to metalloproteins such as ceruloplasmin or metallothionein to prevent cytotoxicity of free copper. Metallochaperone proteins direct copper in a pathway-specific manner to organelles for incorporation of copper into metalloenzymes. MNK and WND transport copper into the Golgi network for processing and packaging. MNK can also transport copper out of the cell, with this function being performed by WND in hepatocytes
Fig. 28.4 Basic cellular zinc transport. Mechanisms of cellular zinc transport within the brain are illustrated, including known and hypothesized transport proteins and pathways. Zinc may enter the cell via zinc transporter 1 (*ZnT-1*) or through Zn/Irt proteins (*ZIP*). Inside the cell, zinc may be transported via ZnT-2 or ZnT-4 into organelles, ZnT-3 into vesicles, ZnT-5 into secretory granules, or ZnT-6 or ZnT-7 into the Golgi network. Free zinc in the cell is usually bound to a metalloprotein such as metallothionein to prevent toxicity

28.2.4 Zinc

The presence of zinc within the brain, particularly the cerebellum, has been known for the past several decades (Reviewed in: Sandstead et al. 2000). Brain zinc concentrations are highest in the telencephalon, hippocampus, amygdala, and gray matter of the cortex. The vast majority of zinc in the brain is bound to metalloproteins, such as metallothionein, with the rest found in presynaptic vesicles (Szewczyk et al. 2008). Zinc is found highly concentrated within neurons of the CNS (Sandstead et al. 2000). Several zinc transporters (ZnT) have been identified and are crucial for the movement of zinc within mammalian systems (Fig. 28.4). ZnT-1 lowers intracellular zinc, preventing toxicity, since moderate increases in the concentration of intracellular zinc can lead to cytotoxicity. ZnT-2 and ZnT-4 sequester zinc into organelles, with ZnT-6 and ZnT-7 moving zinc into the Golgi and ZnT-5 transporting zinc into secretory granules. ZnT-3 and ZnT-4 are found in the CNS, with ZnT-3 responsible for transporting zinc into vesicles (Sandstead et al. 2000). Zrt/Irt-like proteins (ZIP) transport zinc into the cytoplasm from both the extracellular space and from zinc-containing organelles (Nakashima and Dyck 2009) (Fig. 28.4).

28.3 Role of Metals in Brain Development

28.3.1 Iron

Iron is extremely important to the developing nervous system, with the rate of iron uptake by the brain greatest during fetal life (for review see Madsen and Gitlin 2007), coinciding with a peak in myelinogenesis, with perinatal ID significantly altering myelination of the spinal column and the

white matter of the cerebellum. Iron requirements in the brain far exceed brain iron uptake, suggesting that most of the iron in the brain used daily is recycled behind the BBB, with recycling a major source of iron for brain function following birth. This is analogous to what occurs with regard to iron homeostasis in the periphery (Madsen and Gitlin 2007).

28.3.2 Manganese

Manganese is essential for the functioning and development of the brain and manganese distribution within the brain varies across the life cycle, with concentrations higher in adults than in infants. Alterations in brain Mn levels might be associated with brain maturation and function (Takeda 2003). Manganese is highly concentrated in the hippocampus and pons following birth, structures that may require high levels of manganese, and is found in high concentrations within regions of the basal ganglia in the adult brain, with movement of manganese within the brain likely associated with neuronal activity.

28.3.3 Copper

Copper is essential for CNS development, with studies suggesting a role for MNK and copper in axon extension and synaptogenesis during brain development (Madsen and Gitlin 2007). Disruption of copper homeostasis during fetal life can lead to perinatal mortality, severe growth retardation, and neurodegeneration. Timing of perinatal copper deficiency influences the severity of the neurological outcomes, suggesting a critical period for adequate copper in brain development (Madsen and Gitlin 2007). Rapid growth increases copper demands, with infancy representing the most critical period for copper requirements (Arredondo and Núñez 2005). Diets based on milk provide low amounts of copper and deficiency is of greatest concern during this stage. Also at this stage there is an increased risk of toxic effects due to immature liver functioning unable to handle high copper exposure (Arredondo and Núñez 2005).

28.3.4 Zinc

Zinc plays a role in synaptogenesis and neuronal growth during early brain development, with deficiency during these stages causing malformations and behavioral alterations. Zinc is required for DNA and protein synthesis in the embryo, as well as dendritic growth and motor development. Deficiency of zinc during embryonic development can lead to stunted fetal growth, though concentrations of zinc are higher in adults than in newborns (Sandstead et al. 2000).

28.4 Effects of Metals on Neurotransmitter Systems

28.4.1 Iron

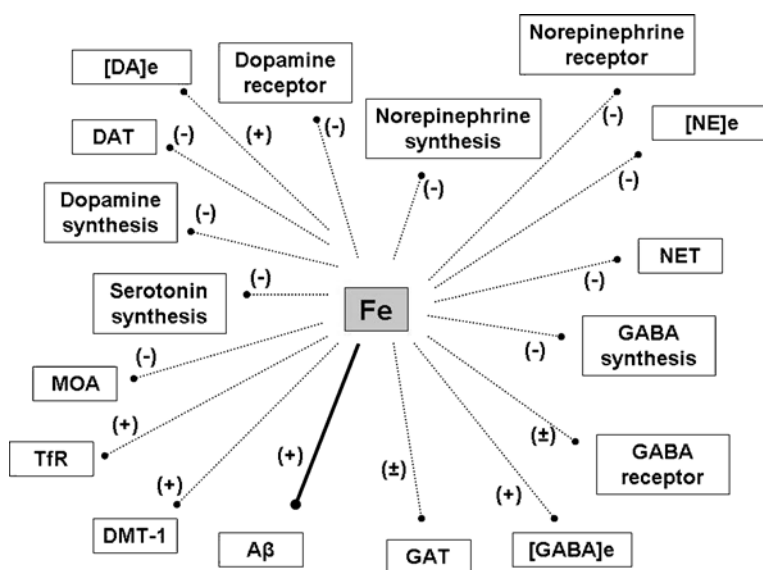
The role of intraneuronal iron includes incorporation of iron into enzymes for oxidation-reduction reactions, electron transport, and synthesis, packaging, uptake, and degradation of neurotransmitters (Beard et al. 1993) (Fig. 28.5). Iron is involved in the synthesis of catecholamines, with iron status


Fig. 28.5 Role of iron in neurotransmitter biology. Increases (+) and decreases (−) in activity resulting from the effects of iron on neurotransmitter biology are illustrated during normal homeostasis, deficiency (*dotted line*), and toxicity (*heavy line*)

hypothesized to affect both monoamine oxidase and aldehyde dehydrogenase, enzymes critical for the catabolism of these biogenic amines. Alterations in iron homeostasis can negatively impact synthesis of γ-aminobutyric acid (GABA) (Beard et al. 1993), as well as expression of GABA transport and receptor proteins (Anderson et al. 2008). Over two decades ago, ID was linked to alterations in dopamine receptor expression (Youdim et al. 1989), with more recent studies observing increased extracellular dopamine and decreased functioning of dopamine receptors (Beard et al. 2006). Studies have found effects of ID on norepinephrine pool size, norepinephrine uptake, and norepinephrine transporter expression both in vitro and in vivo (Beard et al. 2006).

28.4.2 Manganese

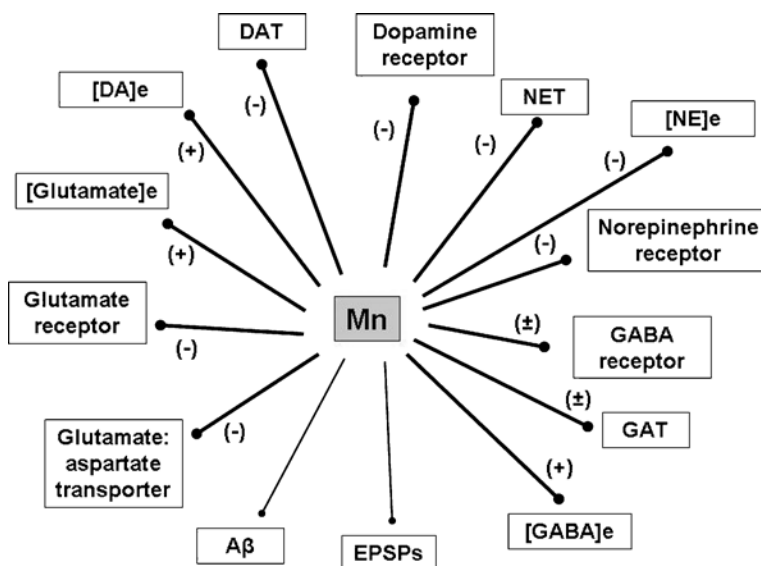
Manganese has been shown to block voltage-dependent Ca channels and nerve-evoked neurotransmitter release (Takeda 2003) (Fig. 28.6). Manganese may be released concurrently with glutamate and can decrease the ability of astrocytes to clear glutamate from the synapse, which is likely linked to downregulation of the glutamate:aspartate transporter (Fitsanakis and Aschner 2005). Additionally, manganese has been shown to increase both the frequency and amplitude of spontaneous excitatory post-synaptic potentials in the striatum, leading to increased extracellular glutamate (Fitsanakis and Aschner 2005). Manganese is known to affect GABA by dose-dependently increasing binding at GABA$_B$ receptors (Kerr and Ong 1995), with manganese exposure leading to perturbations in expression of GABA transport and receptor proteins (Anderson et al. 2008). Manganese exposure has also been shown to decrease density of the dopamine transporter (DAT) in rodent models (McDougall et al. 2008). Data from nonhuman primate studies point to a reduction in dopamine receptors post-synaptically in response to manganese exposure (Eriksson et al. 1992). Loss of autoreceptor control of dopamine activity during early stages of manganese poisoning has been demonstrated in mice as


Fig. 28.6 Role of manganese in neurotransmitter biology. Increases (+) and decreases (−) in activity resulting from the effects of manganese on neurotransmitter biology are illustrated during normal homeostasis, deficiency (*dotted line*), and toxicity (*heavy line*)

well (Cuesta de Di Zio et al. 1995), affecting extracellular levels of dopamine and expression of DAT. Struve et al. (2007) found marginal increases in GABA and norepinephrine in response to manganese exposure in primates. A study by Autissier et al. (1982) found alterations in tissue concentrations of norepinephrine in a rodent model, while manganese was found to inhibit uptake of norepinephrine in a dose-dependent manner ex vivo (Lai et al. 1982). Additionally, manganese exposure has been shown to decrease cellular concentrations of serotonin (Reaney and Smith 2005).

28.4.3 Copper

At some neurons, copper may be co-released at the synapse with classical neurotransmitters (Madsen and Gitlin 2007). Copper plays a role in long-term potentiation, modulating activity of calcium-dependent cascades, and synaptic plasticity (Fig. 28.7). Copper is an antagonist at NMDA receptors, leading to rapid and reversible trafficking by MNK, suggesting a mechanism linking copper homeostasis and neuronal activation. The neurotransmitter norepinephrine is a catecholaminergic neuromodulatory neurotransmitter derived from dopamine by dopamine β-hydroxylase, a copper-dependent enzyme (Madsen and Gitlin 2007).

28.4.4 Zinc

Zinc may be co-released at the synapse with classical neurotransmitters and can modulate GABA, NMDA, and glycine receptors at micromolar concentrations (Fig. 28.8). A special class of glutamatergic neurons has zinc-containing vesicles in the axon terminals, releasing zinc into the synaptic cleft and modulating post-synaptic NMDA receptors (Sandstead et al. 2000). All zinc-containing neurons are glutamatergic, but not vice versa (Donnelly et al. 2007), with zinc-containing somata located almost

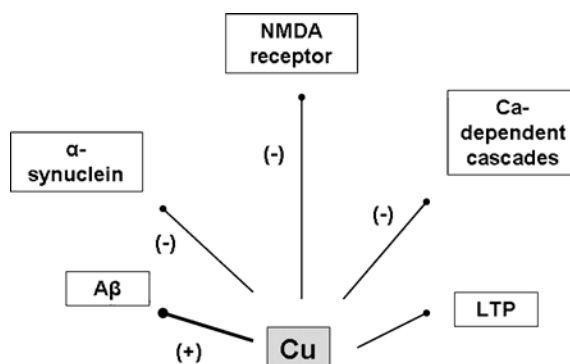
Fig. 28.7 Role of copper in neurotransmitter biology. Increases (+) and decreases (−) in activity resulting from the effects of copper on neurotransmitter biology are illustrated during normal homeostasis, deficiency (*dotted line*), and toxicity (*heavy line*)


Fig. 28.8 Role of zinc in neurotransmitter biology. Increases (+) and decreases (−) in activity resulting from the effects of zinc on neurotransmitter biology are illustrated during normal homeostasis, deficiency (*dotted line*), and toxicity (*heavy line*)
exclusively in cerebral cortex and amygdala. Zinc alters neuronal excitability, plays a role in synaptic plasticity, and can function as a signaling molecule affecting protein function (Szewczyk et al. 2008). Zinc is an inhibitor of GABA receptors, binding to the extracellular domain and allosterically stabilizing the receptor into a shut formation without blocking the channel (Gingrich and Burkat 1998). Zinc also inhibits the GABA transporter (Nakashima and Dyck 2009). Zinc-ATP is necessary for the synthesis of pyridoxal-5-phosphate and flavin adenosine dinucleotide, coenzymes that are essential for the synthesis of biogenic amines and monoamine oxidase metabolism. Severe zinc deficiency has been shown to increase brain concentrations of norepinephrine in rodent models (Sandstead et al. 2000).

28.5 Effects of Altered Metal Homeostasis

28.5.1 *Deficiency*

28.5.1.1 Iron

Iron deficiency is reported as the most prevalent nutritional problem in the world, affecting more than two billion individuals worldwide (WHO/UNICEF/UNU 2006), and is associated with malformation of red blood cells, growth impairment, perturbations in thermoregulation, and deficits in cognitive function (Beard et al. 1993). The neurobiological sequelae of ID in humans include variations in behavior, cognition, and neurotransmitter metabolism, including anemia, reduced immune function, diminished work capacity, and impaired thermoregulation. Disturbances in iron homeostasis

are linked to cognitive dysfunction, neurodegenerative diseases, restless leg syndrome, and Parkinson's disease (Burhans et al. 2005). Iron deficiency in early life may lead to insufficient myelination and dysfunction of dopaminergic tracts (Arredondo and Núñez 2005), as well as neuropsychological effects linked to delayed cognitive development in children and adolescents, delays that may respond to iron therapy (Sandstead et al. 2000). Iron deficiency during late fetal and early postnatal life is associated with cognitive impairments that persist despite repletion, presumably due to alterations in iron-based neuronal cellular processes that occur during the period of rapid brain growth and high iron demand (Siddappa et al. 2003). During the perinatal period, ID results in regionalization of functional brain iron, which may depend on the responsiveness of TfR and DMT-1 and the regulatory proteins IRP-1 and IRP-2 (Siddappa et al. 2003). Studies that have followed children several months after iron repletion suggest that there is an early critical period of brain development during which ID can have a permanent impact (for review, see Youdim 2001).

28.5.1.2 Manganese

Because of its widespread presence in human diets, frank manganese deficiency is generally not clinically recognized in humans. Manganese deficiency has been observed in laboratory animals and has been associated with impaired growth, skeletal defects, reduced reproductive function, birth defects, and abnormal glucose tolerance, as well as altered lipid and carbohydrate metabolism (Aschner et al. 2005). Reduced manganese status may also be observed in individuals with osteoporosis and epilepsy. Blood manganese concentrations are lower in epileptic patients, and alterations in brain manganese homeostasis may be associated with susceptibility to seizures. People with exocrine pancreatic insufficiency, chronic hemodialysis, Perthes' disease, and phenylketonuria may also possess inadequate manganese levels (Aschner et al. 2005).

28.5.1.3 Copper

Frank copper deficiency is rare in humans, though it has been observed in infants fed milk formulas and those recovering from malnutrition, or in adult patients receiving prolonged total parenteral nutrition (Fujita et al. 1989). Symptoms of copper deficiency include anemia, leukopenia, neutropenia, and osteoporosis (Fujita et al. 1989). During severe copper deficiency, iron transport within the body is adversely affected (Arredondo and Núñez 2005), with iron tending to accumulate in many tissues, followed by anemia. Acquired copper deficiency in adults leads to myelopathy, limb spasticity, and sensory ataxia due to neurodegeneration (Madsen and Gitlin 2007).

28.5.1.4 Zinc

Zinc deficiency is not uncommon and may present simultaneously with ID. Both metals are most bioavailable from similar food sources and absorption of both is inhibited by the same dietary substances (Sandstead and Smith 1996). Zinc deficiency causes abnormal development of the nervous system, leading to distinct behavioral effects (Sandstead et al. 2000). Depression and impaired cognitive function are early clinical manifestations of zinc deficiency, with lower serum zinc levels found in depressed individuals, which may be normalized after successful antidepressant therapy (Szewczyk et al. 2008). Zinc deficiency has been reported in Alzheimer's disease (AD) patients and could be a contributing factor in development of this condition (Shcherbatykh and Carpenter 2007).

28.5.2 Overload/Toxicity

28.5.2.1 Iron

Dysregulation of iron homeostasis in the brain leading to increased concentrations of iron result in saturation of iron transport and storage proteins, increased free iron in the cell, production of reactive oxygen species, oxidative damage, and cell death via apoptosis (Beard et al. 1993). Accumulation of iron in the brain occurs with aging, along with an increase in ferritin. This increase may lead to oxidative damage as a result of proxidant-free iron, which may be released from ferritin under acidic condition caused by excess concentrations of SOD or ascorbate, intracerebral hemorrhage, or hypoxic ischemia (Gaasch et al. 2007). High concentrations of brain and dysregulation of iron homeostasis in the brain are associated with Parkinson's disease (PD) and Alzheimer's disease (AD), which will be described further in the Applications to Health and Disease section of this chapter. Interestingly, inherited disorders of iron metabolism such as hemochromatosis do not always correlate with increased brain iron (Gaasch et al. 2007).

28.5.2.2 Manganese

Manganese toxicity resulting from environmental exposure has been documented since the early nineteenth century, when a small group of workers grinding manganese oxide developed an unsteady gait and muscular weakness (Normandin et al. 2004). At present, manganese toxicity is most often associated with occupational exposure of welders, miners, and steel workers to chronic high levels of airborne particulate manganese (Pal et al. 1999). When inhaled, the manganese can lead to inflammation in the lungs and potential respiratory symptoms, including cough, bronchitis, pneumonitis, and impaired pulmonary function (Roels et al. 1987). Cases from drinking contaminated well water have also been reported in several countries, resulting in impaired cognitive function (Sahni et al. 2007). Working memory, concentration, and spatial orientation have all been shown to be affected following toxic manganese exposure (Mergler et al. 1994). Manganese neurotoxicity is characterized by a psychiatric disorder resembling schizophrenia, and eventually manifests as a neurological disorder sharing similarities with several clinical disorders, in particular Parkinson's disease (Pal et al. 1999).

28.5.2.3 Copper

At steady state the amount of copper excreted into the bile is equivalent to that absorbed from the intestine, with excretion increasing promptly in response to elevated dietary copper. Therefore, excess copper does not occur in the absence of an underlying metabolic defect (Madsen and Gitlin 2007). The consequences of these genetic disorders of copper metabolism are discussed in the section, Applications to Health and Disease.

28.5.2.4 Zinc

High intracellular concentrations of zinc are cytotoxic and can lead to neurodegeneration through the production of ROS, resulting in oxidative damage. It is hypothesized that excess zinc leads to cell death by inhibiting synthesis of ATP at various points in cell metabolism. Zinc has been shown to

disrupt glycolysis, the Kreb's cycle, and the electron transport chain through the inhibition of specific enzymes required for these processes. These high levels of intracellular zinc may be achieved through the influx of zinc from the extracellular space through ion channels of glutamate receptors. Moreover, zinc has been implicated as a potential neurotoxin in models of stroke and epilepsy, and high levels of zinc can lead to aggregation of amyloid plaques and dementia in neurodegenerative diseases (Dineley et al. 2003).

28.6 Applications to Health and Disease

Imbalance of trace metals can play a role in the etiology of various neurodegenerative and neurological disease states. Cellular levels of Fe and transferrin are altered around plaques present in multiple sclerosis, with iron contained in sclerotic plaques and MRI data from multiple sclerosis patients showing a general disruption in regulation of iron (Beard et al. 1993). Human prions have been shown to have binding sites for trace metals (Shcherbatykh and Carpenter 2007). Moreover, individuals suffering from a complete deficiency of ceruloplasmin have alterations in iron metabolism and develop dementia later in life (Madsen and Gitlin 2007). Altered brain metal homeostasis has been implicated in Huntington's disease, Freidreich's ataxia, and amyotrophic lateral sclerosis (Aschner et al. 2005; Gaasch et al. 2007). Parkinson's disease (PD) and Alzheimer's disease (AD) are two neurodegenerative conditions in which altered homeostasis of metals is of keen interest. Additionally, genetic disorders of copper metabolism deleteriously impact neurological function.

28.6.1 Parkinson's Disease

Parkinson's disease is one of the most common neurodegenerative conditions among the elderly, affecting a marginal percentage of the worldwide population (Rommelfanger and Weinshenker 2007). Disturbed iron homeostasis has been linked to cognitive dysfunction and PD (Burhans et al. 2005), with the postmortem brain iron content of PD patients significantly higher than that of age-matched controls (Beard et al. 1993). Manganese neurotoxicity shares similarities with PD (Pal et al. 1999), and manganese accumulation in the brain may play a role in the pathology of idiopathic PD (for review, see Aschner et al. 2005). Copper affects oligomerization of α-synuclein, a protein essential for neurotransmission, during PD (Macreadie 2008). Additionally, alterations in norepinephrine biology brought on by perturbations in metal homeostasis may play a role in the etiology of PD given the profound effects of norepinephrine on brain inflammation, oxidative stress, and the function of protein implicated in the condition (Rommelfanger and Weinshenker 2007).

28.6.2 Alzheimer's Disease

Recently, there has been substantial interest in role of copper, zinc, manganese, and iron in the neuropathology of AD, since these metals are known to be concentrated in and around amyloid plaques at concentrations three to five times higher than in age-matched controls (Shcherbatykh and Carpenter 2007).

Additionally, there is an observed imbalance of these metals (decreased copper; increased iron, manganese, and zinc) in the AD brain, with chelators having been shown to enhance resolubilization of plaques (Cornett et al. 1998). However, the exact role of these trace metals in AD pathogenesis remains uncertain (Shcherbatykh and Carpenter 2007).

Iron is a component of senile plaques and iron encrustation of blood vessels is common in AD. Iron mobility decreases and iron levels in the brain are increased during AD, with an associated decrease in metabolic activity and increase in perioxidative damage. IRE is located on the mRNA for the amyloid precursor protein (Beard et al. 1993). Compared to normal aged tissue, the concentration of transferrin decreases, ferritin levels decrease, and iron levels increase in tissues from AD patients, with loss of the transferrin receptor observed the in AD brains (Beard et al. 1993). The amyloid β protein (Aβ), which forms the senile plaques in AD, reduces copper and iron leading to production of hydrogen peroxide and toxicity (Shcherbatykh and Carpenter 2007). Copper can induce Aβ precipitation, with Aβ having selective binding sites for copper, making the copper in Aβ plaques available for reactive oxygen species production (Macreadie 2008). A clear association exists between excess zinc and formation of amyloid plaques, with an imbalance of zinc a hallmark of the AD brain. Zinc promotes aggregation of endogenous Aβ in CSF in low concentrations and inhibits Aβ-mediated hydrogen peroxide production (Shcherbatykh and Carpenter 2007).

28.6.3 Genetic Disorders of Copper Metabolism

28.6.3.1 Menkes Disease

The neurological features of Menkes disease are present in early infancy, with impaired copper transport into and within the developing brain resulting in demyelination and neurodegeneration, revealing the critical role for MNK and copper in neuronal development (Madsen and Gitlin 2007). Menkes disease is an X-linked disorder characterized by growth failure, brittle hair, hypopigmentation, arterial tortuosity, and neuronal degeneration due to a loss-of-function mutation in the gene encoding the copper transporter Atp7a (MNK). Neuropathological exam reveals a focal degeneration of gray matter and neuronal loss most prominent in hippocampus and cerebellum, with decreased myelination with cerebellar and cerebral atrophy as revealed by MRI (Madsen and Gitlin 2007).

28.6.3.2 Wilson Disease

Wilson disease is an autosomal recessive disorder leading to cirrhosis of the liver and progressive neurodegeneration in the basal ganglia as a result of a loss-of-function mutation in the gene encoding the copper transporter Atp7b (WND) (Madsen and Gitlin 2007). Wilson disease is characterized by impairment in the biliary excretion of copper, leading to hepatocyte copper accumulation, copper-mediated liver damage, apoptosis, leakage of copper into plasma, and copper overload in extrahepatic tissues due to excess accumulation from the plasma following liver injury. Half of the patients with Wilson disease present with signs and symptoms of neuropsychiatric illness, with brain copper accumulation during Wilson disease leading to dystonia, dysarthria, and other Parkinsonian symptoms, as well as psychiatric symptoms of depression, cognitive deterioration, personality change, psychosis, and schizophrenia (Madsen and Gitlin 2007).

Summary Points

- Trace elements are required for proper biological functioning, but homeostasis must be strictly regulated to prevent oxidative damage and neurodegeneration.
- Iron is required for oxidative phosphorylation, nitric oxide metabolism, and oxygen transport.
- Manganese is required for normal immune function, regulation of blood sugar and cellular energy, reproduction, digestion, bone growth, defense against free radicals, and blood clotting in concert with vitamin K.
- Copper is required for cellular respiration, iron oxidation, and pigment formation, neurotransmitter biosynthesis, antioxidant defense, peptide amidation, and connective tissue formation.
- Zinc is required for protein synthesis, all stages of metabolism, synaptic activity, and neuronal function.
- Iron, manganese, copper, and zinc play a critical role in brain development, with metal deficiencies or toxicities during embryogenesis deleterious.
- Iron, manganese, copper, and zinc are essential for proper neurotransmitter biology, influencing synaptic function and neurotransmitter receptor and transport proteins.
- Deficiencies of essential trace metals can have deleterious effects of the functioning of central nervous system, leading to learning deficits and neurodegeneration.
- Overload or toxic levels of trace metals can lead to production of reactive oxygen species, oxidative damage, and neural dysfunction.
- Neurodegenerative diseases such as Parkinson's disease and Alzheimer's disease have been linked to altered brain homeostasis of trace metals such as iron, manganese, copper, and zinc.

Key Terms

Biogenic amine: A biologically active neurotransmitter than contains an amine group.

Blood-brain barrier: A selectively permeable barrier formed by the tight junctions of vascular endothelial cell membranes and astrocytes in the brain; this barrier protects the brain from exogenous molecules; most metabolites and molecules require a specific protein transporter for trafficking across the membrane.

Blood-cerebrospinal fluid barrier: A barrier formed in the choroid plexus of the brain between the cerebral capillaries and the extracellular space containing the cerebrospinal fluid; metabolites, molecules, and toxins may enter the brain through this barrier.

Catecholamine: A classical neurotransmitter that contains a catechol group and an amine group; includes dopamine, norepinephrine, and serotonin.

Ceruloplasmin: A copper-containing protein essential for copper transport and regulation of intracellular copper concentrations that act as a ferroxidase in the brain.

Ferritin: An iron-storing protein composed of a heavy and light chain that regulates intracellular iron concentrations.

Glial cell: a cell within the central nervous system that supports the activity and function of neurons; glial cell types include astrocytes, oligodendroglia, and microglia.

Metalloenzyme: A catalytic protein enzyme that contains one or more metal ions or requires metal ions as a cofactor in order to function.

Metallothionein: A cysteine-rich protein that binds and sequesters metal ions in the cell to prevent cytotoxicity and cellular damage.

Transferrin: A glycoprotein that binds iron for transport in the bloodstream and inside cells; may also bind and transport other metals such as manganese.

Abbreviations

THC	delta-9-tetrahydrocannabinol
DA	dopamine
FR	fixed ratio
c-AMP	cyclic-adenosine monophosphate

29.1 Introduction

Drugs that act upon cannabinoid CB1 receptors can exert a number of physiological and behavioral effects. CB1 agonists, such as delta-9-tetrahydrocannabinol (THC), CP559490, and AM411, affect neural processes related to motor control (Martin et al. 1991; Carriero et al. 1998; McLaughlin et al. 2005a), pain (Martin et al. 1991; McLaughlin et al. 2005a), and cognitive function (Darley et al. 1973; Heishman et al. 1990; Ilan et al. 2004; McLaughlin et al. 2005b). In addition, CB1 agonists have been reported to exert actions related to food intake. Initial findings indicated that consumption of marijuana could be accompanied by feelings of increased hunger and decreased satiety, as well as increases in food intake (Halikas et al. 1985). Laboratory experiments with humans demonstrated that CB1 agonists could increase eating (Foltin et al. 1986, 1988) and increase body weight (Greenberg et al. 1976). Overall, the effects of cannabinoid CB1 agonists on food intake studies conducted in animals appear to depend greatly upon the dose that is used (Giuliani et al. 2000). Some papers have reported that injection of relatively high doses of CB1 agonists that produce catalepsy and suppress locomotion also tend to decrease feeding (e.g., Drewnowski and Grinker 1978). Nevertheless, administration of moderate-to-low doses of CB1 agonists generally has been shown to increase food intake (Giuliani et al. 2000; Johansson et al. 1975; Williams et al. 1998; Koch 2001; Williams and Kirkham 1999, 2002). Because of these actions, CB1 agonists have been investigated for their potential as treatments for anorexia and the wasting syndrome associated with AIDS and cancer chemotherapy (Hao et al. 2000).

With the development of CB1 receptor antagonists such as rimonabant (SR141716A; Rinaldi-Carmona et al. 1994), it was suggested that CB1 receptor blockade could act to reduce food intake.

Table 29.1   Key features of the functional significance of cannabinoid receptors

1. There are two subtypes of cannabinoid receptors – CB1 and CB2
2. Delta 9 THC, the active ingredient in marijuana, is a CB1 agonist
3. Several synthetic CB1 agonists and antagonists have been developed
4. There are endogenous ligands for the CB1 receptor, known as anandamide and 2AG, which act as neuromodulators and physiological signaling molecules
5. CB1 antagonists and inverse agonists block the effects of these endogenous ligands, and also block the effects of pharmacological agents that act as CB1 agonists

This table presents some of the key features of the functional significance of cannabinoid receptors, and drugs that act on cannabinoid receptors.

Arnone et al. (1997) reported that rimonabant decreased intake of high-sucrose food pellets. Rimonabant also was shown to decrease intake of food, but not water, during the first few days of repeated administration in rats (Colombo et al. 1998). In this study, tolerance developed rapidly to the appetite suppression effect, although body weight was decreased during the entire period of drug administration, even at the lowest dose (2.5 mg/kg). As well as studying food consumption, researchers also investigated the effects of rimonabant on food-reinforced operant responding. Rimonabant reduced food-reinforced fixed ratio 15 responding in a dose-related manner, an effect that was partially reversed by coadministration of the CB1 agonist WIN55, 212-2 (Freedland et al. 2000).

 Over the last few years, there has been a rapid expansion of research in this area (see Table 29.1), and a number of different behavioral methods have been used to assess the ever increasing number of compounds that act to interfere with cannabinoid CB1 transmission (Simiand et al. 1998; Hildebrandt et al. 2003; McLaughlin et al. 2003, 2005a, b, c, 2006; Shearman et al. 2003; Chen et al. 2004; Wiley et al. 2005). Clinical trials with the CB1 inverse agonists rimonabant and taranabant have shown these drug to be effective at reducing body weight and waist circumference (Curioni and Andre 2006; Despres et al. 2005; Pi-Sunyer et al. 2006; Van Gaal et al. 2005; Addy et al. 2008). However, there also have been major problems related to the clinical utility of CB1 receptor inverse agonists for the treatment of obesity. Clinical trials have provided evidence of nausea and malaise, and also serious psychiatric side effects including depression and anxiety, with administration of rimonabant and taranabant. Nausea was one of the most common adverse effects reported in clinical trials with rimonabant (Pi-Sunyer et al. 2006; Van Gaal et al. 2005). In terms of psychiatric symptoms, a meta-analysis of rimonabant studies conducted by the Food and Drug Administration (FDA) showed that 26% of subjects treated with 20 mg rimonabant reported adverse psychiatric events versus 14% of those treated with placebo (US Food and Drug Administration Advisory Committee 2007). In the FDA-sponsored meta-analysis of clinical trials using rimonabant, the most commonly reported adverse psychiatric event was anxiety (US Food and Drug Administration Advisory Committee 2007). Clinical trials with taranabant, another CB1 inverse agonist, also were marked by the presence of adverse psychiatric events. Onset of psychiatric symptoms occurred early in the clinical trials, and dropouts related to psychiatric adverse events were frequent (Addy et al. 2008). The induction of adverse psychiatric symptoms was a key factor in the decision of the FDA to deny approval of rimonabant for treatment of obesity in the USA. In turn, this decision has led several pharmaceutical companies to abandon their research programs in this area (Le Foll et al. 2009). Nevertheless, research employing cannabinoid antagonists and inverse agonists remains very useful, in that it can provide insights into the neurochemical mechanisms regulating food motivation. Furthermore, alternative research strategies that focus on novel pharmacological agents with unique profiles, such as peripherally acting drugs or neutral antagonists, could yield clinically useful compounds (Salamone et al. 2007a; Le Foll et al. 2009). For those reasons, the present review will provide a brief summary of some of the studies that have focused upon recently synthesized compounds, and also will discuss novel cannabinoid-based strategies for the development of appetite suppressants.

29.2 Effects of CB1 Receptor Inverse Agonists on Food Intake and Food-Reinforced Behavior

Like rimonabant, the more recently developed drugs AM251 and AM1387 can bind with relatively high affinity to CB1 receptors, and they have a moderate level of selectivity for CB1 receptors relative to CB2 receptors. Furthermore, rimonabant, AM251, and AM1387 all act as inverse agonists at the cellular level, and exert actions on signal transduction mechanisms when administered in the absence of CB1 receptor stimulation (i.e., they inhibit GTPγS binding and increase cAMP production; Landsman et al. 1997; Mato et al. 2002; McLaughlin et al. 2006). These drugs have all been assessed under a standard set of conditions that provide measures of food-reinforced behavior and food intake. A series of experiments examined the effects of rimonabant, AM 251, and AM1387 on food-reinforced operant responding, using two different fixed ratio schedules (fixed ratio 1 (FR1) and 5 (FR5)). These particular ratio requirements were employed because previous studies have indicated that FR1 and FR5 schedules can show differential sensitivity depending upon the pharmacological conditions being studied (Solinas et al. 2003; Ishiwari et al. 2004). Rimonabant, AM251, and AM1387, all suppressed responding on both schedules of reinforcement (McLaughlin et al. 2003, 2005a, b, c), with each schedule being affected at roughly the same dose range for a given drug. In addition to being a useful tool for characterizing the effects of CB1 inverse agonists on food-reinforced responding, the suppression of FR5 lever pressing can be used to assess the duration of action for each compound. Rimonabant and AM251 were shown to have a relatively long duration of action ($t_{1/2}$: rimonabant-15.6 h; AM 251–22.0 h), while the half-life AM1387 was considerably shorter ($t_{1/2}$ = 4.87 h; McLaughlin et al. 2006).

Additional experiments were conducted to characterize the effects of rimonabant, AM251, and AM1387 on the consumption of different types of foods. There has been considerable interest in identifying the role that different diets may play in modulating the appetite-related effects of drugs that act on CB1 receptors. Snacking on sweets between meals was reported to increase after administration of cannabinoid agonists in humans, although meal size was not affected (Foltin et al. 1986). In rats, increases in food intake following administration of Δ9-THC were significantly larger for consumption of a high-fat diet compared to standard laboratory chow (Koch 2001). Although some reports have indicated that interference with CB1 transmission suppressed intake of sweet foods such as sucrose to a greater extent than standard laboratory chow (Arnone et al. 1997; Simiand et al. 1998), others have found that intake of standard diets such as laboratory chow also can be affected (Rowland et al. 2001; Verty et al. 2004a). In view of these discrepancies, a series of studies (McLaughlin et al. 2003; 2006) assessed the effects of rimonabant, AM251, and AM1387 on the intake of three different foods: a high-fat diet (HF; Diet # D12451, Research Diets, New Brunswick, NJ, 45% kcal from fat), a high-carbohydrate diet (HC; Diet # D12450B, Research Diets, New Brunswick, New Jersey, 67% kcal from carbohydrate), and standard laboratory chow (LC, 5P00 Prolab RMH 3000, PMI Nutrition International, St. Louis, MO). In these studies, rats were food deprived and trained to eat their assigned diet in test cages; after successive weeks of training, the drug treatment period began (one drug treatment per week following two baseline days). IP injections of rimonabant, AM251, and AM1387 produced a dose-related suppression of intake of all three food types, including the laboratory chow.

An important aspect of studies involving multiple types of foods is that baseline or control levels of consumption can differ dramatically. Indeed, in the studies described above (McLaughlin et al. 2003, 2006), intake was highest for the high-carbohydrate and high-fat diets, and considerably lower for the laboratory chow. For this reason, data were reanalyzed, with food intake being expressed as a percent of the two previous baseline days, in order to correct for differences in baseline levels. With this type of analysis, there were significant dose-related decreases in food intake with all three drugs,

but no significant interactions, and the dose–response curves for consumption of each food overlapped considerably (McLaughlin et al. 2003, 2006). These results indicate that rimonabant, AM251, and AM1387 do not seem to be selectively suppressing feeding upon diets that are high in carbohydrates or fat. Instead, effects of these drugs on intake of different foods may be due to differences in baseline intake or scaling. Furthermore, it may be difficult to show a suppression of lab chow intake if baseline levels of consumption are very low. It appears that as long as the testing conditions generate substantial levels of chow intake, interference with CB1 transmission can reduce intake of this type of food, which is generally considered not to be highly palatable. However, in considering the potential use of these drugs as appetite suppressants, it also is useful to note that the intake of distinct types of foods can show differential patterns of tolerance after repeated administration of CB1 inverse agonists (Arnone et al. 1997).

29.3 Effects of CB1 Inverse Agonists on Nausea and Malaise

As one evaluates the literature on the effects of CB1 receptor inverse agonists on food-related behaviors, it is critical to consider that drugs can affect food intake by altering a number of different behavioral processes. In addition to food motivation or appetite, effects of drugs on motor slowing, incoordination, nausea, or malaise may also occur, and these actions could affect food consumption. Some of the feeding-related effects produced by drugs that act on CB1 receptors may be due to actions on processes such as food avoidance, food aversion, nausea, or malaise. Several studies have shown that CB1 agonists have anti-emetic effects (Gonzalez-Rosales and Walsh 1997; Simoneau et al. 2001; Darmani and Johnson 2004). CB1 receptors that are associated with triggering emetic responses are present in the dorsal vagal complex in the brainstem (Van Sickle et al. 2003). Rimonabant enhanced lithium chloride-induced conditioned rejection in rats (Parker et al. 2003). Furthermore, administration of rimonabant led to the development of conditioned taste avoidance in the rat (De Vry et al. 2004), vomiting in the least shrew (Darmani 2001), and nausea in humans (Despres et al. 2005; Pi-Sunyer et al. 2006). Despite the fact that rats do not vomit, several papers have used measures of conditioned gaping in rats, which is thought to be a selective marker of nausea in that species (Parker et al. 1998; Limebeer et al. 2004). Gaping responses are induced by conditions that produce vomiting in species capable of emesis (Parker et al. 1998), and treatments that reduce toxin-induced vomiting in emetic species also attenuate toxin-induced conditioned gaping in rats (Parker et al. 2003; Limebeer et al. 2004). Consistent with the observation that CB1 receptor inverse agonists can induce nausea in humans, doses of AM251 that attenuate feeding were shown to be accompanied by the induction of conditioned food avoidance and conditioned gaping (McLaughlin et al. 2005a, b, c). These data indicate that drug-induced food aversions, nausea, and malaise may contribute to the reductions in food intake induced by CB1 receptor inverse agonists.

29.4 Studies of the Effects of CB1 Receptor Neutral Antagonists

As stated above, biochemical studies have indicated that rimonabant, AM251, and AM1387 act as inverse agonists, exerting effects on signal transduction mechanisms that are opposite to those induced by CB1 receptor stimulation (inhibition of GTPγS binding and increase c-AMP production, see Fig. 29.1; Landsman et al. 1997; Mato et al. 2002; McLaughlin et al. 2006). However, the

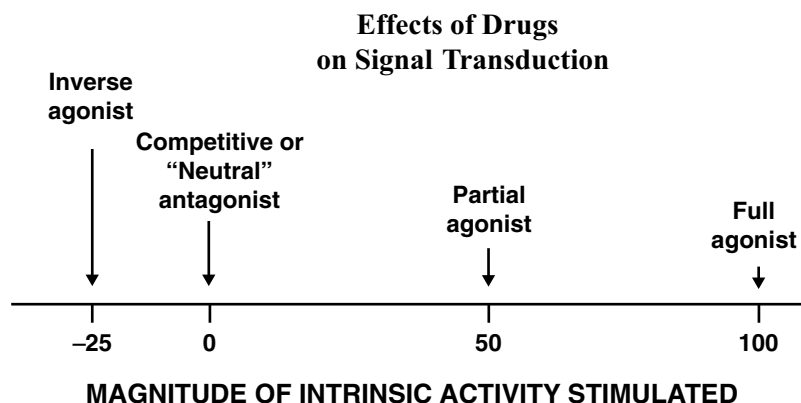
Effects of Drugs on Signal Transduction


Fig. 29.1 Signal transduction effects of drugs. Signal Transduction Effects of Drugs. This figure depicts the continuum of effects upon intrinsic activity that can be induced by different classes of drugs that act on the same receptor site as the neurotransmitter. Each of these drug classes (i.e., agonists, antagonists, inverse agonists) has affinity for the receptor. Agonists bind to the receptor and stimulate the same intrinsic activity as the endogenous transmitter. Full agonists maximally stimulate intrinsic activity, and partial agonists produce low-to-moderate levels of stimulation of the signal transduction mechanism (e.g., the arbitrary value shown here is 50%). Competitive antagonists (i.e., neutral or "silent" antagonists) bind to the receptor but do not instigate signal transduction effects on their own. In contrast, inverse agonists stimulate signal transduction effects in the opposite direction from those stimulated by the agonist and the transmitter. CB1 receptor agonists inhibit cyclic-AMP production, while inverse agonists stimulate production of this second messenger. In neuropharmacology, the identification of compounds as inverse agonists or neutral antagonists is based upon their signal transduction effects, which are determined at the cellular or tissue levels. Nevertheless, in behavioral pharmacology it also is important to determine if neutral antagonists block the behavioral actions of both inverse agonists and agonists

behavioral significance of these inverse agonist actions is unclear. Compared to wild-type mice, CB1 receptor knockout did not affect progressive ratio responding reinforced by corn oil, while administration of rimonabant to wild-type mice reduced responding (Ward and Dykstra 2005). This pattern of effects indicates that rimonabant may exert inverse agonist effects in addition to simply blocking CB1 receptors. The development of CB1 receptor neutral antagonists, weak partial agonists, or inverse agonists with very low intrinsic activity, would yield important tools for research in this field. The ability of these drugs to decrease feeding would indicate that there is a tonic influence of endogenous cannabinoids on food intake. Perhaps most importantly, it is possible that CB1 receptor neutral antagonists might be able to suppress food intake at doses that do not affect food avoidance, aversion, anxiety, or depression, a pattern of effects that would offer several clinical advantages (Salamone et al. 2007a; Sink et al. 2008a, b; Le Foll et al. 2009).

Within the last few years, investigators have begun to investigate the behavioral effects of drugs that have little in the way of CB1 receptor inverse agonist activity, and may be acting largely as neutral or "silent" antagonists. Gardner and Mallet (2006) reported that O-2050 suppressed food intake in non-deprived rats. Several recent papers have focused upon the effects of AM4113, which is a pyrazole analog that is structurally related to rimonabant and AM251 (Chambers et al. 2007; Sink et al. 2008a, b, 2009a). AM4113 blocked the locomotor suppression and analgesia induced by the CB1 agonist AM411 (Sink et al. 2008a), and also produced many of the food-related effects induced by rimonabant, AM251, and AM1387 (see above). AM4113 reduced food-reinforced FR1 and FR5 responding (Sink et al. 2008a, 2009a), and in fact was more potent at suppressing FR1 lever pressing than it was at reducing FR5 performance. AM4113 reduced intake of high-carbohydrate, high-fat, and laboratory chow diets, and as was the case with the inverse agonists, the degree of suppression

Table 29.2 Key points: effects of the CB1 receptor neutral antagonist AM4113 (Chambers et al. 2007; Sink et al. 2008a, b)

- High Affinity for CB1 receptors
- Can block effects of CB1 antagonists
- Tests of signal transduction show that this drug has no intrinsic activity, i.e., it is not an inverse agonist
- Important for showing behavioral significance of endogenous cannabinoid tone
- Suppresses food intake and food-reinforced behavior at doses that do not induce nausea or food aversion

This table summarizes some of the key points related to the actions of AM4113. See text for details

of intake for each food type relative to baseline was roughly comparable (Sink et al. 2008a). These data demonstrate that CB1 receptor neutral antagonists can suppress feeding and food-reinforced behavior, which suggests that blockade of endogenous tone at CB1 receptors is sufficient to produce a suppression of food-motivated behaviors.

In addition to demonstrating that drugs such as AM4113 can reduce food intake, it also is important to determine whether or not this suppression of feeding is accompanied by signs of nausea, malaise, or food aversion (Limebeer and Parker 2000; Parker and Limebeer 2006). Clinical studies have shown that nausea was one of the most common adverse effects reported in clinical trials with the antagonist/inverse agonist rimonabant (Pi-Sunyer et al. 2006; Van Gaal et al. 2005). AM4113, in contrast to the inverse agonist AM251, did not induce vomiting in ferrets (Chambers et al. 2007). In addition, doses of AM4113 that substantially suppressed food intake did not induce conditioned gaping (Sink et al. 2008a), which is a marker of nausea in rats. Another recent study demonstrated that, unlike the inverse agonist AM251, AM4113 did not produce anxiogenic effects in the elevated plus maze (Sink et al. 2010). Thus, if CB1 receptor neutral antagonists can suppress feeding without producing food aversions or anxiety-related effects in humans, it might mean that neutral antagonists would offer some clinical advantages over drugs that also have inverse agonist properties (Table 29.2).

29.5 Comparisons Between the Effects of CB1 Antagonists and DA Antagonists or Depletion

Rimonabant administration in moderate doses does not lead to obvious signs of sedation or motor slowing. Nevertheless, high doses can produce other effects such as reductions in spontaneous locomotion, and the induction of grooming, scratching, and head twitching (Darmani and Pandya 2000; Jarbe et al. 2002). It has been suggested that drug-induced grooming could be interfering with engagement in feeding behavior (Tallett et al. 2007), however, recent evidence indicates that response competition between grooming and feeding may not provide a sufficient explanation of the feeding suppression produced by AM251 and AM4113 (Hodge et al. 2008). Other motor dysfunctions, such as forepaw incoordination, also could act to interfere with normal feeding behavior. However, in order to evaluate the possible role that various aspects of motor function play in feeding behavior, it is important to emphasize that it is inadequate to obtain measures of gross locomotor activity. As shown in several papers, impairments in locomotion can be easily dissociated from impairments in motor control and food handling during food intake. Dopamine (DA) depletions in the ventrolateral neostriatum do not suppress spontaneous locomotion, but to reduce food intake and impair feeding efficiency and food handling (Jicha and Salamone 1991; Cousins et al. 1993; Salamone et al. 1993). By contrast, DA depletions in nucleus accumbens suppress locomotion but do not impair feeding or food handling (Salamone et al. 1993; Cousins et al. 1993; Correa et al. 2002). Because locomotor impairments

are easily dissociable from deficits in motor patterns related to food intake, direct observations of feeding behavior are necessary to determine if CB1 receptor inverse agonists impair motor functions specifically related to feeding. When these analyses were conducted, it was demonstrated that AM251 failed to suppress feeding rate or disrupt forepaw usage during feeding at doses that substantially suppressed food intake (McLaughlin et al. 2005a, b, c). Thus, CB1 receptor inverse agonists do not appear to reduce food intake simply by disrupting the motor patterns necessary for feeding behavior. Despite the fact that the neostriatum contains a relatively high concentration of CB1 receptors (Herkenham 1992; Egertova and Elphick 2000; Gonzalez-Rosales and Walsh 1997), the effects of CB1 inverse agonists do not closely resemble those produced by neostriatal DA depletions (Salamone et al. 1990).

In fact, it has been suggested that drugs that act on cannabinoid receptors could be modulating DA transmission, particularly in the nucleus accumbens (Cohen et al. 2002; Wenger et al. 2003; Gardner 2005). CB1 receptor stimulation has been shown to increase extracellular DA in nucleus accumbens (Gardner and Lowinson 1991; Tanda et al. 1997; Gardner 2005), and this effect can be blocked by CB1 receptor antagonism (Tanda et al. 1997). Recent evidence indicates that the CB1 receptor inverse agonist rimonabant can reduce the increase in extracellular DA in nucleus accumbens that accompanies consumption of a palatable food (Melis et al. 2007), and it has been suggested that interference with CB1 receptor transmission could reduce feeding by suppressing mesolimbic DA activity (Melis et al. 2007). Nevertheless, there appear to be some difficulties with the idea that drugs that interfere with CB1 transmission act on food-motivated behaviors by decreasing activity of DA systems that are hypothesized to mediate primary food motivation. Considerable evidence has demonstrated that the mesolimbic DA system does not mediate primary food "reward," motivation, or appetite (Salamone et al. 1997, 2003, 2005, 2007b; Salamone and Correa 2002; Kelley et al. 2005). It has been shown repeatedly that nucleus accumbens DA depletion or antagonism does not suppress food intake (Ungerstedt 1971; Koob et al. 1978; Salamone et al. 1993; Baldo et al. 2002). Based upon this evidence, it does not seem highly likely that CB1 antagonists decrease food intake because they reduce accumbens DA release.

Very few studies have offered direct comparisons between the behavioral effects of DA and CB1 antagonists. If CB1 antagonists or inverse agonists are exerting their effects on food motivation by reducing DA transmission, then it is reasonable to suggest that the effects of these CB1-related drugs should closely resemble the effects of DA antagonists. Recent studies were undertaken to assess this possibility. These experiments employed a concurrent lever-pressing/chow-feeding procedure that has frequently been used to assess the effects of dopaminergic manipulations (Salamone et al. 1991, 1997, 2002, 2003, 2007b; Cousins et al. 1993; Cousins and Salamone 1994; Nowend et al. 2001; Farrar et al. 2007). With this task, rats can press a lever to receive a preferred food (Bioserv pellets), or, alternatively, approach and consume a less-preferred lab chow that is concurrently available in the operant chamber (Salamone et al. 1991, 1996, 1997; Cousins et al. 1993, 1994; Cousins and Salamone 1994; Nowend et al. 2001; Farrar et al. 2007). Untreated rats pressing on a fixed-ratio 5 (FR5) schedule will typically obtain most of their food by pressing the lever, and will consume very little of the laboratory chow. Several papers have provided a behavioral and pharmacological characterization of performance on this task. In rats performing this procedure, prefeeding to reduce food motivation suppressed both lever pressing and chow intake (Salamone et al. 1991). In contrast, low-to-moderate doses of DA antagonists, injected systemically or directly into nucleus accumbens, as well as accumbens DA depletions, generally produce a very different pattern of effects. Systemic injections of DA antagonists with varying profiles of selectivity for DA family receptors, including cis-flupenthixol, haloperidol, raclopride, SCH23390, and SKF83566, all decreased lever pressing for food, but substantially *increased* intake of the concurrently available chow (Salamone et al. 1991, 1996, 2002; Cousins et al. 1994; Koch et al. 2000). The low dose of haloperidol that produced this shift in

behavior (0.1 mg/kg) did not alter intake of the preferred or non-preferred foods, and DA antagonism did not affect food preference in free-feeding choice tests (Salamone et al. 1991). The shift from lever pressing to chow intake that is produced by systemic DA antagonists also was induced by accumbens DA depletions and intra-accumbens injections of DA antagonists into core or shell regions (Salamone et al. 1991; Cousins et al. 1993; Cousins and Salamone 1994; Sokolowski and Salamone 1998; Koch et al. 2000; Nowend et al. 2001), while DA depletions in ventrolateral neostriatum produced severe motor dysfunctions that impaired both lever pressing and chow intake (Cousins et al. 1993).

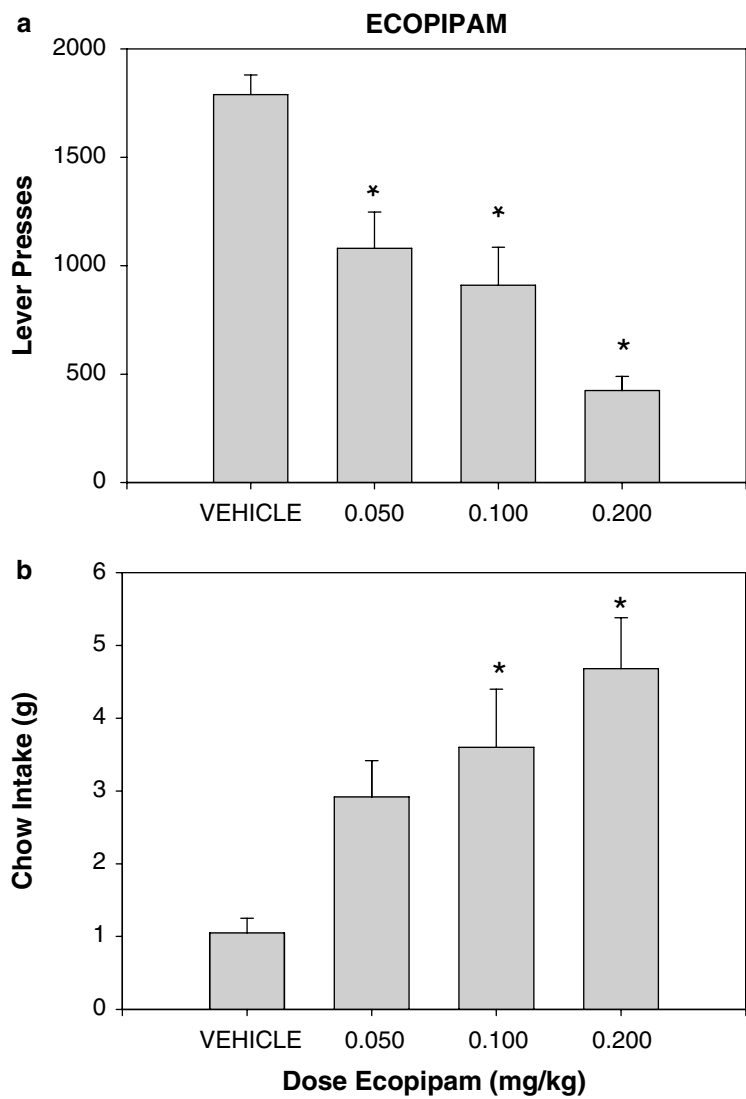
In order to directly compare the effects of DA antagonists with those of CB1 antagonists/inverse agonists, Sink et al. (2008b) used this concurrent lever pressing/chow intake procedure. Rats treated with IP injections of the DA D1 antagonist ecopipam (0.05–0.2 mg/kg) or the D2 antagonist eticlopride (0.025–0.1 mg/kg) showed substantial decreases in lever pressing and concomitant increases


Fig. 29.2 Effects of the DA D1 receptor antagonist SCH 39166 on the concurrent lever-pressing/chow-feeding procedure. (2008b))
in chow intake (Figs. 29.2 and 29.3). In contrast, IP administration of the CB1 inverse agonist AM251 (2.0–8.0 mg/kg), as well as the CB1 neutral antagonist AM4113 (4.0–16.0 mg/kg), decreased operant responding for pellets, but failed to increase chow intake (Figs. 29.4 and 29.5). These effects of CB1 antagonists/inverse agonists were similar to those produced by the serotonergic appetite suppressant fenfluramine (Salamone et al. 2002). Thus, low doses of DA antagonists leave primary food motivation (i.e., "appetite") intact, but shift behaviors toward food reinforcers that can be obtained with lower effort. In contrast, interference with cannabinoid CB1 receptor transmission appears to suppress food-motivated instrumental behavior because of direct actions on food intake regulation mechanisms. These results demonstrate that the effects of interference with CB1 transmission are easily distinguishable from those of reduced DA transmission (Sink et al. 2008b).

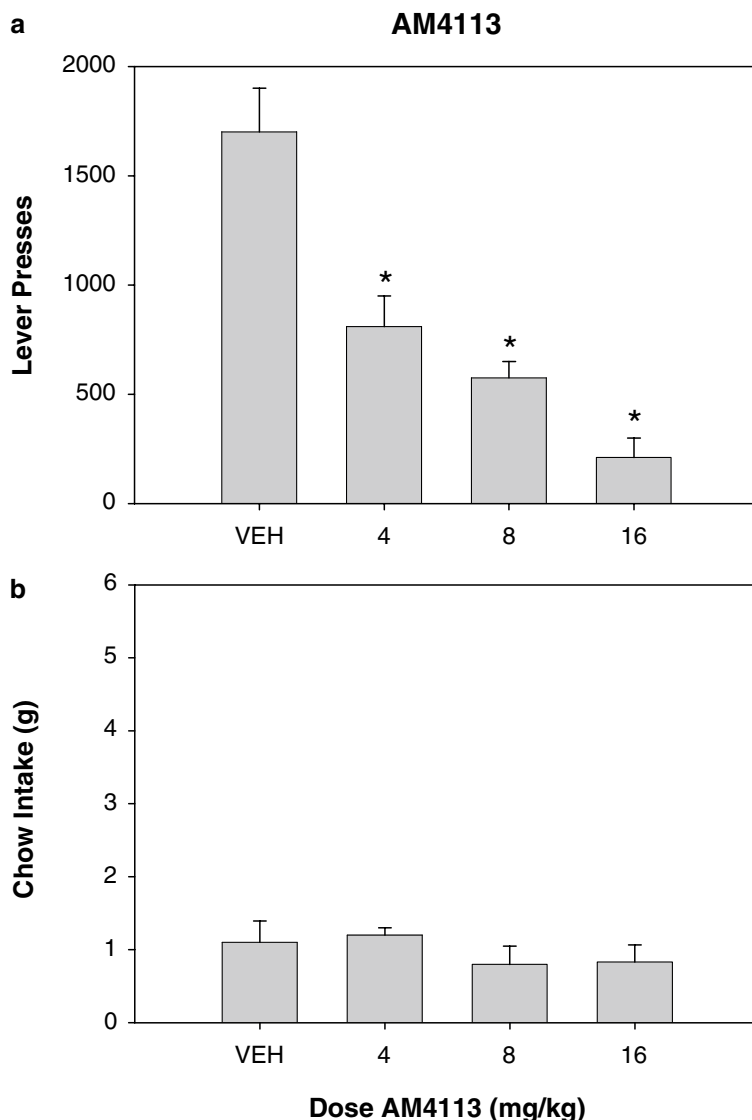
29.6 Possible Importance of Peripheral CB1 Receptors

While it now seems clear that these CB1 antagonists and inverse agonists decrease food intake and food-reinforced behavior, there is still controversy as to the primary locus of action for these effects. CB1 agonists injected directly into hypothalamic nuclei related to feeding, or into nucleus accumbens, which is involved in various aspects of motivated behavior, have been shown to induce hyperphagia (Jamshidi and Taylor 2001; Williams and Kirkham 1999; Verty and Mallet 2005; Soria-Gomez et al. 2007). Moreover, these effects were blocked by administration of CB1 inverse agonists. However, these particular studies did not demonstrate that administration of a CB1 inverse agonist on its own could affect feeding. Although a few papers have demonstrated that forebrain injections of CB1 inverse agonists reduce feeding (Werner and Koch 2003; Verty et al. 2004b, c), it also has been argued that the actions of CB1 inverse agonists on feeding may not depend substantially on

Fig. 29.5 Effects of the cannabinoid CB1 receptor neutral antagonist AM4113 on the concurrent lever-pressing/chow-feeding procedure. Effects of the cannabinoid CB1 receptor neutral antagonist AM4113 on the concurrent lever pressing/chow feeding procedure. (**a**) Mean (± SEM) number of lever presses after treatment with vehicle and various doses of AM4113. (**b**) Mean (± SEM) intake of lab chow (in grams) after treatment with vehicle and various doses of AM4113. *$p < 0.05$, different from vehicle, planned comparison (Data are from Sink et al. (2008b))


forebrain sites. Gomez et al. (2002) reported that food intake could be suppressed by systemic, but not intraventricular administration of SR141716. Furthermore, capsaicin-induced deafferentation of peripheral vagal nerves eliminated the changes in feeding induced by systemic administration of a CB1 agonist and the inverse agonist SR141716 (Gomez et al. 2002). Therefore, these authors suggested that drugs acting on CB1 receptors may modulate feeding via sites located on these peripheral sensory nerve terminals.

Recent studies were conducted to determine if AM251 and AM4113 could affect food-reinforced behavior after administration into the lateral ventricle (Sink et al. 2009b). Although systemic administration of both drugs has been shown to suppress food-reinforced behavior, neither

AM251 (40, 80, and 160 μg) nor AM4113 (60, 120, and 240 μg) produced any suppression of food-reinforced operant responding in rats tested on an FR5 schedule. Because locomotor effects of drugs that act on CB1 receptors are thought to be dependent upon actions on the forebrain (e.g., basal ganglia and related structures), AM251 and AM4113 also were assessed for their ability to reverse the locomotor suppression produced by the CB1 agonist AM411. Intraventricular administration of either AM251 or AM4113 reversed the locomotor suppression induced by the CB1 agonist AM411 in the same dose range that failed to produce any effects on feeding. This pattern of effects indicated that both AM251 and AM4113, when administered into the lateral ventricle, can interact with forebrain CB1 receptors, and are effective at producing forebrain-mediated functions unrelated to feeding. Taken together, these results suggest that CB1 neutral antagonists or inverse agonists may not be affecting food-reinforced behavior via interactions with forebrain CB1 receptors located in nucleus accumbens or hypothalamus, and indicate that lower brainstem or peripheral receptors may be involved.

An important line of future investigation that could further clarify this issue would be the measurement of food consumption or food-motivated behaviors after systemic administration of a CB1 inverse agonist or antagonist with poor blood-brain barrier penetrability. If the suppression of food intake could be observed following systemic injection of such a compound, this would support the hypothesis that peripheral CB1 receptors are involved in the modulation of feeding. It has been reported that LH-21, a compound that is purported to be a CB1 antagonist with poor blood-brain barrier penetrability, did act to decrease feeding (Pavón et al. 2006, 2008). However, continued pharmacological evaluation of this compound will be necessary in order to determine which of its effects are peripheral and which are central (Chen et al. 2008a; Pavón et al. 2008), and additional compounds need to be evaluated. Recently, a novel CB1 antagonist, AM6545, was developed as a tool for investigating the behavioral actions of peripherally active CB1 antagonists. Although this drug has poor penetrability into the brain compared to AM251 (i.e., sevenfold less penetration in a mouse model), it was shown to suppress feeding and food-reinforced FR5 lever pressing at doses of 4.0–16.0 mg/kg IP (Randall et al. 2010). These results indicate that a peripherally active CB1 neutral antagonist with poor central penetration could be useful as an appetite suppressant, and it is possible that such a drug could avoid side effects related to central actions.

29.7 Applications to Other Areas of Health and Disease

In addition to the suggestion that CB1 antagonists and inverse agonists could be useful for the suppression of appetite and the induction of weight loss, it also has been suggested that these drugs could be employed for treating substance abuse disorders, including smoking, alcoholism, and drug addiction (Fattore et al. 2007; Chen et al. 2008a). In fact, the results of clinical research on the effects of rimonabant for cessation of smoking are rather mixed (Stapleton 2009; Rigotti et al. 2009). In a recently published clinical trial, rimonabant had little efficacy to induce smoking cessation on its own, but combined treatment with rimonabant plus a nicotine patch yielded a stronger effect, and the presence of rimonabant suppressed the weight gain that is commonly seen with smoking cessation (Rigotti et al. 2009). This effect is not trivial for individuals who have gained substantial amounts of weight after successfully quitting smoking. Nevertheless, because of the psychiatric problems described above, the FDA is not currently considering rimonabant as a treatment for smoking (Stapleton 2009).

In some ways, the conception of rimonabant as a "wonder drug" that could treat obesity, smoking, alcoholism, and drug addiction was predicated on the misconception that this drug acted on a

dopaminergic "reward" system that mediates all forms of primary motivation, for both natural reinforcers and drugs of abuse. As reviewed above, this view of DA function has been strongly challenged (e.g., Salamone et al. 1999, 2001, 2006, 2007b, 2009), and the hypothesis that the effects of CB1 antagonism closely resemble those produced by DA antagonism has numerous problems (Sink et al. 2008b). Yet despite these conceptual issues, it remains to be determined if future development of drugs that act on CB1 receptors could generate compounds that are useful for the treatment of substance abuse disorders.

29.8 Conclusions

Considerable evidence indicates that drugs that interfere with cannabinoid CB1 receptor transmission can reduce food intake. These effects are evident across a variety of tasks, and different food types, and can occur under conditions involving food-reinforced behavior as well as feeding. Nevertheless, there also is evidence that cannabinoid inverse agonists can induce signs of nausea, malaise, food aversion, anxiety, and depression. Recent studies have been undertaken to characterize the behavioral effects of CB1 receptor neutral antagonists such as AM4113 to determine if these drugs can reduce feeding and food-reinforced behaviors at doses that do not have deleterious effects on other behavioral processes. AM4113 affects food-motivated behavior in ways that are very similar to the effects of CB1 inverse agonists. Moreover, this drug did not induce conditioned gaping in rats or vomiting in ferrets. These results suggest that CB1 neutral antagonists may decrease appetite by blocking endogenous cannabinoid tone, and that these drugs may be less associated with nausea than CB1 inverse agonists. Future studies should place great emphasis on characterizing the effects of CB1 neutral antagonists that do not easily penetrate the blood-brain barrier, to determine whether the use of these drugs can minimize the occurrence of some of the aversive motivational and psychiatric events. Another useful strategy would be to investigate the effects of combined administration of opiate antagonists along with drugs that interfere with CB1 transmission (e.g., Tallett et al. 2009). Such a combined drug treatment may produce conditions in which food intake is suppressed, but the occurrence of deleterious side effects is reduced.

Summary Points

- Drugs that act to interfere with cannabinoid CB1 receptor transmission can suppress food intake and food-reinforced behavior.
- The effects of interfering with cannabinoid CB1 receptor transmission do not closely resemble the effects of dopamine antagonism.
- Drugs such as rimonabant, which act as CB1 inverse agonists at the cellular level, produce undesirable side effects such as food aversion, nausea, and psychiatric problems.
- It is possible that neutral or "silent" antagonists such as AM4113 can suppress food intake at doses that are lower than those that induce nausea or psychiatric symptoms such as anxiety.
- Although much emphasis has been placed upon the central actions of drugs that act on CB1 receptors, it also is possible that peripheral mechanisms contribute to this effect. Thus, it is possible that a CB1 receptor neutral antagonist that does not penetrate well into the central nervous system could be useful as an appetite suppressant.

Definitions and Explanations of Key Terms

Agonist: A drug that binds to the receptor and stimulates the same intrinsic activity (i.e., signal transduction effect) as the endogenous neurotransmitter.

Full agonist: A drug that stimulates maximal levels of intrinsic activity (i.e., near the level stimulated by the transmitter itself).

Partial agonist: A drug that produces only low-to-moderate levels of stimulation of the signal transduction mechanisms.

Neutral antagonist: A competitive antagonist (i.e., neutral or "silent" antagonist) is a drug that binds to the receptor but does not instigate signal transduction effects on its own. This occupation of the receptor blocks the effect of an agonist or the neurotransmitter.

Inverse agonist: A drug that stimulates intrinsic activity (i.e., signal transduction effects) that is in the opposite direction to that stimulated by the agonist and the transmitter.

N[3]	Nutritional neurotrophic neoteny

30.1 Introduction

Several prominent phenotypic features distinguish humans from other apes. Humans live longer, develop more slowly, have a temporally reduced reproductive range and exhibit exceptional encephalization – that is, a high brain to body weight ratio. This collection of biological traits I have denominated the *Quadripartite Complex*. Certainly there are other important elements of the human bio-behavioral repertoire, not the least of which include bipedal locomotion and language. What makes the Quadripartite Complex particularly important and interesting is the apparent interrelationship among its components. In a theoretical paper published in the journal *Medical Hypotheses*, it was argued that the Quadripartite Complex arose as a unified response to a single selective force – environmentally imposed dietary restriction (Amen-Ra 2006). Quite tellingly, each of the aforementioned attributes – lengthened lifespan, delayed development, reduced reproductive range, and increased encephalization – are effectuated in animals that are experimentally subjected to chronic caloric restriction. Added to this is compelling evidence indicating that human evolution was heavily influenced by climatic changes – changes that likely reduced the availability of food to our hominin forbears. Furthermore, the phylogenetic generality of the caloric restriction response – the fact that organisms respond physiologically in strikingly similar ways to protracted dietary deficits – makes this experimental protocol a particularly valuable model for evolutionary theorization. To elaborate, because caloric restriction induces almost identical alterations in numerous animal models via similar

such metabolic suppression
molecular mechanisms, the stereotypic response thereto is suggestive of substantial evolutionary conservation. It is plausible that climatic conditions which curtail dietary resources for prolonged periods can select adaptive traits identical to those influenced by ontogenetic caloric restriction. Thus, we may surmise that the Quadripartite Complex emerged as a consequence of environmentally imposed caloric restriction incurred during a critical stage of human evolution (Figs. 30.1 and 30.2). This theory is developed in greater detail in a book entitled *Evolutionary Nutrition* (Amen-Ra 2003). The purpose of the present exposition is to expatiate upon the evolution of encephalization, undoubtedly the most momentous element of the Quadripartite Complex (Table 30.1).

Table 30.1 Comparative similitude of QC and DR

The Quadripartite Complex	Effects of dietary restriction
1. Encephalization – high brain weight/body weight ratio	1. Encephalization – high brain weight/bodyweight ratio
2. Neoteny – depressed rate of physical development and sexual maturation	2. Neoteny – depressed rate of physical development and sexual maturation
3. Reduced reproductive receptivity	3. Reduced reproductive receptivity during dietary deprivation
4. Enhanced longevity	4. Enhanced longevity

This table lists the hominin evolutionary attributes known as the Quadripartite Complex (QC) in apposition to the effects of ontogenetic dietary restriction (DR) so as to illustrate their similarity

30.2 Discussion

In metabolic terms, the brain is extraordinarily expensive. In view of the fact that hominins evolved under ecological conditions that likely limited their metabolic resources, the excrescence of the encephalon seems paradoxical. The paucity of theories purporting to explain human encephalization may be partly attributable to this seeming paradox. Indeed, one of the few such theories sufficiently coherent to warrant the designation is the Aiello–Wheeler Expensive Tissue Hypothesis (ETH). Advanced by anthropologist Leslie Aiello and biologist Peter Wheeler, this theory posits metabolic compensation as the key to human encephalization. They identify the brain as one of several of the body's "expensive tissues" and opine that evolutionary accretion of brain tissue was offset by evolutionary extirpation of another expensive tissue – namely, the gastrointestinal tract. As to how a reduced alimentary apparatus could extract the requisite resources to support a burgeoning brain, the theorists invoke an inveterate explanation in the anthropological arena – meat. It is their contention that meat is of a "higher" nutritional quality, being more easily digestible than vegetal fare. Subsistence upon meat would, *ex hypothesi*, permit pronounced reduction of gastrointestinal mass and/or volume. Hence, consistent consumption of meat would have facilitated alimentary attenuation and this, in consequence, would have conduced to neural augmentation. The interested reader is referred to their erudite manuscript published in *Current Anthropology* for details and poignant critiques from contributors to the article (Aiello and Wheeler 1995).

Before presenting an alternative theory of human encephalization, let us briefly consider several logical lapses in the ETH. The first flaw is the theory's lack of conservatism. Human encephalization can be conceived as an evolutionary extremum of a continuum. That is, humans are relatively more encephalized than extinct hominins (i.e., bipedal apes such as those of the genus *Australopithecus*); hominins are relatively more encephalized than other hominids (i.e., "great apes" such as gorillas and orangutans); hominids are relatively more encephalized than other hominoids (i.e., "lesser apes" such as gibbons); hominoids are relatively more encephalized than other anthropoids (i.e., monkeys); anthropoids are relatively more encephalized than prosimian primates (i.e., lemurs and lorises); and primates are relatively more encephalized than other mammals. Clearly, members of the Primate Order cannot be collectively characterized as carnivorous inasmuch as most subsist preponderantly on vegetation. If encephalization is an entrenched attribute of the Order and if carnivory cannot be correctly conceived as a contributor to the general trend of increased encephalization among the primates, then something other than meat must be offered as an explanation for the accentuated encephalization of humans. Ostensibly, this something must amount to a dietetic difference of degree and not of kind.

In keeping with the concept of conservatism, there are substantive reasons for doubting the obstinately held notion that meat consumption catalyzed human evolution. As argued in *Evolutionary*

Nutrition, it strains the intellect to assume that humans could have consistently consumed meat before the advent of sophisticated lithic projectile weapons of the sort that appeared in Europe only ~10,000–20,000 years ago. Presumably, humans had been fully modern (anatomically) for over one hundred thousand years before hunting could have been a habitual practice. The period commencing ~20,000 years ago is evidently the surest juncture at which humans began to consume considerable quantities of meat for it coincides with the paleontological record of mass extinctions of mammalian fauna – extinctions that are reasonably interpreted to have been caused by humans (Stanley 1987).

Added to the non-conservative character of the ETH is its logical circuitousness. In terms of strength, speed, and agility, humans are decidedly disadvantaged compared to other apes and especially compared to felid and canid carnivores and scavengers. Human hunting undoubtedly required technical innovations enabled by evolutionarily augmented intelligence. Thus, increased encephalization likely facilitated human hunting and other technology-assisted activities. The theory espoused by Aiello and Wheeler contends the converse – that reliable access to copious quantities of meat enabled encephalization. The ETH affirms that voluminous viscera constrain the evolutionary expansion of the encephalon and that meat – in virtue of its alleged ease of assimilation – enabled alimentary reduction. Meat purportedly permitted the relaxation of a metabolically mediated constraint against encephalization. This asynchronous scenario is untenable – it inverts cause and effect.

It would seem that the designation of meat as a "high-quality" food warrants qualification or indeed castigation. A high-quality food in the context of the ETH, we may surmise, is one that can be digested efficiently enough to enable eventual alimentary reduction. This cannot be the only criterion, however, for a diet that ensures encephalization must support the physiological functioning of the brain. While meat is replete with protein, the major nutrient upon which the brain is dependent is glucose – a nutrient for which meat is a poor precursor. Moreover, when protein intake exceeds nutritional requirements, the excess is metabolized in such a way that removes the constituent nitrogenous moieties from amino acids. A product of this process is ammonia – an agent that is particularly toxic to the brain (Guyton and Hall 2006). Notably, human breast milk – the sole source of sustenance for the developing neonate – reportedly has the lowest protein concentration of any primate, with primates exhibiting lower levels than most mammals (Oftedal 1991). This may reflect the fact that slowly growing infants necessitate less protein provisioning during their protracted developmental period. As with encephalization, humans seem to exhibit an accentuation of this primate attribute.

Finally, Aiello and Wheeler neglect to identify an ontogenetic example of the phylogenetic phenomenon upon which they focus. For example, the theorists in question convincingly catalog correlations between gut size and brain size. They unconvincingly conclude that improved diet quality (i.e., meat) caused visceral contraction which, perforce, facilitated encephalization. They fail to substantiate this claim with corroborative ontogenetic evidence. This deficit in inductive reasoning could be rectified by determining whether in fact liquefied nutrients (an idealized proxy for "high-quality" food), administered enterally or parenterally, effectuate alimentary atrophy. As it were, a sound study published in the *Journal of Parenteral and Enteral Nutrition* found no such causative relationship (Zaloga et al. 1991). Using murine subjects, the authors of the aforesaid study observed the effects of four different isocaloric, isonitrogenous dietary regimens – a standard rodent diet and three liquid diets (enterally administered), the nitrogen sources of which were comprised of whole proteins, peptides, or amino acids, respectively. They assessed proximal, mid, and distal gut dimensions and found no reduction in proximal or mid gut size secondary to any of the liquid nutrients. This study would seem to suggest that improved diet quality does not appreciably alter alimentary magnitude. Such experimental investigations as this can be instructively extrapolated to phylogenetic phenomena. In the case of Aiello and Wheeler's gut/brain correlation, extrapolation indicates that meat (far more crude than the nutrients utilized in the aforementioned study) could not likely have catalyzed visceral contraction. Conversely, dietary deprivation and dietary diminution routinely result in

reduced gut size (Wang et al. 2006; Chappell et al. 2003). What is more, several studies suggest that dietary restriction induces adaptations in intestinal cells, augmenting their ability to absorb nutrients (Casirola et al. 1996, 1997). Increased enteric absorptive ability apparently offsets the effects of alimentary reduction. If this adaptive ontogenetic effect were mirrored evolutionarily, it would have been beneficial to dietetically restricted hominins. Therefore, it is dietary diminution, not dietary enrichment, which plausibly promotes the kind of gut size reduction that the ETH invokes as a critical catalyst of encephalization. While the theory to be presented forthwith does not consider visceral contraction as a key to human encephalization, it can explain this effect as an epiphenomenon of environmentally imposed dietary restriction.

30.3 The Homo Hypothalamic Hypometabolic Theory

The Homo Hypothalamic Hypometabolism (H³) theory posits that the climatic changes that ensued ~4 million years ago were sufficient to alter the ecological environment in which the hominin lineage evolved. Cooler temperatures, increased aridity, and marked oscillations of climatic conditions characterized these changes, which would have reduced the availability of vegetal resources upon which hominins depended for food. Hominins, I hypothesize, responded to this reduction in resources in a manner commensurate with ontogenetic dietary restriction. That is, they experienced a reduction in the rapidity of physical and sexual maturation, a lengthening of lifespan, and – as a concomitant consequence of the aforementioned alterations – an increase in the relative proportions of their brains. The concomitancy of the Quadripartite Complex is an important explanatory element of encephalization inasmuch as the economizing effects of reduced growth and temporally truncated sexual receptivity enable appreciable metabolic resources to be diverted to the brain (and also allocated to preservative processes that maintain the physiologic integrity of the body such that lifespan is lengthened). Interestingly, a single structure in mammals mediates most of the effects of ontogenetic dietary restriction – the hypothalamus and its associated endocrine effectors. Notably, the hypothalamus controls somatic growth by modulating levels of somatotrophic hormones (e.g., growth hormone); it controls sexual receptivity by modulating levels of gonadotrophic hormones such as luteinizing hormone and follicle-stimulating hormone; it likely influences lifespan by modulating metabolic rate (via thyroid hormone) which may determine, in part, the rapidity of aging; and it indirectly influences encephalization by ensuring virtually invariant nutrient allocation to the brain (via corticotrophic control) during bouts of dietary deprivation or diminution.

The centrality of the hypothalamic/neuro-endocrine complex in the mediation of ontogenetic dietary restriction makes it an ideal focus for selective pressure under evolutionary conditions of environmentally imposed dietary restriction. This may explain the uniformity of the metabolic response to caloric restriction exhibited by diverse organisms. Over evolutionary time, animals inevitably experience food shortages and have evolved mechanisms by which to mitigate dietary deficits. These evolutionarily conserved, compensatory mechanisms are activated under conditions of ontogenetic dietary restriction. Having abandoned arboreality for a terrestrial niche, hominin bipeds may have been especially sensitive to ecologically imposed food shortages. Thus, they may have been under increased pressure to adopt accentuated attributes enabling subsistence on marginal dietary resources. Concomitantly, there would have been increased selective pressure for augmented intelligence. Augmented intelligence undoubtedly ensures more successful foraging and recourse to novel methods of food acquisition. Note that, in contradistinction with the Expensive Tissue Hypothesis, the model delineated herein posits dietary diminution, not dietary enrichment, as the critical catalyst for encephalization. Moreover, N³ identifies specific molecular mechanisms that likely mediated neural expansion.

30.4 Molecular Mediators of Encephalization

One of the most striking effects of chronic caloric restriction is body weight reduction (Mattison et al. 2007). Less commonly considered, however, is the simultaneous salvaging of brain mass (Greenberg and Boozer 2000). This ontogenetic encephalization is effectuated by molecular mechanisms which ensure that the brain is provisioned with an adequate amount of energy at the expense of other organs amidst dietary depreciation. Insight into one such mechanism was provided by Gyorgy Bodoky and colleagues in an intriguing study published in the journal *Physiology & Behavior*. The investigators subjected groups of rats to three different dietary dispensations: ad libitum access to food; continuous parenteral infusion of nutrients equivalent to 100% of the daily caloric intake of the freely fed subjects; and complete food deprivation (4 days in duration). They sought to determine the effects of continuous feeding, intermittent feeding, and prolonged fasting on levels of energy (specifically ATP concentration) in the brain relative to the liver. In accordance with their hypothesis of preferential provisionment of nutrients to the brain, they found that while ATP levels in the livers of fasted animals were substantially reduced, levels of ATP in the *brains* of the deprived subjects were comparable to the nutrient-replete groups (Bodoky et al. 1995). Clearly, the energy deficits induced in these experimental subjects were borne by the body to the exclusion of the brain.

Glucose plays a central role in animal metabolism. Moreover, as mentioned previously, glucose is the chief fuel currency of the brain. However, food deprivation induces substantial suppression of circulating glucose concentration. Considering the centrality of glucose in brain metabolism, it is interesting to note that neurotrophins facilitate influx of glucose into neurons (Burkhalter et al. 2003). Thus, neurotrophins ostensibly ensure adequate allocation of glucose to the brain, a function of vital import under conditions of dietary diminution. Of greater interest is the body of research (upon which much of my theorization rests) that caloric restriction increases expression of neurotrophic factors (Mattson et al. 2004; Duan et al. 2001; Lee et al. 2000). Neurotrophins are known to promote proliferation and differentiation of neural precursor cells (Kandel et al. 2000). As to why dietary deprivation should eventuate in accretion or preservation of precursor cells we shall consider shortly. For now, we note with interest that caloric restriction reportedly improves indices of mental acuity by augmenting neurotrophin production and, consequently, promotes the preservation of progenitor neurons in regions of the cerebral cortex that are instrumental in learning and memory (Lee et al. 2000, 2002a, b; Kandel et al. 2000). Teleologically, this makes sense: enhanced memory and learning capacity likely enable more successful foraging. Hunger can be conceived as a psycho-physical stimulus intended to impel acquisitive action. Two momentous studies involving fasting corroborate this contention. The first study, published in the journal *Frontiers in Systems Neuroscience*, subjected rodents to a bout of fasting 18 hours in duration. They subsequently assessed the state of a particular family of transcription factors known to be operative in influencing brain development and various aspects of cognition. Called CREB (cyclic adenosine monophosphate (cAMP) response element-binding protein) they found this substance to be significantly elevated in animals subjected to fasting as compared to fed controls. More specifically, they found that fasting-induced CREB production was particularly prominent in regions of the brain crucial to cognition, such as the hippocampus, piriform cortex, and entorhinal cortex. Additionally, CREB was elevated in the hypothalamus, underscoring the importance of this structure in mediating neuro-behavioral responses to metabolic stressors. Importantly, CREB is known to play a regulatory role in *neurogenesis* – the origination of new neurons (Jagasia et al. 2009; Dworkin et al. 2009). It is interesting to note that cAMP indicates energy depletion – specifically ATP depletion. cAMP therefore abounds in the fasted/food deprived state. The interplay among fasting, cAMP, and CREB and the dependence of neurogenesis, learning, and memory upon the latter provide crucial clues to the relationship between nutrition and cognition.

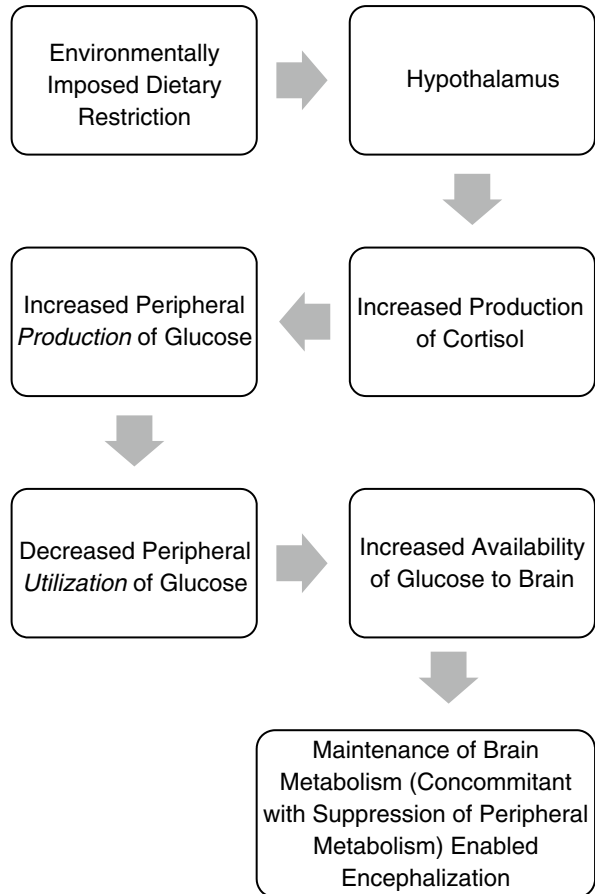
The second study to which I would like to direct the reader's attention was published in the journal *Nature Neuroscience*. This study found that a peptide called *ghrelin* – released by the gastrointestinal organs in response to fasting – is translocated from the gastric mucosa to the brain (Diano et al. 2006). Ghrelin subsequently binds to receptors in the hippocampus and, by so doing, mediates *synaptogenesis* – the formation of synaptic connections between neurons. Synaptogenesis is known to modulate cognitive processes and the investigators in the said study found that the synapse formation secondary to the action of ghrelin was associated with improved functioning of mice on learning and memory tasks. Like the aforementioned fasting study, this finding offers an explanatory link between dietary deprivation and the augmentation of neurophysiological functioning. Intuitively, I reiterate, it makes sense that hunger should heighten cognition insofar as enhanced cognition conduces to successful food acquisition. More pointedly, increased expression of neurotrophic factors elicited by dietary restriction offers an intriguing explanatory framework for evolutionary encephalization. First, it should be noted that mammals are known to exhibit supernumerary neurons neonatally, such that nearly half those generated during development are eventually eliminated through programmed cell death or *apoptosis* (Kandel et al. 2000). The extent of apoptotic extirpation is determined largely by levels of neurotrophins. Presumably, profuse overproduction of neurons provides for plasticity. Such plasticity could conduce to increased encephalization under certain selective circumstances. Ecological dietary diminution placed a premium on intelligence (and its morphological corollary, encephalization). Selection for increased intelligence/encephalization elicited attenuation of neural apoptosis, a process promoted by enhanced expression of neurotrophins. This resulted in retention of neurons that would otherwise have been expunged. This model – herein termed Nutritional Neurotrophic Neoteny (N^3) – provides a mechanistic basis for the evolutionary induction of encephalization in humans. The term neoteny is intended to convey the notion that humans appear to retain robust expression of neurotrophins at a developmental stage at which they apparently diminish in other mammals. This results in protracted production of progenitor neurons and eventual differentiation of these into mature neurons. The selection of this adaptive trait was arguably effected by environmentally imposed nutritional deprivation (Fig. 30.3).
Fig. 30.3 Neuro-endocrine underpinnings of neoteny. This figure illustrates the conjecture that the relative developmental delay that distinguishes humans from other apes may have been mediated by a reduction in the output of growth hormone, control over which is exerted by the hypothalamus

Environmentally Imposed Dietary Restriction

Hypothalamus

Decreased Production of Growth Hormone

Prolongation of Physical Maturation

Fig. 30.4 Neuro-endocrine underpinnings of enceph-alization. This figure illustrates the manner in which encephalization may have been facilitated via preferential provisionment of metabolic resources (i.e. glucose) to the brain at the expense of peripheral tissues. This physiological effect may have been mediated primarily by cortisol, an endocrine hormone whose release is regulated by the hypothalamus


The N^3 theory is a subset of a metatheory of human evolution – H^3. The critical link between the two is that somatic hypometabolism (induced by dietary diminution and mediated by the hypothalamus) enabled energy to be preferentially provided to the brain (Fig. 30.4). The strength of these wedded theories derives, I aver, from their empirical underpinnings. That is, empirical investigations have established the ability of experimentally imposed energy restriction to augment energy efficiency and this improved energy efficiency arguably enables appreciable amounts of energy to be allocated, alternatively, to the brain (Lopez-Lluch et al. 2006; Sanz et al. 2005). Further, empirical evidence indicates that humans and other primates typically respond to chronic caloric restriction by reducing their metabolism (Blanc et al. 2003; Heilbronn et al. 2006). Suppression of somatic metabolic rate facilitates maintenance of brain metabolism which, as it were, is not amenable to much modulation. Somatic metabolic suppression, it would seem, correlates with developmental depression in the human lineage: Reduced rate of development reflects reduced energy expenditure which, in turn, reflects reduced energy availability and intake. Sexual maturation is mitigated by somatic metabolic suppression; developmental depression and the energy salvaged by reproductive repression can commensurately be allocated to neural metabolism; lifespan prolongation proceeded passively in accordance with reduced metabolism and depressed development. This reasoning reinforces the notion that the Quadripartite Complex – lengthened lifespan, depressed development, reduced reproductive range, and increased encephalization – evolved contemporaneously in response to a single selective stressor: Dietary restriction (Fig 30.5).

Fig. 30.5 Neuro-endocrine regulation of reproduction. This figure illustrates how the constricted reproductive range that characterizes humans could have been catalyzed by the neuro-endocrine system through reductions in the circulating concentration of gonadotro-phins (i.e. luteinizing hormone and follicle stimulating hormone)

Environmentally Imposed Dietary Restriction

Hypothalamus

Decreased Production of Gonadotrophins

Reduced Reproductive Receptivity
Scientists and scholars are often impelled to evaluate the merits of competing theories invoked to explain identical phenomena. One indication of a theory's explanatory superiority is its encompassment, incorporation, or obviation of competitors. The N^3/H^3 theoretical complex evidently does so. The model presented herein not only provides a plausible, empirically informed explanation of enhanced human encephalization, it explains the logical linchpin of the ETH (i.e., gut reduction) as a minor evolutionary epiphenomenon of environmentally imposed dietary diminution. Moreover, it supersedes the ETH by casting encephalization as a concomitant of a larger, interrelated complex – the Quadripartite Complex. The N^3/H^3 model also comports with the scientific aesthetic of conservatism in that it explains the cardinal phenotypic characteristics of the human lineage as elaborated, accentuated simian traits. Its conservative comportment is further exemplified by its identification of known molecular mechanisms to infer antecedent evolutionary conditions in an effort to explain consequent phenotypic features.

30.5 Applications to Other Areas of Health and Disease

It is evident from the foregoing exposition that humans exhibit adaptations to protracted, pronounced dietary deficits. What is more, it is clear that the human brain is exquisitely suited to self-sustainment under conditions of caloric curtailment. As such, it is of practical interest to consider whether this adaptability of the brain to nutritional deprivation can be advantageously exploited to enhance cognitive acuity or neurophysiological functioning ontogenetically – that is, in the context of a single human lifespan. The available evidence suggests that it can. Indeed, the optimization of cognitive capacity is among the aims I have sought to effectuate in formulating the lifestyle regimen known as the Amen Optimal Health Protocol (AOHP). Details of the AOHP have been delineated elsewhere (Amen-Ra 2007) so we shall concern ourselves with only the general elements thereof. Though the

primary purport of the AOHP is the maximization of human lifespan potential, it is interesting to note that those experimental interventions which have most consistently conduced to lifespan prolongation – caloric restriction and cyclic fasting – have evidenced the most impressive augmentation and preservation of neurocognitive functioning in animals (Fontán-Lozano et al. 2007; Halagappa et al. 2007). I hasten to add at this juncture that the AOHP incorporates both caloric restriction and cyclic fasting. Specifically, the caloric content of the diet (which is thoroughly vegetal, devoid of meat and animal by-products) ranges from 1,000 to 1,500 kcal. The single daily meal is consumed in the nocturnal period over a span of time not exceeding 1 hour. Throughout the 23-hour daily fast, certain non-caloric beverages are imbibed – namely, teas of various sorts. Practitioners of the Amen Protocol (myself included) engage in exercise twice daily, in the morning and evening. Morning exercise is aerobic in nature while evening exercise is resistive in nature.

Underlying the aforementioned elements of the AOHP is the ability of each measure – restrictive feeding, fasting, exercise, and selective supplementation – to influence cognition by modulating the expression of genes and promoting the production of peptides that are known to regulate neurogenesis, synaptogenesis, and other molecular mediators of complex behavior. One molecule in particular plays an important role in this regard: brain-derived neurotrophic factor (BDNF). BDNF is but one of a family of neurotrophic factors that profoundly influence the morphology and physiology of the brain. The formulation and consolidation of memories and the facilitation of learning is dependent upon such neural peptides as BDNF and a host of integral molecules that interact therewith. One such molecule is CREB, the protein mentioned previously in the context of fasting. The reader will recall that fasting (18 hours in the cited study) reportedly increased the concentration of CREB in specific regions of the brain that control complex cognition. The 23-hour fast prescribed by the Amen Protocol is ostensibly sufficient to elevate levels of CREB as well as ghrelin – the gastrointestinal peptide that reportedly strengthens synapses and is augmented under conditions of food deprivation. The tea that is customarily consumed during the fast has a specific effect conducive to cognitive enhancement. The catechins in green and black teas and the ginsenosides in ginseng tea have been found to elevate levels of CREB and BDNF in murine models of memory impairment (Li et al. 2009; Zhao et al. 2009).

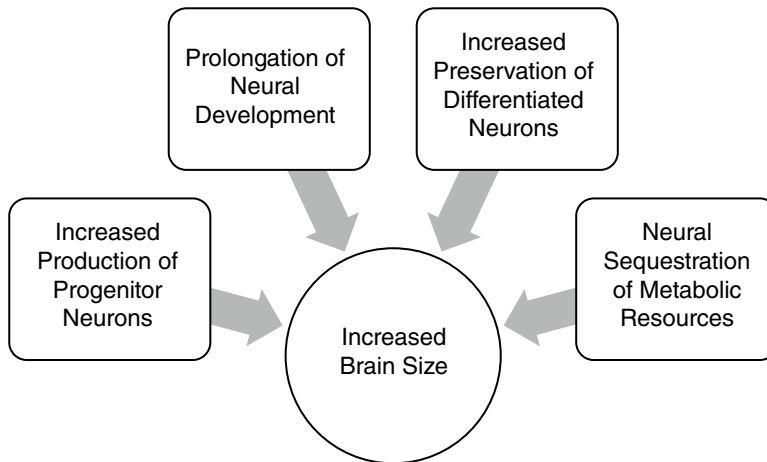
The temporal organization of the AOHP is of some practical import. To formulate a protocol that is predicated upon magnifying mental acuity, measures must be taken to ensure that the functioning of the brain is not merely maximized but that it is maximized at precisely those junctures at which productive, purposive activity is most desired. It will be noted that the Amen Protocol prescribes aerobic exercise in the morning, after an overnight fast of approximately 8–10 hours. The effects of these measures should be to stimulate cognition and also to elevate mood by augmenting neurotrophin production (Deslandes et al. 2009; Duman et al. 2008). Fasting ensues for another 10–12 hours, an interval during which only tea is partaken. Both measures – fasting and tea consumption – augment production of peptides that promote cognition. This period – the diurnal phase – is the time at which individuals ideally engage in productive work. It is significant that during this most auspicious interval that several signals converge to heighten cognition – the stimulatory effects of exercise, fasting, and nutraceutical agents in tea. Next, an evening resistance exercise session ensues. Evening exercise is followed by the single daily feeding session. Feeding for an hour or less practically ensures caloric restriction. Sufficient restriction of caloric content is further ensured by the vegetal composition of the diet. Caloric restriction, I reiterate, independently increases expression of neurotrophic factors. Thus, each component of the Amen Protocol – fasting, feeding, exercise, and tea intake – facilitates augmentation of cognitive acuity by advantageously altering the molecular milieu of the brain. What is more, the prolongation of chronological life that is a common characteristic of caloric restriction and cyclic fasting is accompanied by improvements in cognitive function, effectively promoting the extension of healthful mental life in a complementary manner. Humans, we must acknowledge, are


Fig. 30.6 Neuro-endocrine underpinnings of encephalization. This figure illustrates the physiological factors that likely contributed to the augmentation of human encephalization

quintessentially intellectual entities. To heighten intellectual acumen is to heighten the capacity for uniquely human gratification and this, in the vein of utilitarianism, is the *summum bonum* – the highest conceivable good. A protocol that could defensibly make this momentous claim would warrant attention. It is of course controversial whether appreciable numbers of people could consistently comply with such a restrictive regimen. However, having practiced the protocol for nearly a decade, my collaborators and I are confident that whoever deigns to adopt it will experience benefits that far exceed any inconveniences attendant to the daily exercise of dietary discipline. What is more, the mind is capable of such conditioning that the ascetic application of self-restraint can become a source of solace in and of itself. Such an ideal is well worth pursuing in the eyes of this theoretician (Fig. 30.6).

Summary Points

- Any theory of human evolution must explain encephalization—the dramatic increase in human brain size, specifically since the emergence of australopithicines.
- Evolutionary theorization about the underpinnings of encephalization must be reliant upon reasonable extrapolations from empirical data.
- Empirical data indicate that energy restriction induces increased expression of neurotrophic agents that promote the production and preservation of neurons.
- Empirical data indicate that hominins incurred environmental conditions that presumably constrained the availability of food (i.e. imposed energy restriction).
- Hominins faced selective pressure for increased intelligence/ingenuity amidst environmentally-imposed energy restriction.
- Selection for increased intelligence/ingenuity was mediated by increased expression of neurotrophic factors, particularly during neonatal development.
- Increased expression of neurotrophic factors during development eventuated in the expansion of the hominin brain.

Key Terms:

Encephalon [f. Greek (Gr.) *egkephalos* **brain]:** The brain.

Encephalization: Proportional increase in the size of the brain.

Lithic [f. Gr. *lithos* **stone]:** Pertaining to stone.

Murine [f. classical Latin *mūrīnus* **mouse]:** Relating to the Family Muridae, comprising rats and mice.

Neurotrophic [neuro- f. Gr. *neuron* **nerve, tendon +** *troph* **nourishment]:** Relating to neural control over the development, maintenance, or activity of cells, tissues, or organs.

Neoteny [f. Gr. *neos* **young +** *teinein* **to extend]:** The exhibition or retention of juvenescent characteristics suggestive of slow or protracted maturation.

Ontogenetic [f. Gr. *ont-,* **on being +** *genesis* **origin]:** Concerning or occurring within the lifespan of an individual organism.

Phylogenetic [f. Gr. *phylon* **race +** *genesis* **origin]:** Concerning attributes of organisms that develop over evolutionary time.

Chapter 31
Forebrain Activation by Postoral Nutritive Substances

Takashi Kondoh and Kunio Torii

Abbreviations

CS+   Conditioned stimulus paired with test unconditioned stimulus
CS-   Conditioned stimulus paired with control (neutral) unconditioned stimulus
EAAC-1   Excitatory amino acid carrier-1
fMRI   Functional magnetic resonance imaging
GIP   Glucose-dependent insulinotropic polypeptide
GLP-1   Glucagon-like peptide-1
5-HT$_3$R   Serotonin receptor type 3
mGluR   Metabotropic glutamate receptor
MRI   Magnetic resonance imaging
MSG   Monosodium L-glutamate
NOS   Nitric oxide synthase
NST   Nucleus of the solitary tract
TRPM5   Transient receptor potential cation channel M5
TVX   Subdiaphragmatic total vagotomy

To survive and maintain normal physiological functions, all animals need to ingest nutrients. Digestion and nutrient absorption take place in the gut, whereas sensations of hunger and satiety originate in the neuronal circuits in the brain. Nutritional stimuli in the gut elicit hormonal release into the circulation as well as vagal activation, which are key components of the gut-brain crosstalk. Brain regions that regulate homeostasis, such as the brainstem and the hypothalamus, receive inputs from a variety of sources, including forebrain structures involved in reward processes (Chaudhri et al. 2008). Neuroendocrine signals arising from the gastrointestinal tract are also integrated in these brain regions, and contribute to homeostatic regulation. However, the precise mechanisms supporting gut-brain communication remain poorly understood.

L-Glutamate is a multifunctional amino acid involved in perception of umami taste, intermediary metabolism, and excitatory neurotransmission (Table 31.1). In addition, recent studies have uncovered new roles for glutamate in gut-brain axis activation and energy homeostasis. Glutamate receptors

Table 31.1 Key features of L-glutamate

1. L-Glutamate is the anionic part of acidic amino acid, L-glutamic acid.
2. There are two distinct forms of glutamate, i.e., free and protein-bound forms. Specific actions of glutamate are mediated via free form.
3. Glutamate is a multifunctional amino acid involved in perception of umami taste, intermediary metabolism, and excitatory neurotransmission.
4. Although glutamate is typically classified as a nonessential amino acid in textbooks, it plays physiologically "essential (indispensable)" roles in our body, especially in the intermediary metabolism.
5. In addition, recent studies have uncovered new roles for dietary glutamate in gut-brain axis activation and energy homeostasis.
6. These glutamate effects are mediated via specific glutamate receptors (ionotropic and metabotropic receptors) located in the mouth, gastrointestinal tract, and central nervous system.
7. Glutamate in the mouth elicits umami taste (one of five basic tastes) via activation of taste nerves. Glutamate also enhances palatability of most foods and hence is used as a flavor enhancer in cuisines.
8. One of the most pronounced features is the synergism of umami taste observed between glutamate and 5′-ribonucleotides.
9. Glutamate in the gut is thought to convey food (protein)-related signals to the brain via activation of vagal afferent fibers.
10. As glutamate is the single largest contributor to energy production in the mucosal cells of the small intestine, most of the glutamate absorbed is metabolized in the gut and hence it does not reflect changes in blood glutamate levels.
11. Glutamate acts as the major excitatory neurotransmitter in the brain, and its activity regulates synaptic plasticity, learning, memory, motor activity, and neural development.
12. Glutamate in the brain is not derived from ingested glutamate but is synthesized within the brain from glucose.
13. Glutamate intake suppresses obesity without changing caloric intake.
14. Therefore, dietary glutamate influences numerous physiological functions, suggesting a broad, integrative role for dietary glutamate in body homeostasis.

This table lists the key facts of glutamate in our body

and their cellular transduction molecules have now been identified in gut epithelial cells (Bezençon et al. 2007; Mace et al. 2007; San Gabriel et al. 2007; Mace et al. 2009), and stimulation of these receptors by luminal monosodium L-glutamate (MSG) activates gut vagal afferent nerve fibers (Niijima 2000; Uneyama et al. 2006). In addition, such activation of gut glutamate receptors is behaviorally relevant, since ingestion of a flavored solution paired with intragastric infusion of MSG enhances preference for the flavored solution (Uematsu et al. 2009). As a consequence the activation of vagal terminals by glutamate, brain regions targeted directly or indirectly by vagal inputs respond to intragastric infusions of MSG (Kondoh and Torii 2008a; Tsurugizawa et al. 2008; Kondoh et al. 2009a, 2009b). In contrast, lesions to the dopaminergic neurons of the ventral tegmental area, a brain area involved in reward processing, interfere with preferences for sucrose, but not umami solutions (Shibata et al. 2009). Therefore, current evidence supports distinct brain-sensing mechanisms for dietary glutamate and carbohydrates, with the former depending on subdiaphragmatic vagal transmission and latter on dopaminergic signaling. These nutrient-specific brain responses to dietary glutamate might underlie some of the beneficial metabolic effects produced by MSG intake. Recently, it has been found that chronic, elective ingestion of a palatable solution of MSG by rats ameliorates obesity as well as the elevated fat deposition and plasma leptin levels induced by high calorie foods (Kondoh and Torii 2008b). Such effects of MSG may be initiated by gut glutamate receptors linked to afferent branches of the vagus nerve, taste glutamate receptors in the oral cavity (Chaudhari et al. 2000; Li et al. 2002; Nelson et al. 2002; San Gabriel et al. 2005), or both. This review focuses primarily on these recent findings concerning postingestive mechanisms of dietary glutamate involved in the gut-brain crosstalk.

31.1 Glutamate Content and Monitoring of Dietary Protein Levels

Glutamate is one of the most abundant molecules in our body. Glutamate content accounts for approximately 10% or more of total animal protein (Giacometti 1979). Therefore, considering that proteins correspond to approximately 20% of the human body composition, glutamate content should account for approximately 2% of the total. Therefore, a person who weights 50 kg should have approximately 1,000 g of glutamate distributed throughout the body (Fig. 31.1a). However, activation of glutamate receptors requires the presence of the free, rather than bound, form of glutamate in the mouth and gastrointestinal tract (Fig. 31.1b). Therefore, by stimulating glutamate receptors, free glutamate can trigger both gustatory and visceral signals. For glutamate absorption, both the glutamate receptors and glutamate transporters are required (*see* next). Being an essential link in intermediary metabolism, the free form of glutamate is in fact found in large quantities in animal and plant tissues (Giacometti 1979).

It has repeatedly been suggested that the sensing of protein ingestion by animals might be linked to the glutamate content in foods (Torii et al. 1987). It is unlikely that such protein "sensing" would depend (exclusively) on glutamate taste in the mouth, since only free, but not to protein-bound, glutamate activate taste receptors; in addition, the free glutamate content of natural foods is not tied to their protein content (e.g., tomatoes are high in free glutamate, but not in protein-bound glutamate; Yamaguchi and Ninomiya 2000; Giacometti 1979). However, the total glutamate content in foods (free + protein-bound forms) might provide a reasonable index of protein ingestion, as glutamate is the most abundant amino acid in almost all dietary proteins (Giacometti 1979).

31.2 Roles of Glutamate in the Intermediary Metabolism and Neurotransmission

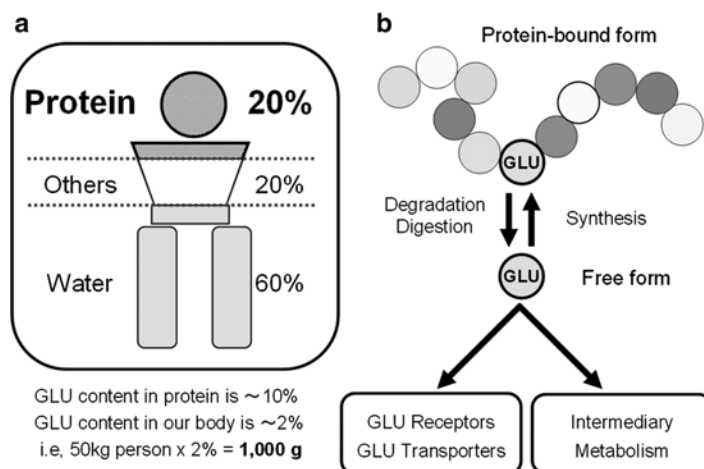
In cells, glutamate functions as an interface between amino acid and carbohydrate metabolism, given its key role as a substrate in transamination reactions. Although glutamate is classified as a nonessential amino acid, dietary glutamate has an "essential" functional role, especially in the intestinal


Fig. 31.1 Content of L-glutamate (*GLU*) in human body (**a**) and the importance of free glutamate as a bioactive molecule (**b**). Glutamate content is about 2% of the body weight. Glutamate in free form plays multiple functions through receptor activation, transportation, and intermediary metabolism

mucosa. For example, glutamate is: (1) the single largest contributor to energy production, (2) the specific precursor for the biosynthesis of two conditionally essential amino acids (proline, alanine) and glutathione (an antioxidant), and (3) the essential oxidative substrate in intermediary metabolism (Reeds et al. 2000; Young and Ajami 2000).

Glutamate also acts as the dominant excitatory neurotransmitter in the brain, and its activity regulates synaptic plasticity, learning, memory, motor activity, and neural development. Glutamate also acts as a transmitter outside the brain [e.g., between enteric neurons of the gut (Liu et al. 1997)].

31.3 Detection and Perception of Umami Taste

Umami taste is one of the five basic tastes, and is represented by the characteristic taste of the traditional Japanese soup "dashi" (Yamaguchi and Ninomiya 2000). Glutamate is a prototypical umami substance found in both natural and processed foods such as kelp, cheese, tea, vegetable, meat, fish, and human milk.

Multiple glutamate receptors, expressed in the taste cells of the oral cavity, mediate the transduction of umami taste. Such receptors include the heterodimer T1R1/T1R3 and the truncated forms of metabotropic glutamate receptors 1 and 4 (mGluR1 and mGluR4; Chaudhari et al. 2000; Li et al. 2002; Nelson et al. 2002; San Gabriel et al. 2005). T1R1/T1R3 receptors couple to G-proteins such as α-gustducin and/or transducin and activate phospholipase C β2-dependent pathways to increase intracellular Ca^{2+} concentration (Li et al. 2002; Nelson et al. 2002). T1R1/T1R3 receptors may also activate a cyclic AMP-dependent pathway (Margolskee 2002). In contrast, truncated mGluR4 reduces cyclic AMP levels (Chaudhari et al. 2000). Concerning the truncated mGluR1, signal elements were not identified. The coding of taste modalities is accomplished by the separation of subsets of taste cells expressing modality-specific taste receptors (Chandrashekar et al. 2006).

The excitation of taste cells is then transmitted to the rostral part of the nucleus of the solitary tract (NST) via four taste nerves (Fig. 31.2). Neurons in the NST project to the parabrachial nucleus, and then relay to a variety of forebrain areas via dorsal and ventral routes. In general, it is considered that the taste quality and intensity are represented in the taste cortex, while hedonic aspects are represented in the ventral forebrain regions (Yamamoto 2006).

31.4 Visceral Mechanisms

Intestinal brush cells or solitary chemosensory cells lining the mucosa have a structure similar to lingual taste cells. Recently, several investigators have reported that the gut epithelial cells express receptors for umami, sweet, and bitter substances that are indistinguishable from those found in the oral cavity (Wu et al. 2002; Bezençon et al. 2007; Jang et al. 2007; Mace et al. 2007; Margolskee et al. 2007; San Gabriel et al. 2007; Mace et al. 2009). The downstream elements found to be required for glutamate taste transduction in the oral cavity are also coexpressed in gut cells. What roles might such "taste" receptors play in the gut? Since glutamate receptors are expressed in the gut epithelium (luminal side), would they be involved in physiological responses such as nutrient digestion, absorption, and metabolism? In what follows, we describe the existence of a glutamate-sensing system in the gut linked to glutamate absorption and activation of vagal afferent fibers that transmits food-related signals to the brain.
Fig. 31.2 Ascending neural pathways for nutrient-related signals in rats. Taste information is transmitted to the brain via four taste nerves, while visceral sensory information is transmitted via vagal and splanchnic afferents. The first relay in the brain is the nucleus of the solitary tract (*NST*). The neurons in the NST project to the parabrachial nucleus (*PBN*), and then project to a variety of forebrain areas via dorsal and ventral routes. Neurons in the NST also project to the reticular formation (RF) for reflex responses. *CT* chorda tympni nerve; *GSP* greater superficial petrosal nerve; *GP* glossopharyngeal nerve; *SL* superior laryngeal nerve; *VPMpc* ventral posteromedial nucleus of the thalamus, parvicellular part; *ICx* insular cortex; *AMc* central nucleus of the amygdala; *LHA* lateral hypothalamic area; *ZI* zorna incerta; *BST* bed nucleus of the stria terminalis. VII, IX, and X denote the 7th, 9th and 10th cranial nerves, respectively

31.4.1 Glutamate Receptors in the Gut

Currently, two candidate glutamate receptors have been identified in the gut, i.e., mGluR1 and T1R1/ T1R3. The mGluR1 is located in chief cells (pepsinogen-secreting cells) of the stomach (San Gabriel et al. 2007), whereas the T1R1/T1R3 heterodimer is found in epithelial cells of the stomach, small intestine, and colon (Bezençon et al. 2007). The cellular transduction molecules of taste glutamate receptors, including α-gustducin, transducin, phospholipase C β2, protein kinase C βII and transient receptor potential cation channel M5 (TRPM5) are also coexpressed in these cells (Bezençon et al. 2007; Mace et al. 2007, 2009), indicating the presence of the complete receptor transduction machinery. These findings suggest that taste-like gut glutamate receptors might detect ingested glutamate on the luminal side of the gut, and provide this information to adjacent cells and neurons.

31.4.2 Glutamate Transporters and Absorption

The intestinal absorption of glutamate presumably occurs for the most part in the epithelial cells lining the mucosa, namely enterocytes. Glutamate is transported from the intestinal lumen across the apical membrane to cytosol mainly via the high affinity X^-_{AG} system and to a lesser extent by the low

affinity B^0 system (Burrin and Stoll 2009). These systems also transport a second acidic amino acid, aspartate. Studies with pig and mice tissue show that excitatory amino acid carrier-1 (EAAC-1) is the most abundant glutamate transporter among four proteins capable of X^-_{AG} system activity in the intestine (Fan et al. 2004). An important and yet unresolved question is to what extent the gut microflora competes in the process of glutamate absorption (Burrin and Stoll 2009).

In the jejunum of a fed rat, T1R1 and T1R3 are colocalized in enterocytes, solitary chemoreceptor cells, and Paneth cells (Mace et al. 2007). Stimulation of the T1R1/T1R3 receptor activates an intracellular signaling cascade involving α-gustducin, transducin, phospholipase C β2, and protein kinase C βII, which will eventually lead to enhanced expression of EAAC-1 in the apical membrane thereby facilitating glutamate absorption (Fig. 31.3). EAAC-1 levels in the apical membrane are doubled after glutamate stimulation (Mace et al. 2009). As glutamate is the single most important energy source in the intestinal mucosa (Reeds et al. 2000), most of the glutamate absorbed is used for energy production and biosynthesis of amino acids (aspartate, alanine, proline), glutathione, and protein. This is one of the reasons why glutamate levels in the blood and brain remain stable for several hours following food intake (Adibi and Mercer 1973; Young and Ajami 2000; Kondoh and Torii 2008a).

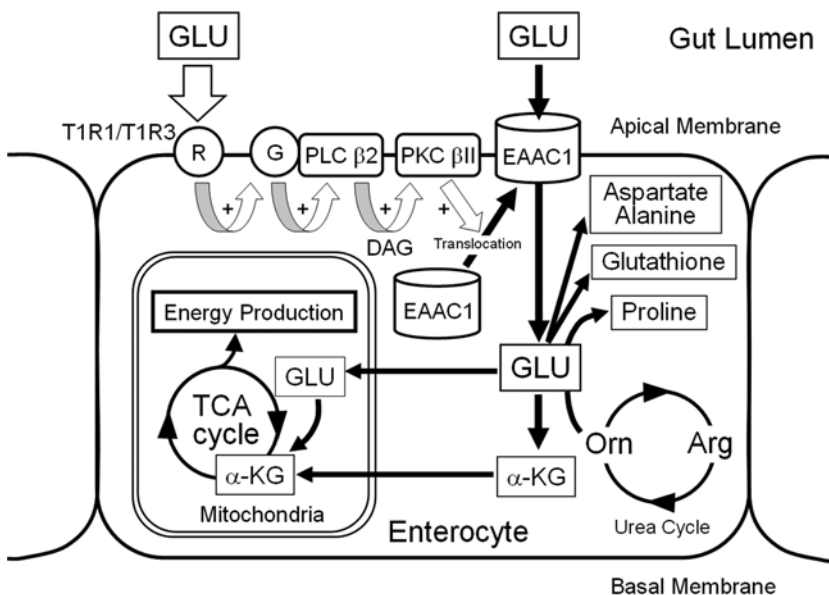
Addition of glutamate to an intestinal perfusate induces rapid internalization of T1R1, T1R3, and transducin (Mace et al. 2009), suggesting the presence of a dynamic regulatory system mediating glutamate absorption. Interestingly, this glutamate absorption system acts to coordinate the regulation of apical transporters for glucose and oligopeptides reciprocally through a common enterocytic pool of protein kinase C βII. This network may be important for the control of energy supply to the body.


Fig. 31.3 Regulation of L-glutamate (*GLU*) absorption and metabolism in the small intestine. Stimulation of T1R1/T1R3 receptor by luminal glutamate enhances expression of a high affinity glutamate transporter, the excitatory amino acid transporter-1 (*EAAC-1*), in the apical membrane of enterocyte. After absorption, most glutamate is consumed for catabolism and oxidization. *R* glutamate receptor; *G* GTP-binding protein (including α-gustducin and transducin); *PLC* phospholipase C; *PKC* protein kinase C; *DAG* diacylglycerol; *α-KG* α-ketoglutarate; *TCA* tricarboxylic acid; *Orn* ornithine; *Arg* arginine

31.4.3 Hormonal Release

The gastrointestinal tract is the largest endocrine organ of the body. Hormones released into the systemic circulation from the gut in response to nutritional stimuli form a key component of the gut-brain crosstalk (Chaudhri et al. 2008). Gut peptides such as cholecystokinin, glucagon-like peptide-1 (GLP-1), oxyntomodulin, pancreatic polypeptide, and peptide YY_{3-36} reduce food intake and are thought to act as satiety signals and meal terminators. Typically, appetite-modifying actions of most of these peptides are partly reduced or completely abolished after vagotomy, suggesting importance of vagus nerve on appetite control and energy homeostasis.

However, there is no evidence to this day indicating that dietary glutamate stimulates hormonal release from the gut into the circulation. This is in sharp contrast to the case of sweet receptor stimulation, despite the fact that the T1R1/T1R3 umami receptor shares common intracellular signaling pathways to T1R2/T1R3 sweet receptor. For example, stimulation of gut T1R2/T1R3 by sugars and artificial sweeteners causes release of incretins such as glucose-dependent insulinotropic polypeptide (GIP) and GLP-1 (Jang et al. 2007). In addition to the enhancement of glucose-induced insulin release, these hormones act on enterocytes to stimulate the absorption of glucose from the intestinal lumen through upregulation of apical expression of Na^+/glucose cotransporters 1 and 2 (Mace et al. 2007, 2009; Margolskee et al. 2007). GLP-1 exerts additional physiological actions, including stimulation of insulin biosynthesis, inhibition of glucagon secretion, inhibition of gastric emptying and acid secretion, reduction of food intake, and trophic effects on the pancreas (Gautier et al. 2008). Gut sweet receptors thus appear to participate in the coordination of dietary carbohydrate absorption and their release into the circulation. In contrast to this concept, however, there is a contradicting report that artificial sweeteners do not produce incretin release in vivo (Fujita et al. 2009).

Although glutamate stimulates the vagus nerve through the release of bioactive substances such as nitric oxide and serotonin in the stomach (*see* next), it remains to be clarified whether gut peptide release can be triggered by luminal sensing of glutamate.

31.4.4 Activation of Vagal Afferent Fibers

The ascending pathway of abdominal vagal information is parallel to the taste pathway (Yamamoto 2006). Signals detected in the abdominal regions are transmitted to the NST via the hepatic, gastric, and celiac branches of the vagus nerve (Figs. 31.2 and 31.4a). Each branch carries both afferent and efferent fibers. The vagal afferent fibers project to a region of the NST located caudal to the NST area receiving gustatory inputs.

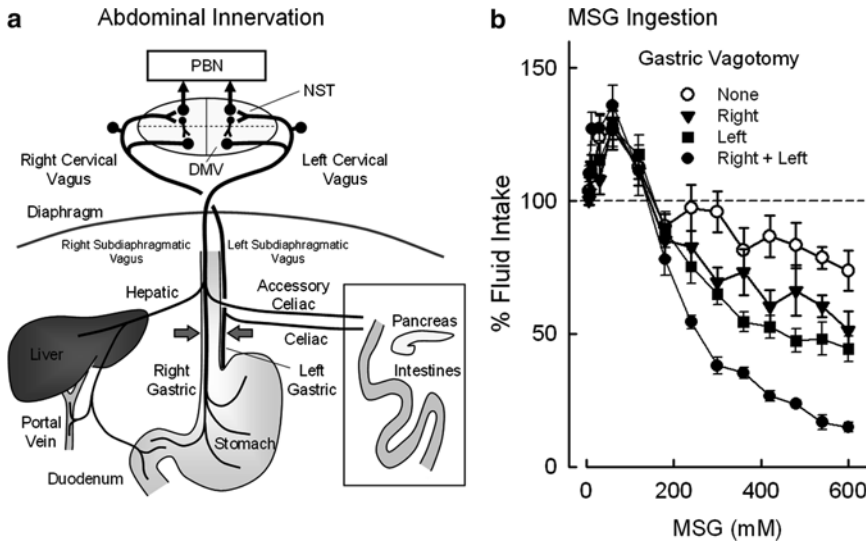
The administration of MSG into the stomach, duodenum, and portal vein activates vagal afferents of the gastric, celiac, and hepatic branches, respectively (Niijima 2000). Such findings suggest the existence of glutamate-sensing mechanisms at these sites (stomach, small intestine, and hepato-portal region). Of the three vagal components, gastric afferents respond specifically to MSG; i.e., *no* response is elicited by infusing *any* of the other amino acids or NaCl into the stomach (Uneyama et al. 2006). The specific response to MSG cannot be explained by activation of T1R1/T1R3 because, at least in rodents, it functions as a broadly tuned L-amino acid receptor (Nelson et al. 2002). In contrast, hepatic afferents respond to all amino acids delivered into the portal vein (Niijima and Meguid 1995). The response of gastric afferents to MSG is concentration-dependent (Uneyama et al. 2006). Moreover, the vagus does not respond to the intravenous administration of MSG (Uneyama et al. 2006), implying that the vagal effects of luminal glutamate administration are restricted to the gastrointestinal tract since any leakage into the circulation would in principle have no effects.


Fig. 31.4 Abdominal innervation of the vagus nerve (**a**) and effects of selective gastric vagotomy on monosodium L-glutamate (*MSG*) ingestive behavior in 30-min one-bottle acceptance test (**b**) in rats. Abdominal vagal branches carry both afferent and efferent fibers. Consumption of MSG solution is reduced by half after the partial vagotomy of gastric branch at the level either in the right gastric or left gastric compared with their combination (*arrows*). Vertical represents percentage fluid intake relative to water intake. *NST* nucleus of the solitary tract; *DMV* dorsal motor nucleus of the vagus; *PBN* parabrachial nucleus. Results are expressed as mean ± SEM, $n = 6$

The afferent endings of the vagus are not in direct contact with gut epithelial cells. Hence, how does the activation of glutamate receptors stimulate vagal nerve endings? We have observed that the activation of gastric vagal afferents by intragastric MSG can be suppressed by either (a) luminal perfusion with lidocaine, a local anesthetic, (b) pretreatment of animals with *p*-chrolophenylalanine, which depletes gut endogenous serotonin stores, (c) administration of granisetron, a selective antagonist at serotonin receptor type 3 (5-HT$_3$R), or (d) administration of N^ω-nitro-L-arginine methyl ester [a nonselective inhibitor of nitric oxide synthase (NOS)] (Uneyama et al. 2006). Moreover, the vagal response to MSG can be mimicked by intragastric administration of sodium nitroprusside (a nitric oxide donor), an effect that is abolished by pretreatment with granisetron (Uneyama et al. 2006). Together, these findings suggest that luminal glutamate activates the vagal nerve indirectly via the production and release of nitric oxide and serotonin.

Anatomical and immunohistochemical evidence reveals that serotonin-immunoreactive cells are found in the stomach, particularly in the superficial part of the mucosal epithelium and at the base of the fundic glands (Iijima et al. 2008). 5-HT$_3$R immunoreactivity is localized to the neck of the fundic glands. NOS1/neuronal NOS-immunoreactive cells of bipolar shape in the stomach are found in the *lamina propria*, where a dense network of neuronal cells is present. These findings suggest that complex cellular events mediate glutamate signaling in the stomach.

31.4.5 Effects of Vagotomy on MSG Ingestive Behavior

Behavioral data obtained from vagotomized rats indicates that gut glutamate signaling via the afferent vagus is an important regulator of food intake. In particular, selective abdominal vagotomy reduces the ingestion of MSG solutions (240–600 mM), as measured by 30-min one-bottle acceptance tests

(Kondoh et al. 2000; Kondoh and Torii 2008a). Importantly, the strength of these effects depended on which vagal branches has been severed, as follows: subdiaphragmatic total vagotomy (TVX) = gastric vagotomy > celiac vagotomy > hepatic vagotomy = intact controls (where the symbol ">" means "lower intake levels than"; Kondoh et al. 2000; Kondoh and Torii 2008a). Since the effects of gastric vagotomy are comparable to those of TVX, the glutamate signal appears to be mediated mainly via the gastric branches. This conclusion is further confirmed by experiments employing partial vagotomy of the gastric branch (Fig. 31.4). Selective transection of either right or left branch of the gastric vagus showed moderate (approximately 50%) reduction of MSG ingestion compared to bilateral transections.

In contrast to MSG, ingestive behavior of proline (a sweet amino acid) is unaffected by TVX (Kondoh et al. 2009a), suggesting that the vagotomy-induced reduction of MSG intake is not related to a local unpleasant sensation in the gut.

If nonvagal neural inputs to the brain have any significant roles, transection of these nerves would alter the behavior. Surprisingly, MSG ingestive behavior was little affected by bilateral transections of taste nerves (chorda tympani, glossopharyngeal nerve, and their combination) or splanchnic nerve (Fig. 31.5). Altogether the results suggest that the vagus nerve, especially the gastric branches, have crucial roles for transmission of glutamate signals to promote MSG ingestion. Splanchnic afferents have least contribution on the glutamate signaling in the gut.

31.4.6 Luminal Glutamate Triggers Reward Signals

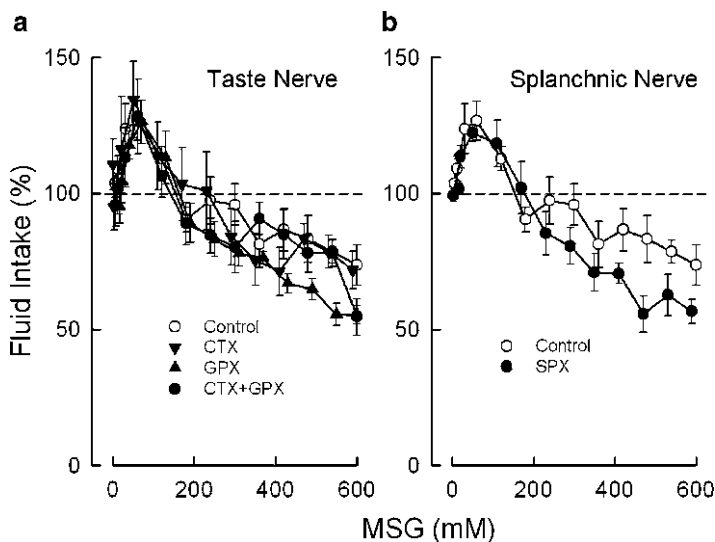
Postingestive consequences (nutrition, satiation, and food memories) are important factors determining long-term preferences for foods and fluids. Preference is increased for flavored solutions paired with intragastric infusions of highly caloric substances (carbohydrates, long-chain fatty acids, and


Fig. 31.5 Bilateral transection of the taste nerves (**a**) and splanchnic nerve (**b**) had little influence on monosodium L-glutamate (*MSG*) ingestive behavior in 30-min one-bottle acceptance test in rats. Taste nerves and splanchnic nerve do not play crucial roles for transmission of glutamate signals to the brain to alter ingestive behavior of MSG consumption. Vertical represents percentage fluid intake relative to water intake. *CTX* transection of the chorda tympani nerve; *GPX* transection of the glossopharyngeal nerve; *SPX* transection of the splanchnic nerve. Control represents intact animals. Results are expressed as mean ± SEM, *n* = 6

Conditioned Flavor Preference Learning
Fig. 31.6 Scheme of conditioned flavor preference learning experiment. Licking of the drinking spout triggers an infusion pump through computer software to deliver a cue solution (an orange- or grape-flavored solution) in the spout and simultaneously a nutrient solution in the stomach via intragastric cannula. The volumes delivered are equal each other. Another flavored solution paired with intragastric water infusion acts as a control. After training (learning), rats are subjected to two-bottle preference tests. *MSG*, monosodium L-glutamate

ethanol), as shown in conditioned flavor preference paradigms (Sclafani 2004). Until recently, however, the influence of postingestive effects produced by umami substances on flavor preference learning had been poorly studied. We set out to investigate flavor preferences conditioned by intragastric infusions of MSG in rats. We hypothesized that MSG intake produces reinforcing postingestive effects that are sufficient to enhance preferences for flavors associated with intragastric MSG infusion.

To test this hypothesis, a conditioned flavor preference paradigm was employed (Fig. 31.6). Rats implanted with chronic intragastric cannulae were trained to drink either a fruit-flavored solution (conditioned stimulus; CS+) paired with intragastric infusions of a test solution (MSG, NaCl, or glucose at 60 mM, so that orosensory receptors for these tastants were not activated) or a second flavored solution (CS−) paired with intragastric infusion of water. CS+ and CS− solutions were presented (along with their respective intragastric infusions) on alternate days. After this conditioning phase, the MSG group showed significantly higher intake and preference for the CS+ over CS− solution during two-bottle preference tests. Neither NaCl nor glucose infusions produces significant increases in preferences (Uematsu et al. 2009). The findings with respect to glucose are intriguing and imply that at this concentration (60 mM) intragastric infusions of glucose produce no reinforcing effects on conditioned flavor preferences. The results clearly suggest that postingestive MSG is rewarding for animals at a low caloric concentration. The MSG effect can be explained neither by Na^+ effect nor by a caloric effect. A glutamate-specific sensing mechanism involving vagal activation following gut glutamate receptor stimulation is a plausible explanation for the behavioral effects observed.

31.5 Brain Mechanisms

As the ingestion of high protein foods (and thus glutamate) does not lead to appreciable changes in plasma glutamate levels (Adibi and Mercer 1973; Young and Ajami 2000; Kondoh and Torii 2008a), the brain is unlikely to monitor protein intake via meal- or diet-related variations in plasma glutamate.

However, luminal glutamate content, which should rise once proteins are digested, may well reflect protein ingestion, and thus might constitute a reliable signal for protein intake. In this case, the stimulation of gut glutamate receptors by luminal glutamate following protein digestion, and the subsequent activation of afferent vagal fibers, might constitute a primary mechanism by which the brain senses protein ingestion.

31.5.1 Forebrain Activation by Intragastric Nutrient Administration

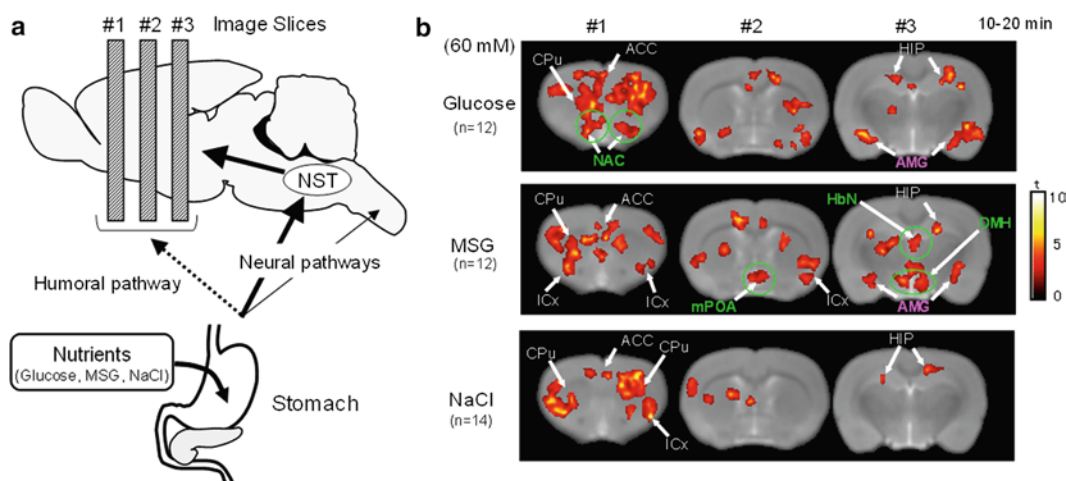
The vagal afferent fibers project to neurons in the caudal part of the NST, from where projections arise that spread to numerous areas in the brain (Berthoud and Neuhuber 2000). Some of these brain areas might be responsive to the activation of the afferent vagus by luminal glutamate. Functional magnetic resonance imaging (functional MRI or fMRI) studies in anesthetized rats indicate that intragastric administration of nutritive substances [glucose (sweet), MSG (umami) and NaCl (salty) at 60 mM, which is the most preferred concentration of MSG by rats (Kondoh et al. 2000; Kondoh and Torii 2008a)] activates a number of brain areas, including the cortex, basal ganglia, limbic system, and hypothalamus (Kondoh and Torii 2008a; Tsurugizawa et al. 2008; Kondoh et al. 2009a, 2009b). All of these regions receive vagal information through the NST (Berthoud and Neuhuber 2000). Notably, three areas of the brain (the medial preoptic area, the dorsomedial nucleus of the hypothalamus, and the habenular nucleus) are activated only by MSG, while the nucleus accumbens is activated only by glucose (Fig. 31.7). The amygdala is activated by both glucose and MSG. Other areas, such as the insular cortex (the primary visceral sensory cortex), anterior cingulate cortex, caudate-putamen, hippocampus, and lateral hypothalamic area are activated by all three substances. The medial preoptic area and dorsomedial nucleus of the hypothalamus have both been proposed to play a role in thermoregulation (Dimicco and Zaretsky 2007; Kumar et al. 2007), while the habenular


Fig. 31.7 Scheme of functional magnetic resonance imaging (fMRI) experiments (**a**) and typical examples of activated areas in the rat brain at 10–20 min after intragastric administration of nutritive substances (**b**). Fluids of nutritive substances [glucose, monosodium L-glutamate (*MSG*), and NaCl at 60 mM, 1.0 mL/100 g body weight] were delivered directly into the stomach via gastric cannula for 10 min. Three images were taken from the forebrain regions (+2.0, -0.5, and -3.0 mm to bregma, slice thickness = 1.5 mm) by using T_2*-weighted MRI. Results are expressed as mean ± SEM, n = 12–14
Fig. 31.8 Forebrain activation induced by intragastric administration of nutritive substances. Brain activation is observed in several forebrain regions in the cortex, basal ganglia, limbic system, and hypothalamus. Notably, the medial preoptic area (*mPOA*), dorsomedial nucleus of the hypothalamus (*DMH*), and habenular nucleus (*HbN*) are activated by monosodium L-glutamate (*MSG*) alone. In contrast, the nucleus accumbens (*NAC*) is activated by glucose alone. The amygdala (*AMG*) is activated by both glucose and MSG. *NST* nucleus of the solitary tract; *ICx* insular cortex; *ACC* anterior cingulate cortex; *CPu* caudate-putamen; *HIP* hippocampus; *LHA* lateral hypothalamic area

nucleus, especially the lateral habenula, participates in affective decision-making by influencing the activity of midbrain dopamine and serotonin neurons (Matsumoto and Hikosaka 2007). The amygdala is a key structure in the evaluation of the biological significance of foods (Nishijo et al. 1998). Such findings suggest that luminal glutamate may play a role in thermoregulation, energy homeostasis, reward processing, and emotional behavior. Figure 31.8 is a summary of activated areas in the rat forebrain induced by intragastric administration of typical nutrients.

The temporal patterns of the brain responses were also distinct for each luminal stimulus. The glucose response develops slowly, with the peak at 20–30 min after the beginning of gastric infusion; the response was sustained for up to 60 min (Tsurugizawa et al. 2008). This response pattern parallels changes in blood glucose levels. However, the MSG-induced response develops rapidly, with the peak occurring just at the end of the 10-min infusion period. The response then dropped off to baseline values within the next 15 min. The response to NaCl infusion paralleled (in time) that for MSG, but was much weaker. In another experiment, 150 mM NaCl produces no response (Tsurugizawa et al. 2008), suggesting that the response to 60 mM NaCl is likely a hypotonic effect (Mei and Garnier 1986), as the experimental conditions (gastric expansion, temperature change, and anesthetic) are otherwise the same for each solution tested. An analysis of the response to 60 mM MSG minus that to 60 mM NaCl shows a result for MSG like that to MSG alone (though reduced).

In addition to these findings, the brain activation induced by intragastric glutamate, but not by intragastric glucose, is abolished after the TVX (Tsurugizawa et al. 2009). This result suggests that gut luminal glutamate is "sensed" in the brain by a signal provided by the afferent vagus. Afferent vagus information is critical for the transmission of glutamate signals to the brain, and circulating factors (e.g. direct sensing of blood chemicals by the brain) appear to be the primary pathway for

glucose signals. If this difference holds, it is interesting to note that the mechanism by which the gut handles ingested glucose (relatively little metabolism) and glutamate (almost complete metabolism) is consistent with the signaling pathways used by these compounds to communicate their presence in the gut to the brain.

31.5.2 Cerebral Blood Flow Changes by Intraduodenal Nutrient Administration

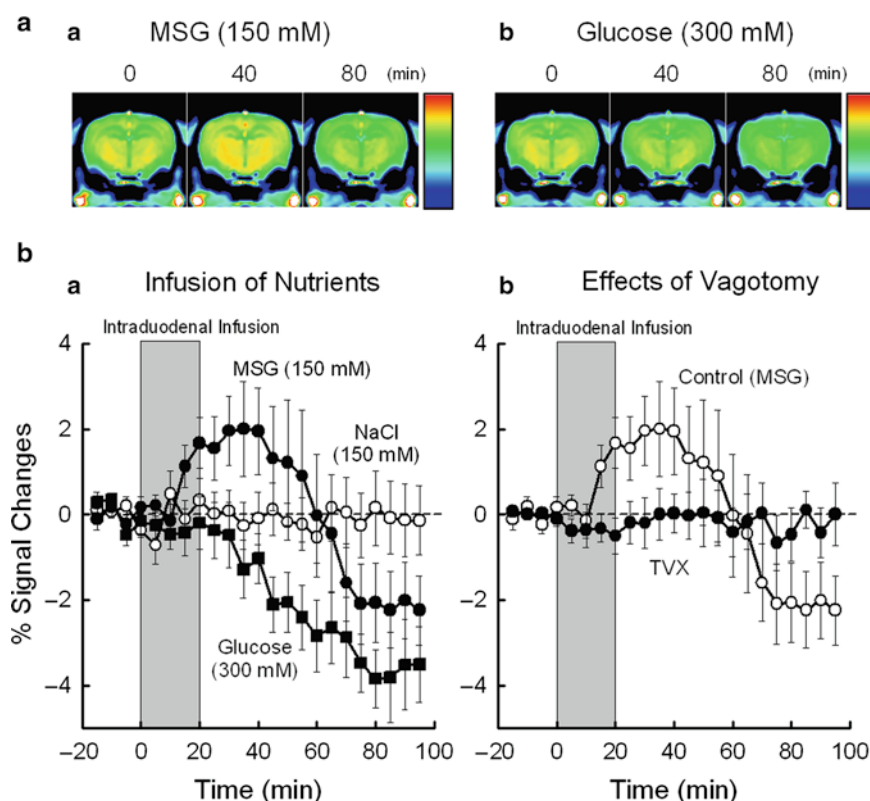
Changes in cerebral blood flow are physiological events associated with brain activation (Kwong et al. 1992). Effects of intraduodenal nutrient infusions on cerebral blood flow were investigated by using T_1-weighted MRI in awake and nonfasted rats. Infusion of isotonic MSG solution (150 mM) into the rat duodenum enhances overall cerebral blood flow with the responses peaking at 20–40 min after the start of the infusion, with flow levels decreasing with respect to baseline levels after 60 min of the start of the infusion (Fig. 31.9). In contrast, isotonic glucose (300 mM) infusions reduce blood


Fig.31.9 Cerebral blood flow responses by intraduodenal infusion of nutrients in awake and nonfasted rats. *A* Examples of flow images after intraduodenal infusions (2.0 mL/100g body weight for 20 min) of 150 mM monosodium L-glutamate (*MSG*) (**a**) and 300 mM glucose (**b**) scanned by T_1-weighted magnetic resonance imaging (*MRI*). *Ba*,changes in cerebral blood flow after infusion of isotonic nutrient solutions (glucose, MSG and NaCl); *Bb* effects of subdiaphragmatic total vagotomy (*TVX*) on MSG (150 mM)-induced cerebral blood flow changes. MSG-induced response was completely blocked after vagotomy. Results are expressed as mean ± SEM, $n = 10$–12

flow only after peaking at 80 min. Neither isotonic NaCl (150 mM) nor water infusions produced significant effects. These results suggest that the MSG response is not ascribed to Na^+ nor caloric component but to glutamate. Importantly, the MSG-induced response is again completely abolished after the TVX, suggesting the crucial role of the vagus nerve on this blood flow response.

31.5.3 Preference for Umami Taste and Reward Circuits

The dopaminergic neurons in the ventral tegmental area have a crucial role in regulating behavioral responses to natural rewards such as sweet solutions, as well as artificial rewards such as drugs of abuse. However, lesions of the ventral tegmental area dopaminergic neurons by microinjection of 6-hydroxydopamine do not interfere with preferences for umami (MSG and 5′-ribonucleotides) or NaCl solutions (Shibata et al. 2009). Interestingly, enhanced preference for lysine (a bitter amino acid) in lysine-deficient rats is also unaffected by ventral tegmental area lesions. These results suggest that preferences for umami (MSG and 5′-ribonucleotides), essential amino acids, and NaCl, but not for sweet, operate through reward circuits that are independent of ventral tegmental area dopaminergic neurons. Contribution of dopaminergic neurons from other brain areas and the identification of the reward circuits regulating preferences for umami substances must be clarified in future experiments.

31.6 Effects of Oral Glutamate on Body Energy Metabolism

Since MSG generally enhances the palatability of food, effects of MSG ingestion on food intake and development of obesity are of growing interest. To verify whether MSG provides protective effects against obesity, rats were given free access to two drinking bottles, one containing a 1% (w/v) MSG solution and the other plain water (Kondoh and Torii 2008b). Rats given free access to MSG and water show a high preference (93–97%) for the MSG solution. Interestingly, rats ingesting the MSG solution show smaller weight gain over the 15-week study, compared to rats ingesting no MSG (water only; Fig. 31.10). In addition, abdominal fat mass and plasma leptin levels are also lower in rats ingesting MSG than in animals ingesting no MSG. Naso-anal length, lean mass, food and caloric intakes, blood pressure, blood glucose, and plasma levels of insulin, triglyceride, total cholesterol, albumin, and glutamate do not differ between the two groups. Taken together, these results suggest that MSG ingestion reduces weight gain, the rise in body fat mass, and plasma leptin levels. These changes are most likely mediated by increased energy expenditure, since food intake is unaffected by MSG ingestion (Kondoh and Torii 2008b; Kondoh et al. 2009a, 2009b). In support of this possibility, ingestion of MSG enhances diet-induced thermogenesis (Viarouge et al. 1992; Smriga et al. 2000). Conceivably, such effects of MSG might include neural links involving the afferent branches of the vagus nerve in the gut, the afferent sensory nerves in the oral cavity, and perhaps activation of the medial preoptic area and dorsomedial nucleus of the hypothalamus, the areas activated by intragastric MSG (Kondoh and Torii 2008a; Tsurugizawa et al. 2008; Kondoh et al. 2009a, 2009b) and known to be involved in thermoregulation (Dimicco and Zaretsky 2007; Kumar et al. 2007).

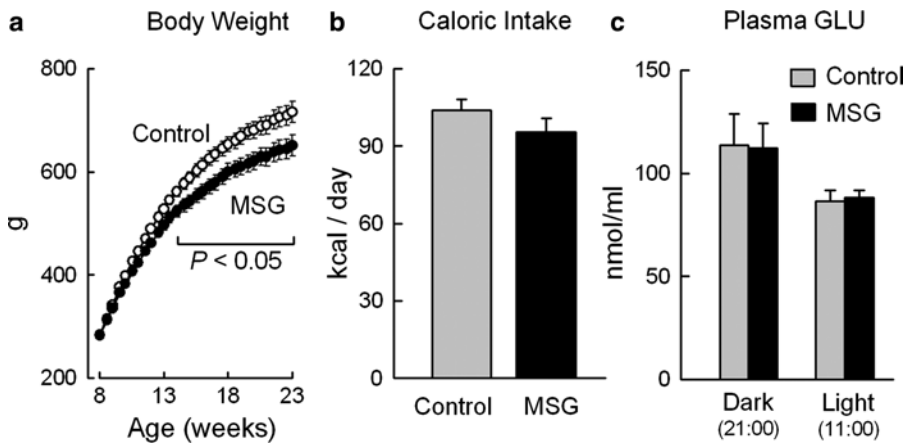
    In nursing home elderly, addition of 300 mg MSG with or without flavor to the cooked meal for 16 weeks does not lead to a higher overall energy intake at lunch, not does it increase body weight (Essed et al. 2007). Interestingly, both the MSG group and flavor + MSG group show a mean 0.7–0.8 kg reduction in body weight (0.1 kg increase in the control group). The MSG group also shows a mean


Fig. 31.10 Effects of monosodium L-glutamate (*MSG*) intake on body weight (**a**), daily caloric intake (**b**), and plasma glutamate (*GLU*) levels (**c**). Rats were given free access to high fat diet (45% of total calorie as fat) and water with or without 1% (60 mM) MSG solution. Weight gain was slowed by MSG intake while the caloric intake and plasma glutamate levels both in the light and dark periods were unchanged by MSG intake. Results are expressed as mean ± SEM, *n* = 8–9 (Reprinted from Kondoh and Torii (2008). With permission)
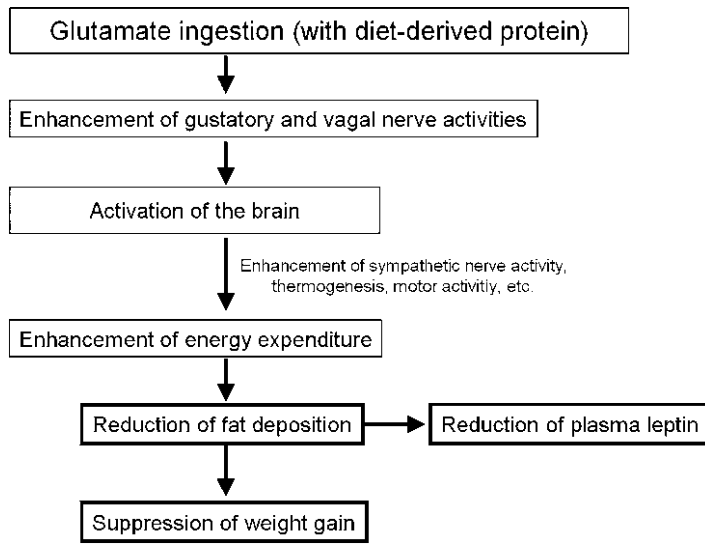

Fig. 31.11 Proposed mechanisms of dietary glutamate on energy expenditure, fat deposition, plasma leptin levels, and weight gain. Ingestion of dietary glutamate reduces weight gain by enhancing energy expenditure. Caloric intake is not modified by glutamate ingestion

0.7 kg reduction in body fat (0.1 kg increase in the control group). Plasma leptin was not measured in this experiment. These results suggest that MSG might also reduce body weight and body fat mass in humans without changing caloric intake. Enhanced thermogenesis may be involved in the MSG effects on energy homeostasis.

Taken together, proposed mechanisms of dietary glutamate on energy expenditure, fat deposition, plasma leptin levels, and weight gain are shown in Fig. 31.11. Such possibilities need to be examined in the future experiments.

31.7 Applications to Other Areas of Health and Disease

Obesity increases a risk of lifestyle-related diseases such as type II diabetes, hypertension, hyperlipidemia, cardiovascular disease, and ischemia. Many people desire an alternative remedy instead of medication and exercise for prevention of body fat accumulation and obesity. Ingestion of functional foods or ingredients is one of the ideal means for their prevention and remedy. Addition of glutamate on cuisines enhances food palatability but suppresses fat deposition and obesity by increasing energy expenditure. Usage of glutamate does not produce overeating (no changes in caloric intake). Therefore, manipulation of glutamate signals arising in the mouth and gut may be an effective strategy for treatment of obesity and metabolic syndrome.

Summary Points

- Glutamate has several physiological functions including perception of umami taste, intermediary metabolism, and excitatory neurotransmission.
- In addition, new functions for dietary glutamate in gut-brain axis activation and energy homeostasis have been found.
- A current hypothesis regarding the physiological function of the glutamate receptor transduction cascade relates to signaling the brain on the amounts of protein ingested by an organism.
- Glutamate levels in both blood and brain remain stable throughout the day.
- Glutamate receptors are expressed in the gut mucosa producing local actions on gut function including apical expression of glutamate transporters (glutamate absorption) and vagal activation (gut-brain communication).
- The gastric vagal afferent fibers respond specifically to glutamate but not to other amino acids or NaCl delivered in the stomach.
- The release of signaling molecules (nitric oxide and serotonin) is involved in the observed increases in afferent vagus nerve activity upon stimulation with glutamate and consequently in a number of different areas of the brain.
- Intragastric infusion of MSG specifically activates three brain areas, i.e., the medial preoptic area, dorsomedial nucleus of the hypothalamus, and habenular nucleus.
- Glutamate activates the brain through vagal route while glucose activates the brain through nonvagal (humoral) route.
- Glutamate in the gut is rewarding.
- Umami preference is unaffected by lesions of dopaminergic neurons in the ventral tegmental area.
- Chronic intake of a palatable MSG solution is effective to reduce weight gain, fat deposition, and plasma leptin levels in rats, most likely through an enhancement of energy expenditure.
- These findings indicate that dietary glutamate influences numerous physiological functions, suggesting a broad, integrative role for dietary glutamate in body homeostasis.

Definitions and Explanations

Dorsomedial nucleus of the hypothalamus: A nucleus in the hypothalamus involved in regulation of feeding, drinking, body weight, energy consumption, and behavioral circadian rhythms.

Functional magnetic resonance imaging (fMRI): A noninvasive MRI approach that measures brain functional changes based on blood oxygenation level-dependent contrast of hemoglobin (an endogenous contrast agent) in blood. Because activation of the brain causes increase in blood flow (oxygen supply) over the oxygen consumption to reduce deoxyhemoglobin levels, signal increases in general can be detected.

ʟ-Glutamate: An acidic and multifunctional amino acid involved in perception of umami taste, intermediary metabolism, and excitatory neurotransmission. In addition, it plays important roles in the activation of gut–brain axis, reward processing, and regulation of energy homeostasis. Several types of glutamate receptors (ionotropic and metabotropic receptors) are expressed in the body.

α-gustducin: A GTP-binding protein expressed in type II taste cells and also in epithelial cells in the gut. In the oral cavity, it transduces sweet, bitter, and umami stimuli into cellular excitation via activation of phospholipase C β2.

Incretin: A concept of peptide hormones released during meals from endocrine cells located in the gut mucosa and stimulate insulin secretion from pancreatic β-cells in a glucose-dependent manner. Glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1) are the two major incretin hormones in humans.

Medial preoptic area: A nucleus in the anterior hypothalamus involved in regulation of body temperature, sleep–wakefulness, and male sexual behavior.

Nucleus accumbens: A nucleus involved in regulation of motivation, reward, feeding, pleasure, fear, attention, and drug addiction. Dopaminergic neurons originating in the ventral tegmental area terminate the nucleus accumbens, which is thought to be involved in reward and reinforcement and appears to be implicated in most if not all addictions.

Nucleus of the solitary tract: A nucleus in the medulla oblongata that receives afferent information concerning taste, cardiovascular, respiratory, and visceral sensation via the facial (VII), glossopharyngeal (IX), and vagus (X) cranial nerves.

Splanchnic nerve: A nerve carrying nerve fibers from the lower thoracic paravertebral ganglions to the collateral ganglions. It innervates the viscera, carrying fibers of the autonomic nervous system (visceral efferent fibers) as well as sensory fibers from the organs (which are also known as visceral afferent fibers).

T1R: The receptors belong to class C G protein-coupled receptors for detection of umami and sweet tastes. There are three subunit proteins in T1R: the T1R1/T1R3 heterodimer detects umami taste while the T1R2/T1R3 detects sweet taste. These receptors are expressed in the mouth and gut mucosa.

Umami taste: One of five basic tastes (salty, sweet, sour, bitter, and umami) elicited typically by glutamate, inosine-5′-monophosphate, and guanosine-5′-monophosphate. Umami taste is often described as the meaty, savory, or broth-like taste.

Vagus nerve: The Xth cranial nerve that innervates the larynx, heart, lungs, and visceral organs. It consists of both afferent and efferent fibers at the abdominal levels.

Ventral tegmental area: An area in the midbrain implicated in drug and natural reward circuitry, motivation, cognition, drug addiction, and several psychiatric disorders. Dopaminergic cell bodies originate and their two primary efferent projections are the mesocortical (innervates the prefrontal and insular cortices) and mesolimbic (innervates septum, hippocampus, amygdala, and nucleus accumbens) pathways.

Chapter 32
Oral Administration of Phosphatide Precursors Enhances Learning and Memory by Promoting Synaptogenesis

Mehmet Cansev and Ismail H. Ulus

Abbreviations

PUFA   Polyunsaturated fatty acid
DHA   Docosahexaenoic acid
EPA   Eicosapentaenoic acid
AA   Arachidonic acid
UMP   Uridine-5′-monophosphate
UDP   Uridine-5′-diphosphate
UTP   Uridine-5′-triphosphate
CMP   Cytidine-5′-monophosphate
CDP   Cytidine-5′-diphosphate
CTP   Cytidine-5′-triphosphate
PC   Phosphatidylcholine
PE   Phosphatidylethanolamine
PS   Phosphatidylserine
PI   Phosphatidylinositol
SM   Sphingomyelin
DAG   Diacylglycerol

32.1 Introduction

Phosphatides are major constituents of brain membranes, particularly of synaptic membranes. Synthesis of phosphatidylcholine (PC), the major brain membrane phosphatide, requires uptake into brain of various circulating precursors. These precursors include the pyrimidines uridine and cytidine; polyunsaturated fatty acids (PUFA), particularly the omega-3 PUFA docosahexaenoic acid (DHA); and choline.

Animals exhibit improvements in cognitive behaviors if they are treated for several weeks with food constituents normally present in the blood – uridine, DHA, and choline (Teather and Wurtman 2006; Holguin et al. 2008a, 2008b). These improvements are associated with biochemical and structural

e-mail: mcansev@uludag.edu.tr

changes in the brain. For example, the amounts of brain phosphatides that are formed from these compounds increase significantly (Wurtman et al. 2006; Cansev and Wurtman 2007). Parallel changes are observed in levels of proteins known to be associated with pre- and postsynaptic membranes (e.g., PSD-95; synapsin-1), but not the amount of a ubiquitous structural protein, beta-tubulin (Wurtman et al. 2006; Cansev and Wurtman 2007). In addition, the brains show such signs of enhanced synaptic activity as increased numbers of dendritic spines (Sakamoto et al. 2007) and increased release of certain neurotransmitters (Wang et al. 2005, 2007). In addition, the treatment has been shown in a recent clinical trial to improve cognitive functions in Alzheimer's disease (Scheltens et al. 2008), a neurodegenerative disease that associates the loss of synapses.

This review considers the behavioral consequences with regard to learning and memory of consuming these food constituents by showing evidence on the involvement of such biochemical mechanisms as increased quantity of synaptic membrane, and perhaps enhanced number of brain synapses. These mechanisms appear to involve an essential kinetic property – poor affinities for their substrates – of some of the brain enzymes that transform the three constituents to biologically active products as well as the activation of neuronal receptors by some of the products of the enzymes (e.g., UDP and UTP, which activate various P2Y receptors).

The review starts with brief descriptions of biosynthesis of membrane phosphatides, enzymes that mediate brain phosphatide synthesis, and the availability of phosphatide precursors to brain cells. It then describes the experimental and human studies of learning and memory in order to provide evidence for the behavioral consequences of administering phosphatide precursors and its relation with biochemical and structural alterations in the brain, such as enhanced levels of phosphatides, synaptic proteins, and dendritic spines in adult gerbils as well as rat pups. As no data yet are available on the effects of this or related biochemical treatments on the actual number of synapses, estimates of such numbers must be extrapolated from surrogate measurements, like numbers of dendritic spines which is generally believed to provide the best correlations with the actual number of synapses (Knott et al. 2006).

32.2 Biosynthesis of Membrane Phosphatides

Mammalian cells utilize DHA and other fatty acids, uridine, and choline to form the phosphatide subunits (e.g., PC) which, when aggregated, constitute the major components of their membranes. PC, the principal such subunit in brain, is synthesized from these precursors by the "Kennedy Cycle" (Fig. 32.1). Phosphatidylethanolamine (PE) likewise is synthesized via this pathway, utilizing ethanolamine instead of choline as a precursor, while phosphatidylserine (PS), the third major structural phosphatide, is generated by exchanging a serine molecule for the choline in PC or the ethanolamine in PE.

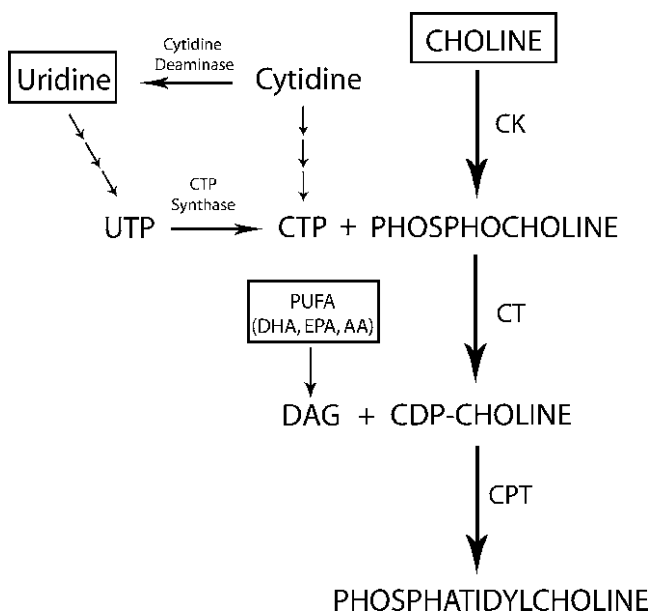
The Kennedy cycle involves three sequential enzymatic reactions. In the first, catalyzed by choline kinase (CK), a phosphate is transferred from ATP to the hydroxyl oxygen of the choline, yielding phosphocholine. The second, catalyzed by CTP:phosphocholine cytidylyl transferase (CT), transfers cytidylylmonophosphate (CMP) from cytidine-5′-triphosphate (CTP) to the phosphorus of phosphocholine, yielding cytidylyldiphosphocholine (also known as CDP-choline, or citicoline). As discussed next, much of the CTP that the human brain uses for this reaction derives from circulating uridine. The third and last reaction, catalyzed by CDP-choline:1,2-diacylglycerol choline phosphotransferase (CPT), binds the phosphocholine of CDP-choline to the hydroxyl group on the 3 C of diacylglycerol (DAG; particularly DAG containing DHA), yielding the PC. All three of these PC precursors must be obtained by brain entirely (DHA) or in large part (uridine; choline) from the circulation, and do in fact readily cross the blood–brain barrier (BBB; reviewed in Wurtman et al. 2009). Moreover, because the PC-synthesizing enzymes that act on all three have low affinities for them, treatments that increase blood levels of all three can affect the overall rate of PC synthesis.


Fig. 32.1 Phosphatidylcholine (PC) biosynthesis via the Kennedy cycle. In rats, plasma cytidine is the major circulating pyrimidine; in gerbils and humans, the primary circulating pyrimidine is uridine. Only small amounts of circulating cytidine are converted to brain CTP, since the blood–brain barrier (BBB) is a high-affinity transporter for pyrimidines (CNT2) and has a very low affinity for cytidine; uridine, in contrast, readily enters the brain via CNT2, yielding UTP which can then be converted to CTP by CTP synthase (Cansev 2006). CTP then reacts with phosphocholine to form endogenous CDP-choline, which combines with diacylglycerol (DAG), preferentially species containing PUFAs like DHA, EPA, or AA to form PC. Boxes indicate the compounds that are obtained from the circulation (From Cansev and Wurtman 2007)

The ability of each of the three circulating phosphatide precursors to affect the rate of phosphatide synthesis results principally from the low affinities of the enzymes for which these nutrients are substrates. CK has a very low affinity for its choline substrate; its *Km* for choline in brain (which, of course, describes the choline concentrations at which the CK operates at only half-maximal velocity) is reportedly 2.6 mM, whereas brain choline levels are only about 30–60 μM (Wurtman et al. 2009). *Km* values of CT for CTP and phosphocholine in brains of laboratory rodents and humans are reportedly 1–1.3 mM and 0.30–0.31 mM, respectively, while brain levels of these compounds are only 70–110 μM and 0.32–0.69 mM, respectively (Wurtman et al. 2009). The choline phosphotransferase reaction catalyzed by CPT also is unsaturated with the enzyme's substrates: its *Km* values for CDP-choline and DAG in rat liver are 200 and 150 μM, respectively, while the concentrations of these compounds in liver are approximately 40 and 300 μM. (A DAG concentration of at least 1,000 μM thus would probably be needed to saturate the enzyme.) Brain CDP-choline and DAG levels are even lower, i.e., about 10–30 and 75 μM, respectively (Wurtman et al. 2009).

32.3 Availability of Phosphatide Precursors to Brain Cells

32.3.1 Choline

Mammalian brains contain choline as the free base; as water-soluble phosphorylated metabolites, phosphocholine and glycerophosphocholine (Nitsch et al. 1992), and as constituents of membrane, phospholipids including PC, sphingomyelin, and lyso-PC. Free choline molecules in the brain derive

from four known sources – uptake from the plasma; liberation from the PC in brain membranes; high affinity uptake from the synaptic cleft after acetylcholine released from a cholinergic terminal has been hydrolyzed; and, probably to a minor extent, the breakdown of newly synthesized PC formed from the methylation of PE.

The brain can obtain circulating choline via two routes: small amounts can pass from the blood to the cerebrospinal fluid through the action of a specific transport protein, organic cation transporter 2 (OCT2), which is present in cells that line the choroid plexus (Sweet et al. 2001). However orders of greater magnitude pass bidirectionally between the blood and the brain's extracellular fluid (ECF) by facilitated diffusion. This process is catalyzed by a different transport protein, not yet cloned, which is localized within the endothelial cells that line the brain's capillaries (Oldendorf and Braun 1976). The protein is unsaturated at physiological plasma choline concentrations, and its net activity is affected by variations in these concentrations. It might constitute a kind of pore through which choline can pass in either direction, based on the gradient between its blood and brain levels. It has been estimated that the plasma choline concentration in rats required in order for the net choline flux to pass from blood to brain is about 15 μM; below this concentration net choline flux presumably is from brain to blood (Klein et al. 1990).

Once circulating choline has entered the brain's ECF it can be taken up into all cells by a low affinity transport protein (Km = 30–100 μM), or into cholinergic nerve terminals by a high affinity uptake protein (Km = 0.1–10 μM; Wurtman et al. 2009).

Besides the uptake from blood, brain free choline is derived from other sources including liberation of choline in membrane PC through the actions of the phospholipase enzymes, phospholipase C and D, which catalyze the hydrolysis of various bonds between PC's three oxygen molecules and fatty acids or its phosphate moiety; rapid hydrolysis of acetylcholine released into synapses to free choline and acetate; and breakdown of newly synthesized PC formed from the methylation of PE.

32.3.2 Uridine and Cytidine

Uridine and cytidine are transported across cell membranes, including the BBB, via two families of transport proteins, i.e., the Na⁺-independent, low affinity, equilibrative transporters (ENT1 and ENT2) and the Na⁺-dependent, high affinity, concentrative (CNT1, CNT2, and CNT3) nucleoside transporters (reviewed in Cansev 2006). Inasmuch as their Km values for the pyrimidines are in the high micromolar range (100–800 μM) they probably mediate BBB pyrimidine uptake only when plasma levels of uridine and cytidine have been elevated experimentally. In contrast, CNT2, which transports both the pyrimidine uridine and purines such as adenosine, probably does mediate uridine transport across the BBB under physiologic conditions (Cansev 2006). CNT2 can also transport cytidine, however with a much lower affinity than that for uridine (Cansev 2006).

It should be noted that, while both uridine and cytidine are present in the blood of laboratory rats, human blood contains unmeasurably low quantities of cytidine even among individuals consuming a cytidine source like oral CDP-choline (Wurtman et al. 2000); the cytidine is quantitatively deaminated to uridine in the human liver. Hence, in humans, circulating uridine, and not cytidine, is the precursor of the brain CTP utilized for phosphatide synthesis. Gerbil blood contains both of the pyrimidines, but proportionately less cytidine than blood of rats; hence, gerbils are often used as a model for studying the effects of uridine sources on the human brain.

Like other circulating compounds, pyrimidines may also be taken up into brain via the epithelium of the choroid plexus (CP) and the ENT1, ENT2, and CNT3 transporters; all of these proteins have

been found in CP epithelial cells of rats and rabbits (Cansev 2006). However, the surface area of BBB is probably 1,000 times that of the CP epithelium (i.e., 21.6 m² vs 0.021 m² in humans); hence, the BBB is the major locus at which circulating uridine enters the brain.

Uridine and cytidine are converted to their respective nucleotides by successive phosphorylations catalyzed by various kinases. Uridine-cytidine kinase (UCK; ATP:uridine 5′-phosphotransferase, EC 2.7.1.48) phosphorylates uridine and cytidine to form UMP and CMP, respectively. UMP-CMP kinase (UMP-CMPK; ATP:CMP phosphotransferase, EC 2.7.4.14) then converts UMP or CMP to UDP or CDP. These nucleotides are further phosphorylated to UTP and CTP by nucleoside diphosphate kinases (NDPK). Various interconversions between uridine and cytidine, and between their respective nucleotides, are known to occur in mammalian cells. Cytidine and CMP can be deaminated to uridine and UMP, while UTP is aminated to CTP by CTP synthase (UTP:ammonia ligase (ADP-forming), EC 6.3.4.2). This enzyme acts by transferring an amide nitrogen from glutamine to the C4 position of UTP, thus forming CTP.

All the enzymes described above apparently are unsaturated with their respective nucleoside or nucleotide substrates in normal brain. For example, the *Km* values for uridine and cytidine of UCK prepared from various tissues varied between 33 and 270 μM, and the *Km* for uridine of recombinant enzyme cloned from mouse brain was 40 μM (Wurtman et al. 2009). Brain uridine and cytidine levels are about 22–46 pmol/mg wet weight and 6–43 pmol/mg wet weight, respectively. Hence, the syntheses of UTP and CTP, and the subsequent syntheses of brain PC and PE via the Kennedy pathway, depend on available levels of their pyrimidine substrates. Indeed, increasing the supply of uridine or cytidine to neuronal cells, in vitro or in vivo, enhanced the phosphorylation of uridine and cytidine, and elevated cell and tissue levels of UTP, CTP, and CDP-choline (Wurtman et al. 2009).

32.3.3 DHA and Other PUFA

The omega-3 polyunsaturated fatty acids DHA and eicosapentaenoic acid (EPA), and the omega-6 fatty acid arachidonic acid (AA) are essential for humans and other animals, and must be obtained from the diet either as such or as their also-essential precursors, alpha-linolenic acid (ALA) and linoleic acid (LA). PUFAs enter the brain probably by both simple diffusion (Kamp et al. 1993) and protein-mediated transport (Abumrad et al. 1984). DHA, EPA, and AA are then transported from the brain's ECF into cells, and can be activated to their corresponding CoA species (e.g., docosahexaenoyl-CoA; eicosapentaenoyl-CoA; arachidonoyl-CoA) and acylated to the sn-2 position of DAG to form PUFA-rich DAG species.

DHA is acylated by a specific acyl-CoA synthetase, Acsl6 (Marszalek et al. 2005) which exhibits a low affinity for this substrate (*Km* = 26 μM); relative to usual brain DHA levels (1.3–1.5 μM). Hence, treatments that raise blood DHA levels rapidly increase its uptake into and retention by brain cells and its availability for incorporation into PC. EPA can also be acylated to DAG by the acyl-CoA synthetase or it can be converted to DHA by brain astrocytes, allowing its effects on brain phosphatides and synaptic proteins to be mediated by DHA itself. Exogenously administered AA, like DHA, is preferentially incorporated into brain phosphatides, as well as into other lipids, e.g., the plasmalogens. AA shares with DHA the ability to activate syntaxin-3 (Darios and Davletov 2006); however, as described next, its oral administration to laboratory rodents apparently does not promote phosphatide or synaptic membrane synthesis (Cansev and Wurtman 2007), the formation of dendritic spines (Sakamoto et al. 2007), nor improve rodent cognitive processes (Sarah Holguin, personal communication).

DHA and AA are major components of brain membrane phospholipids. While AA is widespread throughout the brain and is abundant in phosphatidylinositol (PI) and PC, DHA is concentrated in synaptic regions of gray matter and is especially abundant in PE and PS. EPA is found only in trace amounts in brain phosphatides, mostly in PI.

The ability of orally administered DAG, given daily for several weeks, to increase brain phosphatide levels does not necessarily imply that the quantities of DHA in the phosphatides, relative to those of other fatty acids, also are increased. Indeed this has not been demonstrated. Conceivably, DHA-rich DAG is preferentially utilized for PC synthesis, but once the DAG-containing PC is formed it is rapidly hydrolyzed to form lyso-PC lacking DHA and then reacylated to PC by addition of a different fatty acid.

32.4 Effects of Phosphatide Precursor on Learning and Memory

32.4.1 Experimental Studies

Experimental evidence indicates that chronic administration of phosphatide precursors enhances cognitive function and ameliorates impairments in memory. A UMP-supplemented diet (0.1%) can reverse the memory impairments observed among rats reared under impoverished environmental conditions (Teather and Wurtman 2006). DHA administration ameliorates the impairment of spatial cognition learning ability in β-amyloid-infused rats (Hashimoto et al. 2002, 2005) or in aged rats (Kotani et al. 2006). Giving aging mice a choline-rich diet chronically counteracts the age-associated decline in learning and memory (Golczewski et al. 1982). Perinatal supplementation with choline causes long-lasting improvements in spatial memory (Meck and Williams 1999) and protects memory impairments associated with normal aging (Tees 1999), prenatal alcohol exposure (Thomas et al. 2004), or epileptic seizures (Holmes et al. 2002).

Coadministration of these phosphatide precursors further enhances their effects on memory, learning, and cognitive functions (De Bruin et al. 2003; Teather and Wurtman 2003, 2005; Holguin et al. 2008a, 2008b). Chronic uridine supplementation, combined with choline, normalizes cognitive deficits in spontaneously hypertensive rats (De Bruin et al. 2003). Dietary administration of CDP-choline, a drug which provides both choline and cytidine/uridine (Wurtman et al. 2000), protects against the development of memory deficits in aging (Teather and Wurtman 2003), and prevents memory impairments caused by impoverished environmental conditions (Teather and Wurtman 2005). Among socially impoverished rats chronic (4 weeks) dietary supplementation of uridine (as its monophosphate, UMP; 0.5%) and choline (0.1%) enhances the improvement in learning and memory produced by administering DHA (300 mg/kg/day) in gerbils (Holguin et al. 2008a). UMP plus DHA and choline significantly enhances cognitive function in normal adult gerbils (Holguin et al. 2008b).

32.4.2 Human Studies

CDP-choline improves verbal memory in aging (Spiers et al. 1996) and benefits memory in elderly subjects (Alvarez et al. 1997).

One study has examined effects on humans of daily consumption of a liquid mixture (Souvenaid™) containing UMP, DHA, choline, and additional nutrients that promote endogenous choline synthesis, suppress auto-oxidation, and/or enhance the solubility of other ingredients. This randomized, controlled,

double-blind, parallel group, multicenter, multicountry trial (the Dutch Trial Registry, No: ISRCTN 72254645), involving 212 drug-naïve subjects with mild Alzheimer's disease and directed by Prof. Phillip Scheltens examined the treatment's effects on a delayed verbal memory task and the 13-item modified Alzheimer's Disease Assessment Scale-cognitive subscale at 12 weeks. In the group receiving Souvenaid a significant benefit was found in mild and very mild Alzheimer's disease patients on the delayed verbal memory task (Scheltens et al. 2008).

32.5 Relation of Enhancement in Learning and Memory with Enhanced Synaptogenesis

Learning and memory result from changes in the neural representation of stimuli through plastic events that modify the way neurons communicate with each other. Morphological change events including alterations in the structure, distribution, and number of synapses underlie memory formation. Accumulating evidence suggests that synapse formation is a major factor contributing to cognitive functions like learning and memory (Ramirez-Amaya et al. 2001). On the contrary, loss of synapses is generally believed to underlie the impaired learning and memory in degenerative diseases of the brain like Alzheimer's (Selkoe 2002).

Our previous studies demonstrated that chronic administration of various phosphatide precursors (uridine, DHA, and choline) to experimental animals induced biochemical and morphological changes in pre- and postsynaptic regions. For example, the amounts of brain phosphatides and of proteins (e.g., PSD-95; synapsin-1) known to be associated with pre- and postsynaptic membranes increased significantly (Wurtman et al. 2006). Uridine or UMP treatment also enhanced release of certain neurotransmitters (e.g., acetylcholine, dopamine) in brains of laboratory rodents. In addition, numbers of dendritic spines in CA1 region of the hippocampus were increased by this treatment. Since spine changes are associated with learning and memory (Muller et al. 2000), summarized next, the biochemical and structural alterations observed in the brain after chronic treatment with phosphatide precursors are likely to lead to the abovementioned enhanced cognitive functions in normal and in environmentally impoverished animals and Alzheimer's patients.

32.6 Effects of Phosphatide Precursors on Levels of Brain Phosphatides and Synaptic Proteins in Adult Gerbils and Rat Pups

If adult gerbils are given a standard diet supplemented with choline and uridine (as its monophosphate, UMP) and, also, by gavage, DHA, brain PC synthesis rapidly increases and absolute levels of PC per cell (i.e., DNA) or per mg protein rise substantially (e.g., by 40–50% after several weeks of daily treatment; Wurtman et al. 2006; Cansev and Wurtman 2007; (Table 32.1). Similar increases in levels of membrane phosphatides are observed if DHA in the diet is replaced by another omega-3 PUFA EPA, but not the omega-6 PUFA AA (Table 32.2). This treatment also increases the levels of particular proteins known to be localized within pre- and postsynaptic membranes (e.g., synapsin-1, PSD-95) and syntaxin-3 (Fig. 32.2), but not of β-tubulin, a ubiquitously distributed protein (Wurtman et al. 2006; Cansev and Wurtman 2007). As seen in Fig. 32.2, EPA shares the property of enhancing levels of synaptic proteins with DHA, while AA fails to alter such parameters (Cansev and Wurtman 2007).

Table 32.1 Effects of various PUFA, given with a UMP-supplemented diet, on gerbil brain phosphatide levels. Data are nmol/mg protein (From Cansev and Wurtman 2007)

	Total PL	PC	PE	PS	PI
UMP diet + vehicle	332 ± 7	131 ± 2	70 ± 1	29 ± 1	16 ± 1
UMP diet + AA	379 ± 21	132 ± 3	81 ± 6	31 ± 3	20 ± 2
UMP diet + DHA	384 ± 7*	147 ± 3**, y	88 ± 2**	39 ± 2**	22 ± 1**
UMP diet + EPA	407 ± 7***	148 ± 2**, y	91 ± 1***	41 ± 2**, x	25 ± 1***

Groups of gerbils were given a UMP-containing (0.5%) diet, and received by gavage AA, DHA, or EPA (each 300 mg/kg; in a vehicle of 5% gum Arabic solution) or just its vehicle for 28 days. On the 29th day their brains were assayed for phosphatides. Data are given as means ± SEM

*$P < 0.05$, **$P < 0.01$, and ***$P < 0.001$ compared to Control diet + Vehicle group

[x]$P < 0.05$ and [y]$P < 0.01$ compared to UMP diet + AA group by one-way ANOVA

In addition to the findings in adult animals, if the combination of uridine, DHA, and choline is administered chronically to rat dams from prenatal 10th day (E10) through weanling (postnatal 21st day; P21) levels of phosphatides also are increased in brains of weanling rat pups (Cansev et al. 2009) (Table 32.3). Likewise, levels of synaptic proteins (Synapsin-1, mGluR1, and PSD 95) in weanling rat pups also are increased following treatment of their dams chronically with the combination of uridine, DHA, and choline (Cansev et al. 2009) (Fig. 32.3).

32.7 Effects of Phosphatide Precursors on Dendritic Spine Formation and Synaptogenesis in Adult Gerbils and Rat Pups

Numbers of mature dendritic spines in particular brain regions are highly correlated with numbers of synapses (Knott et al. 2006) and it has been proposed (Toni et al. 1999) that "more than 90% of excitatory synapses occur on dendritic spines." This suggests that processes that damage the spines (e.g., β-amyloid; amyloid plaques or that increase spine number; treatment with uridine, DHA, and choline, discussed next) will cause parallel changes in synapse number. The formation of dendritic spines is induced physiologically by synaptic inputs that induce long-term potentiation in CA1 pyramidal neurons, probably mediated by enhanced calcium influx into the postsynaptic neuron.

The effects of administering the phosphatide precursors DHA (300 mg/kg) and uridine (as UMP, 0.5%) on dendritic spine number (in CA1 pyramidal hippocampal neurons) were examined in adult gerbils treated daily for 1–4 weeks; animals received one or both compounds. DHA alone caused dose-related increases in spine density; its effect was doubled if animals also received UMP (Sakamoto et al. 2007) (Fig. 32.4). In contrast, administration of AA with or without uridine had no effect on spine density like its effects on phosphatide or synaptic protein levels. DHA administration has been described as promoting cognition (Hashimoto et al. 2002, 2005) yet its effects on neurotransmission have been obscure. Perhaps its effect on cognition is mediated in part by the increases it produces in numbers of dendritic spines or synapses.

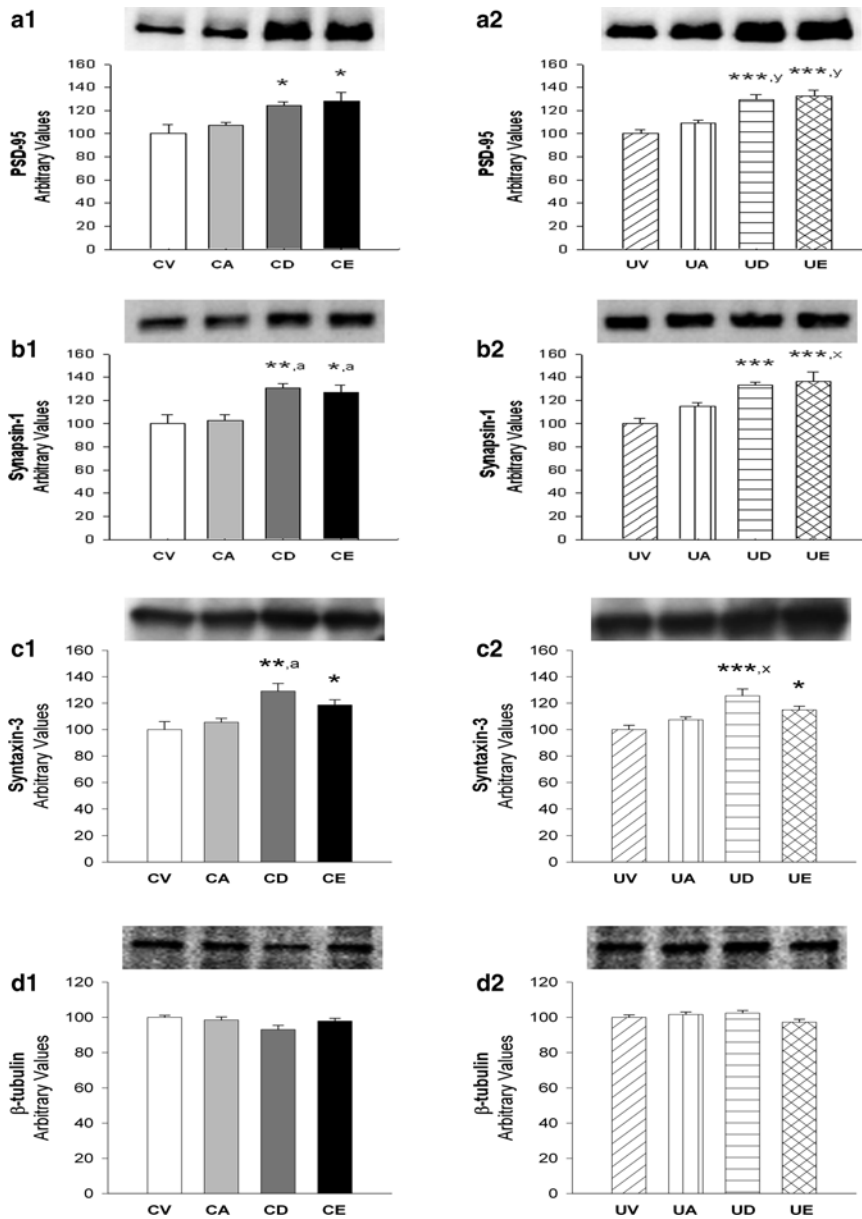
Similar studies were performed on pregnant rats and their offspring (Cansev et al. 2009). The dams consumed UMP, DHA, or both compounds for 10 days prior to parturition and 21 days while nursing. By day 21, brains of weanlings exhibited significant increases in hippocampal dendritic spine density (Cansev et al. 2009) (Fig. 32.5).


Fig. 32.2 Effects of AA, DHA, or EPA, alone or in combination with a UMP-supplemented diet, on levels of the presynaptic or postsynaptic proteins PSD-95 (a1, a2); synapsin-1 (b1, b2) and syntaxin-3 (c1, c2). CV, control diet + vehicle; CA, control diet + AA; CD, control diet + DHA; CE, control diet + EPA; UV, UMP-supplemented diet + vehicle; UA, UMP-supplemented diet + AA; UD, UMP-supplemented diet + DHA; UE, UMP-supplemented diet + EPA. *$P < 0.05$, **$P < 0.01$, and ***$P < 0.001$ compared with CV, and $^{a}P < 0.05$ compared with CA on the left-sided columns (a1, b1, and c1) using one-way ANOVA. *$P < 0.05$, **$P < 0.01$, and ***$P < 0.001$ compared with UV, and $^{x}P < 0.05$ and $^{y}P < 0.01$ compared with UA on the right-sided columns (a2, b2, and c2) using one-way ANOVA (From Cansev and Wurtman 2007)

Table 32.2 Effects of various PUFA, given with a control diet, on gerbil brain phosphatide levels (Data are nmol/mg protein)

	Total PL	PC	PE	PS	PI
Control diet + Vehicle	322 ± 3	113 ± 3	63 ± 3	25 ± 1	15 ± 1
Control diet + AA	326 ± 5	114 ± 1	65 ± 2	28 ± 1	16 ± 1
Control diet + DHA	344 ± 13	133 ± 6*	77 ± 4*	32 ± 2***	18 ± 1*
Control diet + EPA	347 ± 6	125 ± 8	76 ± 4*	31 ± 1**	19 ± 1**,[a]
[b]UMP diet + Vehicle	332 ± 7	131 ± 2*	70 ± 1	29 ± 1*	16 ± 1

Groups of gerbils were given a control diet, and received by gavage AA, DHA, or EPA (300 mg/kg; in a vehicle of 5% gum Arabic) or just its vehicle for 28 days. On the 29th day their brains were assayed for phosphatides. Data are given as means ± SEM

*$P < 0.05$; **$P < 0.01$; and ***$P < 0.001$ compared to Control diet + Vehicle group

[a]$P < 0.05$ compared to Control diet + AA group by one-way ANOVA

[b]Data from gerbils receiving the UMP diet but no PUFA are included in the table to illustrate that uridine alone also affects phosphatide levels.

Table 32.3 Key features of phosphatide precursors

Precursor	Key features
Choline	Choline is a water-soluble essential nutrient and a natural amine that is found in membrane lipids and is a precursor for the neurotransmitter acetylcholine. Choline is found in blood and in tissues.
Uridine	Uridine is a pyrimidine nucleoside which is involved in syntheses of nucleic acids, glycogen, membrane phosphatides, and is a ligand to various P2Y receptors after being phosphorylated to UDP or UTP. Uridine is the major circulating pyrimidine in humans.
Cytidine	Cytidine is a pyrimidine nucleoside which, after being phosphorylated to CTP within the cell, determines the usual limiting step in phosphatide synthesis. Cytidine is almost undetectable in human blood and its nucleotides have not yet been shown to activate P2Y receptors to an extent that can induce a cellular response.
DHA	DHA is an omega-3 essential fatty acid with a 22-carbon chain and 6 *cis* double bonds (22:6n−3). It is found in fish oil and small amounts can be synthesized from alpha-linolenic acid. DHA is incorporated into sn-2 position of phosphatides thus serving as a phosphatide precursor. It is essential in the development of nervous system and retina and is known to help lower heart disease.
EPA	EPA is an omega-3 essential fatty acid with a 20-carbon chain and 5 *cis* double bonds (20:5n−3). It is found in fish oil and small amounts can be synthesized from alpha-linolenic acid. EPA also serves as a phosphatide precursor by incorporating into sn-2 position of phosphatides.
AA	AA is an omega-6 essential fatty acid that has a 20-carbon chain and 4 *cis* double bonds (20:4n−6). AA can be obtained from dietary animal sources and be synthesized in the body from linoleic acid.

Key facts of phosphatide precursors have been listed

32.8 Effects of Uridine or UMP on Neurotransmitter Release

Consumption by rats of a diet containing uridine (as UMP) and choline can increase dopamine (DA) and ACh levels in, and – as assessed using in vivo microdialysis – their release from, corpus striatum neurons. Dietary supplementation of aged male Fischer 344 rats with 2.5% w/w UMP for 6 weeks, ad libitum, increased the release of striatal DA that was evoked by potassium-induced depolarization from 283 ± 9% in control rats to 341 ± 21% in those receiving the UMP ($P < 0.05$; Wang et al. 2005). Giving both uridine and DHA amplifies uridine's effect on dopamine levels (Cansev et al. 2008).

In general, each animal's DA release correlated with its striatal DA content, measured postmortem. The levels of neurofilament-70 and neurofilament-M proteins, two markers of neurite outgrowth, were also increased after UMP treatment, to 182 ± 25% of control levels for the neurofilament-70 ($P < 0.05$) and to 221 ± 34% ($P < 0.01$) for the neurofilament-M (Wang et al. 2005).

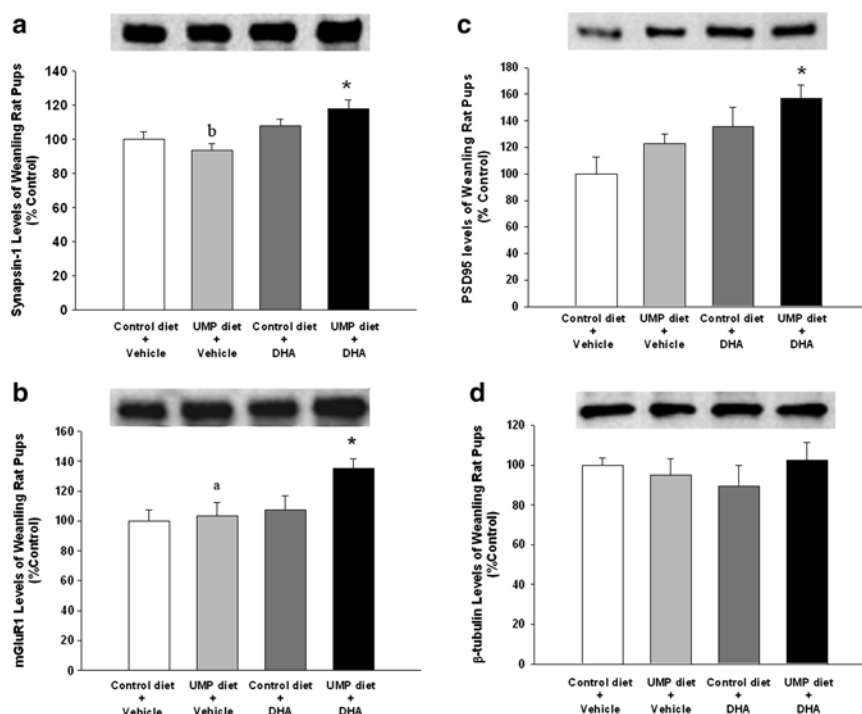
In a similar microdialysis study, ACh release, basally as well as after administration of atropine (a muscarinic antagonist which blocks inhibitory presynaptic cholinergic receptors), was found to be enhanced following UMP consumption. Among aged animals consuming a 2.5% diet for 1 or 6


Fig. 32.3 Levels of synaptic proteins in weanling pups (P21). Dams were treated and brains of weanling pups were obtained. Samples were analyzed for (**a**) synapsin-1, (**b**) mGluR1, (**c**) PSD-95, and (**d**) β-tubulin using Western Blotting. $N = 6$ per each group. *$P < 0.05$ compared with "Control" group and [a]$P < 0.05$, [b]$P < 0.01$ versus "UMP diet + DHA" group using one-way ANOVA followed by Tukey's test. (From Cansev et al. 2009)

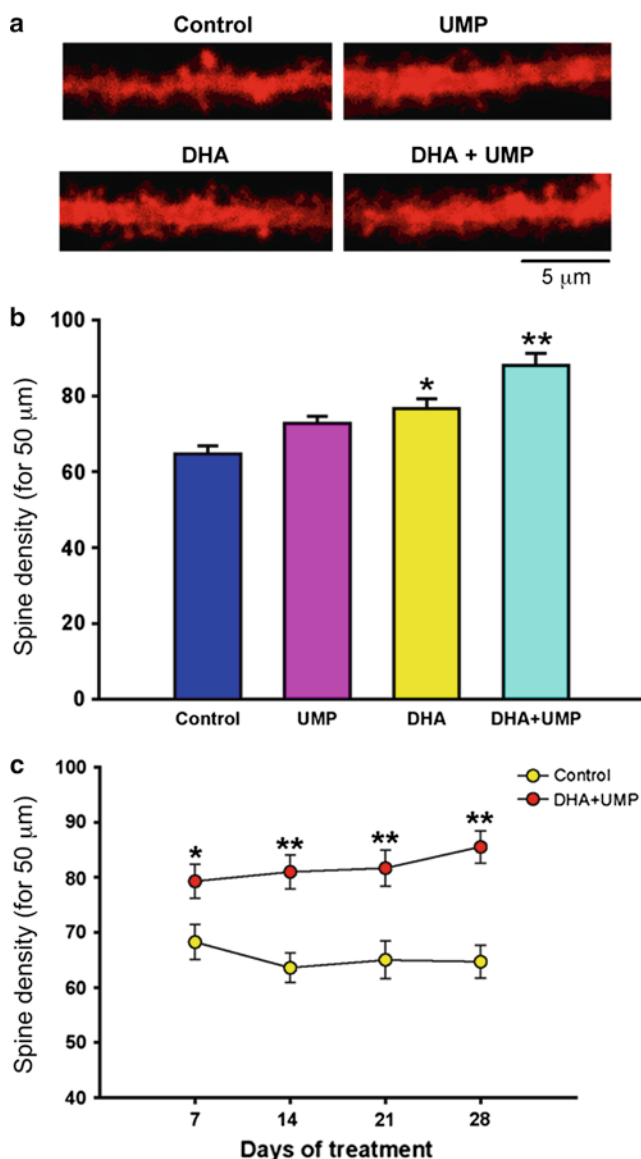
weeks, baseline ACh levels in striatal microdialysates rose from 73 to 148 fmol/min after 1 week of treatment ($P < 0.05$), and to 197 fmol/min after 6 weeks ($P < 0.05$) (Wang et al. 2007). A lower dose of dietary UMP (0.5%, 1 week) also amplified the increase in ACh release caused by giving atropine (10 μM, via the artificial CSF); atropine alone increased ACh concentrations from 81 to 386 fmol/min in control rats and from 127 to 680 fmol/min in those consuming UMP ($P < 0.05$; Wang et al. 2007). Young rats eating the UMP-containing diet exhibited similar responses. These data suggest that giving a uridine source may enhance some cholinergic functions, perhaps by increasing the amount of synaptic membrane, or the quantities of ACh stored in synaptic vesicles. Apparently, no data are available on effects of UMP plus DHA on neurotransmitter release.

32.9 Possible Involvement of Uridine-Nucleotide-Stimulated P2Y Receptor Activation

Administration of uridine results in increased levels of cellular proteins, specifically of certain pre- and postsynaptic neuronal proteins most likely by a second mechanism in which uridine's phosphorylated products act as ligands for P2Y receptors which then activate protein synthesis and normal neuronal differentiation.

Extracellular nucleotides can serve as ligands for various ionotropic P2X and metabotropic P2Y receptors. While P2X receptors recognize adenine nucleotides, P2Y receptors can recognize both adenine and uridine nucleotides. Members of the P2Y family, G-protein-coupled receptors, are

Fig. 32.4 Dendritic spine formation in adult gerbil hippocampus is enhanced by cosupplementation of DHA with UMP. (**a**) Apical dendrites of CA1 pyramidal neurons. (**b**) DHA supplementation increased spine density (by 19%, *$P = 0.004$ vs Control); both DHA and UMP caused a greater increase (by 36%, **$P < 0.001$ vs Control or by 17%, $P = 0.008$ vs. DHA). $n = 20–25$ neurons from four animals per group. One-way ANOVA followed by Tukey's test. (**c**) The treated groups received both UMP (0.5%) and DHA (300 mg/kg) daily for 1, 2, 3, or 4 weeks; the control groups were given only a regular diet. $n = 12–20$ neurons from two animals per group. Two-way ANOVA followed by Tukey's test. *$P = 0.02$ and **$P < 0.001$ (From Sakamoto et al. 2007)


widely distributed throughout the body, including in the brain (Burnstock 2007). To date, eight P2Y receptors of human origin (P2Y1, 2, 4, 6, 11, 12, 13, 14) have been cloned and characterized (Abbracchio et al. 2006).

P2Y receptors that recognize adenine but not uridine nucleotides, and comprising the P2Y1, P2Y11, P2Y12, and P2Y13 subtypes, exist principally outside the brain (Abbracchio et al. 2006). P2Y2 receptors, in contrast, are abundant in brain and are activated by UTP or ATP; P2Y4 receptors are activated by UTP, and P2Y6 receptors by UDP (Abbracchio et al. 2006). Their activation, through coupling to phospholipase C (PLC), increases intracellular concentrations of DAG, IP3, and calcium (Cansev 2007).

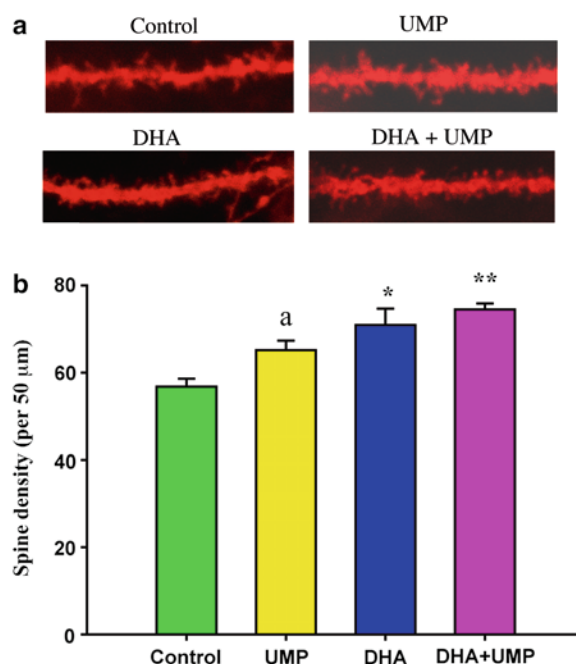
That uridine nucleotides affect both neurite outgrowth and neuronal differentiation by stimulating P2Y receptors has been demonstrated mainly by using in vitro assay systems (Cansev 2007). UTP increases neurite outgrowth by Nerve Growth Factor-stimulated PC-12 cells and the expression of some neurofilament proteins (Pooler et al. 2005). The uridine nucleotides also cause receptor-mediated neuronal proliferation and differentiation (e.g., of dopaminergic neurons during development [Milosevic et al. 2006]),


Fig. 32.5 Hippocampal dendritic spine density in weanling pups (P21). Rat dams received UMP (0.5%), DHA (300 mg/kg), or both daily from E10 to P21 (weaning); their pups were examined for CA1 spine density at P21. (**a**) Apical dendrites of CA1 pyramidal neurons. (**b**) Changes in dendritic spine density following UMP and/or DHA administration. $*P < 0.01$ and $**P < 0.001$ compared with the "Control" group and $^aP < 0.05$ versus "UMP diet + DHA" group using one-way ANOVA followed by Tukey's test. $n = 15–21$ neurons from 4 animals per group (From Cansev et al. 2009)

and can mediate signaling events such as release of the neurotransmitters noradrenaline and glutamate (Boehm et al. 1995; Von Kugelgen et al. 1999), long-term potentiation (Price et al. 2003), and neuroprotection (Cansev 2007). Such P2Y-receptor-mediated actions could argue for the possible utility of P2Y agonists in enhancing learning and memory and in treating Alzheimer's disease, especially since P2Y2 receptors are known to be deficient in parietal cortex of Alzheimer's disease brains (Lai et al. 2008).

32.10 Conclusions

Chronic oral administration of membrane phosphatide precursors – uridine, DHA, and choline – enhances learning and memory and improves diminished cognitive performance in both experimental animals as well as patients with Alzheimer's disease. The enhancement in cognitive performance is likely to be resulted from biochemical and structural changes in the brain. The three Kennedy cycle enzymes that catalyze the formation of brain phosphatides from circulating precursors, and the proteins that take up uridine into the brain and convert it to UTP and CTP, all have low affinities for these substrates and are thus unsaturated. Hence administering these substrates can accelerate the biosynthesis, and elevate brain levels of membrane phosphatides. Moreover brain levels of pre- and postsynaptic proteins and, ultimately, the quantity of synaptic membrane and the formation of additional dendritic spines, and, therefore, numbers of synapses are elevated in animals after such treatment. Since this treatment revealed promising improvements in cognitive functions of Alzheimer's patients in a recent clinical trial, it is reasonable to hypothesize that the treatment results in similar biological changes, leading to enhanced learning and memory in human brain as well.

32.11 Applications to Other Areas of Health and Disease

Although this review focused specifically on the role of phosphatide precursors-induced synaptogenesis in the enhancement of learning and memory, stimulation of membrane phospholipid synthesis and promotion of synaptogenesis in the brain could have several applications to other areas of health and disease. Availability of these precursors (i.e., choline, DHA, and uridine/cytidine) in sufficient amounts is particularly important during the prenatal and postnatal period for normal development of the human brain. Human breast milk contains these precursors in high amounts and their supplementation through infant formulas to preterm and term infants may also be beneficial for normal development and in enhancing long-term learning and memory. By increasing membrane synthesis, phosphatide precursors could prevent, slow, and/or restore the decline in several brain functions that occur physiologically in normal aging due to progressive neuronal and synaptic loss. In addition, since most neurodegenerative diseases are associated with membrane breakdown and loss of neurons and synaptic structures, chronic treatment with phosphatide precursors may also be beneficial in treatment of Parkinson's disease, as well as metabolic, toxic, and ischemic/traumatic brain injuries. Phosphatide precursors affect neuroinflammation and immunity by altering the rate and amount of production of phospholipid-derived lipid mediators (i.e., prostaglandins, resolvins, docosatrienes, neuroprotectins, lysophosphatidylcholine) in brain.

Some of these phosphatide precursors, i.e., DHA and choline, also alter inflammation in the periphery and protect organs from metabolic, toxic, ischemic, and traumatic insults. Dietary intake of DHA and/or choline modulates carcinogenesis and development of atherosclerosis. DHA has important roles in health and disease of retina (i.e., increases visual acuity and protects retinal ganglion cells from toxic insults).

Choline, by acting as a precursor of the neurotransmitter acetylcholine, may increase cholinergic neurotransmission in the central and peripheral cholinergic synapses and may help improve cholinergic functions. Choline, by acting as a methyl donor, alters methylation and related epigenetic effects on gene expression and DNA repairs.

Uridine prevents mitochondrial, hepatic, and hemotopoetic toxicity during antiretroviral drug therapy.

Summary Points

- Chronic oral treatment with phosphatide precursors uridine, DHA, and choline enhances learning and memory in experimental animals, as well as humans with Alzheimer's disease.
- The treatment enhances the amount of membranes in brains of adult and developing rodents.
- The treatment enhances the amount of synaptic proteins in brains of adult and developing rodents.
- The treatment also increases the numbers of dendritic spines in brains of adult and developing rodents.
- Treatment with uridine or UMP stimulates the release of certain neurotransmitters in brains of adult rats.
- These observations suggest that such cognitive functions as learning and memory are enhanced via enhanced synaptogenesis in rodent brain.
- Such morphological alterations are likely to occur in human brain since impaired cognitive functions were partly restored in patients with Alzheimer's disease by the treatment.

Key Terms

Phosphatide: Naturally occurring phospholipids that are derivatives of glycerol phosphate and which normally contain a nitrogenous base. Phosphatides include phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, and phosphatidylinositol Phosphatidylcholine is the most abundant phosphatide in brain membranes.

Polyunsaturated fatty acid: Fatty acids which have more than 2 *cis* double bonds which are separated from each other by a single methylene group. The essential fatty acids are all omega-3- and -6 methylene-interrupted fatty acids. Omega-3 fatty acids have a double bond three carbons away from the methyl carbon, whereas omega-6 fatty acids have a double bond six carbons away from the methyl carbon. Most studied omega-3 or omega-6 polyunsaturated fatty acids include alpha-linolenic acid (ALA; 18:3n−3), eicosapentaenoic acid (EPA; 20:5n−3), and docosahexaenoic acid (DHA; 22:6n−3) or linoleic acid (LA; 18:2n−6) and arachidonic acid (AA; 20:4n−6).

Synapse: Junctions through which neurons signal to each other and to non-neuronal cells such as those in muscles or glands. Synapses allow neurons to form circuits within the central nervous system. They are essential to biological processes that underlie perception, thought, and memory.

Dendritic spine: Postsynaptic structures which are precursors to mature synapses. A dendritic spine is a small membranous protrusion from a dendrite that receives input from a single synapse of an axon. They serve as a site for synaptic strength and help transmit electrical signals to the neuron's cell body.

Synaptogenesis: Formation of synapses. Brain synapses are formed by a presynaptic bouton (i.e., the terminal site of an axon) and a postsynaptic spine (i.e., the dendritic spine).

Chapter 33
Gender Differences in Brain Activation by Food Stimulation

Gene-Jack Wang, Nora D. Volkow, Frank Telang, Panayotis K. Thanos, and Joanna S. Fowler

Abbreviations

BMI   Body mass index
BOLD   Blood oxygen level dependent
DA   Dopamine
FDG   2-deoxy-2-[^{18}F]fluoro-d-glucose
fMRI   Functional magnetic resonance imaging
PET   Positron emission tomography
SPM   Statistical parameter mapping

33.1 Introduction

Human appetite control and weight regulation are modulated by the nutritional need, hedonic influences over eating, and responses to stress. Obesity can derive from a variety of causes (i.e., genetic, cultural, nutrition intake, physical activity). Of particular relevance is the environment, which has made food not only widely available but also increasingly more varied and palatable. It is likely that a gene–environment interaction(s) (in which genetically susceptible individuals respond differently to an environment with increased availability of palatable energy-dense foods and reduced opportunities for energy expenditure) contribute to the current high prevalence of obesity.

Gender is another contributing factor to obesity. Gender differences in the prevalence of obesity have been reported in the USA and in many countries of the world. In the USA, the last National Health and Nutrition Examination Survey reported overall prevalence rates of obesity in adult women (35.3%) that did not differ from those in men (33.3%) but reported much higher rates in African American (54% vs 34%) and Hispanic (42% vs 32%) women (Ogden et al. 2006). Similarly, reports from the WHO and the International Obese Task Force (IOTF 2008) document significantly higher rates of obesity in women than in men. There are many factors (i.e., hormones, frequent dieting, stress reactivity, socioeconomic status, physical activity; Matheson et al. 2008), which may contribute to the difference. Several studies had previously reported that women, when compared with men, more frequently attempt to lose weight, have significantly higher disinhibition scores (Matheson

e-mail: gjwang@bnl.gov

et al. 2008), and report having higher scores on measures of dietary helplessness and disinhibition in weight control programs (Carmody et al. 1995; Provencher et al. 2004). Obesity-related metabolic disorders are much lower in premenopausal women than men; however, there is a dramatic increase following menopause in women (Shi et al. 2009). Understanding the mechanism(s) contributing to overeating behaviors in women can provide a scientific basis for pharmacological and behavioral approaches to its prevention and treatment.

In this chapter we explore and answer the following questions: What gender differences contribute to the desire to eat and to inhibition of the desire to eat? Answers to these questions will be described based on findings from brain imaging experiments and from relevant preclinical studies.

33.2 Gonadal Steroid Hormones and Food Intake

There are very few overt gender differences in eating behavior. Meal size and meal frequency are similar between females and males in both humans and rodents. Body size estimates tend to match total energy intake and energy expenditure in both sexes. However, women display higher rates of morbid obesity (BMI > 40) than men (Ogden et al. 2006; IOTF 2008). Gonadal steroid hormones (i.e., the androgens, estrogens, and progestins) have many actions that might affect body weight and adiposity independent of eating (i.e., energy expenditure, gastrointestinal function, metabolism, growth, body composition; Asarian and Geary 2006). The mechanisms underlying these effects and their relation to eating are unknown. A functional neuroimaging study showed great similarity between men and women in response to fasting and satiety. The study found greater perfusion of subcortical regions in men during fasting and greater perfusion in occipital and parietal sensory associated regions in women during satiety. It has also been reported that total energy intake varies during the menstrual cycle (Del Parigi et al. 2002).

Rodent and human studies reported that females eat less during the peri-ovulatory phase of the ovarian cycle. The highest food intake occurs in the luteal phase, which has been demonstrated both in primate and human studies (Reimer et al. 2005). This pattern was not seen in women using hormone replacement preparations or in those with anovulatory cycles. Women were reported to prefer sweet foods with a higher carbohydrate and a higher fat content; they also appear to eat more sweets during the luteal phase of the cycle than other phases, which has been ascribed to increases in estradiol and progesterone (Fong and Kretsch 1993).

33.3 Food-related Cues and Eating Behavior

Emotional responses to food are important influences on food intake. An increasing proportion of human food consumption appears to be driven by pleasure and not just nutritional needs. Food ingredients such as glucose modulate dopamine (DA) neuronal activity directly in the ventral tegmental area and substantia nigra (Levin 2000). DA is a neurotransmitter that is known to play a major role in motivation and is involved with reward and prediction of reward. Daily bingeing on sugar repeatedly releases DA in the nucleus accumbens (Avena et al. 2009). A human PET study with [^{11}C]raclopride that measured DA release in the striatum following blind intravenous administration of glucose solution (300 mg/kg) showed significant DA release in fasting men but not in women (Haltia et al. 2007).

Sensory processing of food and food-related cues also plays an important role in the motivation for food and it is especially important in the selection of a varied diet. The hedonic reward value of food is

closely linked to the sensory perception of the food. DA in these brain regions is associated with sensory perception of food (Rolls 2007). An imaging study showed that DA release in the striatum follows the consumption of a favorite food and the amount of striatal DA release correlated with the ratings of meal pleasantness (Small et al. 2003). It is likely that the reinforcement related to eating is not only associated with food ingredients (i.e., sugar) but also with other stimuli (i.e., sensory experience of food). The hedonic value of a food is modulated by the motivational state of the individual. Sensory inputs of taste, vision, olfaction, temperature, and texture are first sent to the primary sensory cortices (i.e., insula, primary visual cortex, pyriform, primary somatosensory cortex) and then to the orbitofrontal cortex and amygdala (Rolls 2007). Recently, a preclinical study from our laboratory (Thanos et al. 2008) examined rats under food stimulation with micro-PET and FDG showed activation in the hippocampus, a region involved in memory, the insular cortex, a region involved with interoception (perception of internal sensations), the medial thalamus (region involved in alertness), and in regions involved with sensory perception (olfactory bulb, olfactory nucleus, occipital cortex, superior colliculus, and parietal cortex), which corroborates their relevance in the perception of food.

Food deprivation potentiates the rewarding effects of food (Cameron et al. 2008). During fasting, the role of DA is not selective for food but rather signals the salience for a variety of potential biological rewards and cues that predict rewards (Carr 2007). Chronic food deprivation also potentiates the reinforcing effects of most addictive drugs (Carr 2002). The striatum, orbitofrontal cortex, and amygdala, which are brain regions receiving DA projections are activated during the expectation of food. Using PET and FDG with food-related cue paradigm (visual, olfactory, and gustatory display of food without eating in food deprived subjects) we showed that cues increase DA in dorsal striatum in fasting (14–16 h) normal weight men and women (Volkow et al. 2002). Exposure to food cues increased metabolism in orbitofrontal cortex (Fig. 33.1) and these increases were associated with the perception of hunger (Fig. 33.2) and the desire for food (Wang et al. 2004) in men and women. The enhanced orbitofrontal cortex activation by the food stimulation is likely to reflect downstream dopaminergic effects and is likely to participate in DA's involvement in the drive for food consumption. The orbitofrontal cortex also participates in learning stimulus-reinforcement associations and conditioning including conditioned cues eliciting feeding. Thus, its activation secondary to food-induced DA stimulation could result in an intense motivation to consume food. Dysfunction of the orbitofrontal cortex is associated with compulsive behaviors including overeating. This is relevant because food-induced conditioned responses very likely contribute to overeating irrespective of hunger signals.

Excessive and repeated food intake in obese subjects might lead to a downregulation of DA signaling in the reward circuitry. An fMRI study looking at consumption of anticipated food showed decreased activation in the caudate nucleus in response to food consumption in adolescent obese women (Stice et al. 2008). Thus, hyposensitivity to food stimuli in brain regions modulated by DA in obese individuals could increase their risk of overeating. In fact our (Wang et al. 2001) and other (Haltia et al. 2007) PET studies with [^{11}C]raclopride have previously documented a reduction in striatal D2/D3 receptor availability in obese subjects that was inversely related to BMI.

33.4 Gender Differences in Response to Food Cues

Gender differences in sensory experience of food might contribute to eating behaviors. A study that showed photographs of food revealed that both men and women reported pleasant responses to food that were associated with ratings of hunger in a nonfasting state. However, fasting enhanced the pleasantness of food images to a greater extent in women than in men (Stoeckel et al. 2007). Similar results were reported in an fMRI study; women had greater reactivity to food stimuli in brain regions

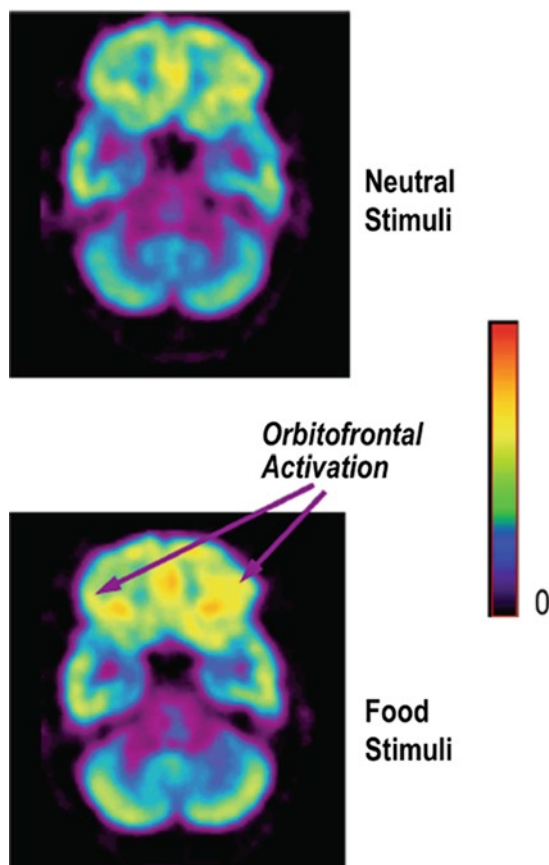
Fig. 33.1 PET-FDG brain images of food stimulation. Transaxial PET-FDG brain images of a male subject during food stimulation and during neutral stimulation at levels of orbitofrontal cortex. The metabolic images for both scans are scaled with respect to the maximum absolute metabolic value obtained on the neutral intervention and presented using the rainbow scale where red represents the highest value and dark violet represents the lowest value. (Adapted from NeuroImage (Wang et al. 2004))


Fig. 33.2 Correlation analysis of food stimulation. Correlation between changes in right orbitofrontal metabolism and self-report rating of hunger was significant ($r = 0.84$, $p = 0.001$) (Adapted from NeuroImage (Wang et al. 2004))
that process visual and taste sensations after 24 h of fasting (Uher et al. 2006). Responses in the occipital visual-related cortex to visual stimuli and in the insula and prefrontal cortex to taste stimuli were stronger in women than in men.

Using our food stimulation paradigm (presentation of palatable food without consumption) with PET-FDG after 14–16-h fasting (Wang et al. 2004), we observed a greater reactivity in the right anterior prefrontal and left orbitofrontal cortex in women than in men (Fig. 33.3) during food stimulation
Fig. 33.3 Gender differences in food stimulation. SPM results ($p < 0.05$) for the difference between women and men during food stimulation without cognitive inhibition. Color-coded SPM results are displayed in a transaxial plane superimposed on a structural brain MR image. The results (T value) are presented using the color scale where blue represents deactivation as a result of lesser metabolic activation in men than women (Adapted from PNAS (Wang et al. 2009a))

(Wang et al. 2009a). The prefrontal dorsolateral cortex is associated with attention/alertness, working memory, and with inhibition of intentional actions, whereas the orbitofrontal cortex is associated with salience attribution to reinforcers (e.g., food). The greater activation of the prefrontal cortex and orbitofrontal cortex in the women during food stimulation could reflect the modulation of these brain regions by gonadal steroid hormones. Indeed in women, activation of the frontal cortex during a working memory task is associated with estradiol levels in the menstrual cycle. fMRI studies have also shown that estrogen levels modulate the responses of brain regions that process emotions and reward signals (Dreher et al. 2007). Thus, these findings suggest that estrogen may have contributed to the gender differences in the regional brain responses during food stimulation.

When a certain food is eaten, the pleasant responses to the food item and motivation to eat gradually decrease. One may still motivate to consume other food items, particularly those foods with different sensory characteristics (Rolls 2007). It is likely that highly palatable foods can override internal homeostatic mechanisms through action on brain DA pathways (i.e., orbitofrontal cortex) and lead to overeating and obesity (Batterham et al. 2007). When food is ingested, the feeling of fullness increases and the motivation to eat decreases. The effect of satiation on brain activation has been reported for visual, olfactory, and gustatory stimuli. Brain regions particularly orbitofrontal cortex significantly decreased after satiation (Rolls 2007). An fMRI study assessed gender differences in taste of chocolate before and after eating chocolate until the subjects were satiated (Smeets et al. 2006). When satiated, men had less response to taste activation in the hypothalamus than women. The decreased activation in hypothalamus could reflect the decrease in hunger. Chocolate satiation was associated with a greater decrease in taste activation in orbitofrontal cortex, ventral striatum, and medial prefrontal cortex in men than in women. The study suggests that women are more affected than men by the hedonic value of food.

33.5 Gender Differences in Cognitive Inhibition During Food Stimulation

The decisions to eat are complex and involve higher brain function circuits (i.e., prefrontal cortices). Impaired cognitive function (i.e., inhibitory control) may contribute to behavioral disorders such as addiction and pathological overeating (Goldstein et al. 2009). We evaluated the responses of the

brain when subjects were exposed to highly desirable food either with or without a prior directive to suppress the desire for food (cognitive inhibition) in men and women (Wang et al. 2009a). Regional brain metabolic responses to food stimulation with and without cognitive inhibition were assessed with PET and FDG. Specifically with cognitive inhibition as compared with no inhibition the male subjects showed significant decreases in anterior cingulate, left orbitofrontal cortex, left amygdala, and right striatum (Fig. 33.4a), which are regions involved in emotional regulation, conditioning, and motivation. These regions, which decreased metabolism, had been shown by prior studies to be activated by food stimuli when presented via pictures, smells, taste, recall, or a combination of these. The suppressed activation of the orbitofrontal cortex with inhibition was also associated with decreases in self-reports of hunger (Fig. 33.5a), which corroborates the involvement of this region in processing the conscious awareness of the drive to eat. This finding suggests a mechanism by which cognitive inhibition decreases the desire for food.

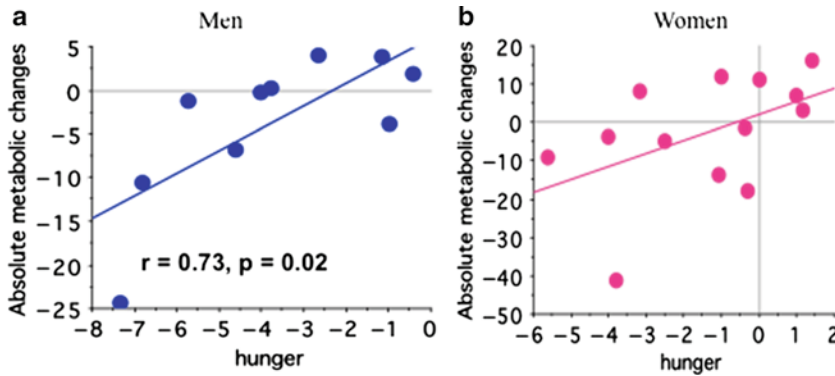
Using the same food stimulation paradigm with PET-FDG, we found a significant gender difference (Fig. 33.4) in the regional brain responses to cognitive inhibition (Wang et al. 2009a). In women, different from what was observed in men, the decrease in the self-reports of hunger was not paralleled by deactivation in limbic and paralimbic brain regions (Fig. 33.5b). Our findings of a lack of response to cognitive inhibition in women are consistent with behavioral studies showing significantly higher scores in disinhibition (tendency to overeat in response to food stimuli when presented with palatable food or under emotional distress) in women than in men (Matheson et al. 2008;
Fig. 33.4 Gender differences in purposeful cognitive inhibition of the desire for food during food stimulation. SPM images ($p < 0.01$) of cognitive inhibition during food stimulation (comparison between food stimulation with and without cognitive inhibition) in women (**b**) and in men (**a**). Color-coded SPM results are displayed in a transaxial plane superimposed on a structural brain MR image. The results (*T* value) are presented using the color scale where blue represents deactivation as a result of cognitive inhibition. (**c**) The SPM results ($p < 0.01$) for the difference between women (**b**) and men (**a**), showing the areas where males showed greater decrements with cognitive inhibition than females. Women did not show showed greater metabolic decrements than men during cognitive inhibition for any of these regions (Adapted from PNAS (Wang et al. 2009a))


Fig. 33.5 Correlation analysis of cognitive inhibition. Correlation analysis between the differences in the behavioral and regional brain metabolic changes induced by the food stimulation with and without cognitive inhibition revealed that they were significant for the changes in self-reports of hunger and the changes in the orbitofrontal cortex ($r = 0.73$, $p = 0.02$); the greater the suppression in metabolism the greater the decreases in the self-reports of hunger in men (**a**). This correlation did not reach significance in women ($r = 0.49$, $p = 0.09$) probably due to the modest sample size (**b**) (Adapted from PNAS (Wang et al. 2009a))

Provencher et al. 2004). The decreased inhibitory control in women could underlie their lower success in losing weight while dieting when compared with men.

Sex hormones directly influence food intake, body weight and fat distribution, and modulate the signaling of leptin and insulin. Leptin concentrations increased significantly during the luteal phase as compared with the follicular phase (Anim-Nyame et al. 2000). Indeed female rats are more sensitive to the anorexic effects of leptin than male rats. Leptin in the brain enhances the response to satiety signals and decreases perception of food reward during food consumption (Kruge et al. 2003). Leptin also modulates food-related mesolimbic sensitivity to visual food stimulation (Farooqi et al. 2007). Furthermore, gonadal steroid hormones affect neurotransmitter turnover in prefrontal regions and in the ventral tegmental area, where DA cells are located. Female gonadal hormone levels fluctuate during the rat estrous cycle affecting the release and reuptake of neurotransmitters (i.e., DA, serotonin, and norepinephrine) that are involved in satiety and motivation to eat (Thompson and Moss 1997). Several studies have reported increases in appetite and food intake during luteal phase of the menstrual cycle when estrogen and progesterone are high (Reimer et al. 2005).

33.6 Applications to Other Areas of Health and Disease

Obesity is becoming an increasing public health problem. This has triggered the high prevalence rates of dieting seen as an attempt to confront a vast array of highly desirable food products and heavily promoted foods. Obesity is associated with abnormal eating behaviors. Brain imaging studies show that obese individuals have significant deficits in circuits that regulate abnormal eating behaviors (i.e., motivation, reward, emotion, learning, memory, and inhibitory control; Wang et al. 2009b). Women more frequently diet but are less successful in weight control program than men. Brain imaging studies showed that female sex hormones modulate brain regions related to reward response and women had greater reactivity to food stimuli in brain regions that process sensations and salience attribution. Women lacked the ability to inhibit the activation of brain regions involving emotional regulation, conditioning, and motivation during food stimulation even when they attempted to do so (Wang et al. 2009a). This may underlie their inability to control food intake when exposed to highly palatable food.

The regular hormone fluctuations that are associated with the menstrual cycle influence appetite control and eating behavior. These cyclic variations might affect regional brain responses to favorite foods and the ability to exert inhibitory control. The gender differences in eating behaviors are likely to reflect the confluence of peripheral metabolic signals (i.e., leptin, insulin, ghrelin), female sex hormones (i.e., estrogen, progesterone, luteinizing hormone), and reactivity of neuronal circuits. Understanding the relationships between these circuits, their neuromodulation by food stimulation, peripheral metabolic markers, and the overall impact on hunger and desire for food, may be helpful in devising strategies to counteract the overwhelming salience that palatable food has on women to help reduce overeating behaviors.

Summary Points

- Exposure to food cues increased DA in dorsal striatum and increased metabolism in orbitofrontal cortex in normal weight individuals. These increases were associated with the perception of hunger and the desire for food.
- Women had greater activation in brain regions associated with attention/alertness, working memory (i.e., prefrontal cortex), and with salience attribution to food (i.e., orbitofrontal cortex) during food stimulation than men.
- Men when exposed to food cues with cognitive inhibition decreased activation in limbic and paralimbic brain regions involved in emotional regulation, conditioning, and motivation.
- Women when exposed to food cues with cognitive inhibition did not decrease activation in limbic and paralimbic brain regions. The decreased inhibitory control in women could underlie their lower success in losing weight while dieting when compared with men.
- The results of imaging studies have the potential to facilitate understanding the mechanisms underlying obesity and gender-related overeating behaviors as well as the development of strategies for prevention and treatment.

Definitions and Explanations

[^{11}C]raclopride: A dopamine D2/D3 receptor radioligand that measures D2/D3 receptor availability. Since it binds reversibly to D2/D3 receptors, it can be used to measure changes in extracellular dopamine.

Dopamine: A neurotransmitter that is known to play a major role in motivation and is involved with reward and prediction of reward.

FDG (2-deoxy-2-[^{18}F]fluoro-D-glucose): A radiotracer which measures brain glucose metabolism.

Functional magnetic resonance imaging (fMRI): An imaging method that measures changes in neural activity levels in the brain in response to various stimulations. fMRI measures the vascular correlate of neuronal activity via the blood oxygen level-dependent (BOLD) signal.

Positron emission tomography (PET): Imaging method that measures the distribution and movement of radiolabeled compounds in the living human and animal body. With these methods, it is possible to measure the distribution and concentration of many receptors, transporters, and enzymes in the human brain as well as cerebral blood flow and glucose metabolism (Table 33.1).

Statistical parameter mapping (SPM): A statistical method for studying differences in brain activity obtained during functional neuroimaging experiments using fMRI or PET.

Table 33.1 Key features of positron emission tomography

- Positron emission tomography (PET) is an imaging method that measures the distribution and movement of radiolabeled compounds in the living human and animal body.
- PET measures the distribution and concentration of many receptors, transporters and enzymes, and labeled drugs in the human brain as well as cerebral blood flow and glucose metabolism.
- PET with [^{11}C]raclopride has been used to measure brain dopamine D2 receptor availability in obese individuals. The imaging methods with food stimulation paradigms such as consumption of palatable food or food presentation (presentation of palatable food without consumption) are used to assess the association of brain dopamine function and eating behaviors.
- PET with FDG (2-deoxy-2-[^{18}F]fluoro-d-glucose), a radioactive glucose analog, measures brain glucose metabolism. It has been used to assess brain function in obese individuals during fasting state and gender differences in baseline (no stimulation) condition. With food stimulation paradigms, PET-FDG scan measures brain circuits involved during eating behaviors and cognitive function.
- PET with O-15 water measures cerebral blood flow, which was used to assess brain circuits during stimulation paradigms involving food intake (i.e. glucose), eating disorders, and obesity.

This table lists the key features of using PET to investigate effects of food stimulation in humans, including brain dopamine function and brain circuits involved in eating behaviors

Chapter 34
Food Perception in Adults: Neuroimaging Findings

Alexandra P.F. Key, Evonne J. Charboneau, and Ronald L. Cowan

Abbreviations

BA   Brodmann area
BOLD   Blood oxygen level dependent
EEG   Electroencephalogram
ERP   Event-related potential
fMRI   Functional magnetic resonance imaging
PET   Positron emission tomography
PFC   Prefrontal cortex
PWS   Prader-Willi syndrome

34.1 Introduction

Over the past 20 years, research in the area of diet, nutrition, and general food perception has expanded from relying primarily on behavioral measures to also include brain-based assessments. Examination of brain processes associated with perception of food stimuli provides information about the areas of the brain involved in processing specific food characteristics (e.g., visual appearance, smell, taste) and how these perceptual processes may differ based on internal physiological states as well as personal choices and beliefs. Neurophysiological measures can also help disambiguate the contributions of hunger and appetite, sensory systems (e.g., sensitivity to smell) or higher cognitive functions (e.g., attention, motivation, emotion regulation) to typical and atypical behavioral responses to food. Another important contribution of brain imaging techniques is their ability to provide information about perceptual and other cognitive processes even in the absence of overt verbal or motor responses. These characteristics make neuroimaging methods especially valuable for studying processes that may not be adequately captured by behavioral assessments due to response bias (e.g., tendency to provide socially desirable answers) or insufficient cooperation (e.g., lack of motivation, limited communication skills, or poor comprehension of the instructions).

Table 34.1 Key features of neuroimaging

1. Neuroimaging refers to a collection of techniques for documenting brain structures and their activity in a live human.
2. Many neuroimaging techniques are noninvasive, can be obtained from persons of any age, and do not require an overt behavioral response.
3. Neuroimaging techniques vary in the type of signal source (e.g., electrical, magnetic, or chemical), temporal resolution, and spatial resolution.
4. Psychophysiological measures (EEG/ERP) reflect electrical activity of groups of neurons firing in temporal synchrony and offer the best temporal resolution (millisecond level) but limited spatial resolution (~2 cm). These measures are best suited for studying the speed and overall time course of sensory and cognitive processes.
4. Functional MRI methods track changes in blood oxygen levels and provide excellent spatial resolution (2–3 mm) but limited temporal resolution (2–6 s). This technique is best suited for identifying specific brain structures involved in performing various tasks.
5. Positron emission tomography (PET) reflects regional metabolic changes and locations and amounts of neurotransmitters and neuroreceptors. PET provides reasonable spatial resolution (2–4 mm) and poor temporal resolution (15–45 s). PET procedures involve brief radiation exposure.

EEG electroencephalogram, *ERP* event-related potential, *MRI* magnetic resonance imaging

This table lists the key features of neuroimaging techniques frequently used to investigate food perception processes in humans, including temporal and spatial resolution, signal type and sources.

While technological advancements gave rise to a number of diverse neuroimaging techniques, electroencephalography (EEG), event-related potentials (ERP), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI) are the most frequently used in research on food-related behaviors (see Table 34.1). In this chapter, we will briefly discuss how each of these methods works and illustrate their use for understanding how typical persons process food-related information. Finally, we will discuss applications of these methods for studies of atypical eating behaviors.

34.2 Techniques for Studying Brain Processes

34.2.1 Electrophysiology

Electroencephalogram (EEG) has long been used as an indicator of ongoing brain activity. The EEG involves placing at least two or as many as 256 sensors on the person's scalp and recording electrical activity of the brain. Such recordings typically span several minutes and are quantified in terms of signal frequencies. They allow one to examine general brain state characteristics, such as level of arousal and degree of connectivity among various brain regions, as well as specific processes underlying among others, attention, perception, and working memory.

A brief temporary change in the EEG in a response to a specific external or internal event (e.g., seeing an image, making a decision) is known as an *event-related potential* (ERP). ERP waveforms are represented as a series of positive and negative peaks following the onset of the eliciting event and varying in amplitude, onset latency, and scalp distribution. Generally, variations in ERP peak characteristics are interpreted to reflect speed (latency) or degree (amplitude) of processing. Shorter latencies are assumed to indicate more rapid processing while larger amplitudes might suggest increased processing (i.e., a greater number of neurons firing in synchrony). Because their millisecond-level resolution is comparable to the speed of many sensory and cognitive processes, ERPs have been widely used to examine both automatic (e.g., sensory) and controlled (e.g., memory, attention, inhibition) stages of stimulus processing (Zani and Proverbio 2003).

One limitation of the EEG/ERP technique is that it does not offer detailed spatial resolution needed to directly link activity recorded on the scalp to specific brain regions. Even with high-density electrode arrays, not all brain electrical activity is captured due to variations in signal strength, distance from various cortical areas to the scalp, and the orientation of cortical columns generating the signal. However, other neuroimaging can offer the needed spatial resolution.

34.2.2 Functional Neuroimaging

Functional neuroimaging includes several techniques that assess brain function and indirectly measure neuronal activity. These techniques have been used to learn about the functional anatomy of the living brain, to investigate the neural pathophysiology of psychiatric and neurological disorders, and to measure patterns of brain activation associated with cognition and specific human behaviors. In this section, we will focus primarily on *functional magnetic resonance imaging* (fMRI) and *positron emission tomography* (PET), which both provide indirect quantitative information about changes in local neuronal activity.

The fMRI blood oxygen level dependent (BOLD) method indirectly measures regional brain activity. An increase in neuronal activity in a specific brain region is associated with an increase in blood flow, providing glucose and oxygen resources in the form of oxygenated (oxy)hemoglobin. In general, the supply of oxyhemoglobin to an active region exceeds that necessary for neuronal metabolism. Thus, an increase in neuronal activity in a specific brain region is associated with a net increase in oxyhemoglobin and a decrease in deoxyhemoglobin in that area. Since deoxyhemoglobin has paramagnetic qualities (that reduce the fMRI BOLD signal), deoxyhemoglobin can be used as an intrinsic contrast agent, such that the reductions in deoxyhemoglobin associated with increased neuronal activity produce a larger fMRI signal. The fMRI BOLD technique provides excellent spatial resolution (a few mm on average) and requires no radiation exposure.

Positron emission tomography (PET) is another versatile imaging technique that depends on the use of a pharmacological compound that is labeled with a positron-emitting radioisotope. Similarly to the fMRI BOLD method, PET can be used to indirectly assay neuronal activity via changes in regional blood flow associated with neuronal activation. PET approaches that employ radioisotopes coupled to glucose can also be used to measure regional glucose metabolism, which is a measure of energy used in meeting neuronal metabolic demands. PET can also be used to determine the location and binding levels of many cellular constituents, most commonly neurotransmitters and neuroreceptors. This method has recently been extended to include measures of neurotransmitter release, which provide critical information about the specific neurotransmitter effects of food or food cue exposure. Limitations of PET include radiation exposure and lower spatial and temporal resolution compared to fMRI.

34.3 Perception of Food Characteristics

Food stimuli present a number of perceptual characteristics, such as visual appearance, smell, taste, and texture, all of which can have a different effect on a person's subjective experience. Investigating the unique roles of these attributes can improve our understanding of food-related behaviors, including preferences and aversions.

34.3.1 ERP/EEG Studies

The earlier studies began examination of food processing by observing changes in EEG characteristics during an exposure to food odors. Martin et al. (1998) reported that the odors of chocolate and spearmint resulted in a significant reduction in theta activity at the right frontal region compared with the odors of almond and cumin or no-odor control. Similar effects have been reported for other odors such as spiced apple (Lorig and Schwartz 1988) and the smell of cooking food when participants were hungry (Stacher et al. 1979). The reduction in EEG theta activity could be interpreted to reflect hedonic properties of the odor; however, similar reduced theta was also observed in the left temporal region for the odor of rotting meat, suggesting that this EEG response may reflect an odor's ability to attract or distract (Martin et al. 1998). Thus, the effects of food odors on EEG are most likely reflecting the general attention-getting rather than hedonic qualities.

More recently, Kettenman (Kettenman et al. 2005) used olfactory N1/P2 ERP responses (thought to be generated in the insular cortex) to investigate the role of taste on odor perception. While participants' attention was distracted by an unrelated visual tracking task, olfactory ERPs were recorded to odors presented concurrently with the taste strips placed at the center of the tongue. Behavioral data revealed that reported pleasantness rating of the odors varied with changes in the background taste: a fruity smell (*n*-butylacetate) was perceived as most pleasant during sweet taste stimulation; a citrus smell (octanal) was rated most pleasant when combined with sour taste; while a floral (linalool) smell was most pleasant in the no-taste condition. ERPs further revealed that when paired with the less optimal taste stimulus, brain processing of the odors was characterized by reduced initial attention (smaller N1 amplitude) to the stimulus and prolonged and enhanced early categorization processes (larger P2 amplitude with longer latency).

In addition to the basic taste and smell properties of food, humans may also perceive the food in terms of its potential energetic and reward value. Toepel et al. (2009) examined brain responses of normal-weight participants while they viewed photographs of high- and low-fat foods intermixed with nonfood images (kitchen utensils). Differences in visual ERPs to high- versus low-fat foods were observed beginning approximately 165 ms after stimulus onset. High-fat images elicited stronger brain responses with estimated sources within the lateral occipital cortex, the superior temporal cortex, and the postcentral gyrus of the left hemisphere. Low-fat images were associated with stronger activity in the left inferior frontal gyrus. Differences between high- and low-fat foods were also present at a later time period (309–371 ms), due to increased activity within the occipitotemporal cortex, the inferior parietal lobe, dorsal frontal areas of the left hemisphere, and in ventromedial as well as more dorsal and lateral prefrontal areas in the right hemisphere. These brain structures are typically engaged in decision-making processes and follow-up correlational analyses revealed greater strength of the responses in trials with shorter reaction times for both stimulus types. Such correlations were not observed in the earlier time period (166–230 ms).

34.3.2 fMRI/PET Studies

Neuroimaging studies have investigated various sensory food cues (e.g., taste, smell, visual, tactile), the effects of satiety and hunger, and the effects of food imagery (see Tataranni and Del Parigi 2003, for review). Multiple brain areas are involved in food perception, including frontal and occipital cortex and subcortical areas such as the brainstem dopaminergic regions, hypothalamus, and striatum (see Figs. 34.1–34.3). Visual food cues activate the fusiform gyrus (Killgore and Yurgelun-Todd 2005a, b). Food smells activate the olfactory bulb and signal the pyriform cortex (Rolls et al. 2005).

Fig. 34.1 Brain structures
implicated in processing of
food-related information.
The figure represents a
coronal (*upper*) and axial
(*lower*) T1-weighted
structural MRI image
depicting brain structures
implicated in processing of
food-related information.
Primarily limbic components
include amygdala, cingulate
gyrus, and hippocampal
gyrus. Hypothalamus has a
primary role in feeding and
satiety. Additional cortical
regions (insula, prefrontal,
and occipital) play a role in
detecting, assessing, and
integrating food-related
information. Dorsal striatum
integrates cortical and limbic
input. Thalamic regions are
involved in processing
stimuli (Based on Tatarranni
and Del Parigi 2003)
The taste of food activates cranial nerves V, VII, and IX, and this sensory information is integrated
in the nucleus tractus solitarius. Sensory information about taste is sent to the cortex via the ventral
preoptic nucleus of the thalamus and interpreted in the insula (Rolls et al. 2005). These sensory inte-
gration areas of the cortex then activate reward system structures including the orbitofrontal cortex
(OFC) and amygdala. The hippocampus is also activated in reward recognition (Rolls et al. 2005).
The ventral striatum/nucleus accumbens appears to be important in integrating information concern-
ing feeding and hunger, including information about reward and energy homeostasis (Kelley 2004).

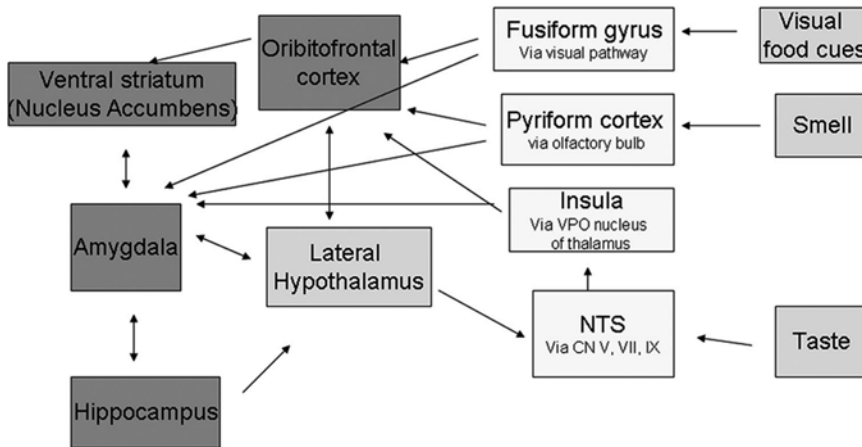
To demonstrate the specificity of food cues across visual and tactile domains, St-Onge et al. (2005)
used fMRI at 1.5 T to examine regional brain activity in response to tactile or visual presentation of
foods compared with nonfoods in normal-weight participants who fasted for 12 h. Using a conjunc-
tion analysis to isolate regions activated in both tactile and visual presentations, these investigators
found that right the cingulate, left hippocampal, and parahippocampal gyri and bilateral regions of


Fig. 34.2 Reward system activated by external stimuli. Feeding, as a survival behavior, is controlled not only by energy homeostasis but also by reward drive. While energy homeostasis is maintained by monitoring internal status, the natural reward system also responds to external signals, especially the recognition of certain foods as rewards
Fig. 34.3 A midline brain slice showing activation to viewing food cues using fMRI. Several brain regions activate in response to food cues, including the frontal cortex, occipital cortex (including vision centers), brainstem (areas including reward nuclei), hypothalamic region, and striatum. The right side of the figure is the front of the brain

superior temporal gyrus, insula, and caudate nuclei showed increased activations to food in both stimulus conditions. These structures are typically associated with memory, decision making, and interpretation processes.

Gordon et al. (2000) used PET to examine regional cerebral blood flow (rCBF) in healthy, fasted, normal-weight, female controls in response to high calorie, low calorie, and nonfood cues. Subjects viewed actual objects at a distance of 2 ft. Calorie content, palatability, and nutrient breakdown of the foods were not specified. Subjects were simultaneously given spoken descriptions of the stimuli (e.g., "this is a high calorie food with high fat content") and asked to evaluate their emotions while observing the object. The higher calorie foods elicited greater desire to eat than low calorie foods or nonfoods. Overall, reduced rCBF in the left temporo-insular region was noted during exposure to the high calorie foods versus the low calorie and nonfood conditions.

In a similar study, Killgore et al. (2003) used the fMRI BOLD method at 1.5 T to assess regional brain activation in response to viewing high and low calorie foods in normal-weight adult females. Vegetables, grains, and fruits were used as low calorie food images while prepared foods such as French fries, ice cream, cookies, etc., were used as high calorie food images. Participants rated the

food images for motivational salience on a scale ranging from highly aversive to highly appealing, with high calorie foods rated as significantly more appealing. Thus, the study assayed differences between images differing in calorie content and in motivational salience, with the two qualities inter-correlated. Food images were compared with neutral cues. Interestingly, a conjunction analysis of all food cues found increased activation in bilateral amygdala, bilateral anterior hippocampi, and in medial prefrontal cortex. However, a contrast of high calorie foods with baseline images showed robust activations in bilateral dorsolateral and medial prefrontal cortex, midline thalamus, and hypo-thalamus. A similar contrast of low calorie food images with baseline found relatively weak activa-tions in superior temporal, postcentral, parahippocampal, and orbitofrontal gyri. Additional analyses revealed a complex pattern of differential activations when high and low calorie stimuli were directly contrasted. In a follow-up analysis of this same cohort (Killgore and Yurgelun-Todd 2005a), these investigators examined the correlation between BMI and regional brain activity in the *a priori* selected regions of orbitofrontal cortex and anterior cingulate gyrus. In these healthy, normal-weight females, BMI was negatively correlated with orbitofrontal and cingulate activation in response to both high and low calorie foods. BMI during baseline image viewing was positively correlated with right middle orbitofrontal gyrus activation.

Interestingly, the observed pattern of response to high calorie foods appears to develop over time. In a rare study involving younger participants, Killgore and Yurgelun-Todd (2005b) examined cere-bral responses to food images in normal-weight girls, ages 9–15 years. Using methodology similar to the Killgore et al.'s (2003) study described earlier, adolescents and children underwent fMRI scans while viewing food images. Activation was found within the inferior orbitofrontal cortex, hippocam-pus, and fusiform gyri in response to food images. High calorie food images activated the left hip-pocampus and subgenual cingulate. Age correlated positively with activity within the oribitofrontal cortex and negatively with activity within the anterior cingulate gyrus. Low calorie foods activated the fusiform gyrus and demonstrated age-related increases in the left superior temporal gyrus and anterior cingulate. Nonfood images activated the fusiform gyrus and showed age-related increases in the pre-frontal cortex. On comparing these results with findings from their previous study on adults, Killgore and associates found that adolescents tended to show greater activation of the visual object-processing regions, which suggests that children process food images in a less complex manner than adults, for whom food images elicit a more emotional response. Killgore and Yurgelun-Todd suggest a develop-mental model of adolescent maturation whereby age-related changes in cerebral functioning develop from lower-order sensory processing toward higher-order processing of stimuli via prefrontal cortical systems involved in reward anticipation, self-monitoring, and behavioral inhibition.

Killgore and Yurgelun-Todd (2007) examined the role of the person's affective status (ratings on the Positive and Negative Affect Schedule) in the activity within the occipital cortex in response to high and low calorie foods. The results from a sample of 13 healthy women indicated that positive but not negative affective state affected early visual sensory processing of high calorie food stimuli, as reflected by activity within the lingual gyrus and calcarine cortex. No affect effects were observed for low calorie foods.

34.3.3 Conclusions

In sum, electrophysiological and neuroimaging studies reveal that food characteristics elicit similar brain responses as other attention-getting and motivationally salient stimuli. In addition, perception of food properties can be modulated by concurrently presented information in other modalities as reflected in smell–taste and sight–touch interactions. Furthermore, responses to food stimuli change

with age, progressing from basic sensory processing to more advanced analysis involving higher cognitive functions, such as motivation and inhibition. The following section will examine the role of the latter processes in greater detail.

34.4 Individual State/Belief Effects on Food Perception

The regulation of food intake is complex and results from integration of neural systems governing energy homeostasis, reward recognition and drive, and behavioral control (for reviews, see Sorensen et al. 2003; Sclafani 2004; Cone 2005; Marzo and Matias 2005; Munzberg and Myers 2005). Therefore, perception of food characteristics may be biased by other cognitive processes.

34.4.1 ERP/EEG Studies

Carretie, Mercado, and Tapia (2000) demonstrated that a person's appetite (motivation toward the food) could alter the amount of attention to food stimuli as reflected by negative parietooccipital ERPs. Participants completed a visual perception task where they were asked to identify whether each stimulus pair (cakes or faucets) made of an upright and inverted photo represented identical or different images. An index of appetite was obtained immediately after the ERP session by asking subjects to depict on a circle the portion of a cake they would like to eat at that moment. The largest appetite-related differences were observed at posterior (parietal and parietooccipital) scalp locations around 600 ms after food stimulus onset, but were not present for the nonfood stimuli.

Using hunger as a more extreme example of food motivation, Stockburger et al. (2008) examined whether 24-h food deprivation would result in increased attentional bias to food alone, to all appetitive stimuli (food and pleasant images), or to all emotional stimuli regardless of hedonic valence. ERPs were recorded while typical adults passively viewed food and appetitive or aversive nonfood images presented as a rapid serial stream to increase perceptual load. All participants were tested in a hungry and a satiated state. Hunger-related ERP effects were reflected in increased positive amplitudes to food pictures over posterior scalp areas within 170–210 ms and 270–310 ms after stimulus onset due to activity originating in occipito-temporo-parietal and frontal regions. The impact of the hunger on brain response to food stimuli was evidenced in the shift of topographic distribution from the pattern more typical of general selective attention to the engagement of food-selective visual-associative brain regions. There were no state-related differences in ERPs to nonfood pictures. Interestingly, hunger did not affect processing of the emotional aspects of the stimuli. Both pleasant and unpleasant pictures elicited a pronounced early posterior negative (EPN) component between 200 and 300 ms after stimulus onset.

Self-imposed food restraint may also alter food perception. Kemmotsu and Murphy (2006) utilized olfactory P3 response to assess attention to food (chocolate) versus nonfood (geraniol) odors in restrained and nonrestrained eaters. All participants completed two tasks that directed their attention to (attend) or away from (ignore) the stimuli. In the "attend" condition, participants performed odor magnitude estimation while in the "ignore" condition, they performed an unrelated visuomotor tracking task. Restrained eaters were expected to pay greater attention to the food odor regardless of the attentional condition, while ERPs to the food odor in nonrestrained eaters were predicted to have higher amplitudes in the "attend" than the "ignore" condition. The stimuli were presented in a single stimulus version of an oddball paradigm where an infrequent target stimulus is presented without the

intervening presentations of the frequent standard stimulus. As would be expected, all participants generated greater P3 amplitudes in the "attend" condition; however, restrained eaters had smaller P3 amplitudes to the food odor than nonrestrained eaters. Furthermore, while the nonrestrained eaters showed higher P3 amplitudes to the food odor in the "attend" than the "ignored" condition, this condition effect was not present in restrained eaters. Self-imposed restrictions in eating appeared to alter attention to food, which in turn may influence sensory processing of olfactory information. Restrained eaters could be trying to suppress thoughts about food and, thus, had a smaller attentional allocation to odor compared to nonrestrained eaters. Examination of an earlier P2 response thought to reflect early perceptual categorization revealed that in restrained eaters, latency of the fronto-central P2 to the chocolate odor correlated with the postsession hedonic rating, with shorter latencies in those who rated the odor to be more pleasant.

Food perception may also be subject to the influence of personal food choices not linked to concerns about body weight or shape. Stockburger et al. (2009) examined whether vegetarians' negative affect toward meat makes such stimuli stand out in passive and active viewing tasks. Viewing emotional (unpleasant and pleasant) versus neutral pictures typically results in the increased late positive potential (LPP) occurring between 300 and 700 ms after stimulus onset. Thus, meat stimuli in vegetarians were expected to generate a larger LPP response. The food images included meat, vegetable, and dessert dishes. Meat and vegetable images were matched with respect to amount, form, and colors of the displayed items. In the passive condition, participants were instructed to view the presented images, while in the active task, participants were asked to silently count the dessert pictures. Finally, they classified each food into liked, disliked, or neither groups. Vegetarians almost exclusively evaluated meat dishes as disliked. As anticipated, meat pictures elicited enlarged LPP response over posterior regions in vegetarians compared to omnivores, whereas there were no group differences in LPP to vegetable dishes. The enlarged LPP to meat dishes was present in vegetarians in both active and passive task conditions. These findings indicate that the attention capture by food stimuli can be altered by the emotional salience associated with symbolic meaning (Rozin 1996) due to the implicit stimulus relevance (Ito and Cacioppo 2000).

Recently, Nijs, Franken, and Muris (2008) examined whether processing of food-related information differs in normal-weight and obese individuals. If obesity were associated with enhanced motivation for food, larger P3 and LPP amplitudes for food stimuli would be expected. Furthermore, as LPP and P3 amplitudes reflect motivational tendencies, they should correlate positively with self-report measures of food craving and hunger. Participants passively viewed pictures of palatable foods as well as neutral (office items) pictures after eating a light meal 2 h before the start of the experiment. Centro-parietal P3 and LPP amplitudes were larger in response to food than the office supplies pictures, but there were no group differences. Positive correlations were observed between posterior P3 and LPP amplitudes and self-reported increase of hunger (but not food craving). However, such correlations were present for food cues and the office stimuli. The authors concluded that subjective feelings of hunger affected overall information processing rather than its food-relevant aspects. These findings were interpreted to suggest that obese individuals without explicit eating disorder symptoms might not respond differently to food cues as compared to normal-weight individuals.

34.4.2 fMRI/PET Studies

While energy homeostasis is maintained by monitoring internal status, the natural reward system also responds to external signals, especially the recognition of certain foods as rewards. The mesocorti-colimbic dopamine system – most notably the ventral tegmental area (VTA) and the nucleus accumbens

(NAc) – mediates the processing of reward and pleasure (Kelley and Berridge 2002). In mechanisms overlapping with those of addictive drugs, ingesting palatable foods (especially high sugar or fat), release brain opioids and dopamine in the VTA and NAc (Rada et al. 2005; Avena et al. 2007).

LaBar et al. (2001) investigated the effect of hunger on the regional brain activation using fMRI. Healthy adults were imaged in fasting and fed conditions. Stimuli consisted of food, tools, and Gaussian-blurred objects. Regions of food-specific activation seen more prominently in the fasting scans included amygdala, parahippocampal gyrus, and anterior fusiform gyrus. A conjunction analysis of regions activated across states revealed food-specific effects in insula and extrastriate cortex.

Amygdala inputs to the lateral hypothalamus can promote eating in response to reward recognition by overriding satiety signals (Petrovich and Gallagher 2003). The importance of the reward system in hyperphagia has been highlighted in recent studies that show subjects with high sensitivity to reward are more likely to be overweight (Davis et al. 2004). In a study to investigate the role of reward system in eating, Beaver et al. (2006) found that individuals high in reward drive have more frequent and intense food cravings and are more likely to be overweight or have other eating disorders. Reward drive as measured by the Behavioral Activation Scale has high correlation with activation of limbic system in response to looking at images of appetizing foods. Regions of increased activation included the ventral striatum, amygdala, midbrain, OFC, and ventral pallidum. This study also found that the left OFC is activated in response to appetizing foods and the right OFC is activated in response to disgusting foods.

There is a complex interaction between energy density, dietary composition, and palatability of food (for reviews, see Sorensen et al. 2003; Stubbs and Whybrow 2004). Palatability has multiple definitions and can be defined by a subjective perception or by directly tasting a particular food. Palatability generally rates the perceived or anticipated pleasurable or desirable aspects of a food. In general, as palatability increases, the amount of food consumed increases. Food content is also important, for example, higher fat and higher sugar foods increase feeding and weight gain in experimental models (Sclafani 2004). Adding variety to the diet also increases food intake (reviewed in Sorensen et al. 2003).

Holsen et al. (2005) examined food cues in fasted and fed healthy-weight children and adolescents ranging in age from 10 to 17 years old. Stimuli were the same as those used by LaBar et al. (2001) except that animal figures were substituted for tools. Subjects were asked to fast for 4 h and were given a standardized meal (similar nutrient content) of 500 kcal prior to the fed-state scan. About half the subjects were scanned initially in the fasting state. Participants were asked to remember the images they had seen and were told they would be tested at the end of the scans. Recall of food items was superior in the fasted state. An analysis of food versus nonfood cues across fasting and fed states produced increased regional brain activity in left insula, left inferior frontal cortex, left ventrolateral prefrontal cortex, right parahippocampal gyrus, and bilateral fusiform gyrus. In the fasting condition, a food versus nonfood contrast revealed increased activation in bilateral medial orbitofrontal cortex, left lateral orbitofrontal cortex, left medial frontal cortex, right superior parietal cortex, and bilateral cerebellum/fusiform gyrus regions. An *a priori* analysis was used to detect brain areas responding more greatly to food in the fasted than fed state. Areas with greater food-related activation in the fasting state included right amygdala, right medial orbitofrontal cortex, bilateral regions of the lateral orbitofrontal cortex, left medial frontal cortex, bilateral opercular and insular cortex, right parahippocampal gyrus, right cingulate gyrus, and left fusiform gyrus.

In addition to brain regions involved in energy homeostasis and reward recognition, the prefrontal cortex (PFC) is also active in response to food. There are several theories concerning PFC activation and feeding. The PFC is theorized to be part of a behavioral control circuit acting to restrain the intake of excessive food (Elman et al. 2006). It has also been suggested that the dorsolateral PFC is involved in recognition of long-term rewards, such as health, while the ventrolateral PFC is involved in recognition of immediate rewards (Tanaka et al. 2004). Tataranni and Del Parigi (2003) theorize that a satiation domain is located in the PFC, and an appetite-stimulating domain includes the OFC, insular cortex, anterior cingulate, and hypothalamic regions. They suggest that greater PFC activation is seen

in obese individuals because their hypothalamus and limbic areas are more resistant to satiety signals. Imaging studies have shown greater activation of the dorsal PFC activation in response to food cues in obese versus lean persons and in the fed state versus fasting state (Tataranni and Del Parigi 2003). Activation of the dorsal PFC is also higher in successful dieters versus obese nondieters (Del Parigi et al. 2007). Compared with adults, children were found to have less activation in the medial PFC and dorsolateral PFC when viewing high calorie foods (Killgore and Yurgelun-Todd 2005b).

Stoeckel et al. (2008) investigated whether the brain's reward system may be hyperactive in obese individuals during viewing of food images. Twelve obese and 12 normal-weight women viewed images of high and low calorie foods. The results revealed that in the obese compared with a control group, increased activation was observed in the regions associated with the reward system (amygdala, nucleus accumbens, and orbitofrontal cortex), as well as regions associated with motivational processes (anterior cingulate cortex, caudate nucleus, putamen, hippocampus, insula, and medial prefrontal cortex). In the control group, greater activation by high calorie foods was seen only in dorsal caudate, whereas low calorie foods were associated with greater activity in the lateral orbitofrontal cortex, medial prefrontal cortex, and anterior cingulate cortex.

In a recent review, Stice et al. (2009) reported that compared with normal-weight controls, obese individuals show greater activation of the gustatory cortex (insula/frontal operculum) and oral somatosensory regions (parietal operculum and Rolandic operculum) in response to anticipated consumption of palatable foods. The obese relative to lean individuals also showed less activation in the dorsal striatum in response to consumption of palatable foods and reduced striatal D2 dopamine receptor density. The latter finding suggests that at least in some cases, obesity may be genetically influenced. In an fMRI study by Stice et al. (2008), obese participants with at least one A1 allele of Taq1A (associated with decreased dopamine D2 receptors and compromised dopamine signaling in the striatum) were characterized by increased striatal activation (the caudate and putamen) in response to tasting a milkshake, with the degree of activation negatively associated with weight gain. For those without an A1 allele, increased striatal activation was related to greater weight gain.

34.4.3 Conclusions

Overall, results from ERP, fMRI, and PET studies consistently indicate that personal beliefs and motivational states have a direct effect on food perception. Evidence of such modulation is present even at early, preattentive stages of information processing (e.g., 100 ms after stimulus onset). Interestingly, studies in obese populations are less consistent in their findings – while fMRI data suggest increased activation of the reward system in response to high calorie foods in obese compared with healthy-weight persons, the ERP study failed to observe such group differences in attentional or motivational processes associated with viewing food images, possibly due to the obese group completing a nutritional training prior to the study. Given the evidence of potential genetic contributions to weight gain as well as the role of personal beliefs and opinions, future studies will need to examine food perception processes associated with obesity in greater detail.

34.5 Applications to Other Areas of Health and Disease

Investigations of food perception in typical healthy participants as well as the studies examining effects of food deprivation and hunger paved the way for an improved understanding of food-related behaviors in atypical populations. Prader-Willi syndrome (PWS) is a genetic condition resulting

from the failure to inherit a normal paternal copy of chromosome 15q11–q13, either through uniparental disomy (PWS-UPD), or when two maternal copies of chromosome 15 are inherited, or paternal deletion (PWS-Del) of 15q11–q13. PWS involves excessive eating and food-seeking, morbid obesity, and a distinctive behavioral phenotype including intellectual disabilities. Persons with this disorder are often identified at birth because of failure to thrive and poor muscle tone. Atypical eating behaviors develop in the early childhood. As they become adults, persons with PWS continue to require 24-h per day supervision due to food seeking, compulsivity, and other behavior problems. One major obstacle to studying food-related behaviors in persons with PWS is their tendency to provide socially desirable answers regarding their food choices and preferences during behavioral testing and interviews. Thus, neuroimaging studies offer an opportunity to improve our understanding of the reasons for observed eating behaviors.

Studies examining brain structures involved in processing food cues in persons with PWS reported abnormal patterns of neural activation when compared with normal-weight and obese controls. Holsen et al. (2006) examined nine participants with PWS and nine healthy-weight controls (HWC). fMRI scans were performed before and after eating a standardized meal. During the MRI scans, participants viewed pictures of food, animals, and blurred control images. The HWC group showed greater activation in the amygdala, orbitofrontal cortex, medial prefrontal cortex, and frontal operculum in the premeal scans when compared with their postmeal scans. The PWS group showed greater activation in the orbitofrontal cortex, medical prefrontal cortex, insula, hippocampus, and parahippocampal gyrus in the premeal scans when compared with their postmeal scans. Persons with PWS showed greater activation to food images after the meal than did the HWC (see also Dimitropoulos and Schultz 2008). Miller et al. (2007) used fMRI to investigate the response of individuals with PWS to food images after ingestion of an oral glucose load. Eight adults with PWS and eight normal-weight adults underwent fMRI while viewing food images after glucose loading. Relative to controls, participants with PWS produced greater activation in the ventromedial prefrontal cortex, suggesting that increased reward value for food may contribute to the excessive hunger commonly experienced by persons with PWS. Interestingly, in a study examining food preferences where participants viewed pictures of highly preferred foods and imagined eating them, Hinton, Holland, and Owen (2006) did not observe any increases in the activation of regions associated with food reward or incentive (amygdala, medial orbital frontal cortex) in adults with PWS (n = 13) compared to healthy-weight typical controls. Thus, although persons with PWS have reliable food preferences, their aberrant satiety may override input from pathways related to rewards from food. If so, aberrant satiety could lead to more indiscriminate food selections, and other properties of food than taste preference alone may be important in food perception and selection in PWS.

In a recent study, Key and Dykens (2008) used ERPs to examine the effect of the genetic subtype of PWS on food perception in 17 adults with PWS (8 UPD, 9 deletions). Given anecdotal evidence of persons with PWS consuming inappropriate food (e.g., raw meats, discarded food), the stimuli in the study (see Fig. 34.4) included color photographs not only of typical palatable foods, but also images of unusual combinations (e.g., an ice cream with bacon strips), and contaminated foods (e.g., a cake with bugs on it). Participants were asked to view the pictures and think whether they would consider eating the depicted foods. Group differences were observed for the N1 and P3 responses, reflecting perceptual categorization and motivational relevance, respectively. More specifically, the two genetic subtypes of PWS differed in their food perceptions processes. Analyses of the N1 amplitude indicated that participants in the deletion group categorized food stimuli in terms of composition (e.g., a hot dog vs hot dog with mustard) and seemed to ignore the quality dimension (odd combinations or contaminated foods). Those in the UPD group performed more similar to the typical controls and initially discriminated stimuli based on the suitability for consumption (i.e., separating
Fig. 34.4 Sample stimuli used in an ERP study of food perception in adults with Prader-Willi syndrome (Key and Dykens 2008). a, b, c, d. (**a**) Single palatable food (ice cream); (**b**) combined palatable foods (ice cream and strawberries); (**c**) single palatable food (ice cream) contaminated by a nonfood element (grass); (**d**) mismatched combination of two palatable foods (ice cream and bacon)

contaminated foods from the rest; see Fig. 34.5). The controls performed the most extensive discrimination, separating contaminated or combined stimuli from mismatched and single foods, respectively. Importantly, these early discrimination effects could not be attributed exclusively to the basic visual properties of the pictures or differences in individual food preferences, as the same food items appeared in each of the four conditions, and minor additions to the same original "single" food were used to create mismatched and contaminated stimuli. The condition effects observed in the P3 time window for all participants with PWS reflect the highly arousing, motivating, and salient nature of food images. The control participants did not show this later ERP effect most likely because they did not have hyperphagia, and given the passive nature of the task and the absence of an acute interest in food, their categorization of the stimuli could have been fully completed prior to the P3 time range. In contrast, persons with PWS show much greater interest in food and may be prone to carry out more extended analyses of food options.

Holsen et al. (2009) used fMRI to examine genetic subtype differences in persons with PWS in response to food images. Compared with the healthy-weight control group, both the deletion and UPD subgroups showed greater activity in response to food stimuli both before and after consuming a meal. Relative to the UPD subgroup, the deletion subtype showed increased activation of the food motivation network, especially in the medial prefrontal cortex and amygdala, regardless of the meal condition. In contrast, the UPD group showed greater activation postmeal in the dorsolateral prefrontal cortex and parahippocampal gyrus. The authors concluded that the deletion subgroup is characterized by reduced behavioral inhibition in response to food, whereas persons with UPD may be more able to maintain cognitive control over food-related impulses.

Summary Points

- Food-related stimuli are processed in the brain similar to other attention-grabbing and motivation-
  ally salient stimuli.
- Perception of food stimuli can be modulated by information from other modalities and/or by
  personal beliefs and motivational states.
- Brain responses to food stimuli change with age, progressing from basic sensory processing to
  more advanced analysis involving higher cognitive functions.
- Obesity may or may not be associated with altered food perception.
- Genetic characteristics may have an effect on brain processing of food-related information.

Definitions and Explanations

Electroencephalogram (EEG): A recording of electrical activity of the brain using electrodes placed on the scalp, typically described in terms of signal frequencies.

Event-related potential (ERP): A temporary brief change in EEG associated with an external or internal stimulus event, typically described as a sequence of negative and positive peaks.

Functional magnetic resonance imaging (fMRI): An imaging method that uses changes in brain blood flow to indirectly assess regional neuronal activity.

Positron emission tomography (PET): A nuclear imaging technique that uses radioactive tracers to measure local brain metabolism, blood flow, and cellular constituents such as neurotransmitter receptors and transporters.

Prader-Willi syndrome (PWS): A genetic disorder occurring in 1 of 10,000 live births and resulting from deletion of a set of genes on the paternal chromosome 15 (15q11–13) or an erroneous inheritance of two copies of the chromosome from the mother. In addition to mild-to-moderate intellectual disability, persons with PWS are characterized by an extreme, insatiable appetite, leading to chronic overeating (hyperphagia) and early onset obesity.

EEG	Electroencephalogram
EKG	Electrocardiogram
NBAS	Neonatal Behavioral Assessment Scale
REM	Rapid eye movement, or active, sleep state
SIgA	Secretory Immunoglobulin A

35.1 Introduction

With increasing regularity and conviction, breastfeeding is being advocated by American health organizations, including the American Academy of Pediatrics (AAP 2005), the American College of Obstetricians and Gynecologists (ACOG 2003), the American Academy of Family Physicians (AAFP 2007), the Surgeon General (Galson 2008), and the US Department of Health and Human Services Office on Women's Health (DHHS 2000), as well as major international organizations, such as the World Health Organization (WHO) and United Nations Children's Fund (WHO/ UNICEF, 2003; WHO/UNICEF/USAID/SIDA, 2009). The growing consensus has halted decreases in breastfeeding rates during the twentieth century that coincided with urbanization, technologic advances, and changing patterns of family life (Lawrence and Lawrence 2005). Although trends in breastfeeding began to change in the 1960s, and rates for 6-month-olds in the US rose from approximately 8% in 1971 (Lawrence and Lawrence, 2006) to approximately 43% in 2005 (CDC 2008), current levels still fall short of the Healthy People 2010 (2005) target of 50%. Similarly, exclusive breastfeeding (in which breast milk is not complemented by formula) occurs at rates of 12%, which is less than half the targeted rate of 25%.

Table 35.1 Key facts about breastfeeding

The breastfeeding mother
- is usually older, more educated, married, and has a higher income;
- in the United States, is more likely to be Asian, Pacific Islander, White, or Latino than non-Latino, American Indian, Alaskan, or Black/African American;
- has later return to fertility;
- has lower incidence of obesity, osteoporosis, premenopausal female-related cancers;[a] and
- may be protected from anxiety and depression;[b]
- in rare instances, breastfeeding is contraindicated. These circumstances pertain primarily to compromised maternal health and medication usage, e.g., HIV positive, HTLV-1.[a,c]

The breastfed infant
- has larger head circumference and is leaner;
- has lower incidence of GI disorders and infections, e.g., cholera, diarrhea, and otitis media, due to superior immune functioning;
- has sometimes been found having lower incidence of obesity, allergies, asthma, diabetes, cancers, cardiovascular disorders, and SIDS.[a,d]

[b]Kendall-Tackett (2008)
[c]Field (2008), Hale (2008)
[d]Walker (2008)

Calls by health organizations, and the resurgence they brought about, have been driven primarily by mounting evidence of health benefits to breastfed infants and their mothers (see Table 35.1). To a lesser extent, breastfeeding is being promoted on the basis of advantages to cognitive development (Lucas et al. 1992; see Chap. 88). In this chapter we focus on the manner in which breastfeeding contributes to the young infant's neurobehavioral development. We consider differences between behaviors of breastfed versus bottle-fed infants, and how findings on various contrasts might explain or help account for some of the apparent benefits of breastfeeding to infant health and cognitive development.

35.2 NeuroBehavioral Development of the Breastfed Infant

Infant behavior has been of longstanding interest to parents. In recent years it has received increasing attention in the fields of developmental psychology and neuro-psychology. Contrastingly, infant behavior *as a function of breastfeeding* has a longer tradition of receiving attention by scholars in the fields of nutrition, nursing, medicine, and public health. Partly as a result of differences in the emphasis on feeding, and due to distinctions between the various disciplines in terms of their goals and methodological approaches, works touching on the breastfed infant's behavior have been scattered across a wide array of outlets, and infant behavior itself has been characterized in disparate ways. As we draw on these literatures, our focus will be on three broad constellations of infant behavior and their biophysiological correlates (Thoman et al. 1972). Following formulations in which the infant's neurobehavioral functioning is conceptualized as being organized on a continuum of "state," or level of consciousness spanning from deep sleep to crying (Als 1978; Brazelton and Nugent 1995), we will explore the two constellations of behavior that appear at either end of this continuum, and a third that appears toward its center, and includes social interaction skills and signs of alertness.

35.2.1 Crying

Early work in which 3- and 4-day-old infants were observed while exposed to sensory stimulation 30 min prior to feeding found that fussing and crying were more frequent among breastfed than bottle-fed infants (Bell 1966). Research on 2-day-olds' responses to different types of soothing techniques, such as rocking and being held upright (Korner and Thoman 1972), found that soothing methods were equally effective among breast- and bottle-fed infants. However, once the intervention had been terminated breastfed infants were more likely to cry. Based on mothers' diary accounts of crying, Bernal (1972) reported that durations of crying on days 5 through 9 among breastfed infants (84 min/day) were greater than those of bottled-fed infants (69 min/day). In a study of the neonate's response to auditory stimulation (Algeria and Noirot 1978), 3-day-olds were more likely to cry if they were being breastfed. In these early studies, findings that breastfed infants demonstrate greater crying were not explained, although several authors mentioned that hunger may have been a factor, especially in light of difficulty some mothers had reported in adhering to current recommendations to breastfeed on a 4-h schedule.

Despite trends in early studies that revealed greater crying among breastfed infants, there were exceptions, such as research by Simmons, Ottinger, and Haugk (1967). This work, comparing neonates before and after feeding, was conducted with the aim of determining the contribution of maternal characteristics. In addition to reporting greater crying among neonates of mothers with higher levels of prenatal anxiety, these investigators noted that crying prior to feeding was greater among bottle-fed infants.

A number of more recent studies have taken approaches that involve observations across lengthier blocks of time, as well as longitudinal designs which draw on parents' 24-h diary entries to discern diurnal variation and patterns of change across the first few months of life. Data based on researchers' observations during 4-h home visits when infants were 1 and 3 months of age (Crockenberg and Smith 1982) reported no differences in durations of crying between breast- versus bottle-fed infants. Using parents' diaries, a longitudinal study across the first 4 months of life (Lee 2000) found that crying peaked at 7 weeks, and differences between breastfed versus bottle-fed infants were nonsignificant. Barr, Kramer, Pless, Boisjoly, and Leduc (1989) found that by the age of 6 weeks overall durations of crying among breastfed infants (93 min/day) and bottle-fed infants (89 min/day) did not differ. They did observe, however, that breastfed infants' crying was more evident during the afternoon and evening, and disbursed across shorter, though more frequent, episodes.

A detailed longitudinal study by Lucas and St James-Roberts (1998) reported on durations of crying as well as colic, which was defined as intense, unsoothable crying, possibly due to pain. They found that whereas durations of crying among bottle-fed infants peaked at 2 weeks, durations among breastfed infants continued to increase until 6 weeks at which point durations among breastfed infants (52 min/day) exceeded those of formula-fed infants (36 min/day). Notably, findings on colic were reversed. Durations among 2-week-olds who were bottle-fed (23 min/day) exceeded those of infants who were breastfed (4 min/day). Similarly, a survey study (van der Wal et al. 1998) reported that "problematic crying," which was defined as crying which lasted for more than 3 h per day, was more likely to occur among formula-fed than breastfed infants.

Crying has also been assessed under conditions where it is elicited by painful procedures, like heel lances and venepuncture. In research on newborns' responses during a blood collection procedure, Gray, Miller, Philipp, and Blass (2002) found that infants who were permitted to breastfeed during the procedure spent less time crying (8.7 s) than controls (72.1 s) who lay swaddled in their bassinettes. This dramatic difference was mirrored by corresponding findings on heart rate. It has also been supported by studies on infants' responses to immunization injections (Abdel Razek and Az El-Dein 2009). To explore mechanisms that underlie the analgesic properties of breastfeeding, a number of

studies have incorporated control group conditions in which infants are provided with skin-to-skin contact, pacifiers, and sucrose solutions (Carbajal et al. 2003; Dilli et al. 2008; Efe and Ozer 2007; Reis et al. 2003). Generally, these find that breastfeeding is at least as effective as the combination of sucrose and a pacifier toward alleviating pain (Shah et al. 2007). Potentially, an argument for a unique effect of breastfeeding can be derived from work which compared four groups of breastfed infants on effects of glucose and/or breastfeeding within 45 min prior to inoculation (Gradin et al. 2004). This study found that the duration of crying among infants who had not received the 1 mL dose of glucose was greater (142 s) than that among infants who had received glucose (93 s). Crying was lower among infants who had been breastfed beforehand (63 s), and lowest among infants who had been breastfed beforehand and had also received glucose (18 s). The combined effects of prior breastfeeding and sucrose are striking. Whether they are limited to breastfed infants is unknown.

Taken together, these studies appear to suggest subtle differences. Peak durations of crying seem to occur later among breastfed infants whose episodes of crying appear also to be shorter in duration and more frequent. Bottle-fed infants may be more likely to cry with greater intensity. Whether breastfeeding reflects unique advantages to pain threshold is still unclear.

35.2.2 Alertness and Social Behavior

The quality of infants' neurobehavioral organization has been assessed using the Neonatal Behavioral Assessment Scale (NBAS; Brazelton and Nugent 1995). This instrument's 18 reflex items and 28 behavioral items are administered individually by a trained researcher during a 30–45-min procedure, generating data which are then reduced, usually to seven cluster scores (Lester et al. 1982), which reflect adequacy of different competencies (see Table 35.2). Since its introduction in the 1970s, the NBAS has become the dominant neonatal behavioral assessment, having been used in several hundred studies on intrauterine deprivation, maternal substance abuse, cesarean section, under-nutrition, prematurity, as well as cross-cultural studies. Although long-term predictive validity of the NBAS has not been established, the instrument is widely regarded as a valid descriptor of contemporary behavior (Lester and Tronick 2001).

The NBAS has been used in several studies which compared breastfed versus bottle-fed infants. Using neonates at the age of 37 h, DiPietro, Larson, and Porges (1987) explored effects of feeding method on NBAS performance as well as on several physiological measures of neurobehavioral functioning. Breastfed infants were found having longer heart rate, elevated heart period variability, and higher vagal tone, suggesting more optimal physiological organization. In contrast, breastfed infants' performance on the NBAS yielded scores on the *Range of State* cluster which suggested greater irritable reactivity. A small-scale study with 6-day olds (Maekawa et al. 1984) found that performance on the NBAS did not differ with the feeding method.

A third comparison (Hart et al. 2003) between breastfed vs. bottle-fed infants' performance on the NBAS used infants who were 9 days old. It was reasoned that because breastfeeding is more likely to have been established by this point (Lawrence and Lawrence 2006), it would be less likely that any differences between the two feeding groups would be confounded by differences in milk intake (Dollberg et al. 2001). In line with indications of the breastfed infant's more optimal physiological organization (DiPietro et al. 1987), findings revealed that breastfed infants had fewer *abnormal reflexes*, and surpassed formula-fed infants on items in the *orientation*, *motor*, and *range of state* clusters. These findings suggest exceptionally dramatic differences in favor of the breastfed newborn in terms of neurological organization, social interactive capacities, and especially in quality of alertness (see Figs. 35.1–35.4).

Table 35.2 Brazelton neonatal behavioral assessment scale (NBAS) clusters (From Brazelton and Nugent 1995; Lester and Tronick 2001; and http://www.brazelton-institute.com)

Cluster	Description of items
Habituation	The four items in this cluster assess the infant's ability to screen out aversive stimuli, including repeated auditory, visual, and tactile stimulation, while asleep. Scores are based on infant responses that are elicited by the examiner. For example, repeated presentation of bright light during the *response decrement to light* item is scored highest by the infant who transitions from sleep to drowsy states and back to sleep after only a few presentations of the light, suggesting superior skill in blocking out aversive stimulation thereby modulating level of consciousness with efficiency.
Orientation	This cluster includes seven items which assess the quality of overall alertness and the ability to attend to social and nonsocial stimuli during presentation by the examiner. A high score on the *animate visual* item, for example, is obtained by the infant capable of visually focusing on the examiner's face and tracking it smoothly as it moves in a range of directions.
Motor system	This cluster's five items evaluate qualities of muscle tone, and the control, integration, and symmetry of movement. Scores are based on an infant's elicited and spontaneously exhibited behaviors throughout the examination procedure. For example, the motor *maturity* item is scored more highly if movement of the arm involves smooth, wide-arc cycling rather than jittery or floppy motion.
Range of state	The four items in this cluster assess an infant's elicited and spontaneous *state*, i.e., level of consciousness, from deep sleep to full cry, and response to stressful stimulation. For example, the *rapidity of build-up* item addresses the onset of crying. Crying that is displayed only in response to a fair amount of stressful stimulation is scored higher than crying which is reached immediately and in response to minimal stress, or if crying fails to occur under even the most stressful conditions.
Regulation of state	These four items capture the infant's ability to modulate level of consciousness and cope with stressful stimulation. Scores are based on an infant's elicited and spontaneously exhibited behaviors throughout the examination procedure. For example, the *hand-to-mouth* item assesses the infant's capacity to self-sooth by voluntarily placing her hand or fist in her mouth and sucking on it for periods up to 15 s.
Autonomic stability	This cluster includes three items which record signs of stress related to homeostatic adjustments of the central nervous system. These include elicited and spontaneously occurring instances in which an infant exhibits markers of physiological stress, including tremors, startles, and changes in skin color.
Reflexes	The 18 items in this cluster aim to reflect the infant's neurological status. Scores are based on the infant's display of reflexive behaviors that are elicited by the examiner. For example, the *rooting* reflex is elicited by gently stimulating a corner of the mouth. The infant's head-turn toward the source of stimulated and movement of the mouth are scored more optimally than over-active mouthing or weak and misdirected movements.

35.2.3 Sleep

Several of the studies mentioned earlier also inquired into the quality and architecture of sleep. Differences in the duration of sleep were explored in a number of works in which contrasts between breast- and bottle-fed infants' sleep were addressed indirectly. Several of these studies reported that sleep duration did not differ with feeding method (Doan et al. 2007; Macknin et al. 1989; Parmelee et al. 1961; Quillin and Glenn 2004). Similarly, research that was more directly related to these contrasts,
Fig. 35.1 Scores of breast- and bottle-fed 9-day-old infants on the *Orientation* cluster of the NBAS (From Hart et al. 2003). Higher scores denote superior performance; *denotes differences between pairs of means at $p < .05$; ** denotes differences between pairs of means at $p < .01$
Fig. 35.2 Scores of breast- and bottle-fed 9-day-old infants on the *Motor* cluster of the NBAS (From Hart et al. 2003). Higher scores denote superior performance; *denotes differences between group means at $p < .05$; *** denotes differences between group means at $p < .001$
Fig. 35.3 Scores of breast- and bottle-fed 9-day-old infants on the *State Organization* cluster of the NBAS (From Hart et al. 2003). Higher scores denote superior performance; ** denotes differences between group means at $p < .01$
Fig. 35.4 Scores of breast- and bottle-fed 9-day-old infants on the *Reflexes* cluster of the NBAS (From Hart et al. 2003). Higher scores denote inferior performance; *denotes a difference at the level of $p < .05$ between this pair of means

such as the study of day-old neonates by DiPietro and associates (1987), reported that breastfed infants' sleep did not differ from that of bottle-fed infants. Diary data over a period of months (Lucas and St James-Roberts 1998) again found no differences in sleep duration between breastfed versus bottle-fed 2- and 6-week olds. In contrast, in their study of 6-day olds, Maekawa and associates (1984) found breastfeeding associated with infants spending more time asleep. Correspondingly, a longitudinal diary report (Lee 2000) noted that breastfed infants spent more time asleep.

Differences have also been sought in terms of frequency of awakening or length of sleep episode. Some studies reported no differences (Alley and Rogers 1986; Anders 1979). More recently, however, Lee's (2000) longitudinal study reported that frequency of awakening was greater among breastfed infants. Ball (2003) reported that feeding group differences were nonsignificant at 1 month but by 3 months, breastfed infants were found awakening more frequently. More frequent awakening was also reported in longitudinal research that was carried out over a period of 2 years (Elias et al. 1986). These investigators noted that the breastfed infant's pattern of adopting shorter sleep episodes appeared to be maintained into the second year among those who had not yet been weaned.

Latency to fall asleep was explored by Maekawa and associates (1984). Their study of 6-day olds found breastfeeding associated with infants falling asleep more quickly. This small-scale study is rather unique. Besides including detailed observations during large time blocks, it utilized a "within subjects" design in which each infant was exposed to both breast milk and formula, and so it stands out as a rare instance of experimental treatment in a field dominated by quasi-experimental approaches since group assignment is almost always based, due to ethical constraints, on self-selection. Higher levels of tryptophan in breast milk and formula have been associated with shorter sleep latency (Steinberg et al. 1992). As concentrations of tryptophan are typically higher in breast milk than formula (Lawrence and Lawrence 2006), corresponding differences in sleep behavior have been expected.

Finally, sleep behavior has been explored in terms of depth as well as arousability, that is, the ability to be awakened from sleep. In research with 1-day olds, DiPietro found no differences on

physiological measures, including electrocardiogram (EKG), and behavioral measures of rapid eye movement (REM) or active sleep and respiratory regularity function. However, work with 6-day olds by Maekawa and associates (1984) reported that breastfed infants spent greater amounts of time in deep sleep. A longitudinal study (Horne et al. 2004) on arousability of infants at three stages of age, 3 weeks, 2.5 months, and 5.5 months, revealed that 2.5-month olds are more easily awakened from active sleep if they are breastfed.

Overall, the few studies which explored the breastfed infant's sleep find evidence of subtle distinctions. Findings are still equivocal, but at present findings beyond the early neonatal stage appear to suggest that in the breastfed infant, sleep latency is shorter, awakening is more frequent which results in shorter sleep episodes, and arousability is greater.

35.3 Applications

Having discussed contrasts between breast- and bottle-fed infants, in the sections that follow we turn to examining features of the breastfed infant's behavior that may act as a moderating influence on child health and cognitive development. Rather than viewing infant behavior as an outcome measure, these works tend to regard infant behavior, or some aspect of behavior, as a driving influence on physical or psychological development.

35.3.1 Child Health

Breastfeeding has been associated with reduced risk for Sudden Infant Death Syndrome (SIDS) (Ford et al. 1993; Vennemann et al. 2009b). Defined as infant deaths that occur suddenly and unexpectedly, and whose manner and cause of death are not immediately obvious prior to investigation, SIDS is the leading cause of infant mortality in infants under 12 months in the United States, accounting for 2,250 deaths annually. Most cases occur in infants between the ages of 2 and 4 months (two websites on July 8, 2009: http://www.mayoclinic.com/health/sudden-infant-death-syndrome/DS00145 http://www.cdc.gov/SIDS/). By some estimates (Vennemann et al. 2009a), breastfeeding has been associated with a 50% reduction in rates of SIDS. The underlying mechanism is poorly understood but may relate to an infant's level of arousability under conditions marked by exceptional vulnerability. This was brought to light in longitudinal research which explored the nature of cortical arousal during sleep (Richardson et al. 2008). This study explored arousability in infants at the ages of 3-weeks, 2.5 months, and 5.5 months during deep/quiet and light/active sleep in both the prone and supine positions. Using physiological and electroencephalogram (EEG) markers, the investigators discovered increased proportions of cortical arousals among 2.5 month-olds while in the prone position, when vulnerability to SIDS is greatest. The investigators postulate that the enhanced propensity for cortical arousal may serve as a protective mechanism to promote arousal while an infant is especially vulnerable, either due to sleep position or period of maturation. Indeed, these results seem compatible with findings that breastfed infants were more easily aroused than formula fed infants at the age of 2.5 months (Horne et al. 2004).

These findings also beg the further question, how does breastfeeding relate to arousability? One possibility relates to sleeping arrangements, such as cosleeping, which tends to coincide with breastfeeding (McKenna et al. 2007). Another pertains to breast milk composition. Often explored in relation to sleep through attention to factors, such as tryptophan, responsible for inducing sleep (Sanchez et al. 2009) breast milk composition has also been explored with respect to factors associated with

arousability. These point to the role of docosahexaenoic acid (DHA) which has more often been investigated for its contribution to visual and neural development (Innis 2009). A small-scale study (Cheruku et al. 2002) explored associations between mothers' levels of plasma phospholipid DHA and several measures of sleep in their 1- and 2-day-old infants. In addition to finding differences in active and quiet sleep, the study reported greater wakefulness in 2-day olds of mothers with higher DHA.

In another area where health issues relate to sleep, the breastfed infant's sleep behavior has also been found associated with later risk for bed-wetting (Barone et al. 2006). Barone and associates reported a lower incidence of nocturnal enuresis among children who had been breastfed than matched controls who had been bottle-fed. They cited neurodevelopmental advantages associated with DHA as a possible underlying mechanism. Although risk for enuresis may be moderated by DHA, perhaps through its association with greater wakefulness (Cheruku et al. 2002), Barone's study has been questioned (Bennett 2006), largely for reliance on retrospective data, and so further work is needed before this possibility is substantiated.

It may be of interest to speculate on whether the breastfed infant's sleep behavior could relate to findings on obesity. Among several factors that have been found associated with risk for childhood overweight, recent research (Gillman et al. 2008; Taveras et al. 2008) identifies both breastfeeding and increased sleep as protective influences. The interrelationship between these two predictors is still unclear. Given that breastfeeding has at times been identified as being causally related to superior quality and duration of sleep (Lee 2000; Maekawa et al. 1984), it is possible to speculate that some aspect of breastfeeding plays the more fundamental role.

Finally, we might speculate on the possibility that the infant's capacity to perceive and regulate painful stimuli is moderated by breastfeeding. Evidence for this is still scant but its unveiling would account for some degree of robustness that generalizes across a range of health-related conditions that involve tolerance for discomfort.

35.3.2 Social and Cognitive Functioning

Research on infant cognition that has burgeoned during the past few decades has generated compelling evidence that the infant's perception of environmental stimuli and the ability to learn from such exposure is mediated by her current state (Cohen et al. 2006; Thoman 2001). It has also been well established that learning occurs during all the infant states. The crying infant learns to withdraw from painful stimuli, and as shown in research on infants' performance of the *Habituation* cluster of the NBAS, infants learn even while asleep. Indeed, the sleeping infant learns to filter sensory and perceptual stimuli, and if these are found to be sufficiently aversive, the high functioning infant will learn to screen them out completely. However, the most optimal state for learning to take place is one in which the infant is awake and alert. For example, research on memory in 3-month olds (Ohr et al. 1989) showed that the ability to re-learn a forgotten skill, in this case, the ability to activate a toy mobile using a kicking technique, depended on whether the infant happened to be alert or crying during the period in which the skill was being acquired. Findings revealed that upon returning to the lab a week following training, infants who had cried during the initial training visit were unable to reactivate the kicking technique, whereas those who had not cried had no difficulty.

The breastfed infant's more optimal performance of the NBAS, and especially behaviors which suggest superior alertness (Hart et al. 2003), may reflect the enhancing effects of some component of breast milk. For example, breastfed infants' more optimal performance on the NBAS has been found associated with naturally occurring higher concentrations of cortisol, SIgA, and DHA in breast milk (Hart et al. 2004, 2006). DHA may be especially important to neurological development

and intelligence, and more specifically, to key features of intellectual functioning, such as the ability to maintain attention. For example, a longitudinal study by Colombo and associates (2004) of infants and toddlers across the first 2 years of life explored maternal DHA levels at delivery in relation to infants' later skills on tasks relating to attention. Findings revealed that by the second year of life, infants of mothers with high DHA demonstrated superior ability to maintain attention. These infants were also found less easily distracted by the intermittent presentation of competing auditory/visual stimuli. Some have suggested that the breastfed infant's superior alertness may contribute to lower incidence of symptoms relating to attention-deficit/hyperactivity disorder (AD/HD) that have sometimes been reported in these children (Al Hamed et al. 2008; Julvez et al. 2007; Kadziela-Olech and Piotrowska-Jastrzebska 2005).

The breastfed infant's more optimal performance on the NBAS, and especially findings which suggest superior sociability (Hart et al. 2003) are also of importance to parenting behavior. Interactions among breastfeeding and bottle-feeding dyads (Jones et al. 2004; Kuzela et al. 1990; Lavelli and Poli 1998) are enhanced by the infant's prosocial behavior and responsivity to social stimulation, and these interaction contexts impact child outcomes. For example, an intervention study (Hart et al. 1998) found improved performance on the NBAS *sociability* cluster among 1-month olds who had been provided with daily exposure to stimulating parent–infant interactions. Not only do we find that infants are influenced by their parents, but, as suggested by the title of one of the more influential works in modern infancy research, *The Effect of the Infant on its Caregiver* (Lewis and Rosenblum 1974), the reverse is also true, that is, parents are influenced by their infants. Infants who are attentive and responsive are highly effective toward optimizing parents' behaviors and the nature of the dyadic context (Brazelton and Nugent 1995; Crockenberg and Smith 1982). Notably, this context of bidirectional influences serves as a platform for social development and the process through which attachment is gradually nurtured. In addition, it serves as the forum on which cognitive development takes place. Thus, we conclude by noting that while it is possible that breastfeeding may be beneficial to cognitive development through its enhancing effects on alertness, it is also possible that it does so through other avenues as well (Soliday 2007). One of these pertains to the more affectionate and stimulating parenting environment that is cultivated by the infant who is more sociable and responsive due to having been breastfed.

Summary Points

- Crying in the breastfed infant may be more frequent but of shorter duration and lesser intensity. Its relation to pain threshold is unclear.
- Breastfed newborns show more optimal social behavior, alertness, motor development, and neurological organization. Correspondingly, they are found having longer heart rate, elevated heart period variability, and higher vagal tone, suggesting more optimal physiological organization.
- Findings on the breastfed infant's sleep appear to suggest that sleep latency is of shorter duration, sleep episodes are shorter in duration, and arousability is greater.
- The breastfed infant's sleep architecture may relate to child health. Some potential benefits relate to SIDS, enuresis, and obesity.
- The breastfed infant's superior alertness may be implicated in more optimal cognitive performance and fewer symptoms of ADHD that have been found associated with breastfeeding.
- The breastfed infant's superior sociability and responsivity may have an enhancing effect on parenting behavior which, in turn, provides the infant with enhanced access to a stimulating environment that is advantageous to learning.

Key Terms

AD/HD: A neurobiological disorder, more typical in children and associated with developmentally inappropriate behavior, including poor attention skills, impulsivity, and hyperactivity.

Cortisol: A steroid hormone released by the cortex, outer layer, of the adrenal gland when a person is under stress. Classed as a glucocorticoid, it is synthesized in response to ACTH in the pituitary gland and acts by reducing the reserves of protein in all body cells except cells of the liver and gastrointestinal tract. It also makes fatty acids available for metabolic use.

DHA: A long-chain omega-3 polyunsaturated fatty acid important for optimal functioning of the brain and retina.

ECG: The recording of the brain's spontaneous electrical activity produced by the firing of neurons within the brain.

NBAS: Developed by T. Berry Brazelton and associates, this instrument is used to evaluate reflexes and behavior in neonates and infants up to the age of 60 days.

SIgA: Secretory IgA is a class of immunoglobulin found in some body secretions, e.g., saliva, respiratory secretions, milk, and colostrum, which is responsible for local immunity.

Chapter 36
Meal Composition and Cognitive Function

Louise Dye, Alexa Hoyland, Daniel Lamport, and Clare Lawton

Abbreviations

5-HT	5-hydroxytryptamine
Ach	Acetylcholine
BBB	Blood Brain Barrier
NA	Noradrenaline
CHO	Carbohydrate
IGT	Impaired glucose tolerance
NGT	Normal glucose tolerance
IFG	Impaired fasting glucose
OGTT	Oral glucose tolerance test
HbA1c	Glycated haemoglobin
MMSE	Mini Mental State Examination
GI	Glycaemic index
GL	Glycaemic load
LCPUFA	Long chain polyunsaturated fatty acids
DHA	Docosahexaenoic acid
EPA	Eicopentaenoic acid
ARA	Arachidonic acid

36.1 Introduction

36.1.1 What Are Cognitive Functions?

Cognitions (or cognitive functions) include those activities that allow animals (including humans) to perceive, understand, and act upon the environment in such a way as to optimize adaptation and performance. The development of cognitive abilities through evolution has clearly played a large role in allowing humans to gain mastery over the environment. Possessing brain processes that provide

accurate perception and memory of environmental events enables organisms to function successfully. Cognitive abilities clearly play a large part in daily activities and tasks, such as car driving, operating machinery, and school or work performance. These complex skills are composed of a number of individual cognitive processes such as attention to and perception of the environment, the acquisition, storage, organization, and retrieval of information, and the organization of effective response patterns. These processes form the basis for laboratory-based tests of individual cognitive functions. However, even memory, the cognitive function most widely studied in terms of macronutrient effects, is not comprehensively examined in these studies. Memory formation can be divided into encoding, storage, and retrieval; working memory is short-term memory used while performing a task; long-term memory can be declarative or explicit (knowing that) and nondeclarative or implicit (knowing how). Declarative memory includes episodic memory (personal experience) and semantic memory (known facts). Implicit memories consist of conditioning, priming, and skills, and are nonassociative. Hence memory when measured in the context of nutrition is unlikely to consider or discriminate between these various parameters of the cognitive function.

The validity and sensitivity of laboratory tests are an essential part of the methodology to assess the effects of foods and food components. In practice, a limited number of tests have been used to assess the effects of diet on mental performance. Because cognitions are so important to human functioning, they are usually operating at a high level and can be protected from degradation by applying extra effort. Consequently, it is not always easy to demonstrate the effect of any intervention (food or other) on performance on these tests. Despite this, there has been considerable interest and coverage of the possible effects of a multitude of meal components and nutraceuticals on mental performance. In addition to the relative effectiveness of the basic macronutrients, studies have also evaluated differences within each macronutrient, particularly carbohydrate (CHO). Other studies have considered the role of antioxidants, vitamins, and isoflavones (IF), as well as nutraceuticals such as ginseng (e.g., Kennedy and Scholey 2003) in the enhancement of cognition function and the prevention of cognitive decline. This review provides an overview of the effects of the major meal components on cognitive performance, considers how habitual dietary status may affect these relationships, and describes the how these effects impact on individuals suffering from relevant disease states.

36.1.2 Effects of Macronutrients on Mental Performance

In a comprehensive review of the effects of macronutrients on mental performance, Dye, Lluch, and Blundell (2000) concluded that macronutrients do appear to have effects on cognitive function. Studies of macronutrients given in combination suggest that fat slows reaction time but may produce greater performance accuracy (Smith et al. 1994). CHO improves memory but can impair peripheral processing, attention, and reaction time, depending on the time of day and type of CHO ingested as well as the CHO:protein ratio (Dye and Blundell 2002). It is also associated with feelings of fatigue (Reid and Hammersley 1999). The most heavily researched hypothesis regarding the effects of food on cognition involves brain utilization of glucose, because glucose provides the brain's only metabolic fuel. The normal level of blood glucose is 4–5.5 mmol/L, and this is tightly controlled by a series of hormonal mechanisms. When it falls below 2.2 mmol/L, hypoglycemia occurs. The decline in glucose associated with hypoglycemia in Type II diabetics has been shown to impair cognitive performance (Awad et al. 2004). Moreover, some nutritional interventions which facilitate a rise in blood glucose have been shown to enhance performance.

Glucose administration has been shown to benefit short-term and working memory in young adults and the elderly (Hall et al. 1989; Sünram-Lea et al. 2001). Performance on three memory tasks

was measured in participants who had, and had not, consumed breakfast (Benton and Parker 1998). Omission of breakfast was associated with poorer recall in two of the three memory tasks, but this effect was reversed by the administration of a glucose drink. Recovery from nadir and rising blood glucose have also been associated with better recall than falling blood glucose levels (Donohoe and Benton 1999). Blood glucose level has also been shown to be positively correlated with decision time (Benton and Owens 1993). However, the enhancement of cognitive function by glucose is not consistently reported (e.g., Craft et al. 1994; Scholey and Kennedy 2004), and induced hypoglycemia is not necessarily detrimental to cognitive function in normal samples (Gold et al. 1995). There are many participant and experimental factors which may modulate the relationship (Green and Gibson 2002).

Task difficulty influences the apparent effects of glucose on cognition. More difficult tasks produce higher cognitive demands, which may lead to an increase in glucose metabolism in the brain. In one study (Scholey et al. 2001), 25 g glucose was administered, and memory performance was tested after either serial sevens (a highly demanding task), or a control task. Both tasks were followed by word retrieval (verbal fluency). Glucose consumption improved performance on serial sevens and verbal fluency. Moreover, peripheral measures of blood glucose declined in the high cognitive demand condition. The potential mechanisms by which glucose availability might interact with task demand are considered next.

Some studies suggest that the absolute level of glucose may not be directly predictive of cognitive function (see Messier 2004 for a review). Messier et al. (1999) reported that the effects of 50 g glucose on word recall performance were dependent on glucoregulatory processes. Glucose ingestion reversed the performance decrement associated with poorer glucoregulation but did not impact on participants with better glucoregulation. It is also possible that a food may exert conflicting effects on different aspects of cognitive performance, by enhancing one function but simultaneously impairing another. In a recent study of the effects of breakfasts differing in macronutrient and calorie content on cognition in young adults, lower blood glucose levels tended to be associated with enhanced memory function (immediate and delayed word recall), particularly in participants with poorer glucose tolerance. In contrast, higher blood glucose levels were associated with better vigilance and RT performance (Nabb and Benton 2006). Further, the effect of 50 g glucose on memory for trigrams was dependent on initial blood glucose levels (Martin and Benton 1998). Those with higher levels of blood glucose showed better performance. However, after the glucose drink, falling levels of blood glucose were associated with better memory performance.

Not all effects of meals on performance are due to changes in glycemia, changes in performance can be mediated by serotonin (5-hydroxytryptamine, 5-HT) as well as glucose availability. Glucose is required for the synthesis of neurotransmitters such as serotonin (5-HT), noradrenaline (NA), and acetylcholine (ACh). The action of glucose on the cholinergic system may increase the synthesis of ACh (Messier 2004). Hence, the effects may not be solely related to the increased availability of neural fuel. Other studies suggest that stable performance is related to a balanced glucose metabolism and state of metabolic activation. The CHO:protein ratio of a meal can produce depletion or enhancement of tryptophan via an effect on the tryptophan : large neutral amino acid ratio (for a review of these mechanisms, see Gibson 2007). Where tryptophan availability is enhanced, faster memory scanning has been demonstrated in stress-prone subjects who may have receptor sensitization of the serotonergic system or 5-HT deficiency (Markus 1999). Tryptophan depletion selectively impairs memory consolidation in normal volunteers (Riedel et al. 1999).

Recently, a systematic review evaluated studies of the acute effects of macronutrients on cognitive performance, which met certain criteria in terms of experimental control, and which should therefore reflect most reliable research in the area (Hoyland et al. 2008). The review reported three major outcomes.

First, effects of macronutrients on cognitive performance were most often reported for memory in comparison with the other cognitive domains assessed, e.g., attention and psychomotor performance.

Second, tasks that required greater cognitive load tended to be more sensitive to macronutrient manipulations. In particular, tasks undertaken in a delayed context tended to report effects of macronutrients more consistently than those undertaken immediately following manipulation administration.

Third, tasks identified as consistently sensitive to glucose manipulations were working memory tasks (e.g., Serial Sevens Task) and verbal memory tasks (e.g., free word recall and cued word recall). The tasks appeared to be more sensitive when administered in a delayed context. There was also some evidence for improved word recognition, in addition to retrieval, when administered after a delay. Visuo-spatial memory also appeared to be sensitive to glucose, but other macronutrients also affected this cognitive domain.

Taken together, studies of the effects of glucose on cognition suggest that it enhances memory *provided* tests of sufficient difficulty are used to produce high cognitive demand in normal adults who are less vulnerable than undernourished or elderly samples (Dye et al. 2000).

36.1.3 Effects of Breakfast on Cognitive Function

Many studies have administered manipulations at breakfast time, partly because testing at this time of day means participants can present in a fasted state. Effects of breakfast manipulations have been reported on a range of cognitive functions. Breakfast studies suggest that the absence of breakfast consumption can lead to impaired cognitive performance on tests of reaction time and short-term memory (e.g., Smith et al. 1994). A "realistic" breakfast of cereal and milk improved visuo-spatial memory in a task requiring memory for sequences of lights relative to no breakfast (Smith et al. 1999).

However, beneficial effects of breakfast on cognition are not consistently reported and the null findings may relate to the cognitive domain examined. Despite quite confident claims that the absence of breakfast consumption is deleterious to mental performance, Pollitt and Mathews (1998) argue that no definitive conclusions about the cognitive benefits of breakfast can be drawn. There was no difference in word recall following a fast or one of three isoenergetic breakfasts of varying CHO and fat content nearly 3 h post breakfast (Lloyd et al. 1996). In addition, Uijtdehaage et al. (1994) reported no performance differences between CHO-rich and protein-rich breakfasts and a fast on a working memory task.

Other studies indicate that a mid-morning snack may be more important than breakfast. Benton et al. (2001) measured delayed free word recall in a breakfast and mid-morning snack manipulation. The provision of breakfast had no impact on performance but the provision of a 25 g CHO snack did; free word recall was enhanced 20 min after the snack. It is possible that individuals tend to perform at a high level on rising at the start of the day and performance may be harder to alter via nutritional manipulations at this time. This idea is supported by indications of time-of-day effects. Performance on the same task was better when measured at breakfast compared with lunch (Sünram-Lea et al. 2001). Consumption of breakfast may also influence motivation or introduce demand characteristics to the experiment as it is impossible to blind breakfast–no breakfast comparisons. In one study for example, breakfast consumption did not improve performance on a verbal recall task but participants spent longer attempting to recall the words in the breakfast condition (Benton et al. 2001) which could reflect greater motivation following breakfast.

Studies in samples other than healthy adults indicate that the effects of breakfast may be more profound in the elderly (e.g., Kaplan et al. 2001). In addition, there is a widely held belief that breakfast is important for the performance of children at school. This belief has promoted intense interest

in the capacity for breakfast to exert long-term effects on scholastic performance. Studies of school breakfast programs suggest that breakfast omission may detrimentally affect children's mental performance (e.g., Grantham-McGregor et al. 1998; Murphy et al. 1998). Studies most commonly report improved mathematics scores. However, these observed effects may not be the direct effect of breakfast. Often, the introduction of school breakfast programs leads to a concomitant rise in school attendance. Improvements in school performance may therefore be an artifact of increased attendance, rather than improvements to the ability to concentrate during the school or nutritional profile.

Intervention studies which examine the acute effects of breakfast on the cognitive performance of children have been reviewed by Hoyland et al. (2009) who concluded that while there is reasonable evidence to suggest beneficial effects of breakfast compared with breakfast omission, there is little evidence to recommend specific foods be consumed at breakfast to improve the performance of well-nourished children. Table 36.1 summarizes the impact of breakfast on cognitive function.

36.1.4 Effects of Lunch and the Postlunch Dip

The consensus view is that daytime sleepiness, or the afternoon decline in mental alertness (the so-called postlunch dip, PLD), is a circadian rhythm. This phenomenon has sparked considerable research interest in many European countries, given its association with a loss of work efficiency. It is difficult to disentangle the effects of lunch consumption from the rhythmic effects underlying the PLD. Cognitive declines could simply reflect the effect of a negative energy balance or a lack of available glucose.

In an early review of six studies examining circadian rhythms in mental performance, deficits (particularly those related to attention) were reported in the early afternoon (Monk and Folkard 1985). Increasing meal size at lunchtime produces more momentary lapses of attention, however, irrespective of food consumption performance on sustained attention tasks is impaired in the early afternoon, compared with the late morning (Smith and Miles 1986). This PLD effect is abolished by caffeine (Smith et al. 1990). See Table 36.2 for a summary of the PLD.

Circadian patterns in mood may interact with food intake. Diurnal variation in postprandial hormone and metabolic responses has been well documented (Hampton et al. 1996). Glucose and cortisol secretion (as responses to food intake) vary across the day and alertness peaks midmorning, then falls throughout the day (van Cauter 1990). The natural rhythm of cortisol exhibits diurnal attenuation. These rhythms may explain the different effects of meals on mood and performance across the day.

Table 36.1 Key features of breakfast and cognitive function

- Breakfast is more beneficial to cognition than no breakfast.
- It is not possible to define an "optimal" breakfast for cognitive function.
- School breakfast programs show benefits for cognition but this could be due to increased school attendance.
- Some groups are more likely to benefit from breakfast consumption, such as children and the elderly.
- Memory performance may be most influenced by breakfast consumption.

This table shows the key features of the impact that breakfast consumption has on cognitive performance

Table 36.2 Key features of the PLD

- The PLD is a natural circadian rhythm.
- Subjective alertness decreases postlunch consumption.
- The same food can have different effects at lunch compared with morning.
- The PLD can be abolished by caffeine.

Thus, the effects of alertness-enhancing foods are most likely to be detected if they are ingested at a time when alertness is naturally declining, and cognitive capacity is challenged by an appropriate cognitive test. For instance, the beneficial effects induced by afternoon snacks do not occur when these snacks are consumed in the late morning (Kanarek and Swinney 1990). Therefore, task selection in the design of a test battery and test meal design, should embrace these considerations. Furthermore, physiological measures, e.g., blood glucose, cortisol and heart rate, are important to confirm the metabolic state of the individual, at staggered times post ingestion.

Dietary interventions that potentially modulate the PLD are of research interest. Varying the glycemic index (GI; see next) offers a considerable opportunity for functional food development, with potentially positive effects on the extent and timing of postlunch inefficiency. Maintaining blood glucose appears to be beneficial. This can impact advice about breakfast consumption, snacking, and the development of functional foods, which modulate blood glucose. The effect of CHO at lunchtime is therefore an important consideration. See Table 36.2 for a summary of the PLD.

36.1.5 Effects of CHO at Lunchtime

No studies examining the effects of CHO at lunchtime have detailed the GI of the dietary manipulation. However, numerous studies have documented attenuated reactions following CHO at lunchtime. High CHO lunches produce a greater impairment on reaction time, than standard high fat meals, high protein meals, or conditions in which no lunch is given (for review, see Dye et al. 2000).

Reaction time has been shown to be slower after a low CHO/high fat lunch compared with a high CHO/low fat lunch. In contrast, reaction times were impaired following both high fat/low CHO and low fat/high CHO lunches when compared with a medium fat/medium CHO lunch, which produced optimal performance (Lloyd et al. 1994). Higher than usual proportions of fat or CHO may induce drowsiness or uncertainty, or potentially affect cognitive efficiency and motor performance.

36.1.6 Effects of GI and GL on Cognitive Function

Dietary interventions based on CHO are typically described using terms such as GI, glycemic load (GL), the ratio of slowly to rapidly available glucose, the proportion of simple to complex CHO, or the amount of rapidly versus slowly digested CHO. Both the quality (e.g., type/nature/source) and quantity of a CHO are important determinants of its glycemic response. As the GI by definition compares equal quantities of available CHO, it provides a measure of CHO quality not quantity.

Several studies have shown that low GI foods consumed at breakfast lead to better verbal memory over the morning (0–3 h post ingestion) compared to high GI foods in healthy adults, type 2 diabetics, and children (Benton et al. 2003; Ingwersen et al. 2007; Papanikolaou et al. 2006). The evidence examining acute effects of GI on attention is inconsistent. One study with children has shown improved attention following a high GI breakfast (Mahoney et al. 2005), whereas in contrast a low GI breakfast has been associated with improved attention in children (Ingwersen et al. 2007) and healthy middle-aged adults (Nilsson et al. 2009). In the healthy elderly and type 2 diabetics no associations between attention and GI have been observed (Kaplan et al. 2000; Papanikolaou et al. 2006).

The GL is the product of a food's GI and the amount of CHO per serving. GL imparts information about CHO quantity and reflects the glycemic response of actual food portions. In healthy individuals,

stepwise increases in GL have been shown to predict stepwise elevations in postprandial blood glucose and/or insulin response to specific foods (Brand-Miller et al. 2003). Low GI is not the same as low GL and meals which differ with respect to these characteristics could result in a different cascade of postprandial hormonal responses with the potential for different cognitive effects.

Gilsenan, De Bruin, and Dye (2009) provide a critical evaluation of eight studies that have explored the relationships between food CHO and cognitive performance and allow GL to be used as a basis for comparison. The key finding is that these provide insufficient evidence to support a consistent effect of GL on short-term cognitive performance. Both acute and long-term cognitive effects of GI and GL require further investigation, since the present evidence cannot support any definitive conclusions. However, the association between improved memory and low GI foods is consistent with the evidence linking a low GI diet to health benefits. A high GI diet has been associated with an increased risk of cardiovascular disease, type 2 diabetes, obesity, and cancer possibly due to postprandial hyperglycemia, and hyperinsulinemia (Gnagnarella et al. 2008). Given that there are prominent health recommendations to adopt low GI diets, the long-term cognitive impact of doing so requires evaluation. See Table 36.3 for a summary of GI and GL.

36.1.7 Effects of the Evening Meal

There is very little evidence examining the effect of evening meal manipulations on cognitive function. Smith et al. (1994) found that consumption of a 1,200–1,500 kcal meal resulted in better completion of sentences on a logical reasoning task compared to having no meal; however, there were no differences in sustained attention, word recall, or word recognition. To date there are no other studies that have examined cognitive performance in the evening and therefore the effects of GI, GL, or macronutrient manipulations of the evening meal on cognitive performance in the evening remain speculative.

Interestingly, a recent study found that the composition of the evening meal can affect cognition the following morning (Lamport et al. submitted). A high GI evening meal was associated with better word recall the following morning compared to a low GI evening meal. This suggests that nutritional manipulations may exert cognitive effects beyond the initial postprandial period. One explanation for a previous meal influencing cognitive function at the next meal relates to the "second meal effect" (Wolever et al. 1988). The second meal effect can influence glucose, insulin, fatty acids, and serotonin levels. For example, a low GI evening meal is associated with an improved glycemic response at breakfast compared with a high GI evening meal, even after an overnight fast (Wolever et al. 1988). The circadian rhythm of insulin sensitivity, when a relative insulin resistance occurs in the evening and night-times (Morgan et al. 2003) could explain why the same meal consumed in the evening can impair glucose and lipid tolerance much more than an equivalent daytime meal (Morgan et al. 1998).

Table 36.3 Key features of glycemic index and glycemic load

- High glycemic index foods typically cause blood glucose to rise rapidly to a high peak, whereas low GI foods are characterized by a slower rise and lower peak.
- High GI foods are often referred to as RAG (rapidly available glucose).
- Low GI foods are often referred to as SAG (slowly available glucose).
- HGI foods are associated with cardiovascular disease and diabetes.
- Glycemic load of a food is a calculated by GI × grams of carbohydrate/100.
- There is some evidence that the GI and GL of foods can affect cognitive function.

This table explains the nature of high and low glycemic index foods, and summarizes the impact these foods have on health and cognition. The definition of glycemic load (GL) is also shown

These findings suggest that the effect of evening meal manipulations on cognition should be examined during the postprandial period, the next day, and in relation to our habitual eating patterns which could contribute toward risk of cardiovascular disease (CVD) and type 2 diabetes and which in themselves may be associated with cognitive impairment (see next). A late eating pattern is part of our Western, industrial lifestyle, and could over time impair gluco-regulation, which could promote obesity and associated conditions. An extreme example of this relates to nightshift workers, whose postprandial metabolic profiles are impaired (Al-Naimi et al. 2004) and whose risk of CVD is approximately 1.4 times that of dayworkers.

36.2 Mechanisms of Action

Glucose level in the brain and the periphery is kept under tight control. The regulation of glucose transport across the blood–brain barrier (BBB) which occurs via GLUT1 transporters is not well understood (Convit 2005). Glucose levels in the brain are about 30% of those in peripheral blood and long-term elevations in peripheral glucose result in decreased glucose transport across the BBB (Pardridge et al. 1990) providing a hypothesis to explain impaired cognitive function in conditions associated with dysfunctions of glucoregulation such as diabetes. This would not however, explain the facilitatory effects of glucose in healthy adults.

There have been several processes proposed, operating alone or in combination, by which glucose might exert effects on cognition (Messier 2004). There is convincing evidence that astrocytes play an important role in energy regulation. These star-shaped glial cells, which surround neurons and lie in close proximity to the cerebral vasculature, are believed to constitute a likely site of glucose uptake as it crosses the BBB (Pellerin and Magistretti 1994). It is hypothesized that during neuronal activation, glucose is taken up by astrocytes, converted into lactate (by glycolysis), which is then released into the extracellular space to be taken up as an energy substrate by neurons (Tsacopoulos and Magistretti 1996).

During brain activation, e.g., under high cognitive task demand, utilization and local concentrations of glucose have been shown to alter. An increase in glucose uptake by the brain in young males undertaking a complex visuo-spatial motor task was observed in a study using Positron Emission Tomography (PET) suggesting that increased neural activity (e.g., learning a complex visuo-spatial motor task or verbal working memory) is associated with an increased use of glucose by the brain (Haier et al. 1992). In rats, a decrease in hippocampal interstitial glucose levels proportional to the difficulty of the maze was observed (McNay et al. 2000). However, in both studies peripheral glucose concentrations remained unchanged. This suggests that cognitive demand is accompanied by increased local glucose metabolism in those brain areas engaged in specific tasks.

The mechanisms by which GI and GL may affect cognitive function are currently unclear. GL is influenced by several factors which relate to the food itself (i.e., the other food components such as nature of starch, content of fat, protein, and fiber), eating behavior (i.e., rate of ingestion, frequency of food intake, composition of a meal), and physiological factors (i.e., gastric emptying rate, intra- and interindividual variation in glycemic response and hormonal responses; Arvidsson-Lenner et al. 2004). The mechanisms by which GI could affect cognition in relation to acute postprandial effects are likely to differ from those involved in the second meal cognitive effects seen later in the day or overnight. Acute effects may be driven by changes in glucose as described earlier. Overnight effects may involve insulin and free fatty acid fluctuations. Hormonal responses can affect brain function and behavior either through peripheral or central mechanisms. The memory-enhancing effects of peripherally injected peptide hormones were attenuated after vagotomy in rats, suggesting that gastrointestinal

hormones relay neural signals to the central nervous system which could influence cognitive processes (Flood and Morley 1998). Recent evidence suggests that circulating ghrelin crosses the BBB from the periphery where it binds to neurons, alters neuronal morphology, and affects generation of long-term potentiation, an important neural-level cognitive process (Diano et al. 2005).

Insulin also crosses the BBB. Improvements in cognitive function have been observed following infusion of insulin in healthy adults (Kern et al. 2001; see Park 2001 for a review). Glucocorticoids (e.g., cortisol) influence circulating glucose. Cortisol receptors are abundant in the hippocampus, a region strongly implicated in memory. There is evidence from both animal and human studies that glucocorticoids influence memory (see Gibson 2007 for a review). However, several gastrointestinal hormones are typically released in response to food consumption and it is therefore difficult to assess their specific effects on subsequent cognitive function.

36.3   Habitual Diet and Cognitive Function

The composition of the habitual diet could have important consequences for the physiological and behavioral patterns of the consumer. For example, phenotypes of habitual diet composition (low fat vs high fat) can be identified. It has been suggested that individuals habitually consuming different diets vary in certain physiological and behavioral characteristics (Blundell and Cooling 2000). Therefore, habitual diet may have an important influence on the effect of food on cognitive performance. For example, epidemiological studies such as the Rotterdam Study (Kalmijn et al. 1997) suggest that regular intake of oily fish is associated with lower incidence of dementia. Such evidence has led to scrutiny of the diets of those countries whose inhabitants show increased longevity and low incidence of conditions such as Alzheimer's disease and cognitive decline.

It is easy to assume that food and food components exert homogeneous effects in all individuals. However, the effects of foods may depend on usual dietary intake, i.e., habitual diet. Since humans have a strong volitional control over food intake, habitual food intake may mediate the potential of foods to exert effects on appetite and satiety, mood, and cognitive function.

Evidence from animal studies suggests that there may be differences between the chronic and acute impact of diets varying in fat content. Fat appears to affect cognitive performance in rodents, particularly where high fat diets and tasks of learning and memory are employed (Greenwood and Winocur 1990). Habitual consumption of a high fat diet may lead to physiological adaptations which could influence cognitive performance.

Naturalistic studies suggest that a habitual diet which influences parameters such as cholesterol levels may influence levels of performance. Low plasma cholesterol was associated with slower movement and decision time on a choice reaction time task (Muldoon et al. 1997).

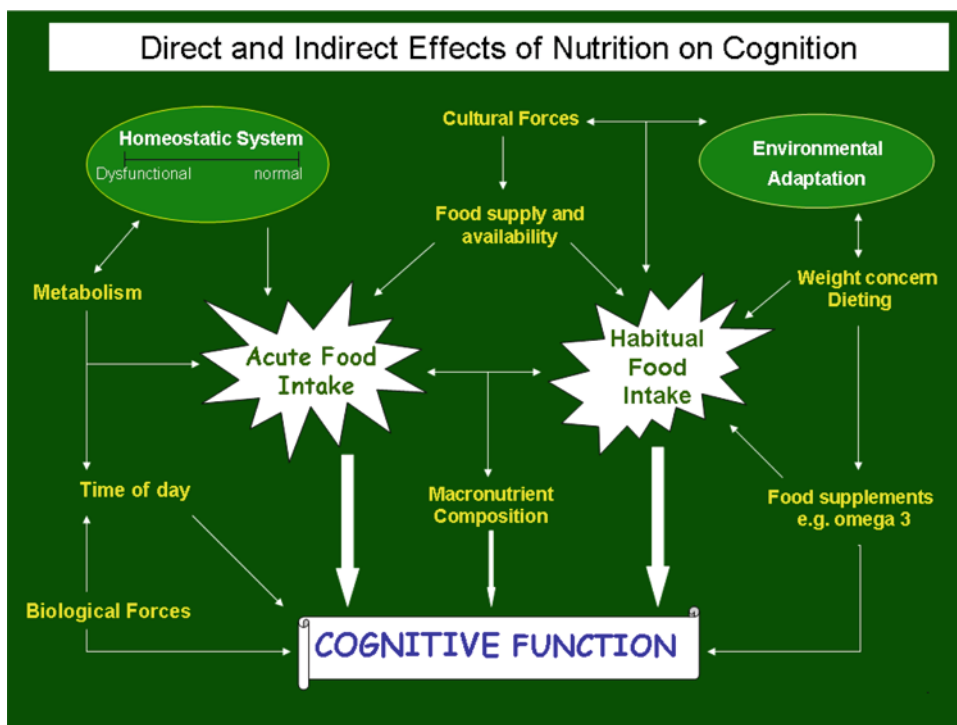
Chronic or longer-term intervention studies are rare. However, the effect of regularity of meals has been studied and this may be important. For example, breakfast consumption is associated with greater wellbeing and a healthier lifestyle and regular breakfast consumers tend to have a healthier body weight and meet daily nutrient intake guidelines (Sjoberg et al. 2003). Cognitive effects of the habitual diet may influence the ease with which individuals are able to change their habitual dietary intake to reduce the likelihood of weight gain and obesity. This is particularly important in those individuals most likely to benefit from changing consumption patterns to prevent weight gain and future obesity (i.e., individuals with a high fat intake). In summary, the impact of the habitual diet and acute food intake on cognitive function is complex, with several other factors having both direct and indirect effects on cognition (see Fig. 36.1).


Fig. 36.1 Direct and indirect effects of nutrition on cognition. This diagram represents the different ways that diet and nutrition can impact upon cognitive function. Some factors such as acute food intake can have direct effects on cognition, whereas other factors such as an individual's metabolism can affect cognition indirectly by, for example, influencing acute food intake

36.4 Phytoestrogens and Cognitive Performance

Soy IF are a common source of phytoestrogens and are commonly consumed as part of the habitual South East Asian diet. Phytoestrogens are able to enter the brain and act both centrally and peripherally. Evidence from human and animal studies suggests that phytoestrogens could affect cognition via direct central action as well as by modulating the hormonal milieu (for a review, see Hill and Dye 2003).

Epidemiological evidence shows there to be a lower incidence of dementia in Asian populations compared to Western populations, particularly in the Japanese (Graves et al. 1996). However, cross-sectional and longitudinal studies have not shown positive associations of soy consumption and cognitive function in older adults (White et al. 2000). This may be because IF intake in Western populations is typically too low for cross-sectional or longitudinal analysis of the relationship between IF consumption and cognitive performance to be viable.

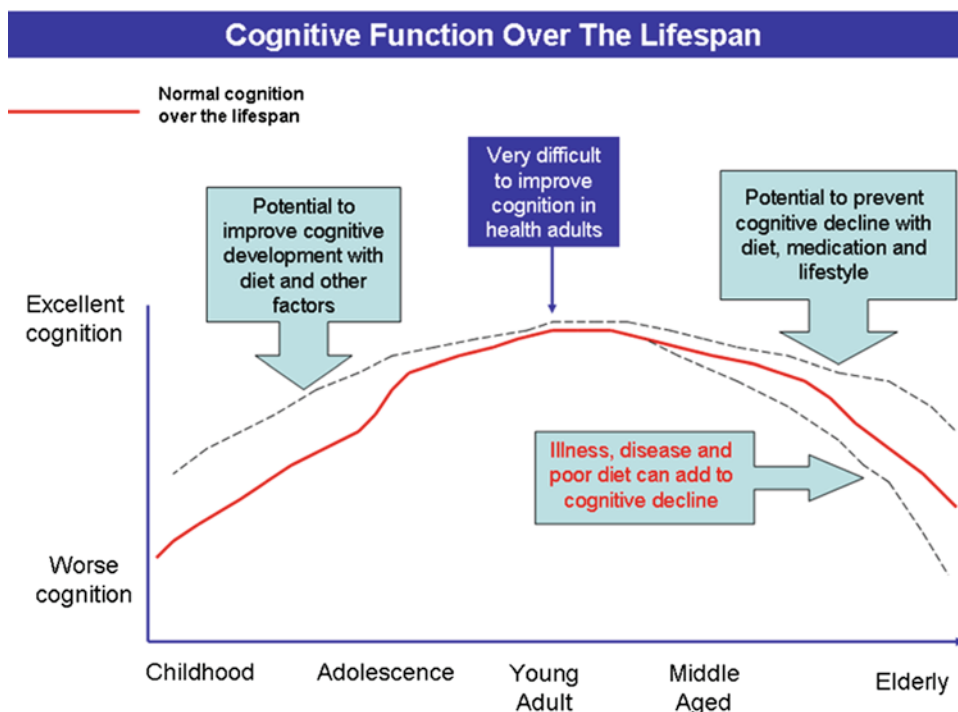
In recent years, there have been a number of attempts to investigate whether phytoestrogens affect cognitive performance using randomized intervention studies. This small body of literature gives a preliminary insight into how and when phytoestrogens might influence cognitive function. These studies suggest that soy IF can impact on cognitive function in healthy samples. For instance, Hill et al. (submitted) demonstrated 8 weeks intervention with 100 mg/day soy IF to be cognitively active in postmenopausal women and an effective treatment for hot flushes and sleep disturbance. Although effects on cognitive tasks sensitive to estrogen levels became apparent in line with an increase in estrogen after 4 weeks of soy IF, improvements in frontal lobe functioning were evident only after 8 weeks which may imply that changes in neuronal functioning may be necessary for these effects.


Fig. 36.2 Cognitive function over the lifespan. This diagram represents how cognitive function develops from childhood to a peak during adulthood, which is then followed by a decline associated with old age. Diet may enhance the development of cognitive function during childhood; however, there is little scope for nutritionally driven cognitive improvement during adulthood. Certain diets may help to prevent cognitive decline associated with old age

In contrast, benefits to symptomatology were evident in the first week of treatment, with no further improvement with increasing duration of the intervention.

36.5 Fish, Omega-3, and Cognitive Function

Derived from fish, the health benefits of cod liver oil (CLO) have widespread public acceptance and CLO was used in the treatment of rheumatism and rickets for almost two centuries. Epidemiological and intervention studies have indicated that modest fish intake was associated with decreased mortality in men with myocardial infarction (Burr et al. 1989) and lower incidence of dementia (Kalmijn et al. 1997). Fish (and CLO) contains long-chain polyunsaturated fatty acids (LCPUFA), particularly the omega-3 PUFAs: docosahexaenoic acid (DHA: 22:6n-3 or 22:6ω3) and Eicosapentaenoic acid (EPA: 20:5ω3 or 20:5ω3) while vegetable oils are the main sources of omega-6 PUFA arachidonic acid (ARA: 20:4n-6 or 20:4ω6). Early observations of a marked increase in LCPUFA in brain in the last trimester of pregnancy and first two years of life suggested their role in brain growth and animal studies confirmed that omega-3 PUFA were essential for the development of vision. Studies which consider the effects of supplementation with LCPUFAs prenatally and in infants are outside the scope of this review and have been the subject of recent Cochrane reviews (Simmer et al. 2008).

A recent Swedish study reported an association between reported fish consumption (more or less than once per week) at age 15 and cognitive performance assessed at military conscription 3 years

later, even after adjustment for socioeconomic factors (Åberg et al. 2009). In contrast, three recent randomized controlled trials which used omega-3 supplementation found no effects on cognitive function of DHA in 10–12-year-old children (Kennedy et al. 2009), EPA and DHA in mild to moderately depressed adults (Rogers et al. 2008) or elderly adults (van de Rest et al. 2008) treated for 8, 12, and 26 weeks, respectively. There have however, been no published studies which have examined the effects of interventions based on increased fish consumption so it is difficult to draw inferences about effects of consuming LCPUFAs delivered via the food chain versus supplementation with extracted LCPUFAs. Indeed, it is also possible that the health and possible cognitive benefits of fish consumption are related to other nutrients present in fish which remain to be investigated.

36.6 Applications to Other Areas of Health and Disease

Some physical illnesses are associated with impairment of cognitive function and dietary intake is a risk factor for the development of these conditions, e.g., atherosclerosis, type 2 diabetes, and hypertension. Obesity is a significant risk factor in the development of all these conditions, and has been associated with cognitive impairments independently of medical comorbidities (Boeka and Lokken 2008). Hence, our habitual diet can influence the development of diseases for example by promoting obesity.

The development of obesity and nutritional overconsumption are strongly associated with the development of diabetes and impaired glucose tolerance (IGT; see Table 36.4 and Fig. 36.3). Both IGT and diabetes, which are characterized by abnormalities in glucoregulation, are associated with cognitive impairments (Lamport et al. 2009). Consumption of certain foods and diets such as a low GI diet have been recommended as a method to control and potentially improve the abnormalities in glucose handling seen in individuals with IGT and type 2 diabetes. Although the cognitive effects of a habitual low GI diet are unknown, research has shown that long-term improvements in glucose handling produced by increased physical activity are associated with cognitive benefits (Watson et al. 2003). If improved glucoregulation is the mechanism by which cognitive benefits occur, then

Table 36.4 Diagnostic criteria for type 2 diabetes, impaired glucose tolerance (IGT), impaired fasting glucose (IFG), normal glucose tolerance (NGT)

	World Health Organization (WHO) 1999	American Diabetes Association (ADA) 2003
Diabetes		
Fasting glucose level	≥7.0 mmol/L	≥7.0 mmol/L
	or	or
2-h glucose level[a]	≥11.1 mmol/L	≥11.1 mmol/lL
IGT		
Fasting glucose level	<7.0 mmol/L (if measured)	Not required
	and	
2-h glucose level[a]	≥7.8 and <11.1 mmol/L	≥7.8 and <11.1 mmol/L
NGT		
Fasting glucose level	<6.1 mmol/L	<5.6 mmol/L
	and	and
2-h glucose level[a]	<7.8 mmol/L	<7.8 mmol/L

The ways in which the World Health Organization and the American Diabetes Association define normal glucose tolerance (NGT), impaired glucose tolerance (IGT), and type 2 diabetes. Diagnosis is determined by examining venous plasma glucose 2 hours after ingestion of a 75g oral glucose load

[a] Venous plasma glucose 2 h after ingestion of a 75 g oral glucose load
Fig. 36.3 Type 2 diabetes, impaired glucose tolerance, and normal glucose tolerance. Glucose regulation status is measured by examining blood glucose levels 2 h following consumption of 75 g glucose. Normal glucose tolerance is defined as <7.8mmol/L, impaired glucose tolerance is defined as ≥7.8 and <11.1 mmol/L, and type 2 diabetes is defined as >11.1 mmol/L

there is clear potential for cognitive benefits to accrue from a habitual diet which improves gluco-regulation, such as a low GI diet.

It is evident that cognitive decline could also be increased or prevented by our habitual diet. Rogers (2001) has reviewed the long-term impact of diet on mood and cognitive function in relation to these conditions. Intake of various nutrients (including LCPUFA, antioxidant vitamins, folate, and vitamin B12), chronic diseases (such as atherosclerosis, type 2 diabetes, and hypertension), and cognitive function appear to be associated. However, the majority of evidence comes from correlational and epidemiological studies rendering determination of cause and effect problematic. A sensible approach to this problem would be to assess the cognitive impact of prescribed dietary interventions for which the primary endpoint is to improve health and prevent disease.

36.7 *Key Points:* Design Issues

Overall, relationships between macronutrients and cognitive performance are not pervasive or clear-cut (Hoyland et al. 2008). For many measures of cognitive performance in young adults, findings are equivocal and beneficial effects are not universally reported. The choice of cognitive task may be important in the elucidation of an effect. Some tasks are more appropriate for use when a short-term effect of food is expected and others when a chronic long-term adaptation to a diet is being examined. The former, and arguably simpler, approach has been the focus of most recent research. Reaction time, attention, and memory measures are commonly used, with less evaluation of problem solving, verbal fluency, and psychomotor skill. Selection of task may be based on accessibility rather than likely effect of a nutrient on a particular cognitive process. Null findings may be observed because the chosen task requires cognitive processing that is largely unaffected by the nutrient under examination. A manipulation is unlikely to affect cognitive processing globally, and may be specific to certain faculties.

Future research would benefit from a greater range of more sensitive tasks, in order to identify effects of food on mental performance and to uncover causal relationships. Although Hoyland et al. (2008) identify memory as the most pertinent cognitive domain, tasks sensitive to performance changes in other modalities are lacking from the literature nor are all aspects of memory considered

simultaneously. There is a need for further rigorous investigation of the effects of macronutrients on performance, particularly the effects of protein, fat, and complex CHO on a wider range of cognitive functions. There is also a need to evaluate nutrients ingested via the usual diet versus those components ingested in a pure, derived, or supplement form.

Inconsistencies in findings may be explained by the multiple factors that may impact on mental performance in a study situation. Performance will be altered by individual ability, motivation, general arousal, previous learning, time of day, fatigue, the general ability of the sample, and individual differences in glycogen stores during study participation. Mood and arousal level may also exert effects on performance (Finnigan et al. 1998). Few studies have ensured that glycogen stores are not depleted on arrival for testing by providing a suitable meal on the evening prior or at breakfast before test sessions. The type of stimuli presented to participants may impact on outcome; emotional and neutral stimuli have been shown to alter the direction of the effect of glucose on a spatial memory task (Mohanty and Flint 2001).

Determining the optimal time to test postconsumption performance is also difficult. Two hours postconsumption appears to correspond to the peak response of diet-induced mood change but mental performance may not follow the same time course. The macronutrients consumed, glucose tolerance, and time of day will all affect timing of peak effects. Macronutrients in mixed composition meals may have interaction and/or temporal effects on performance. Moreover, meals designed to deliver different macronutrient compositions may differ in energy content, volume, and sensory properties (taste, pleasantness, and consistency), all features which may influence behavior and mental performance.

The chosen study design, baseline measures, outcome variables, and analysis performed may also lead to differences in observed findings. A macronutrient may alter only a small element of performance on a cognitive task, and a limited analysis of overall performance will not necessarily be sufficiently discerning to identify changes in performance. Study sample sizes are also frequently too small to detect effects of the magnitude likely to result from nutritional manipulations.

Summary Points

- Cognitive processes are well protected and glucose level in the brain is maintained under tight control.
- Many studies report that memory function may be improved by intake of glucose or more complex CHO, but this is not consistently reported.
- It is important to consider the role of habitual dietary status in studies of the acute effects of meals on cognitive function. A lack of experimental control over dietary status may obscure relationships between a particular food and cognitive function, and instead should be considered as a potentially important modulator of the relationship.
- There is gathering evidence that low GI breakfasts benefit memory in the short-term (0–3 h post ingestion); however, the long-term cognitive effects of GI and GL require further investigation. The association between improved memory and low GI foods is consistent with the evidence linking a low GI diet to health benefits.
- Future research should investigate the effect of nutritional manipulations in evening meals on cognitive function both in the evening and the following morning, which remains largely unexplored.
- The mechanisms by which GI and GL may affect cognitive function are currently unclear. However, it seems likely a combination of postprandial hormonal responses and changes in insulin, glucose, and free fatty acids contribute.
- Habitual diets which prevent the development of obesity and associated diseases such as diabetes may also serve to protect against cognitive decline. Future research should assess the cognitive impact of habitual dietary interventions the primary focus of which is to improve health and prevent disease (see Fig. 36.1).

Definitions and Explanations of Key Terms

GL: Glycemic load: This represents the quantity of CHO in a food portion and indicates the glycemic response to that portion. It is calculated as the food GI multiplied by the amount of CHO in grams, divided by 100.

GI: Glycemic index: This is an index of the blood glucose raising potential of the available CHO in foods. Glycemic responses to high GI foods are typically characterized by a rapid rise to a relatively high peak followed by a sharp decline, whereas low GI foods are characterized by a low peak and slow decline.

IGT: Impaired glucose tolerance. This is an abnormality in glucose regulation which is not as severe as diabetes. It is defined by plasma glucose levels between 7.8 and 11.1 mmol/L following consumption of 75 g of glucose (see Fig. 36.3).

Type 2 diabetes: This is the most severe abnormality in glucose regulation. It is defined by plasma glucose levels greater than 11.1 mmol/L at 2 h following consumption of 75 g of glucose.

CHO: Carbohydrate

LCPUFA: Long-chain polyunsaturated fatty acid.

Chapter 37
Dietary Amino Acids and Mood

Reeta Rintamäki and Timo Partonen

Abbreviations

ArAA   Aromatic amino acids
BCAA   Branched-chain amino acids
GABA   Gamma-aminobutyric acid
LNAA   Large neutral amino acids
MDD   Major depressive disorder
NMDA   N-methyl-D-aspartate

37.1 Introduction

It is known that the dietary amino acids have an effect on brain functions. Some of the amino acids have influence on mood in particular through their actions as precursors for neurotransmitters. Tryptophan is a precursor for serotonin, tyrosine is a precursor for dopamine and noradrenaline, and glutamate is a precursor for gamma-aminobutyric acid (GABA; Table 37.1). These neurotransmitters are involved in the regulation of mood and behaviors. Mood disorders such as major depressive disorder (MDD) and bipolar disorder are often associated with dysfunction of these neurotransmitters, and the current medication for mood and anxiety disorders is based on drugs whose mechanisms of action influence serotonin, dopamine, and noradrenaline. Currently used sleeping pills have their effect through GABA receptor complexes.

Mood disorders are a significant public health problem worldwide. Patients with MDD have depressed mood, increased sadness and anxiety, and a loss of interest in usual activities. Patients with bipolar disorder have both depressed and manic episodes, during the latter mood being abnormally elevated. A single meal, depending on its protein and carbohydrate contents, can modify the uptake of the large neutral amino acids (LNAA) into the brain and their subsequent conversion to neurotransmitters. A hypothesis has been that some amino acids can thereby be helpful in treating mood disorders. However, there are limited data about the dietary amino acids in relation to mood or mood disorders.

Table 37.1 Neurotransmitters synthesized from amino acids

Amino acid	Neurotransmitter
Tryptophan	Serotonin
Tyrosine	Dopamine, noradrenaline
Glutamate	GABA

GABA gamma-aminobutyric acid

This table lists dietary amino acids which work as precursors for neurotransmitters.

37.2 Amino Acids and Neurotransmitters

The 20 amino acids on which the proteins of the human body are built each has a metabolic fate of its own. Humans can produce 10 of these 20 amino acids. The remaining must be supplied in and taken from the food. There are eight (ten in infants) essential amino acids for us: isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. Histidine and arginine are essential amino acids for the children but not for the adults.

Amino acids are divided into subgroups by their chemical character. LNAAs include the aromatic amino acids (ArAAs, i.e., tyrosine, phenylalanine, and tryptophan) and the branched-chain amino acids (BCAA, i.e., leucine, isoleucine, and valine). The major source of amino acids is protein-rich food, like meat, fish, poultry, eggs, milk, and dairy products.

Many amino acids participate in a range of functions of the brain such as regulation of mood. Certain neurotransmitters (serotonin, dopamine, noradrenaline, and GABA) have a role in the pathogenesis of mood disorders, both MDD and bipolar disorder. These neurotransmitters are synthesized from the dietary amino acids in the brain.

Serotonin is an inhibitory neurotransmitter, which appears to play an important role in the central nervous system circuits that regulate mood, emotional behaviors, and sleep. Serotonin also influences appetite regulation, and it provides one of the links between mood and food. In the brain, serotonin is synthesized from tryptophan (Fig. 37.1). Reduced serotonergic transmission is associated with the pathogenesis of depressive illness. There is an increase in the activity of serotonin transporters in the brain of the depressed compared with healthy individuals. Most of the antidepressant medications act through the increase in serotonin neurotransmission. Abnormalities in the brain serotonin regulation are associated with eating disorders as well.

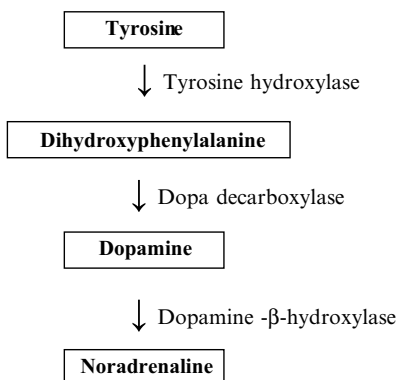
Dopamine is an inhibitory neurotransmitter, which is involved in regulation of motivation, concentration, psychomotor speed, and the ability to experience pleasure. In the brain, dopamine and noradrenaline are synthesized from tyrosine (Fig. 37.2). Reduced concentrations of dopamine metabolites
Fig. 37.1 Serotonin synthesis from tryptophan. This figure presents synthesis of serotonin from tryptophan. Tryptophan is first converted to 5-hydroxytryptophan by the enzyme tryptophan hydroxylase, 5-hydroxytryptophan is thereafter decarboxylated to 5-hydroxytryptamine (also called serotonin) by the enzyme aromatic acid decarboxylase


Fig. 37.2 Dopamine and noradrenaline synthesis from tyrosine. This figure presents synthesis of dopamine and noradrenaline from tyrosine. Tyrosine is converted to dihydroxyphenylalanine by the enzyme tyrosine hydroxylase, and thereafter dihydroxyphenylalanine is converted to dopamine by the enzyme dopa decarboxylase. Dopamine is converted to noradrenaline by the enzyme dopamine-β-hydroxylase
Fig. 37.3 The synthesis of gamma-aminobutyric acid (GABA) from glutamate. This figure is presents the synthesis of GABA from glutamate. GABA is synthesized in a single step from its precursor glutamate by the action of glutamic acid decarboxylase

in the brain of the depressed have been demonstrated. Neuroimaging studies support the hypothesis that MDD is associated with reduced dopamine transmission (Dunlop and Nemeroff 2007).

Noradrenaline is the primary neurotransmitter of the sympathetic nervous system in the periphery, but it is also prevalent in the brain. It is involved in mood regulation, sleep, expression of behaviors, and the general degree of alertness and arousal. Traditional antidepressants increase the concentrations of noradrenaline.

GABA is a major inhibitory neurotransmitter in the central nervous system. It modulates the activity of several neurotransmitters, including dopamine, serotonin, and noradrenaline. GABA is synthesized in a single step from its precursor glutamate by the action of glutamic acid decarboxylase (Fig. 37.3). GABA is involved in regulation of normal and pathological brain functions such as sleep and memory processes. GABA contributes to not only anxiety but also depressive disorders. Lowered levels of GABA have been found in plasma and platelets of the depressed (Brambilla et al. 2003). Anxiolytic drugs typically increase GABA neurotransmission.

37.2.1 How Dietary Amino Acids Alter Brain Serotonin and Catecholamine Synthesis?

Amino acids are taken into the brain across the blood–brain barrier, which is physically constructed of endothelial cells that line brain capillaries. The blood–brain barrier contains specific transport mechanisms for the LNAAs. All five LNAAs compete with each other for transport across the blood–brain

barrier. A change in the uptake rate of any given LNAA after a meal depends not only on how the level of an LNAA in the circulation is altered by the meal contents, but also on how the blood levels of the remaining LNAAs are modified (Fernström 1990).

Carbohydrates in the food stimulate the secretion of insulin, which increases the plasma concentration of tryptophan and decreases the levels of other LNAAs. This leads to increase in tryptophan and the subsequent serotonin concentrations in the brain (Fernström 1983). In contrast, proteins in the food raise the levels of all the LNAAs about equally, and therefore there is no change in the competition of the LNAA transporter across the blood–brain barrier and no change in the levels of tryptophan and serotonin in the brain.

Concerning tyrosine, nonprotein food reduces the levels of serum tyrosine and the other LNAAs, but does not affect tyrosine levels in the brain. After a protein-rich meal, tyrosine levels increase more than those of the remaining LNAA competitors, and therefore tyrosine and the subsequent dopamine levels rise in the brain (Fernström 1983; Fernström and Fernström 1987).

After ingestion of a meal which contains plenty of BCAAs, the plasma and brain concentrations of BCAAs increase and those of ArAAs decrease. Such effects are likely to reduce the synthesis of neurotransmitters serotonin, dopamine, and noradrenaline.

37.2.2 Tryptophan

Tryptophan is an essential amino acid. It is a precursor for serotonin synthesis. Free tryptophan is transported into the brain across the blood–brain barrier by an active protein shuttle for which five other LNAAs (valine, leucine, isoleucine, phenyalanine, and tyrosine) also compete. In the brain, serotonin is synthesized from tryptophan. Tryptophan is first converted to 5-hydroxytryptophan by the enzyme tryptophan hydroxylase; 5-hydroxytryptophan is thereafter decarboxylated to 5-hydroxytryptamine (also called serotonin) by the enzyme aromatic acid decarboxylase (Fig. 37.1). Serotonin is stored in synaptic vesicles where it stays until it is released by a neuronal impulse. Serotonin is destroyed by the enzyme monoamine oxidase and converted to an inactivate metabolite, 5-hydroxyindoleacetic acid. In addition, serotonin is converted to melatonin in the pineal gland at night. Melatonin is involved in synchronization of the circadian rhythms and in regulation of seasonal behaviors.

Entry of tryptophan to the brain depends on two key factors: first, the free plasma levels of tryptophan and, second, the concentrations of the remaining LNAAs that compete with tryptophan for transport across the blood–brain barrier. Dietary protein and carbohydrate content can influence the brain tryptophan and serotonin levels by having an effect on plasma amino acid profiles.

37.2.2.1 Tryptophan and Mood

Tryptophan is a precursor for serotonin, which is known to play a key role in many brain functions, such as mood regulation. Tryptophan depletion is used to investigate the actions of serotonin. The aim of tryptophan depletion is to lower down the brain serotonin levels by eliminating the amino acid precursor tryptophan and thereby causing the depletion.

Two techniques are commonly used in depletion studies. Removal of tryptophan from the diet reduces plasma tryptophan levels by 15–20%. Alternatively, a marked effect on tryptophan levels can be achieved by giving participants an amino acid load that does not contain tryptophan. Such amino acid load stimulates protein synthesis in the liver, which then uses up tryptophan free in the circulating plasma together with the other LNAAs that are administered.

Tryptophan depletions induce a rapid and substantial lowering of the total and free plasma levels of tryptophan. A number of studies have shown that acute tryptophan depletion causes depressive symptoms and results in worsening of mood in the depressed and those having vulnerability to depression. However, persons with no personal or family history of MDD tend not to have any change in mood following tryptophan depletion, despite the fact that tryptophan depletion did lower serotonin levels and metabolic activities in regions of the brain having relevance to regulation of mood (Ruhé et al. 2007).

A few studies of tryptophan depletion exist in patients with bipolar disorder. Patients on mood stabilizer have no response to tryptophan depletion, but those patients who have recovered recently have reported of manic symptoms after the depletion (Cappiello et al. 1997; Hughes et al. 2000). Recently, it has been demonstrated that acute tryptophan depletion may have an antimanic effect in patients with acute mania (Applebaum et al. 2007).

Tryptophan depletion has a selective effect on sweet consumption in overweight individuals and patients with binge eating. Acute lowering of the serotonin synthesis by tryptophan depletion increases the intake of sweet-tasting foods (Pagoto et al. 2009).

There are several reports which find that the plasma tryptophan concentration is clearly lower in patients with MDD than in psychologically healthy controls (Cowen et al. 1989). However, the dietary intake of tryptophan did not associate with MDD in a population-based study (Hakkarainen et al. 2003). Patients with bipolar disorder also have decreased tryptophan levels compared with controls (Hoekstra et al. 2006). For this reason, the tryptophan supplementation has been applied for the treatment of depressed patients, but the efficacy of tryptophan supplementation is limited.

Patients with MDD tend to consume more carbohydrates in their diet than nondepressed persons, and they have an increase in preference for sweet carbohydrate foods during depressive episodes (Christensen 2001). These patients are typically having atypical depressive symptoms, such as prolonged sleep duration, increased appetite, and weigh gain. It has been hypothesized that these individuals try to alleviate depression by craving carbohydrates that increase serotonin levels in the brain. The subsequent drowsiness is a common effect of a carbohydrate-rich meal, but in patients with atypical depressive symptoms or those with seasonal affective disorder a carbohydrate meal paradoxically leads to an increase in alertness (Rosenthal et al. 1989). Measurements from the hypothalamus have demonstrated that serotonin levels are low during the time before meals, rise in anticipation of food, and spike during the meal. In line with these findings, such drugs that enhance serotonin usage in the brain are appetite suppressants.

37.2.3 Tyrosine

Tyrosine is not an essential amino acid, because it can be made from the essential amino acid phenylalanine. In the brain, dopamine and noradrenaline are synthesized from tyrosine. Tyrosine is converted to dihydroxyphenylalanine by the enzyme tyrosine hydroxylase, and thereafter dihydroxyphenylalanine is converted to dopamine by the enzyme dopa decarboxylase. Dopamine is converted to noradrenaline by the enzyme dopamine-β-hydroxylase (Fig. 37.2). Tyrosine has the same transporter than the other LNAAs in the blood–brain barrier.

37.2.3.1 Tyrosine and Mood

In order to study the effects of tyrosine on mood, depletion studies similar to tryptophan depletions have been used. In these tyrosine depletion studies, participants are given an amino acid mixture free

of both tyrosine and the tyrosine precursor phenylalanine. Such depletion lowers the plasma tyrosine concentration and inhibits tyrosine brain entry by competition. In most of the studies, acute tyrosine and phenylalanine depletion does not induce depressive symptoms in healthy controls, whereas it affects patients who have been treated with noradrenergic medications and recovered recently. In the depressed, tyrosine depletion induces depressive symptoms and causes metabolic changes in brain areas that are relevant to regulation of mood (Hasler et al. 2008).

Acute dietary tyrosine depletion increases dopamine neurotransmission and reduces the intensity of manic symptoms in patients with bipolar disorder (McTavish et al. 2001; Scarnà et al. 2003). Patients with anorexia nervosa tend to have low plasma tyrosine levels (Ehrlich et al. 2009).

Dietary supplements that contain tyrosine and/or phenylalanine enhance alertness and arousal. However, there was no association between the dietary intakes of tyrosine or phenylalanine and MDD in a population-based study (Hakkarainen et al. 2003).

37.2.4 Glutamate

Glutamate is an essential amino acid. It is a precursor for GABA synthesis (Fig. 37.3). In addition, glutamate itself is a neurotransmitter. Glutamate is the major excitatory neurotransmitter in the cerebral cortex and has been indicated in the pathogenesis of mood disorders. Abnormalities in glutamatergic transmission, particularly concerning *N*-methyl-d-aspartate (NMDA) glutamate receptors, are postulated to play a role in both MDD and bipolar disorder.

37.2.4.1 Glutamate and Mood

The role of the NMDA glutamate receptor has been linked to mood disorders. Mood stabilizers such as lithium and valproic acid have an effect on the uptake and release of glutamate. Further, antiglutamatergic drugs like lamotrigine are demonstrated to have beneficial effects on depressive symptoms in patients with bipolar disorder. Increased levels of glutamate were observed in the frontal cortex and plasma from patients with bipolar disorder and those with MDD (Mitani et al. 2006; Hashimoto et al. 2007). Recently, low cerebrospinal fluid glutamate and glycine concentrations have been reported in mood disorders resistant to medication (Frye et al. 2007). The blood–brain barrier normally prevents any elevation in plasma glutamate levels from having an effect on the brain levels of the amino acid. Even great increments in the circulating glutamate concentration do not raise glutamate levels in the brain. For this reason, the dietary intake of glutamate will not affect the concentrations of glutamate and GABA. In agreement, the dietary intake of glutamate did not associate with MDD in a population-based study (Hakkarainen et al. 2003).

37.2.5 Other Amino Acids

Many amino acids can have a role in the functions of the brain. The following amino acids have also been connected to regulation of mood, but their relevance to mood remains elusive.

37.2.5.1 Serine

Serine is not an essential amino acid in the human diet. It is produced from hydroxypyruvate derived either from glucose or glycerol. Serine is thereafter used as a precursor for glycine through a process that transfers a methylene group to tetrahydrofolate. Serine acts as a partial agonist at the glycine modulation site of the glutamate receptor in the brain and therefore tends to have an effect on brain functions. Previously, high serine plasma concentrations were suggested to be a potential marker for psychotic disorder in general and for depressive disorder in particular (Mauri et al. 1998; Sumiyoshi et al. 2004). However, there are also reports of low serine plasma levels in depressive disorder with psychotic symptoms (Maes et al. 1998). The increased dietary intake of serine has been associated with the increased risk of hospital treatment due to MDD, but this association disappeared after excluding from analysis those who had reported depressed mood at study entry (Hakkarainen et al. 2003).

37.2.5.2 Glycine

Glycine is not an essential amino acid in the human diet. It is produced from serine. Glycine acts as an obligatory coagonist at the strychnine insensitive glycine modulatory site of the NMDA-type glutamate receptor. Increased plasma levels of glycine have been found in the depressed compared with psychologically healthy individuals. Normally, dietary glycine has no influence on the brain glycine levels. However, when glycine is administered in a sufficient quantity, it may pass through the blood–brain barrier and elevate glycine levels in the brain. However, in a population-based study, the dietary intake of glycine did not associate with MDD (Hakkarainen et al. 2003).

37.2.5.3 Lysine

Lysine, an essential amino acid, acts as a precursor for carnitine. Acetylincarnitine has a role in lipid metabolism and is synthesized from carnitine. Currently, there are no consistent data regarding the effect of lysine on brain functions or on mental disorder. The dietary intake of lysine was associated with the increased risk of hospital treatment due to MDD in a population-based study, but this association disappeared after excluding from analysis those who had reported depressed mood at study entry (Hakkarainen et al. 2003). As lysine fortification of wheat was demonstrated to reduce anxiety and distress among an economically disadvantaged population (Smriga et al. 2004), the role of lysine remains an enigma and needs elucidation.

37.2.5.4 Methionine

Methionine is an essential amino acid. It combines with adenosine triphosphate to produce *S*-adenosylmethionine (SAM) that facilitates the production of neurotransmitters in the brain (Papakostas et al. 2003). Depressed patients appear to have lower serum and cerebrospinal fluid SAM levels. However, the dietary intake of methionine did not associate with MDD in a population-based study (Hakkarainen et al. 2003).

37.2.5.5 Histidine

Histidine is an essential amino acid for children. It acts as a precursor for histamine that is a neurotransmitter in the brain. Histamine is derived as a result of the decarboxylation of histidine in a reaction that is catalyzed by the enzyme l-histidine decarboxylase. Histamine has been indicated in the control of arousal and sexual behaviors. There is a shortage of data on the dietary histidine in relation to mood. In a population-based study, the dietary intake of histidine did not associate with MDD (Hakkarainen et al. 2003).

37.2.6 The Recommendations of Amino Acids

In the Western industrialized countries, the intake of essential amino acids usually exceeds the daily recommendations. The recommendations for the daily intake of essential amino acids are presented in Table 37.2. Unlike with fat and starch, the human body does not store excess amino acids for later usage. This is the reason why we have to have amino acids every day.

Animal sources such as meat, fish, seafood, poultry, eggs, milk, and dairy products provide all the essential amino acids. In addition, some plant sources such as buckwheat contain a balanced set of the essential amino acids. It is not necessary to have all the essential amino acids from a single food product. All the essential amino acids will be supplied by consuming a range of plants such as a combination of cereal grains (wheat, corn, rice) and legumes (beans, peanuts).

37.2.6.1 Special Groups

The intake of particular amino acids can be disturbed in certain bowel diseases. For instance, Crohn's disease and celiac disease can compromise the absorption of amino acids. Celiac disease has been associated with the increased prevalence of depression prior to the diet treatment. Recently, it has been demonstrated that those celiac disease patients with depression have lower prediet serum tryptophan concentrations and improvement in depressive symptoms after start of the gluten-free diet. The improvement coincided with a decrease in celiac disease activity and an increase in serum concentrations of tyrosine and other BCAAs (Pynnönen et al. 2005).

Table 37.2 Daily requirements of essential dietary amino acids in adults (FAO/WHO/UNU 2007)

Amino Acids	mg/kg/day	mg/70 kg/day
Isoleucine	20	1400
Leucine	39	2730
Lysine	30	2100
Methionine + cysteine	15	1050
Phenylalanine + tyrosine	25	1750
Threonine	15	1050
Tryptophan	4	280
Valine	26	1820

This table presents daily requirements of essential amino acids in adults. In the first column, requirements are presented as mg/kg/day and in the second column as mg/70 kg/day

Intake of nutrients is abnormal in patients with anorexia nervosa or bulimia nervosa. These two eating disorders can affect the intake of the essential amino acids, on which there are however no published data.

There is a range of special diets with which the intake of proteins may not meet the daily recommendations in full. Strict vegetarian diets can reduce the intake of the essential amino acids as well. With a vegetarian diet, the individual should use a variety of plant food in order to have essential amino acids enough. Good sources of proteins for vegetarians are nuts and seeds, pulses, soy products and cereals. With weight-reducing diets, the individual should have enough proteins of a good quality. Athletes may use nutrients which may include BCAAs in order to improve physical performance. However, such nutrients tend to reduce tryptophan, tyrosine, and phenylalanine concentrations in the brain. This may have an impact in those with depression or having vulnerability to depression, if their habitual diet is limited.

37.2.7 The Timing of Eating

Both the timing and macronutrient contents of a meal influence sleep. A meal consumed close to the bedtime is associated with sleep disturbances. A number of macronutrients influences sleep through the actions of tryptophan. High carbohydrate diet tends to increase the ratio of the circulating tryptophan to the remaining LNAAs via a direct action of insulin. A high carbohydrate meal is likely to promote sleep via an increase in the brain tryptophan and serotonin levels. High carbohydrate meals induce more tiredness afterwards than low carbohydrate meals (Afaghi et al. 2007). Levels of tryptophan tend to peak at 2–4 h after the high carbohydrate meal. In contrast, tryptophan and LNAAs tend to peak at about 4 h after the ingestion of a high protein meal (Rogers 2001). A high intake of proteins appears to increase alertness.

37.2.8 Applications to Other Areas of Health and Disease

There are no data on the use of the dietary amino acids to improve mood beyond mood disorders (Table 37.3). However, the dietary intake of amino acids needs to take into account for chronic diseases in which the diet or the absorption of macronutrients does not meet the daily recommendations. For example, patients with bowel diseases have low tryptophan levels that may affect mood subsequently. Cancer patients may benefit from a good balance in the dietary amino acids intake.

Table 37.3 Key features of dietary amino acids and mood

1. Some amino acids influence the brain function directly or indirectly, but there is a lack of consistent data concerning dietary amino acids and mood.
2. Dietary amino acid tryptophan works as a precursor for neurotransmitter serotonin.
3. Serotonin is a neurotransmitter which is known to play an important role in the regulation of mood and sleep.
4. Dietary amino acid tyrosine works as a precursor for neurotransmitters dopamine and noradrenaline.
5. Also neurotransmitters, dopamine and noradrenaline, are involved in the regulation of mood.
6. Dietary amino acid glutamate is a precursor for GABA and it also works as a neurotransmitter itself.
7. In the future, more studies are needed to elucidate the effects of dietary amino acids on mood.

This table lists the key facts of dietary amino acids and mood including the three most important dietary amino acids to mood. GABA: gamma-aminobutyric acid

Poor therapeutic equilibrium in diabetes patients increases the plasma concentrations of BCAAs and reduces the transport of tryptophan, tyrosine, and phenylalanine into the brain. As a result, ArAA levels are low. Nutritionist and other professionals need to pay attention to and guide these patients.

Summary Points

- There are 20 amino acids and humans can produce 10 of them. Eight amino acids are essential for humans and these must be supplied for food. The major sources of amino acids are protein-rich food, such as meat, fish, poultry, eggs, milk, and dairy products.
- Some amino acids influence the brain function directly or indirectly, but there is a lack of consistent data concerning dietary amino acids and mood.
- Amino acid tryptophan is a precursor for neurotransmitter serotonin. Serotonin has a key role in mood and sleep regulation and dysregulation of serotonergic system is associated with low mood and mood disorders.
- Amino acid tyrosine is a precursor for neurotransmitters dopamine and noradrenaline. Dopamine and noradrenaline are involved in the regulation of motivation, psychomotor speed, concentrations, and the ability to experience pleasure. Low levels of dopamine and noradrenaline are associated with mood disorders.
- Neurotransmitter GABA is synthesized from amino acid glutamate, which also works as a neurotransmitter itself. GABA and glutamate also participate in mood and sleep regulation.
- Single meals, depending on their protein and carbohydrate content, can rapidly influence uptake of the LNAAs into the brain, as a result, directly modify their conversion to neurotransmitters.
- Carbohydrate meal increase tryptophan and serotonin levels in the brain and, usually induces drowsiness in healthy subjects but alertness in patients with seasonal affective disorder. Subjects with depression could try to alleviate the low mood by craving carbohydrates.
- Both timing and macronutrient content of meal can affect mood and sleep.
- Generally the daily recommendations of essential amino acids exceed. Individuals with special diet for example, vegetarians, should pay attention to their diets.

Definitions of Key Terms

Major depressive disorder (MDD) is a mood disorder in which patients have low mood or a loss of interest in usual activities. They have feelings of worthlessness, inappropriate guilt, or loss of self-esteem. Common symptoms are altered appetite and sleep. Patients could also have thoughts of death and suicide.

Bipolar disorder is a mood disorder where patients have mood swings that alternate between periods of mania and periods of depression. In mania patients have abnormally elevated or irritable mood accompanied symptoms such as increased energy, decreased need for sleep, rapid thinking and speech, and in some cases psychotic symptoms.

Mood is a relative long-lasting emotional state. Long-term disturbances of mood such as depression and bipolar disorders are considered mood disorders.

Amino acids have a carboxyl carbon group and an amino nitrogen group attached to a central alpha-carbon. They have variety roles in metabolism. Amino acids are joined together in long strings by peptide bonds to form proteins of differing shapes and sizes.

Essential amino acids have no synthetic pathways in humans; hence, these amino acids are essential to the diet.

Large neutral amino acids (LNAA) are tryptophan, valine, leucine, isoleleucine, phenyalanine, and tyrosine. They have one specific transporter in blood–brain barrier which they compete with each other.

Blood–brain barrier is the regulated interface between the peripheral circulation and the central nervous system. This restricts the passage of various chemical substances between the bloodstream and the neural tissue itself, while still allowing the passage of substances essential to metabolic function.

Neurotransmitters are chemicals which account for the transmission of signals from one neuron to next across synapses.

Serotonin is an inhibitory neurotransmitter in brain activating serotonin receptors. It plays an important role in brain systems that regulate mood, emotional behavior, and sleep. In the brain serotonin is synthesized from amino acid tryptophan.

Gamma-aminobutyric acid (GABA) is a major inhibitory neurotransmitter in the central nervous system. It has been shown to be involved in the regulation of sleep and memory. It is synthesized from glutamate in the brain.

Dopamine is a neurotransmitter in the brain activating the dopamine receptors. It has several functions in the brain, including important roles in behavior and cognition, motor activity, and mood. It is synthesized from amino acid tyrosine in the brain.

Noradrenaline is the primary neurotransmitter of the sympathetic nervous system in the periphery but it is also prevalent in the brain. It is involved in mood regulation, sleep regulation, expression of behavior, and the general degree of alertness and arousal. It is synthesized from amino acid tyrosine in the brain. Noradrenaline is also called norepinephrine.

Chapter 38
Food Coloring, Sodium Benzoate Preservative, and D-serine: Implications for Behavior

Kenji Hashimoto

Keywords Sodium benzoate • NMDA receptor • D-Serine • D-Amino acid oxidase

Abbreviations

CBIO	5-chloro-benzo[*d*]isoxazol-3-ol
CSF	Cerebrospinal fluid
DAAO	D-amino acid oxidase
NMDA	*N*-methyl-D-aspartate
SRR	Serine racemase

38.1 Introduction

It has long been suggested that artificial food colorings and other food additives (AFCA) could affect behavior in children. Feingold (1975) made the initial claims regarding the detrimental effects of AFCA on childhood behavior. The main putative effects of AFCA are to produce overactive, impulsive, and inattentive behaviors including hyperactivity. Children who show these behavioral patterns are often diagnosed with attention-deficit hyperactivity disorder (ADHD). Subsequent studies showed only a small effect of AFCA on behavior in children (Weiss et al. 1980; Conners et al. 1976; Swanson and Kinsbourne 1980; Pollock and Warner 1990), but some studies failed to substantiate these latter findings (Mattes and Gittelman 1981; Gross et al. 1987). A meta-analysis of double-blind, placebo-controlled trials showed a significant effect of AFCA on the behavior of children with ADHD (Schab and Trinh 2004). However, there have been no population-based studies examining the prevalence of hyperactivity related to AFCA in children.

Bateman et al. (2004) reported a double-blind, placebo-controlled, artificial food coloring (20 mg daily) and sodium benzoate (45 mg daily) preservative challenge on hyperactivity in a general population sample of preschool children. There were significantly greater increases in hyperactive behaviors during the active period than during the placebo period based on parental reports, although there were no significant differences detected based on objective testing in the clinic (Bateman et al. 2004). This chapter suggests that a benefit would accrue to all children if artificial food coloring and sodium benzoate preservatives were removed from their diet (Bateman et al. 2004).

Fig. 38.1 The NMDA receptor complex. Glutamate and *N*-methyl-D-aspartate (NMDA) bind to the agonist site on the NMDA receptors. Phencyclidine (PCP), and ketamine bind to PCP receptor site on the inside of the NMDA receptors. Glycine and D-serine bind to a coagonist site (glycine modulatory site) on the NMDA receptors

A subsequent randomized, double-blind, placebo-controlled, crossover trial by the same group demonstrated that artificial coloring or sodium benzoate preservative (or both) in the diet results in increased hyperactivity in 3- and 8/9-year-old children in the general population (McCann et al. 2007). Children with hyperactivity were identified and tested with a mixture of food coloring and sodium benzoate that corresponded to an average daily intake during 1-week crossover challenge periods. Overall, they showed that 3- and 8/9-year-old children might have signs of hyperactivity when on a diet containing average amounts of coloring and addictives. However, the mechanisms underlying the relationship between the mixtures (artificial foods and/or sodium benzoate) and hyperactive behavior are currently unknown, although artificial coloring and sodium benzoate preservative represent only one aspect of hyperactivity in children (McCann et al. 2007; Eigenmann and Haenggeli 2007; Hashimoto 2008b).

In this chapter, the author would like to discuss the role of D-serine, the endogenous coagonist at the *N*-methyl-D-aspartate (NMDA) receptors (Fig. 38.1), on AFCA-associated hyperactivity in children.

38.2   D-Serine and D-amino Acid Oxidase (DAAO)

It was long believed that only L-isomers of amino acids existed in mammals, and D-amino acids were regarded as laboratory artifacts and categorized as "unnatural isomers." This term was widely used in biochemistry textbooks. D-Amino acids were prominent in bacteria, although there were occasional reports of D-amino acids being present in invertebrates (Corrigan 1969). Yet it should be noted that Dr. Hans Krebs accidentally discovered an enzyme (D-amino acid oxidase; oxygen oxidoreductase, EC 1.4.3.3, DAAO) in the kidney that recognized "unnatural" D-amino acids (but not their L-counterparts; Krebs 1935a, b). It was recognized that the job of DAAO was to degrade D-amino acids produced by bacteria from foods in the gut. Currently, DAAO is a well-characterized flavin adenine dinucleotide
Fig. 38.2 Scheme of the reaction catalyzed by D-amino acid oxidase (DAAO). FAD-dependent enzyme DAAO catalyzes the oxidative deamination of D-amino acids with a strict stereospecificity to give α-keto acids and ammonia; FAD then reoxidizes on dioxygen (A slight modification from Pollegioni et al. 2007)

Fig. 38.3 Structure of human D-amino acid oxidase (DAAO). The human DAAO homodimer (A slight modification from Kawazoe et al. 2007)

(FAD)-dependent enzyme that catalyzes the oxidative deamination of D-α-amino acids to yield the corresponding α-keto acid and ammonia (Pollegioni et al. 2007; Fig. 38.2). The crystal structure of human DAAO was determined by molecular replacement of the porcine enzyme. The asymmetric unit contained four molecules of human DAAO in the form of two homodimers (Fig. 38.3). Basically, each of the four molecules showed the same conformation, and the overall dimeric structure of human DAAO was identical to the "head-to-head" structure of porcine DAAO (Kawazoe et al. 2007).

With the advance of chromatographic analysis techniques, it is now possible to measure small amounts of D-amino acids in lower and higher animals, plants, and foods. By the use of two-dimensional thin-layer chromatography and high-performance liquid chromatography, Nagata et al. (1992) reported the presence of free D-amino acids, including D-serine, in the kidneys and blood of mutant mice lacking DAAO. The contrasting maps of D-serine immunoreactivity and DAAO activity in the adult rat brain show the influence of DAAO on D-serine levels (Schell 2004). DAAO in the brainstem, medulla, and spinal cord keeps D-serine levels low. In addition, forebrain DAAO activity is undetected, and D-serine levels are very high, which strongly implies that DAAO is the major enzyme capable of destroying endogenous D-serine in the brain (Schell 2004). In the brain, gene expression of DAAO is detected in astrocytes (Horiike et al. 1994).

38.3 D-Serine and NMDA Receptor

Research in the past decade has consistently revealed significant levels of D-serine in mammalian brains including human (Hashimoto et al. 2007). In the rat brain, the distribution of D-serine was found to be similar to that of NMDA receptors (Fig. 38.1), suggesting that D-serine might be an endogenous agonist on NMDA receptors (Hashimoto and Oka 1997; Schell 2004). The origin of D-serine in mammals was unclear until serine racemase (SRR), which catalyzes the direct conversion of L-serine to D-serine, was isolated from the brain (Wolosker et al. 1999). Very recently, it was demonstrated that knockout mice for the SRR gene show decreased (>80%) levels of D-serine in the brain (Inoue et al. 2008; Basu et al. 2009), suggesting a major role of SRR in the production of D-serine in the mouse brain. A report using SRR knockout mice demonstrated that SRR exists in neurons, not glia (Miya et al. 2008). Therefore, knockout mice for the SRR gene will contribute to the analysis of the physiological and pathophysiological roles of D-serine in vivo.

Multiple lines of evidence suggest that a dysfunction in glutamatergic neurotransmission via the NMDA receptors (Fig. 38.1) might be involved in the pathophysiology of psychiatric diseases such as schizophrenia and ADHD (Goff and Coyle 2001; Hashimoto 2006, 2008a; Hashimoto et al. 2003, 2004, 2005b; Lehohla et al. 2004; Jensen et al. 2009). Treatment with D-serine revealed significant improvements in positive, negative, and cognitive symptoms in schizophrenia patients treated with antipsychotic drugs (Tsai et al. 1998), suggesting that the levels of D-serine may be decreased in the brains of schizophrenia patients. We reported that the serum levels of L-serine were significantly higher in patients with schizophrenia than in normal controls, and that the serum levels of D-serine and the ratio of D-serine to total serine were markedly lower in patients with schizophrenia than in normal controls (Hashimoto et al. 2003; Yamada et al. 2005). Subsequently, we found that the ratio of D-serine to total serine in the cerebrospinal fluid (CSF) was significantly lower in first episode and drug-naive patients with schizophrenia than in controls (Hashimoto et al. 2005a), suggesting that the synthetic and/or metabolic pathway of D-serine may be impaired in the brains of schizophrenia patients. Furthermore, Bendikov et al. (2007) reported a 25% decrease in D-serine levels in the CSF of patients with schizophrenia, although D-serine levels in the cortices of postmortem brains with schizophrenia were not altered (Hashimoto et al. 2007). Taken together, it is likely that alterations in the D-serine levels may play a role in the behavioral abnormalities in humans.

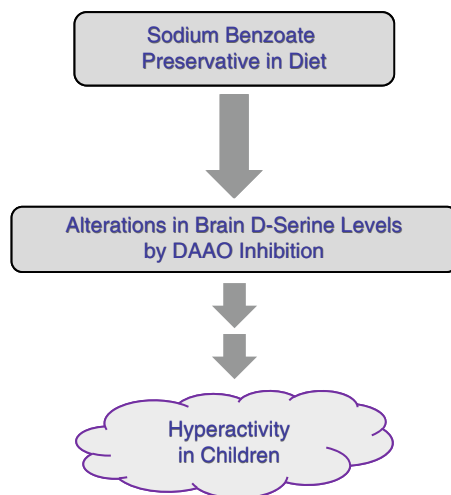
38.4 Sodium Benzoate and D-serine

Sodium benzoate (Fig. 38.4) is the sodium salt of benzoic acid and is used in a wide variety of cosmetic products (Nair 2001). In food chemistry applications, sodium benzoate is often used as a food preservative because it can inhibit microbial growth (Zhao and Doyle 2006). Sodium benzoate is also known as a competitive inhibitor of DAAO that binds to the enzyme's active site (Kd = 3 mM; Yagi et al. 1959, 1960; Massey and Ganther 1965). Mattevi et al. (1996) reported the crystal structure of the DAAO complex with benzoate by single isomorphous replacement and eightfold averaging. The benzoate molecule lays parallel to the flavin ring and is held in position by a salt bridge with Arg-283 (Mattevi et al. 1996; Fig. 38.4). The novel DAAO inhibitor, 5-chloro-benzo[*d*]isoxazol-3-ol (CBIO; IC_{50} = 180 nM for DAAO activity), has a mode similar to that of benzoic acid (Ferraris et al. 2008). The isoxazole group of CBIO plays a role similar to that of the carboxylate group of benzoic acid, forming a critical hydrogen bond network with Arg-283 and Tyr-228 (Ferraris et al. 2008; Fig. 38.4).

Furthermore, we reported that coadministration of CBIO could potentiate the efficacy of D-serine or D-alanine on prepulse inhibition deficits after administration of the NMDA receptor antagonist

Fig. 38.4 Complex of D-amino acid oxidase (DAAO) inhibitors with DAAO. Schematic illustration of the active site of DAAO in complex with sodium benzoate or 5-chloro-benzo[*d*]isoxazol-3--ol. (A slight modification from Ferraris et al 2008.)
Fig. 38.5 Localizations of endogenous D-serine and D-amino acid oxidase (DAAO) in adult rat brain. (**a**) D-Serine was visualized with an antibody that recognizes glutaraldehyde-fixed D-serine. (**b**) DAAO was visualized in fixed brain slices by enzyme histochemistry (A slight modification from Schell 2004)
dizocilpine (Hashimoto et al. 2009; Horio et al. 2009). Therefore, these findings suggest that coadministration of D-serine (or D-alanine) and a DAAO inhibitor has therapeutic potential in the treatment of schizophrenia, as D-serine and D-alanine have been shown to be effective in patients with schizophrenia (Hashimoto et al. 2009; Horio et al. 2009).

It was shown that the distribution of D-serine levels is not correlated with DAAO activity in the adult brain (Fig. 38.5), although a high correlation between D-serine levels and NMDA receptors in the brain was detected (Schell 2004). Furthermore, no changes of D-serine in the forebrain of mice lacking DAAO were demonstrated (Morikawa et al. 2001), suggesting that DAAO is not likely to regulate D-serine levels in the forebrain, where the NMDA receptors are abundant (Hashimoto et al. 2005b). Thus, it seems that the DAAO inhibitors do not affect D-serine levels in the forebrain of adult rodents. Recently, we reported that, using in vivo microdialysis study of conscious and free-moving animals, treatment of the novel DAAO inhibitor CBIO did not alter the extracellular D-serine levels in the frontal cortex of adult rats and mice (Ferraris et al. 2008; Hashimoto et al. 2009). Considering the moderate affinity (Kd = 3 mM) of sodium benzoate with DAAO activity and the absence of changes in the forebrain D-serine levels induced by a DAAO inhibitor, it is unlikely that sodium benzoate can increase D-serine levels in the forebrain of adults, although detailed in vivo studies on the effects of sodium benzoate on brain D-serine levels are necessary (Hashimoto 2010).

Fig. 38.6 Possible mechanism of sodium benzoate preservative on hyperactivity in children. Alteration in brain D-serine levels due to the consumption of sodium benzoate preservative may play a role in hyperactivity in children.


It has been suggested that D-serine may play different roles in the adult brain than in the developing brain, with these roles possible mirrored in distinctive localizations at different ages (Wang and Zhu 2003). A recent study demonstrated that D-serine plays an important role in neuronal migration (Kim et al. 2005), suggesting that D-serine serves as a coagonist for NMDA receptor-dependent cell migration at the developmental stage. Therefore, it is likely that alterations in the D-serine levels in the brains of children due to the consumption of sodium benzoate preservative might contribute to hyperactivity in association with this compound (Fig. 38.6).

In contrast, for many years emerging evidence has suggested the existence of cerebellar abnormalities in the pathophysiology of psychiatric diseases such as schizophrenia (Andreasen and Pierson 2008). Mice lacking DAAO activity show a higher D-serine level in the cerebellum that expresses the NMDA receptors (Morikawa et al. 2001). Therefore, it is possible that the increase in the cerebellar D-serine levels induced by the consumption of sodium benzoate preservative may, at least in part, play a role in the hyperactivity associated with this compound (Hashimoto 2010).

38.5 Conclusion

Considering the important role of D-serine in the neurotransmission via the NMDA receptor, the author proposes that alteration in D-serine levels due to the consumption of sodium benzoate preservative might play a role in hyperactivity in children (Hashimoto 2008b; Fig. 38.6), since D-serine plays a role in the developmental stage. Further investigation using animals is needed to establish whether sodium benzoate could affect hyperactive behavior associated with alteration in the brain levels of D-serine. Additionally, it may also be of interest to examine the effects of sodium benzoate on blood levels of D-serine after the consumption of this agent in children.

38.6 Applications to Other Areas of Health and Disease

The consumption of the preservative sodium benzoate may affect D-serine levels in the brains of children, as this compound is a potent inhibitor of DAAO, which can metabolize D-serine. The alteration in D-serine levels induced by sodium benzoate could alter the NMDA receptor function, which may

affect behavioral patterns in childhood. Therefore, the alteration in D-serine levels due to the consumption of the preservative sodium benzoate may be involved in health and disease in children.

Summary Points

- A double-blind, placebo-controlled study demonstrated that food coloring and/or the preservative sodium benzoate in the diet affects hyperactivity in children.
- Sodium benzoate is a potent inhibitor of DAAO, which can metabolize D-serine.
- Alterations in D-serine levels due to the consumption of sodium benzoate may alter the NMDA receptor function in the brain. Therefore, alterations in the D-serine levels may be involved in hyperactivity in children.

Definitions and Explanations

Sodium benzoate: Sodium benzoate is the sodium salt of benzoic acid and is used in a wide variety of cosmetic products and as a food preservative. Sodium benzoate is also known as a competitive inhibitor of DAAO, which can metabolize D-serine, the endogenous coagonist at the NMDA receptors.

NMDA receptor: The NMDA receptor is a specific type of ionotropic glutamate receptor. NMDA (*N*-methyl-D-aspartate) is the name of a selective agonist that binds to the NMDA receptors but not to other glutamate receptors. NMDA receptors play a role in learning and memory as well as in the pathophysiology of a number of neuropsychiatric diseases.

D-Serine: D-Serine is the endogenous coagonist at the NMDA receptors. D-serine is synthesized by SRR from L-serine, and D-serine is metabolized by DAAO.

Key Points

The preservative sodium benzoate is a potent inhibitor of DAAO, which can metabolize D-serine, the endogenous coagonist at the NMDA receptors in the brain. This compound can affect the levels of D-serine in the brain, resulting in alteration of the NMDA receptor function, which may affect behavioral patterns in children. Therefore, the alteration in D-serine levels by the consumption of sodium benzoate in children may be involved in the hyperactivity associated with this compound.

Chapter 39
Malonyl-CoA Signaling in the CNS: Hypothalamic Control of Feeding Behavior and Energy Expenditure

M. Daniel Lane and Seung Hun Cha

Abbreviations

CNS	Central nervous system
SNS	Sympathetic nervous system
ACC	Acetyl-CoA carboxylase
MCD	Malonyl-CoA decarboxylase
FAS	Fatty acid synthase
icv	Intracerebroventricular
ip	Intraperitoneal
AICAR	5-aminoimidazole-4-carboxamide-1-β-D-ribofuranoside
NPY	Neuropeptide Y
AgRP	Agouti-related peptide
POMC	Propiomelanocortin
CART	Cocaine and amphetamine-regulated transcript

39.1 Introduction

The concept that an intermediate in fatty acid synthesis might function in the regulation of food intake and energy expenditure arose through the serendipitous discovery that fatty acid synthase (FAS) inhibitors, i.e., fungal-derived cerulenin or the structurally related synthetic derivative, C75, produce a dramatic reduction of food intake and massive weight loss (Loftus et al. 2000; Shimokawa et al. 2002; Kumar et al. 2002; Cha et al. 2004). These inhibitors have also been found to reverse adiposity caused by diet-induced obesity or mutations in leptin (*ob*/*ob*) or its receptor (*db*/*db*). Thus, these actions of the FAS inhibitors are independent of leptin, thus implicating a different signaling pathway. As intracerebroventricular (icv) administration of FAS inhibitors at very low levels (too low for systemic effects) was equally effective as intraperitoneal (ip) injection (Hu et al. 2003), it was concluded that the inhibitors acted centrally.

Strong precedents exist for a linkage between fatty acid synthesis and the inhibition of food intake (Lane 2008). Fatty acid synthesis occurs in lipogenic tissues during periods of energy surplus when

Table 39.1 Key features of malonyl-CoA as an intermediate in the hypothalamic signaling pathway that monitors/regulates feeding behavior and energy expenditure

1. Malonyl-CoA levels in the hypothalamus fluctuate as the global energy status of the animal changes. Food restriction gives rise to a low malonyl-CoA level, while refeeding leads to a high level of malonyl-CoA in the feeding centers within the hypothalamus. Malonyl-CoA is an intermediate in a complex signaling pathway in these centers, which communicates through neuronal connections to higher brain centers that integrate this information to formulate a feeding response.
2. Circulating glucose entering/metabolized by the brain/hypothalamus serves as an indicator of global (whole body) energy status. Orexigenic and anorexigenic neuropeptide-producing neurons within the hypothalamus respond to changes in glucose level through the 5′-AMP kinase/malonyl-CoA signaling system by secreting the appropriate amounts of these reciprocally related neuropeptides that control the feeding behavior.
3. In addition to suppressing food intake, increasing hypothalamic malonyl-CoA level with FAS inhibitors or leptin provokes increased energy expenditure. This information, i.e., the "malonyl-CoA signal" is rapidly transmitted via the sympathetic nervous system (SNS) to skeletal muscle, which responds by increasing the expression of enzymes and regulatory proteins that control fatty acid oxidation. After several days of such SNS stimulation mitochondrial biogenesis is activated leading to an increase in the number of mitochondria.

excess physiological fuel is diverted into energy storage pathways – conditions known to cause downregulation of the orexigenic (NPY and AgRP) neuropeptides and upregulation of anorexigenic (POMC/αMSH and CART) neuropeptides in the hypothalamus (Shimokawa et al. 2002; Hu et al. 2003; Lane et al. 2005).

The key regulatory enzyme of fatty acid synthesis is acetyl-CoA carboxylase (ACC; Lane et al. 1979; Wakil et al. 1983; Hardie 1989), which catalyzes the synthesis of malonyl-CoA – a substrate for FAS (see Table 39.1). Thus, FAS inhibitors would be expected to cause a "build-up" of its substrate (malonyl-CoA) in the central nervous system (CNS). As discussed next, this response is now well documented (Hu et al. 2003; Wolfgang and Lane 2006). The "malonyl-CoA hypothesis" predicts that a FAS inhibitor-induced blockade of FAS, which increases hypothalamic malonyl-CoA, should be reversed by inhibiting malonyl-CoA formation with an ACC inhibitor, e.g., TOFA. This, in fact, is the case, as TOFA, administered icv before the FAS inhibitor prevents/reverses both the increase in hypothalamic malonyl-CoA and the closely correlated decrease in food intake (Hu et al. 2003). Together, these findings validated the concept that the level of hypothalamic malonyl-CoA is an indicator of energy status that mediates feeding behavior dependent upon the relative activities of ACC and FAS.

39.2 Inhibition of Brain FAS Alters Expression of Hypothalamic Orexigenic and Anorexigenic Neuropeptides and Suppresses Food Intake

The hypothalamus receives and interprets hormonal and other afferent signals that reflect the energy status of the animal (Schwartz et al. 2000; Schwartz and Porte 2005; see Fig. 39.1). Such signals trigger the expression/secretion of the orexigenic and anorexigenic neuropeptides that regulate food intake and energy expenditure, most notably the orexigens, NPY and AgRP; and the anorexigens, POMC/αMSH and CART. These neuropeptides are expressed by NPY/AgRP or POMC/CART neurons in the arcuate nucleus (Arc) of the hypothalamus, which send projections to other regions of the hypothalamus, e.g., the paraventricular nucleus, lateral hypothalamic area, ventral medial nucleus, and dorsal medial hypothalamus (Schwartz et al. 2000). Second-order neurons from these sites project to higher brain centers, where this information is integrated and behavioral responses are formulated.

FAS inhibitors have reciprocal effects on the expression of key orexigenic (NPY, AgRP) and anorexigenic (POMC and CART) hypothalamic neuropeptides of both lean and obese (*ob/ob*) mice

Fig. 39.1 Energy balance (*energy balance = caloric intake − caloric expenditure*) is monitored by the brain, notably the hypothalamus, which sends signals to higher brain centers where these signals are integrated and adjustments in food intake and energy expenditure are made
Fig. 39.2 Effects of long-term administration of a FAS inhibitor (i.e., C75) on adiposity of obese (*Ob/Ob*) mice. Similar results were obtained with leptin receptor-deficient *Db/Db* mice and dietary-induced obese mice

(Shimokawa et al. 2002; Kumar et al. 2002; Cha et al. 2004). In lean mice, the FAS inhibitor, C75, rapidly and almost completely blocks food intake and prevents fasting-induced upregulation of hypothalamic AgRP and NPY mRNAs, as well as downregulation of CART and POMC mRNAs. Thus, in lean mice FAS inhibitors interrupt the fasting-induced signals that activate expression of NPY and AgRP and suppression of POMC and CART. Likewise, in obese mice, C75 rapidly suppresses food intake, reduces body weight, and normalizes obesity-associated hyperglycemia and hyperinsulinemia (Fig. 39.2). As in lean mice, C75 prevents the fasting-induced increase of hypothalamic NPY and AgRP mRNAs in obese mice. Thus, the suppressive effect of C75 on food intake in lean mice appears to be mediated both by NPY/AgRP and POMC/CART neurons, whereas in obese mice the effect appears to be mediated primarily by NPY/AgRP neurons.

39.3 Identification of Malonyl-CoA as a Key Intermediate in the Hypothalamic Signaling Pathway That Regulates Feeding Behavior

To validate the "malonyl-CoA hypothesis," it was important to directly quantify hypothalamic malonyl-CoA concentration and test its relationship with feeding behavior. Since the amount of hypothalamic tissue in a mouse is small (10–20 mg) and malonyl-CoA concentration is low, the usual enzymatic methods to quantify this metabolic intermediate could not be used. Thus, a more sensitive enzymatic recycling method was adapted to hypothalamic tissue to specifically quantify malonyl-CoA (Hu et al. 2003). The assay utilizes bacterial (*Pseudomonas putida*) malonate decarboxylase, a multienzyme complex that contains both a malonyl-CoA decarboxylase and CoA transferase, to transfer CoA from the acetyl CoA generated by the decarboxylation of malonyl-CoA, to exogenous malonate. Initially, it is necessary to remove any free acetyl-CoA or propionyl-CoA in tissue extracts with citrate synthase and oxaloacetate.

39.3.1 Effect of Systemically Administered FAS Inhibitors

Comparisons were made of mice fed *ad libitum* with mice given a systemic intraperitoneal (ip) injection of the FAS inhibitor, C75, or vehicle (control). An additional pair- (isocaloric-)fed control group whose food intake was limited to that of the C75-treated mice received ip with vehicle. This control ruled out the effect of food intake on changes in food intake caused by the inhibitor. C75 reduced food intake by 90% compared with that of *ad lib*-fed controls during the 24-h period after injection (Kumar et al. 2002; Hu et al. 2003). The fact that pair-fed controls lost less body weight in 24 h than those receiving the FAS inhibitor indicated that the inhibitor, not only lowered food intake, but also increased energy expenditure (discussed next).

As a result of the "pair-fed restriction" of food intake the level of malonyl-CoA in the hypothalami was markedly reduced (by ~60%) compared with that of *ad lib*-fed controls. Despite the same reduction of food intake, the malonyl-CoA level of C75-treated mice was the same as that of *ad lib*-fed mice. Thus, ip administration of the inhibitor prevented the decrease in malonyl-CoA caused by "fasting."

As expected, blood glucose levels were reduced significantly by food intake restriction in the pair-fed mice when compared with that in mice fed *ad libitum* (Kumar et al. 2002). Nevertheless, blood glucose levels in C75-treated mice were still significantly higher than those of pair-fed partially fasted mice. Because blood glucose levels are affected by ip C75 treatment and fasting, it is possible that the observed differences in hypothalamic malonyl-CoA could have been due, at least in part, to peripheral hormonal effects.

These results are consistent with previous experiments (Kumar et al. 2002) in which the FAS inhibitor blocked the fasting-induced increase in orexigenic (NPY and AgRP) and decrease in anorexigenic (POMC and CART) neuropeptide mRNA expression. These findings were later verified by direct calorimetry, which showed caloric expenditure is significantly higher in FAS inhibitor-treated mice (Thupari et al. 2002).

39.3.2 Effect of Centrally Administered FAS Inhibitors

Short-term experiments were carried out with C75 administered by central icv injection to restrict its effects to the CNS (Hu et al. 2003). The central action of the FAS inhibitor was ensured with

a low dose (~1/100 that administered ip) injected directly into the ventricular system of fasted mice. The mice were then either given free access to food (refed and inhibitor-treated) or fasting was continued. Food intake by refed control mice over the next 2 h was substantial, whereas food intake by mice given inhibitor icv was almost totally (≥98%) suppressed. As expected, blood glucose levels of the fasted mice were reduced and within 2 h of being given access to food (refed controls) the levels increased by over twofold. Food intake was almost completely blocked by C75 treatment and the mice maintained the same low blood glucose level as fasted mice. This is in contrast to the longer-term (24 h) effect of the inhibitor where blood glucose levels were higher and blood fatty acid levels were lower than those of "fasted" pair-fed mice. Thus, in the short (~2 h) period following icv injection, FAS inhibitors do not provoke significant peripheral metabolic effects. The importance of glucose metabolism by the hypothalamic signaling system is discussed next.

The level of malonyl-CoA in the hypothalami of fasted mice is much lower than that of fasted mice that have been refed. Further, this difference occurs rapidly thus, within <2 h after refeeding, hypothalamic malonyl-CoA levels increase >5-fold (Hu et al. 2003). The response to icv administration of the FAS inhibitor, C75, to fasted mice is equally rapid increasing by ~4-fold in <2 h. Importantly, the increase is independent of food intake as it occurs despite the FAS inhibitor-induced blockade of food intake. Hence, the effect on malonyl-CoA level appears to be due to the central action of the inhibitor, as the effect is rapid, occurs following icv administration at a low dose, and is not accompanied by changes indicative of altered insulin and/or glucagon status.

The administration of icv FAS inhibitor or vehicle rapidly alters the expression of hypothalamic NPY, AgRP, and POMC. The levels of the orexigenic neuropeptides (NPY and AgRP) messages in hypothalami of fasted mice were >2-fold higher than those of refed mice, while the levels of the anorexigenic neuropeptide (POMC) message was ~2-fold lower than in refed mice. The changes in expression of these neuropeptides were rapid, occurring in ≤2 h (Hu et al. 2003). Likewise, the changes in neuropeptide levels provoked by icv injection of the FAS inhibitor to fasted mice were rapid and occur without a change in food intake, i.e., in effect the mice remained in a "fasted" state. Thus, icv FAS inhibitor blocks the fasting-induced changes in expression of the orexigenic and anorexigenic neuropeptides. The fact that this response is rapid (<2), i.e., similar to that of hypothalamic malonyl-CoA, supports the view that an increase of malonyl-CoA level is responsible for the changes in expression of the hypothalamic orexigenic and anorexigenic neuropeptides.

39.4 Reversal of the Central Effects of FAS Inhibitors Caused by a Blockade of Malonyl-CoA Formation

In the experiments described earlier, it was shown that icv administration of the ACC inhibitor, TOFA, prevented/reversed the suppression of food intake caused by the FAS inhibitor administered ip. Experiments were conducted to determine whether centrally administered TOFA could rapidly prevent/reverse the effect of icv FAS inhibitor on hypothalamic malonyl-CoA and food intake. As anticipated, the FAS inhibitor rapidly suppressed food intake (Hu et al. 2003). The suppressive effect of icv FAS inhibitor on food intake is immediately (<2 h) prevented by coinjected icv TOFA – the increase over that of mice injected icv with C75 alone being ~10-fold. TOFA also rapidly prevents the effect of icv FAS inhibitor administration on hypothalamic malonyl-CoA to the same extent as TOFA prevents the effect of C75 on food intake. The extent of the TOFA-induced changes are inversely proportional, which is consistent with malonyl-CoA acting as a negative mediator of food intake.

39.5 Genetic "Knockdown" of Hypothalamic FAS Gene Expression Increases Hypothalamic Malonyl-CoA Level and Decreases Food Intake and Adiposity

Semenkovich et al. (Chakravarthy et al. 2007) have crossed floxed FAS mice with RIP-Cre mice – Cre expression being driven by the rat insulin promoter. In addition to driving expression in pancreatic β-cells, this promoter also activates expression in select neuronal nuclei within the hypothalamus. While the floxed mice do not exhibit detectable change in the regulation of insulin expression/secretion by pancreatic β-cells, they exhibit a phenotype (FAS "knockdown") virtually identical to that of inhibition of hypothalamic FAS, i.e., a decrease of food intake, body weight, and adiposity (Chakravarthy et al. 2007). In collaboration with Clay Semenkovich and his colleagues, we found that hypothalamic disruption of the FAS gene caused a steady-state ~2-fold increase of hypothalamic malonyl-CoA. Consistent with the proposed regulatory role for hypothalamic malonyl-CoA in the regulation of body weight, mice with hypothalamic disruption/"knockdown" of the FAS gene exhibit decreased adiposity (Chakravarthy et al. 2007).

Thus, two independent lines of evidence, the central administration of FAS inhibitors and the disruption of the FAS gene in the hypothalamus, led to the same phenotype: elevated malonyl-CoA, lowered expression of the orexigenic, and increased expression of the anorexigenic neuropeptides and, as a consequence, a suppression of food intake.

39.6 Overexpression of Malonyl-CoA Decarboxylase (MCD) in the Ventral Hypothalamus Lowers Malonyl-CoA and Increases Food Intake and Adiposity

As shown earlier, increasing hypothalamic malonyl-CoA by icv injection of FAS inhibitors or by genetic knockdown of hypothalamic FAS suppresses food intake and adiposity. The question was raised whether lowering hypothalamic malonyl-CoA would have the inverse effect. To this end, an Ad-cMCD vector harboring a mouse cDNA encoding a cytosolic MCD (cMCD) was constructed with which to lower malonyl-CoA both in vivo in mice and ex vivo in GT1-7 hypothalamic neurons (Hu et al. 2005). The Ad-cMCD expression vector, along with a control vector (encoding adenoviral β-galactosidase) was introduced by bilateral stereotactic injection into the ventral region of the hypothalamus just below the third ventricle. This region encompasses the arcuate nucleus, which contains neurons that function in the regulation of feeding behavior. Expression of β-galactosidase verified the proper placement of the adenoviral expression vectors.

When delivered into the ventral hypothalamus, the expression of Ad-cMCD increases food intake and body weight (Hu et al. 2005). Moreover, Ad-cMCD expression in the ventral hypothalamus prevented/reversed the suppression of food intake provoked by icv-administered FAS inhibitor that increases hypothalamic malonyl-CoA. These findings were later verified by Rossetti's group, who found that expression of an adeno-associated viral vector expressing MCD into the hypothalamus caused a large increase of food intake and obesity (He et al. 2006).

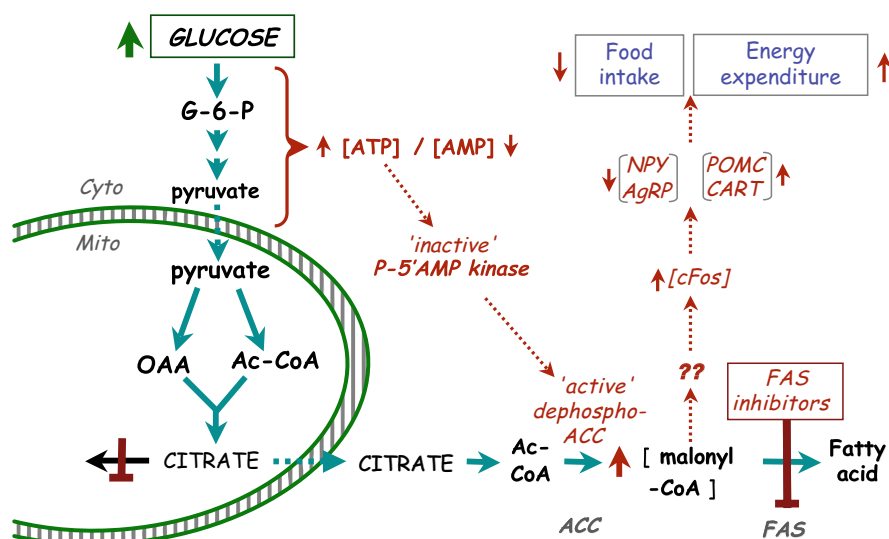
The central (icv) administration of AICAR (5-aminoimidazole-4-carboxamide ribonucleoside) – a potent 5′-AMP kinase agonist – provokes phosphorylation/inactivation of ACC, lowers hypothalamic malonyl-CoA and increases food intake (Hu et al. 2005). These observations are consistent with the fact that treatment of hypothalamic GT1-7 neurons with AICAR, an activator to 5′AMP-kinase that


Fig. 39.3 Schematic model illustrating characterized events of the hypothalamic "AMP-kinase/malonyl-CoA signaling pathway" that regulates global energy balance (see text for details)

suppresses ACC, lowers malonyl-CoA (Hu et al. 2005). These effects correlate closely with the phosphorylation of ACC, an established target of AMP kinase (Hardie 1989).

Together these results confirm the role of malonyl-CoA in the hypothalamic regulation of feeding behavior. Further, they suggest that 5′-AMP kinase and ACC are intermediaries on the signaling pathway (see Fig. 39.3).

39.7 The Hypothalamic 5′-AMP Kinase/Malonyl-CoA Signaling Pathway

It was first discovered that either systemic or central administration of FAS inhibitors provokes a rise in hypothalamic malonyl-CoA level that is correlated with the suppression of food intake (Loftus et al. 2000). Further, the icv administration of an ACC inhibitor, which blocks hypothalamic malonyl-CoA formation, was found to prevent the blockade of food intake by FAS inhibitors (Loftus et al. 2000; Hu et al. 2003). Thus, it appeared that one or both of the enzymes, i.e., ACC and FAS, which bracket malonyl-CoA in the pathway of fatty acid synthesis must be involved in transmitting "malonyl-CoA signal" to neuronal centers that control feeding behavior. These and other findings suggested that fluctuations in hypothalamic malonyl-CoA are linked to changes in feeding behavior. A large body of evidence has since been gathered that places malonyl-CoA as an intermediary in the signaling pathway that senses changes in energy status and prompts changes in feeding behavior.

Changes in malonyl-CoA level during feeding and fasting cycles correlate closely with changes in the phosphorylation state/activity of 5′-AMP kinase and the phosphorylation state/catalytic activity of ACC (Winder et al. 1997). Both the liver and muscle isoforms of ACC, i.e., ACC1 and ACC2, respectively, are known to be phosphorylated and inhibited by 5′-AMP kinase (Hardie 1989; Winder et al. 1997; Winder and Hardie 1999). Both ACC isoforms are found in hypothalamic neurons. ACC2 and CPT1b are outer mitochondrial membrane proteins expressed in tissues in which malonyl-CoA regulates the CPT1-mediated translocation of fatty acids into the mitochondria (McGarry et al. 1978;

McGarry and Foster 1979; McGarry 2001). This provides a metabolic rationale for the participation of 5′-AMP kinase in regulating malonyl-CoA in the hypothalamus by phosphorylating ACC.

At the cellular level 5′-AMP kinase serves as a sensor of cellular "energy charge," i.e., the ATP level of the cell (Hardie 1989; Winder et al. 1997; Winder and Hardie 1999). 5′-AMP kinase responds to fluctuations in the cellular levels of ATP through changes in the level of 5′-AMP, an activator of 5′-AMP kinase whose concentration is inversely related to that of ATP. The relationship of the levels of the adenine nucleotides is determined by the reaction catalyzed by adenylate kinase – a ubiquitous enzyme found in most cells (see Reaction 1).

$$\text{ATP} + \text{AMP} \leftrightarrows \text{ADP} + \text{ADP}$$

adenylate kinase

$$(K_{eq} = 1.0) \qquad \text{Reaction 1}$$
Since total adenine nucleotide concentration is constant and the K_{eq} for the reaction is ~1.0, it is evident that as the ATP level falls, the level of 5′-AMP rises.

A large body of evidence substantiates the key role played by 5′-AMP-kinase and ACC in the hypothalamic malonyl-CoA signaling pathway (see Fig. 39.3): (1) Refeeding or icv glucose administration after overnight food restriction activates 5′-AMP kinase in the hypothalamus or cells in culture – conditions that lead to the phosphorylation/inactivation of ACC (Wolfgang et al. 2007); (2) The level of ATP in the hypothalamus falls immediately (thus, the 5′-AMP level rises) with the onset of glucose metabolism in the CNS and is closely correlated with changes in the activities of other members of the 5′-AMP-kinase signaling pathway (Cha et al. 2008; Wolfgang et al. 2007); (3) Leptin, an anorexigenic hormone, reduces 5′-AMP kinase activity in the Arc and PVN of the hypothalamus, which would be expected to cause activation of ACC (Minokoshi et al. 2004; Kahn et al. 2005; Wolfgang et al. 2007). Subsequently it was found that leptin does, if fact, increase malonyl-CoA concentration in the hypothalamus (23,24); (4) Central administration of 5-aminoimidazole-4-carboxamide ribonucleoside (AICAR), an activator of 5′-AMP kinase, lowers hypothalamic malonyl-CoA and stimulates food intake (Hu et al. 2005). AICAR also activates the phosphorylation/inhibition of ACC and lowers malonyl-CoA concentration in a hypothalamic cell line in culture; (5) Genetic "knockdown" of hypothalamic FAS gene expression increases hypothalamic malonyl-CoA level and decreases food intake and adiposity (Chakravarthy et al. 2007); and (6) Overexpression of malonyl-CoA decarboxylase (MCD) in the ventral hypothalamus lowers malonyl-CoA and increases food intake and adiposity (Hu et al. 2005; He et al. 2006) and finally, (7) The icv administration of a FAS inhibitor rapidly induces c-Fos expression, an indicator of neuronal activation, in the Arc, PVN, and NTS.

These findings led to speculation that during fasting, an indicator of reduced "energy charge," the 5′-AMP/ATP ratio rises in hypothalamic neurons that control feeding behavior. Since ACC is a substrate of 5′-AMP kinase its phosphorylation inactivation produces a decrease in malonyl-CoA (Wolfgang et al. 2007).

To identify a neuronal event/s that occurs concomitant with the expression of the orexigenic and anorexigenic neuropeptides, cFos was selected, since its expression is an established indicator of neuronal activation (Mistry et al. 1994). Intracerebroventricular administration of a FAS inhibitor rapidly activates c-Fos expression in the hypothalamus, notably in the Arc, PVN, and also in the NTS (Gao and Lane 2003). Taken together with the rapid effects on ACC activity, this indicates that malonyl-CoA induces expression of cFos, which serves as the initiating event in the expression of the orexigenic and anorexigenic neuropeptides in the hypothalamic neurons that regulate feeding behavior. Based on these and other findings, the signaling pathway illustrated in Reaction 2 (see also Fig. 39.2) was formulated.

39.8 Glucose Sensing via the AMPK/Malonyl-CoA Signaling Pathway Produces Satiety

Food deprivation gives rise to a decreased blood glucose level – a state in which hypothalamic malonyl-CoA is at a minimum (Hu et al. 2003; Wolfgang et al. 2007). Upon refeeding or the icv administration of glucose, hypothalamic malonyl-CoA increases dramatically. Since glucose is the primary physiological fuel for the brain (Cahill 1970, 1971) and is a precursor of cytoplasmic malonyl-CoA (see Fig. 39.3), which suppresses food intake, the question is raised of whether there is a causal relationship between glucose supplied to the brain and hypothalamic malonyl-CoA. Immediately following glucose infusion into the CNS of fasted mice, malonyl-CoA level increases, orexigenic neuropeptide (NPY and AgRP) expression decreases, and anorexigenic neuropeptide (αMSH and CART) expression increases in the hypothalamus (Fig. 39.3; Wolfgang et al. 2007). Within 30 min after infusion, when the glucose-treated mice are given access to food, food intake is drastically reduced.

Glucose metabolism in the hypothalamus is known to rapidly reduce 5′-AMP kinase activity (Fig. 39.3; Wolfgang et al. 2007). Decreased 5′-AMP kinase activity allows the dephoshorylation/activation of ACC thereby increasing the level of malonyl-CoA – its reaction product. It was established that 5′-AMP kinase and ACC (Wolfgang et al. 2007) both respond to changes in blood glucose and function in transmitting the malonyl-CoA signal. Thus, increased glucose flux to the hypothalamus/CNS causes dephosphorylation and thereby, inactivation of 5′-AMP kinase which leads to activation of ACC and an increase in the level of malonyl-CoA. As discussed, an increase in hypothalamic malonyl-CoA suppresses food intake and increases energy expenditure. The events in this signaling system are outlined in Fig. 39.3 and Reaction 2.

Glucose alters hypothalamic [ATP]/[AMP] ratio and as a consequence, feeding behavior. ATP is the primary energy currency utilized by most cells to drive energy-requiring processes. At the cellular level 5′-AMP kinase serves as a sensor of "energy charge," i.e., the current ATP level of the cell (Hardie 1989; Winder and Hardie 1999; Winder et al. 1997). 5′-AMP kinase responds to fluctuations in the cellular levels of ATP through changes in the level of AMP, an activator of 5′-AMP kinase whose concentration is inversely related to that of ATP. Since total adenine nucleotide concentration is constant and for reasons already discussed, as the ATP level falls, the level of 5′-AMP rises. Thus, as the "energy charge" of a cell decreases due to ATP depletion, 5′-AMP kinase, is activated. From a global perspective, whole body energy status is assessed by the rate of glucose metabolism in the CNS. This in turn is linked to the intraneuronal 5′-AMP kinase system, which senses the "energy charge" of key neurons within the arcuate nucleus and neighboring neuronal nuclei in the ventral hypothalamus. As illustrated in Fig. 39.3, glucose entering the hypothalamic neurons is metabolized via the glycolytic pathway causing a rise in ATP level (Cha et al. 2008) and a fall in AMP level, which lowers phospho-5′-AMP kinase, raising 5′-AMP kinase activity, and thereby lowering the phosphorylation state of ACC and raising ACC activity (Wolfgang et al. 2007; Cha et al. 2008).

As discussed, changes in hypothalamic malonyl-CoA during the feeding and fasting cycles result in changes in the phosphorylation state and activity of ACC mediated by 5′-AMP kinase. ACC is found in hypothalamic neurons and is targeted for phosphorylation (thus, inhibition) by 5′-AMP kinase. Several lines of evidence indicate that hypothalamic ACC and thereby malonyl-CoA concentration, are regulated by 5′-AMP: (1) Conditions that lead to the activation of 5′-AMP kinase in neuronal cell culture and in the hypothalamus provoke phosphorylation/inactivation of ACC (Hu et al. 2005). (2) Leptin, an anorexigenic hormone produced by adipocytes, suppresses 5′-AMP kinase activity in the hypothalamus, including the Arc (Minokoshi and Kahn 2003; Kahn et al. 2005; Wolfgang et al.

2007; Gao et al. 2007). This action depresses ACC and thereby increases malonyl-CoA. (3) The central administration of AICAR, a 5′-AMP kinase activator, lowers hypothalamic malonyl-CoA and promotes food intake (Hu et al. 2005). AICAR also activates the phosphorylation/inhibition of ACC and lowers malonyl-CoA concentration in a hypothalamic cell line in culture. These findings indicate that during fasting the [AMP]/[ATP] ratio increases in neurons in critical hypothalamic nuclei, notably the Arc, causing phosphorylation/activation of 5′-AMP kinase, phosphorylation/inactivation of ACC, and a decreased malonyl-CoA level.

Hypothalamic malonyl-CoA has been shown to function globally in energy homeostasis by modulating food intake and energy expenditure. Only recently, however, was the speculated relationship to malonyl-CoA in the CNS demonstrated (Wolfgang and Lane 2008). It was shown that malonyl-CoA level rises in concert with the carbohydrate content of the diet consumed following food deprivation. Malonyl-CoA concentration peaks ≤1 h after refeeding or after peripheral glucose administration – the response being dependent on the dose of glucose administered and is blocked by the central/icv administration of an inhibitor of glucose metabolism, 2-deoxyglucose (2-DG) (Wolfgang et al. 2007; Cha et al. 2008). It should be noted that in blocking glucose metabolism in the CNS, 2-deoxyglucose blocks all glucose-dependent effects, including the 5′-AMP kinase/malonyl-CoA signaling system. The kinetics of change in hypothalamic malonyl-CoA after glucose administration parallels the suppression of phosphorylation of AMP kinase and ACC. Moreover, the blockade of glucose utilization in the CNS by central/icv 2-DG also prevented the effects of glucose on 5′-AMP-activated protein kinase, malonyl-CoA, all downstream events including hypothalamic orexigenic and an orexigenic neuropeptide expression and ultimately, food intake.

The levels of intermediates "5′-AMP kinase/malonyl-CoA signaling pathway" were quantified and found to change rapidly (≤1 h) following central glucose administration in a pattern consistent with that shown in Reaction 2:

$$\text{glucose} \rightarrow \uparrow [\text{ATP}] \rightarrow \downarrow [\text{5′-AMP}] \rightarrow \uparrow \text{5′-AMP kinase activity} \rightarrow \uparrow \text{ACC activity} \rightarrow \uparrow [\text{malonyl-CoA}] \rightarrow \uparrow]\text{cFos} \rightarrow \downarrow [\text{NPY}][\text{AgRP}] \text{ and } \uparrow [\alpha \text{ MSH}][\text{CART}] \rightarrow \downarrow \text{food intake Reaction 2}$$

Finally, it was shown (Wolfgang et al. 2007) that central/icv leptin increases hypothalamic malonyl-CoA and that the increase is additive with glucose administration. As leptin-deficient *ob/ob* mice showed no defect in the glucose- or refeeding-induced rise in hypothalamic malonyl-CoA after food deprivation, it can be concluded that leptin is not required for the "glucose effect." However, active glucose metabolism by the CNS is required for the "leptin effect" (Wolfgang et al. 2007). These studies show that hypothalamic malonyl-CoA responds to the level of circulating glucose and leptin, both of which affect energy homeostasis.

39.9 Fructose Sensing via the AMP-Kinase/Malonyl-CoA Signaling Pathway Produces Satiety

The metabolism of fructose by the CNS has the inverse effect of glucose on the 5′-AMP kinase/malonyl-CoA signaling pathway and feeding behavior (Cha et al. 2008). Although glucose and fructose enter the metabolism via the glycolytic pathway (see Fig. 39.4), the initial steps of hepatic fructose metabolism differ from those of glucose. Likewise, recent evidence (Cha et al. 2008) indicates that fructose metabolism occurs in regions of the CNS, notably the hypothalamus. It is known
Fig. 39.4 Metabolic differences in the rates of metabolism of glucose and fructose in the hypothalamus. Fructose depletes $ATP \rightarrow \Uparrow [5' AMP] \rightarrow \Uparrow AMPK \rightarrow \Downarrow ACC \rightarrow \Downarrow$ M-CoA $\rightarrow \Uparrow$ food intake

that the initial steps of hepatic fructose metabolism utilize a different set of enzymes that allow this sugar to by-pass the rate-limiting step (catalyzed by phosphofructokinase) in the glycolytic pathway. Similar enzymes of fructose metabolism are found in regions of the CNS that play an important role in monitoring energy balance and satiety control (see (Cha et al. 2008)). These findings are consistent with a recent report (Miller et al. 2002) and a recent report from this laboratory (Cha et al. 2008) that centrally administered fructose provokes feeding. In contrast, the central administration of glucose causes satiety (Wolfgang et al. 2007; Cha et al. 2008). While some uncertainty remains regarding the extent to which fructose in systemic circulation can cross the blood–brain barrier to enter these regions of the brain (Lane and Cha 2009), recent studies show that fructose rapidly enters the hypothalamus (Lane and Cha 2009). It should be noted that these findings raise serious questions regarding the widespread use of "high fructose corn syrup" as a sweetener in numerous foods and soft drinks. This may constitute a heath problem for youth, who are the major consumers of soft drinks.

Investigations in the authors' laboratory (Lane and Cha 2009) show that the levels of intermediates in the hypothalamic pathway change rapidly following central fructose administration in a pattern consistent with Reaction 3:

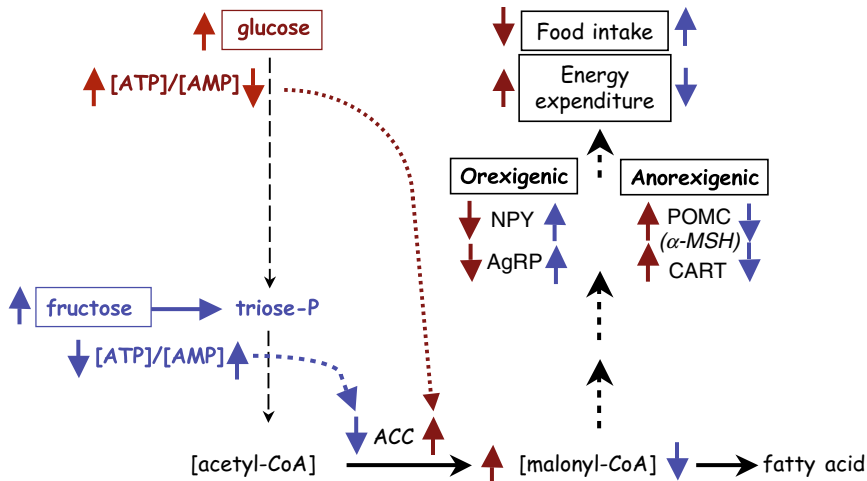
$$\text{Fructose} \rightarrow\downarrow [\text{ATP}] \rightarrow\uparrow [5'\text{-AMP}] \rightarrow\uparrow 5'\text{-AMP kinase activity} \rightarrow\downarrow \text{ACC}$$
$$\text{activity} \rightarrow\downarrow \text{malonyl-CoA} \rightarrow\uparrow \text{food intake Reaction 3}$$
The metabolism of fructose in the hypothalamus is rapid because of its entry into glycolysis downstream of the major control point (the PFK, phosphokinase-catalyzed reaction; see Fig. 39.4). As a result, fructose has the inverse effect of glucose on intermediates in the AMP-kinase/malonyl-CoA signaling pathway and consequently on feeding behavior. The effects of fructose (in blue) *versus* glucose (in red) metabolism on the signaling pathway are illustrated in Fig. 39.5.


Fig. 39.5 Hypothalamic metabolism of and signaling by (**a**) *glucose* versus (**b**) fructose and its consequences on feeding behavior. *Red arrows* refer to hypothalamic glucose metabolism and *blue arrows* refer to hypothalamic fructose metabolism. ⬆ = increased and ⬇ = decreased level or activity of an intermediate, enzyme, or its activity. Entry of fructose into the glycolytic pathway by-passes the slow regulatory PFK-catalyzed step and thus, is metabolized more rapidly than glucose. As a result fructose depletes ATP -> elevated AMP, which lowers malonyl-CoA, increases the expression of the orexigenic, and decreases the expression of the anorexigenic neuropeptides, which leads to an increase in food intake and a decrease in energy expenditure

39.10 Hypothalamic Malonyl-CoA Activates Energy Expenditure in Skeletal Muscle via the Sympathetic Nervous System (SNS)

In addition to suppressing food intake, increasing hypothalamic malonyl-CoA level with FAS inhibitors (Kumar et al. 2002; Thupari et al. 2002; Cha et al. 2005, 2006) or leptin (Minokoshi et al. 2002) provokes increased energy expenditure. This effect was first noted in paired (i.e., isocaloric) feeding experiments in which pair-fed controls lost significantly less body weight than mice treated with a FAS inhibitor (Kumar et al. 2002). Both lean and obese pair-fed mice lost less body weight than their inhibitor-treated counterparts. These findings strongly indicated that, in addition to suppressing food intake, FAS inhibitors increase energy expenditure. Definitive proof that energy expenditure is increased was later obtained by indirect calorimetry (Thupari et al. 2002).

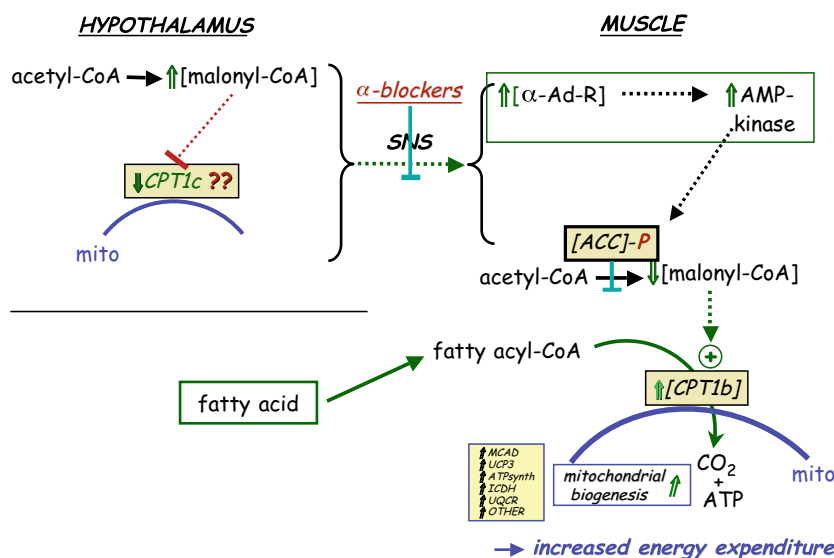
Consistent with signal transmission from the hypothalamus via SNS, centrally administered FAS inhibitor, C75, rapidly (<2 h) upregulated the expression (in skeletal muscle) of: β-adrenergic signaling molecules including norepinephrine; the β3-adrenergic receptor and cAMP; transcriptional regulators PGC-1α and ERRα; and the expression of key oxidative mitochondrial enzymes including pyruvate dehydrogenase kinase, medium-chain length fatty acyl-CoA dehydrogenase, ubiquinone:cytochrome-C reductase, cytochrome oxidase, as well as ATP synthase and UCP3 (Cha et al. 2006). Closely correlated with the increase of fatty acid oxidation in muscle is the rapid (<2 h) phosphorylation/inactivation of ACC2 and thereby, reduction of malonyl-CoA level in skeletal muscle. Lowering muscle malonyl-CoA, a potent allosteric inhibitor of muscle CPT1b, releases CPT1b from inhibitory constraint to facilitate the entry of fatty acids into mitochondria for β-oxidation (Cha et al. 2006). Closely correlated with these events are rapid increases in the expression of skeletal muscle PPARα, a transcriptional activator of fatty acid-oxidizing enzymes, and UCP3, a putative thermogenic mitochondrial uncoupling protein (Cha et al. 2006). Outlined in Fig. 39.5 is the


Fig. 39.6 Hypothalamic malonyl-CoA activates energy expenditure in the skeletal muscle via the sympathetic nervous system

sequence of events by which the hypothalamic "malonyl-CoA signal" is communicated to the skeletal muscle that gives rise to increased energy expenditure.

Also consistent with these rapid changes in mitochondrial enzyme levels is a somewhat slower increase in mitochondrial biogenesis. Thus, daily central administration of the FAS inhibitor, C75, over a 3-day period led to an increase in the number of mitochondria in white and red (soleus) skeletal muscles (Cha et al. 2006). Importantly, both α- and β-adrenergic blockers prevent these effects. Thus, both the SNS and the β-adrenergic nervous system are implicated in the rapid communication of the "malonyl-CoA signal" from the brain to the skeletal muscle.

39.11 Application to Other Areas of Health and Disease

Obesity is a pervasive problem in the USA where approximately 70% of the population is overweight and about 30% are classified as obese. It is evident that energy balance has gone awry in these two groups of individuals who consume more calories than they can burn. These excess calories are diverted into energy storage pathways, primarily fat synthesis and stored as fat in adipose tissue.

Obesity is a major risk factor for several prevalent disease states that are on the rise in the USA, namely type 2 diabetes and heart disease. This review deals with the mechanisms by which inputs to the brain including glucose, hormones, and neural signals are monitored in the hypothalamus and participate in the regulation of feeding behavior and energy expenditure.

39.12 Closing Remarks

Malonyl-CoA plays a key role in the regulation of energy balance by the CNS (Table 39.1). Levels of malonyl-CoA are determined by the complex interplay of enzymes (5′-AMP kinase, ACC, MCD, and FAS) that are responsive to nutrient availability. In the hypothalamus, malonyl-CoA alters the

expression of neuropeptides that regulate food intake and energy expenditure. Glucose metabolism by the hypothalamus triggers the AMP-kinase/malonyl-CoA signaling pathway and leads to a decrease in food intake. In contrast, fructose, which enters metabolism downstream of glucose by-passing the key regulatory control point, has the inverse effects on the activities of intermediates in the hypothalamic signaling pathway and increases food intake. Importantly, through these investigations we now have a better understanding of the mechanism by which food intake is monitored and regulated by the hypothalamus.

Summary Points

- Malonyl-CoA, an intermediate in the pathway of fatty acid synthesis, also serves as an intermediate in the hypothalamic signaling system that controls food intake.
- Malonyl-CoA is synthesized by ACC, which is regulated by phosphoryation/dephosphorylation – phosphorylation being carried out by 5′-AMP kinase.
- At the cellular level 5′-AMP kinase serves as a sensor of "energy charge," i.e., the current ATP level of the cell. 5′-AMP kinase responds to fluctuations in the cellular levels of ATP through changes in the level of AMP, an activator of 5′-AMP kinase.
- From a global perspective, whole body energy status is assessed by the rate of glucose metabolism in the CNS. This in turn is linked to the intraneuronal 5′-AMP kinase system, which senses the "energy charge" of key neurons within the arcuate nucleus and neighboring neuronal nuclei in the ventral hypothalamus.
- The metabolism of fructose by the hypothalamus has the inverse effect of glucose on the 5′-AMP kinase/malonyl-CoA signaling pathway and feeding behavior. Thus, glucose increases hypothalamic malonyl-CoA level and suppresses food intake, whereas fructose lowers hypothalamic malonyl-CoA level and stimulates food intake.

Key Definitions/Terms

Malonyl-CoA: An intermediate in the pathway of fatty acid synthesis, also serves as an intermediate in the hypothalamic signaling system that controls food intake

Energy charge: The current ATP level (or "energy level") of the cell.

Hypothalamus: A region of the midbrain located at the base of the 3rd ventricle. The hypothalamus contains groups of neurons that regulate numerous body functions, including food intake and hunger,

5′-AMP kinase: A regulatory enzyme that catalyzes the phosphorylation of key metabolic enzymes of energy metabolism. 5′-AMP kinase serves as a sensor of energy charge

Orexigenic: Refers to the state of hunger or the desire to eat.

Anorexigenic: Refers to the state of satiation or fullness.

40.1 Introduction

Chocolate is unique: cocoa butter, the fat in chocolate, has an unrivalled melt-in-the-mouth property, which helps to deliver cocoa's special and complex aromas to the nose in such a delicious way. When sufficiently sweetened to counteract cocoa's inherent bitterness, this palatable sensory combination has a salience that is all too easy to recall later, and may even lift our mood. Chocolate's palatability is so widely appreciated that it has assumed a position of treat, gift, or hedonistic pleasure in many different cultures. The flip side of this hedonistic salience is that chocolate is also easily the most commonly and frequently craved of all foods, and is sought after as a comforting experience in times of emotional distress.

This chapter will address these unique facets of chocolate, by examining the nature of food hedonics, or sensory pleasure, and the relationship with food craving, and our understanding of why chocolate should so often be the target of craving, i.e. the irresistible urge to consume. It will also describe the concept of emotional or "comfort" eating, and evaluate the evidence that chocolate is an archetypal "comfort" food, i.e. is chosen during distress because it is able to relieve negative mood, and even enhance positive mood. This conceptualization also allows for individual variation in susceptibility to emotion-related eating, for which differing explanations will be considered here, from psychosocial to neuroendocrinological. In addition, evidence for other possible benefits from chocolate, and the mechanisms by which these might occur, will be examined. Recent evidence from behavioral neuroscience techniques, especially brain imaging such as functional magnetic resonance

imaging (fMRI), relating to the experience of eating chocolate will be considered. The implications of such findings for understanding emotional and behavioral aspects of chocolate eating will be discussed.

40.2 Emotions and Eating

Whenever one is considering a fundamental drive on which survival depends, such as appetite and eating, emotion will always be an important factor. Furthermore, motivational states such as appetite are closely related to emotional states, both being considered "affective states" (Rolls 2007). Essentially, motivational states drive us to achieve goals, whereas emotions arise from achieving, or failing to achieve, those goals. This theoretical view is most clearly described by Rolls (2007, p. 11), who defines emotions as "states elicited by rewards and punishers": his disarmingly simple model is illustrated in Fig. 40.1. Thus, Rolls classifies different emotions on two dimensions (with intensity increasing toward the ends of the axes), one associated with delivery of reward (pleasure, elation) or punishment (fear, anxiety), and the other with the *absence* of (expected) reward (anger, frustration) or of punishment (relief). Naturally, food, and especially chocolate, is normally considered pleasurable, or rewarding; however, we will see that for some individuals, chocolate can induce an approach-avoidance conflict, so that emotional responses are not always positive. This hints at another layer of complexity, in that emotions themselves may be motivating, as those of us who sometimes seek "comfort," solace, or escape from aversive, negative emotions, through eating, can understand (see Table 40.1).
Fig. 40.1 Two-dimensional explanatory model of emotions as states elicited by rewards and punishers. Emotions represented on two dimensions, based on the definition of emotions as states elicited by rewards and punishers (Rolls 2007): intensity increases away from the center of the diagram. The vertical axis describes emotions associated with the delivery of a reward (*up*: S+) or punisher (*down*: S−). The horizontal axis describes emotions associated with the nondelivery of an expected reward (*left*: S+ = omission; S+! = termination) or the nondelivery of an expected punisher (*right*: S− = omission; S-! = termination) (Redrawn from Rolls 2007, Fig. 2.1, p. 14)

Table 40.1 Key features of negative mood

Key points	Explanation
Mood, emotions, and affect	These terms are often used interchangeably; however, emotions are usually considered to be caused by some event, such as obtaining a reward, or failing to do so, whereas moods may occur apparently spontaneously, and be longer lasting. Both could be considered forms of "affect."
Negative versus positive	Moods and emotions are usually classified as either positive (e.g. happy, relaxed) or negative (sad, anxious). Either mood could influence chocolate eating, for example by distracting the eater from conscious resistance.
Acute versus chronic negative mood	Negative mood, like positive mood, can be brief – an acute response to a short-lasting event. However, if the event is serious enough, and longer lasting, negative mood may become chronic, and even result in depression (a disabling level of negative mood). Individuals vary in their susceptibility to this.
Manipulation of mood	Mood can be altered experimentally, by exposing participants to music, films, short stories, or stressful tasks like public speaking. These effects are short-lasting, but can alter eating immediately afterwards, especially in people who eat for emotional reasons.
Chocolate and negative mood	Although eating chocolate is usually thought to be pleasurable, and so should enhance mood, people with ambivalent attitudes to chocolate may feel negative moods such as guilt for several hours later. Moreover, when negative mood occurs, e.g. due to stress, some people choose foods like chocolate as a means to recover from that aversive mood state.

Key features of negative mood are considered, with explanations, in relation to other emotions and to chocolate eating

The interplay between emotions and eating can be bidirectional, and is complicated by the influence of personality differences. In a recent review of the links between eating and emotions, Macht (2008) has proposed a "five-way model": the five components are as follows:

1. Emotions aroused by food stimuli affect food choice.
2. Emotions of high intensity suppress eating due to incompatible emotional responses.
3. Emotions of moderate intensity affect eating differentially depending on motivations to eat:

   (a) In restrained eating (consciously eating less than one would like to), negative and positive emotions enhance food intake due to impairment of cognitive control.
   (b) In emotional (comfort) eating, negative emotions elicit the tendency to be regulated by eating and, as a consequence, enhance intake of sweet and high fat foods (these being powerfully rewarding and so able to alter emotional states).
   (c) In normal eating, emotions affect eating in congruence with their cognitive and motivational features (e.g., food appears more pleasing during positive moods compared to negative moods).

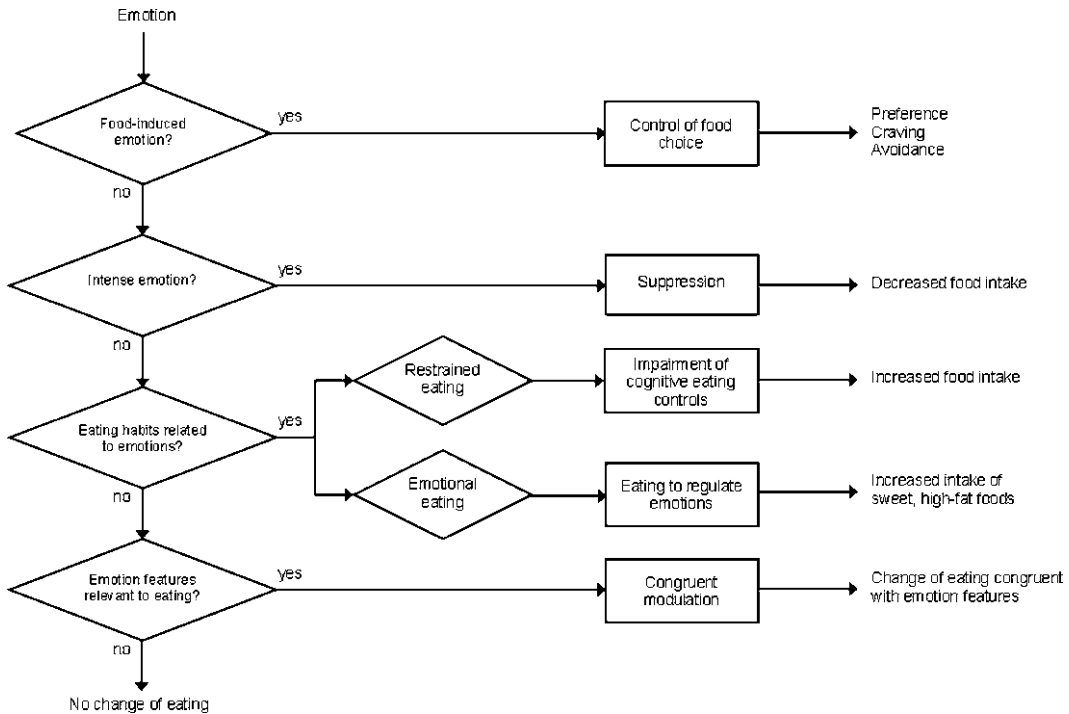
Macht's flow diagram is reproduced here (Fig. 40.2), to help understand the structure and predictions from the model. Some of these concepts will be considered in more detail next, but there are clearly several ways in which eating and emotions can interact. For example, mood or emotions could influence food choice via a change of appetite, or by changing other behavior that constrains or alters food availability. In contrast, alteration of emotion may be an outcome, perhaps even consciously sought, of food choice – an example is "comfort eating," for which chocolate seems to be particularly relevant, as discussed next. Thus, emotions could provide internal stimuli or states that elicit beneficial, e.g. corrective, food choice. Furthermore, eating a particular food, or combination, can alter emotions via sensory (including hedonic) effects, associated social context, cognitive expectations, changes in appetite, or nutritional modulation of brain function (Gibson 2006).


Fig. 40.2 Changes in eating predicted by characteristics of emotions. A flow diagram showing predicted changes in eating from Macht's "five-way model" of interactions between emotions and eating (Macht 2008: redrawn from Fig. 1, p. 5. With permission from the author)

40.3 Chocolate and Pleasure

40.3.1 Innate and Learned Sensory Pleasure

The pleasure that people experience from eating chocolate is an example of the first component of Macht's model; even so, it will be seen next that chocolate's influence on our emotions is not always positive. One of the factors contributing to the palatability of chocolate no doubt includes the way cocoa butter melts in the mouth, at just below body temperature. However, the primary reason is the combination of the creaminess of the cocoa butter and sweetness of sugar – it is well established that human beings love sweet fatty mixtures (Drewnowski and Greenwood 1983), as indeed do many other mammals. There are both innate and learned reasons for this: thus, the newborn infant (of most mammals other than cats) innately likes sweet taste (i.e., prior to any learning, or feeding), as judged by facial and oral responses (but dislikes sour and bitter tastes). Although this is often "explained" as an evolved liking for a sensory predictor of energy, it is at odds with the relatively small and arguably nonessential contribution that sweet foods would have made to our ancestral diets: nevertheless, sweetness is at least one cue to ripeness of nontoxic fruit and roots (Gibson and Brunstrom 2007). Another proposal has been that mammalian sweet liking may promote breastfeeding of nitrogen-rich mother's milk, since sweet" receptors on the tongue respond to chemical groups on both sugars and amino acids (Booth and Thibault 2000). Certainly, human breast milk itself is not a good reason to link sweetness with carbohydrate-derived energy, as it is hardly sweet, and most of the carbohydrate is in

oligosaccharide form (chains of sugar molecules), indigestible to infants: rather, it is thought that this form of carbohydrate in breast milk may have selective prebiotic (i.e., encouraging bacterial growth) and immune defence functions (Kunz et al. 2000).

Over and above any such innate preference, there is abundant evidence that animals including human beings learn rapidly to prefer foods that prove to be a good source of energy (Gibson and Brunstrom 2007). This is underpinned by recent ideas in behavioral neuroscience that show the brain to be a selfish and energy-hungry organ, quite prepared (and equipped) to divert glucose away from the periphery, and seek out energy-rich sources, to feed its constant need, especially during energy-demanding times (Peters et al. 2007). This "selfish brain" evolved to meet energy and nutrient requirements sufficient to ensure genetic continuity, rather than to live a long and healthy life (Palaeolithic hunter-gatherers could be both producing children and be grandparents when reaching the end of their lifespan typically in their early thirties): thus, it could be said that, from middle age onwards, our modern lives involve a struggle to teach our brains to be less selfish, and to care more about the health of our bodies.

Young children have no such concerns, and are particularly sensitive to energy variation in foods, and reliably show just this sort of learned preference for energy-rich foods (Kern et al. 1993): indeed, even among fruits and vegetables, energy density is probably the strongest determinant of their likes and dislikes (Gibson and Wardle 2003). Yet, one of the most energy-dense (and liked) fruits, the banana, is one-fifth as energy-dense as chocolate, so most children offered a free choice between fruit, vegetables, or chocolate have little difficulty making up their minds, to the disappointment of their elders. Thus, the sensory qualities of energy-rich foods like chocolate become predictors of energy delivery, and through experience become targets for our appetites whenever energy is needed: we not only learn to *like* them, but to *want* them when they will be most rewarding, i.e. when hungry. Nevertheless, it should be noted that the taste, or even sight and smell, of such foods, including chocolate, may be so rewarding as to "prime" our desire (wanting, craving) for the food even when not hungry (Lambert et al. 1991).

What is meant by the "reward" value of foods like chocolate? Given Rolls' definition of emotions as "states elicited by rewards and punishers" (before), any discussion of the interaction between chocolate and emotions should consider the rewarding aspects of chocolate. A reward is, in psychological terms, essentially a positive reinforcer: strictly speaking, such a reinforcer is an event which results in preceding, or contingent, behavior being increased, or repeated. However, to most people the term reward also carries connotations of pleasure, and indeed pleasure is one of the key *emotions* which are elicited by rewards. Here is the overlap between emotions and motivation mentioned earlier: feelings of pleasure reinforce our memory of the events that lead up to the pleasure, and motivate us to seek out those rewarding events or stimuli again. The psychological jargon for this acquired motivation, desire or "wanting" is "incentive salience" (Berridge 2009).

In common English, we talk of "liking" a particular food, and largely assume that somehow that also represents quite accurately the tendency to eat that particular food. At a crude level it does: for instance, a list of liked foods will on average be eaten more often by that person than a list of disliked foods (assuming they have the choice; Drewnowski and Hann 1999). Even then, food preferences cannot easily be categorized in simple sensory terms, but rather tend to group into more complex categories of food, such as dairy/dessert, meat, fruit, or vegetables (Wardle et al. 2001). A bit more reflection makes it clear that we often eat foods to which we are at best indifferent, whereas there may be foods that top our list of liking which regrettably we only rarely get to enjoy – life can be complicated. Chocolate may well be such a food for many people. Moreover, liking is really such an overarching way of categorizing our tendency to obtain pleasure from certain foods that we often find the term confusing in everyday use: "Oh, don't you like your dinner, dear?"; "Yes, thank you, it is delicious, but I just can't eat any more." Food liking, then, can be quite independent of any motivation to eat.

This illustrates why we also need a concept of "wanting" that is not synonymous with "liking," even if often they do occur together – indeed, according to Berridge (2009), maximum reward arises

from their co-occurrence. This is reminiscent of the French expression "l'appétit vient en mangeant," i.e. appetite comes with eating; this phenomenon, the "appetizer effect" of eating a liked food when hungry (wanting to eat) has been recorded in controlled conditions (Yeomans 1996) – the desire to eat rises above the level reported immediately before eating. This is echoed by evidence from repeated scans of brain activity using positron emission tomography (PET) while participants ate chocolate beyond satiety: differential activation of brain systems was found, with those areas thought to underlie reward or motivation activated during initial eating, whereas when chocolate eventually was no longer pleasant to eat, let alone wanted, aversive brain systems were active (Small et al. 2001).

"Wanting" reflects the momentary, or current, desire to obtain a goal, i.e. for this chapter, to eat chocolate. It might be thought of as a behavioral subset of "liking" if one assumes that one should not ever want something that one does not like. However, findings in drug addiction research suggest a more complex picture: chronic drug abusers appear often to *want* a drug (or at least objectively they seek and consume it) even when they report gaining little if any pleasure from taking it (Gibson and Desmond 1999). This may reflect the evidence that "wanting" (as mediated by incentive salience) need not be the sort of conscious desire we usually imagine, but instead can be elicited by brain mechanisms responding unconsciously to food (or food-related) stimuli. A major brain pathway for such unconscious wanting is the dopamine neurotransmitter circuitry of the subcortical mesolimbic system of the mid-brain, whereas conscious desire involves higher brain centers known to be critical in assessing reward value relative to need state, such as the orbitofrontal and insular cortices (Berridge 2009). Moreover, studies involving blocking of brain dopamine function show clearly that the ability to respond to palatable tastes with signs of sensory pleasure (liking) is not impaired by such procedures. By comparison, brain circuitry underlying "liking" for foods, or at least enhancement of sensory pleasure from them, involves endogenous opioid (morphine-like) and cannabinoid (cannabis-like) transmitter systems. Although these systems are also linked to food wanting in wider areas of the brain, the ability to stimulate liking seems particularly associated with small "hotspots" in a region of the brain known as the nucleus accumbens shell, and another called the posterior ventral pallidum (Berridge 2009). Both these areas have a history of association with rewarding actions of food and drugs – the latter activating the same systems but to a greater degree. This brings us to the topic of "craving" – a term that seems to be linked to chocolate almost as often as "milk." In the next section, the relevance of these concepts, and of the consequences of one's eating habits, to chocolate craving is discussed.

40.3.2 Chocolate and Craving

40.3.2.1 Craving as Energy Hunger

Craving is a term used to describe a strong urge to consume a substance, such that this impulse is hard to resist and also distracting (Smit and Rogers 2001). In adults, there is experimental support for the importance of the energy supplied by chocolate when hungry in reinforcing the development and maintenance of such a strong appetite, or craving, for chocolate. Thus, participants who were asked to eat chocolate for 2 weeks only when they were hungry, between meals, showed increased craving for chocolate (whether or not they were initially chocolate "cravers"); in contrast, those eating chocolate exclusively when full, just after meals, showed substantial reductions in their chocolate craving (Fig. 40.3; Gibson and Desmond 1999). Those fullness-trained participants also showed a significant reduction in the palatability of chocolate (pleasantness of taste), whereas there was no change in pleasantness of the taste in those eating chocolate hungry (both groups ate about the same amount). This is another example of the ways in which changes in liking (rated pleasantness) and wanting (craving) can be dissociated.

Fig. 40.3 Impact of concurrent appetitive state on chocolate craving. Change in craving for chocolate after eating chocolate exclusively when hungry or full (training state) and effect of test state (hungry, *open symbols*; full, *closed symbols*) before (pre) and after (post) a 2-week training period. Letters indicate significant differences of "post" means from "pre" means (Redrawn from Gibson and Desmond 1999. with permission)
A link between hunger, energy from foods, and the tendency to crave them has recently been established by questionnaire survey (Gilhooly et al. 2007): in particular, participants reporting a susceptibility to overeat when hungry also reported more frequently craving energy-rich foods. This is not to say that we should expect cravings to continue to rise inexorably with hunger, for example during periods of fasting or food restriction: rather, if eating of craved foods is prevented, then the learned reinforcement of the craving will be extinguished, which explains why food cravings decline substantially in patients on very low calorie diets of limited foods (Martin et al. 2006).

A limitation of this "energy repletion" interpretation of chocolate craving is that it does not explain why chocolate so consistently tops the charts of most craved foods (Rozin et al. 1991) – unless one argues that the uniqueness and salience of chocolate's sensory properties provide the added ingredient of irresistibility. Otherwise, other energy-dense foods should be competing more equally for the top craved slot; nevertheless, most popularly craved foods are typically energy-rich and/or able to deliver rapid energy absorption (Gilhooly et al. 2007). In fact, although the experience of chocolate's sensory qualities in their entirety is of course what is craved most, the reliable cues to energy are the sweetness and creaminess, which are also found in white chocolate. Therefore, one might expect white chocolate to satisfy chocolate craving to some extent. This is indeed what has been found (Michener and Rozin 1994): habitual cravers of chocolate were asked to eat whatever the investigators had supplied them at the point at which they were craving chocolate. They then had to rate to what extent that food alleviated the craving. Participants reported that their craving was at least partly satisfied even 90 min later by white chocolate, which has similar sensory properties to milk chocolate but without the flavor of cocoa. This is consistent with an important role in chocolate craving for the experience of consuming the energy in it, though it may also reflect generalization of a learned response from some of chocolate's key sensory properties involved in satisfying craving.

40.3.2.2 Chocolate Craving as Drug Addiction

Interestingly, in that same study, eating capsules of untasted cocoa ingredients alone had no impact on craving, and no additional impact when combined with white chocolate (Fig. 40.4). This was interpreted as evidence against any pharmacological or nutrient-specific basis to the craving. Indeed, a decade ago, Gibson and Desmond (1999) reviewed the evidence for a pharmacological basis to chocolate craving: they concluded that there was little evidence for such a basis at that time. For example, it
Fig. 40.4 Effects of eating cocoa ingredients, white, or milk chocolate on chocolate craving. Reduction in craving for chocolate after eating various chocolate-related treatments, as labeled. Values shown are the mean differences between craving rated on a 100-mm visual analog scale before and 90 min after treatment. Significantly different treatments are indicated by differing letters (Redrawn from Michener and Rozin 1994, Fig. 1. with permission from the authors)

was doubtful whether potentially psychoactive substances in chocolate such as the biogenic amines, tyramine and phenylethylamine, or the cannabinoid agonist, anandamide, actually entered the brain in sufficient quantities to be active, after degradation by enzymes. Moreover, these substances are widely available in other foods that do not appear to be commonly craved (Smit and Rogers 2001).

Nevertheless, chocolate in some form has a long history of being appreciated for its apparent psychoactive properties, whether by Aztec nobles, Spanish *conquistadores*, or seventeenth-century European dilettantes (Hetherington 2001), despite a dearth of scientific proof. Importantly then, it has been shown that the chocolate-specific combination of the methylxanthines, caffeine and theobromine (chemically, norcaffeine) – two stimulant compounds present in chocolate – produced improvements in both positive mood and performance (when administered at levels found in a 50-g bar of dark chocolate; Fig. 40.5; Smit et al. 2004). As shown in Fig. 40.5, these benefits were also matched by the bar-equivalent dose (11.6 g) of cocoa powder taken in a capsule, suggesting that there is no additional benefit from cocoa above that of the methylxanthines. These chemicals may well contribute to our liking, and potentially our craving for chocolate – and presumably its ancient popularity despite originally being consumed as rather bitter concoctions.

Furthermore, recent evidence suggests that the biogenic amine, beta-phenylethylamine, which exists in trace amounts in the brain and may be present in some chocolate (Smit and Rogers 2001), can in fact increase activity of brain neurotransmitter monoamines such as dopamine, noradrenaline, and serotonin, by inducing their release, and inhibition of their reuptake, by presynaptic nerve terminals, at least in rodent models. This has led to renewed interest in a role for phenylethylamine in liking and craving for chocolate (Riederer and Burger 2009), although it is still questionable whether dietary intake of phenylethylamine would influence brain levels, unless enzyme degradation was impaired.

40.3.2.3 Craving as Psychosocial Attribution

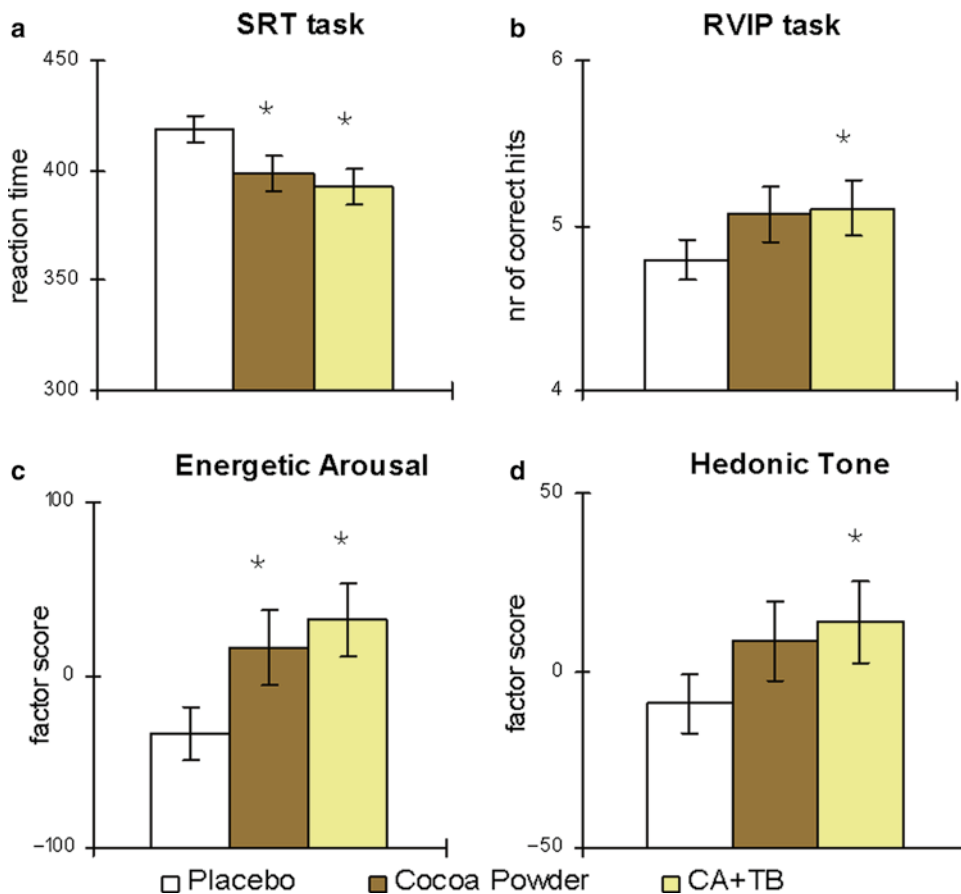
However, even though these chemicals may reinforce liking and consumption of chocolate, there is not yet any direct evidence that they contribute to, or even satisfy, chocolate craving. In fact, explanations for chocolate craving, and other food cravings, have moved away from pharmacological models


Fig. 40.5 Beneficial effects of caffeine and theobromine, or cocoa powder on mental performance and mood. Effects of prior consumption of capsules of placebo, cocoa powder, or combined caffeine and theobromine (CA+TB) on mental performance and mood: (**a**) Simple reaction time, (**b**) rapid visual information processing, (**c**) energetic arousal and (**d**) hedonic tone. Data shown are post-test treatment means ± 0.5 × LSD. Nonoverlapping error bars between placebo and nonplacebo treatments indicate significant difference after Bonferroni correction for multiple comparisons. *$p < 0.05$ (Reproduced from Smit et al. 2004. With permission of the authors and publisher, Springer-Verlag)

toward more sociocultural or psychosocial theories. A common theme that emerges is to consider craving for chocolate to arise from a sort of "approach-avoidance conflict," or ambivalence, as is so neatly captured by the phrase "naughty but nice" (Smit and Rogers 2001; Cartwright and Stritzke 2008). Thus, craving, or its flip side, addiction, may arise from both having a strong desire to eat chocolate but believing that its consumption should be carefully controlled or restricted (a "forbidden" food), presumably because of concern over its high energy, or sugar and fat, content. The difficulty in satisfying both masters leads to the attribution of the conflict as "addiction," which allows loss of control to be blamed on the food, and any desire for chocolate as "craving." This is supported by evidence that eating chocolate increases feelings of guilt in chocolate "addicts" (Macdiarmid and Hetherington 1995).

This "naughty but nice" attributional model also helps to explain another striking aspect of chocolate craving, i.e. the substantial gender difference, with surveys typically finding that the majority of women admit to craving chocolate at some point, whereas often the proportion of men admitting this

is closer to 20% (Rozin et al. 1991; Zellner et al. 2004). This gender difference in craving is clearer for chocolate than for foods in general. Attitudinal differences between men and women may be key: men often interpret food cravings as initiated by hunger, whereas women are more likely to blame negative mood, stress, or boredom (see next), although the data may reflect resistance to change from a lifelong habit.

40.3.2.4 Chocolate Craving and the Menstrual Cycle

However, a biological mechanism has also been proposed, i.e. perimenstrual chocolate craving driven by appetitive effects of sex hormones (Rozin et al. 1991). Certainly, changes in cravings and appetite seem frequently to be reported in association with the menstrual cycle, and sex hormones may well contribute to this (Buffenstein et al. 1995). Even so, there are problems with this interpretation: first, prospective studies of food craving do not show a clear relationship between chocolate craving and menstrual phase (Hormes and Rozin 2009). Second, there are large cultural differences; for example, Zellner et al. (2004) found that, whereas 40% of American women spontaneously reported craving chocolate perimenstrually, only 4% of Spanish women did so. Furthermore, in a cross-sectional survey comparing premenopausal and postmenopausal American women, Hormes and Rozin (2009) recently reported that overall chocolate craving does not decrease much between premenopausal (craved by 90% of women) and postmenopausal (craved by 77%). In particular, this decrease is not nearly as great as would be expected if it were largely driven by hormones of the menstrual cycle. Rather, Hormes and Rozin (2009) suggest that chocolate craving in women may be driven by an interaction between perimenstrual hormones and stress or emotional state (see next).

This raises the issue of chocolate craving or addiction being seen as obtaining relief from negative mood or emotions – a motivation that chocolate "addicts" often refer to, even though any benefit may be transient (Macdiarmid and Hetherington 1995). In this respect, craving for chocolate is often seen as part of a wider tendency to crave "carbohydrates," as a strategy to relieve negative mood or deal with stress. However, the term "carbohydrate craver" is a misnomer, given that the craved foods, like chocolate, are most consistently high in fat, and often sweet, though sometimes savory. This relationship between chocolate craving and relief from negative emotions and stress, and some possible mechanistic explanations, are considered in the next section.

40.4 Chocolate, Emotions, Stress, and Comfort Eating

40.4.1 Chocolate and the "Sugar Rush" Myth

Ask a member of the public, or for that matter a health professional, as to how chocolate might affect mood, and the chances are they will say that chocolate produces a "sugar rush," causing a brief elevation of mood followed by feelings of low or negative mood, even fatigue, apparently due to a rapid increase in blood sugar followed by its precipitous fall below normal levels. Yet, there is no scientific support for this notion: indeed, quite the opposite, since milk chocolate has been shown to be at worst a food of moderate glycemic index (Foster-Powell et al. 2002; i.e. the rise in blood glucose after eating chocolate is considerably below that following white bread of equal carbohydrate content). Possibly related is the finding that cocoa in dairy foods enhances the resulting rise in insulin

(Brand Miller et al. 2003), which might help to dispose of sugar ingested with chocolate. The cocoa butter and dairy fat probably also help to slow the rise in blood sugar after eating chocolate.

Although chocolate can be sugar-rich (over 60% by weight for some brands), contrary to popular opinion, controlled studies have found that dietary sugar does not have a dramatic, especially adverse, effect on behavior: where effects have been found, they tend to be positive, in the sense of improvements in mental function or short-lived increases in positive mood. Moreover, one of the more reliable findings is that people tend to feel calmer or more sleepy after sugar-rich dietary manipulations (Reid and Hammersley 1999; Benton 2008).

40.4.2   Mood Changes after Chocolate

As discussed before, there are sensory, nutritional, and psychopharmacological reasons why eating chocolate should improve mood. However, the impact of chocolate eating on mood and emotions depends, like other foods, on both the motivational, emotional, and attitudinal states of the eater (Reid and Hammersley 1999). Thus, many people who habitually eat, and crave, chocolate have ambivalent attitudes to it, enjoying the acute sensory pleasure of eating it, but subsequently feeling guilty about the health and weight consequences of doing so (Macdiarmid and Hetherington 1995; Cartwright and Stritzke 2008): this seems to be true even for 11–13-year-old children, at least those with aberrant concerns about eating and weight (Cartwright et al. 2007). Indeed, even *prior* to eating chocolate, chocolate "addicts" reported lower positive and higher negative mood than a control group (Macdiarmid and Hetherington 1995). Not surprisingly, such ambivalence is more common in women, and is associated with disordered eating tendencies: for example, when negative mood was induced in women, eating chocolate chip biscuits improved mood, but only in the women with bulimic eating tendencies (Kisler and Corcoran 1997). In contrast, in normal weight men in whom a positive mood was experimentally engendered, chocolate tasted more pleasant and stimulating, and appetite for it was increased, relative to when negative mood was induced (Macht et al. 2002). This evidence supports Macht's (2008) suggestion of emotion-congruent modulation of eating (item 3(c) of his five-way model; Fig. 40.2), i.e. subjective responses to eating depend on prior emotional state, which contrasts with eating to regulate emotions (see next). It may well be relevant that sex differences are also seen in the activity of brain pathways when chocolate is eaten to satiety during fMRI scanning: differential activation between men and women seems to indicate more involvement of brain emotional circuitry in women than in men (Smeets et al. 2006).

Not all women will succumb to negative feelings, such as guilt, after eating chocolate; in fact, Macht and Dettmer (2006) were able to divide women into those who showed a rise in guilt after eating a 50-g chocolate bar and those who did not, and showed that absence of guilt predicted a greater postchocolate rise in happiness. By comparison, after eating an apple, there was no increase in guilt but also a weaker rise in mood, relative to not eating. That study also shed light on the time course of these effects: guilt peaked 5 min after eating chocolate, whereas although mood was also high by 5 min, this increase was sustained at 30 min after eating. This suggests both immediate sensory and delayed postingestive (e.g., psycho-pharmacological or nutritional) components to the effect on mood. Both guilt and mood had more or less returned to baseline after 1 h, although at the last measurement (90 min), mood was still higher after chocolate than when nothing had been eaten.

It is clear then that eating chocolate can result in improved mood: however, it is also apparent that some people are more able to benefit from this than others. This opens up the possibility that chocolate could be used to regulate emotion, and in particular to alleviate negative mood states in vulnerable people. The evidence for this notion is considered in the next section.

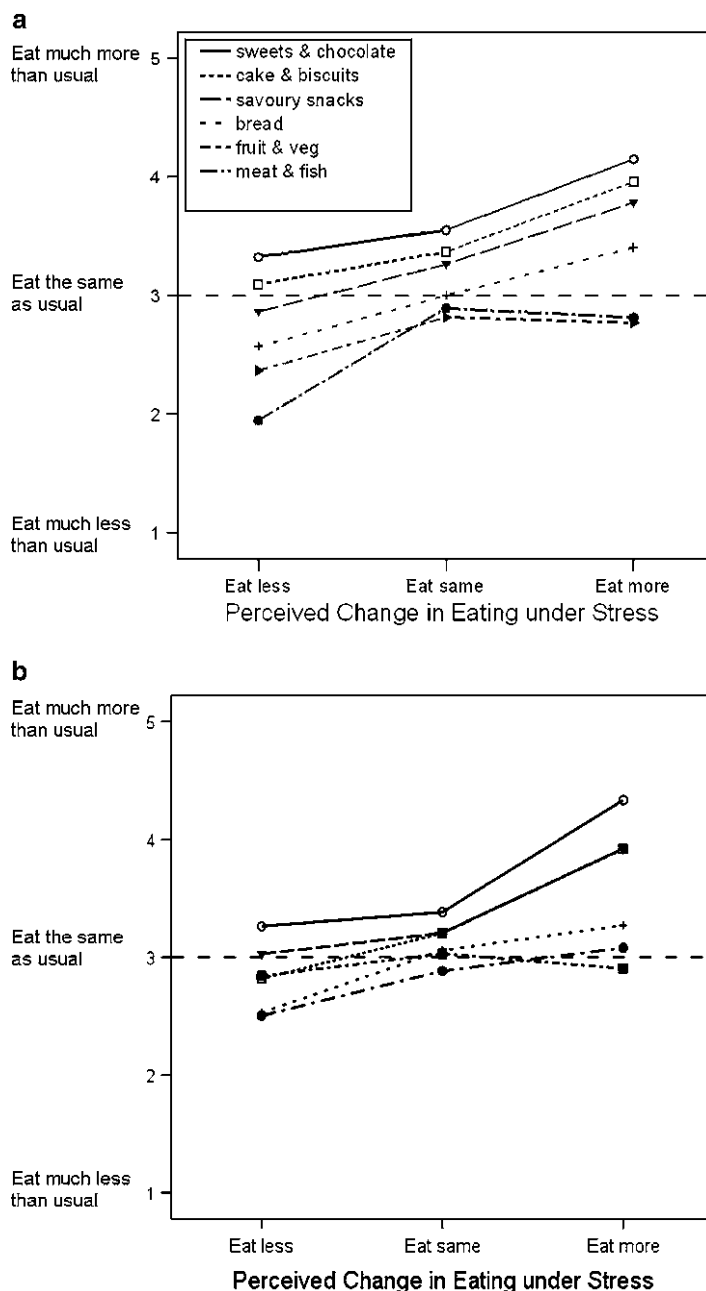
40.4.3 Chocolate, Stress and Comfort Eating

Anecdotally, chocolate is often considered to be the archetypal "comfort food," i.e. a food that is able to relieve stress and negative mood or emotion. It is clear from the previous discussion that chocolate is likely to be a candidate for alleviating negative emotions, at least briefly, and in fact there is mounting evidence that chocolate is indeed particularly sought after in times of stress or discomfort.

Not everyone is a "comfort eater": surveys of people's eating habits under stress suggest that somewhere between a quarter and a half of the surveyed samples report eating more when stressed (Gibson 2006). The remainder report either eating about the same or less. Even so, there is evidence for a pattern of change in food choice under stress that supports chocolate as a key choice for eating when stressed, along with other fatty, energy-dense, and often sweet foods. Oliver and Wardle (1999) asked about perceived changes in intake of a number of specific foods or food categories during stress. This revealed an interesting pattern of effects of stress, which was partly independent of whether participants were grouped as reporting eating more, the same, or less overall when stressed. That is, sweets and chocolate were reported to be eaten more under stress by all groups, even those eating less overall; conversely, intakes of fruit and vegetables, and meat and fish, were reported as less or unchanged under stress in all groups (Fig. 40.6a; data analyzed by Gibson 2006). The changes for the staple food, bread, matched the overall group self-perceptions of changes in eating due to stress. These data imply that mechanisms governing effects of stress on food choice may be somewhat separate from those influencing overall appetite under stress, and that foods such as sweets and chocolate may be particularly useful in ameliorating stress. More recent surveys have leant support to these findings (Wallis and Hetherington 2009). Indeed, E. L. Gibson and K. Harris (unpublished data) have recently replicated the survey findings of Oliver and Wardle (1999) that stress selectively increases consumption of sweets and chocolate, especially in "stress eaters" but even in people who do not report typically eating more under stress (Fig. 40.6b). In that survey, measurement of eating attitudes helped characterize the type of person who may be particularly susceptible to comfort eating: stress eating tendency was strongly predicted by both emotional eating (i.e., stress or comfort eating) and uncontrolled (disinhibited) eating, as well as by the perception of being overweight; in contrast, cognitive restraint (the tendency to try to eat less than one wants to, for fear of gaining weight) did not predict stress eating.

These survey findings are also supported by experimental evidence: in a laboratory study, Oliver et al. (2000) induced stress using a public speaking condition prior to participants choosing lunch from a buffet meal of assorted categories of food. Stress produced a selective increase in the intake of sweet fatty food, chocolate cake, but specifically only in emotional eaters. This is further evidence for a particular relationship between stress, comfort eating, and sweet fatty foods like chocolate. It is intriguing therefore that comfort eating is associated with increased reactivity to stress, as measured by greater release of the stress hormone cortisol (Adam and Epel 2007). Furthermore, a recent fMRI study of brain activity in women found increased responsiveness in reward pathways for emotional versus nonemotional eating women when chocolate milk shake was anticipated or tasted, but only during induced negative mood (Bohon et al. 2009). Given that chocolate cravers also tend to be emotional eaters (Gibson and Desmond 1999), it is notable that another fMRI study of cravers versus noncravers found that chocolate cravers showed increased activation in brain reward pathways in response to the sight and taste of chocolate (Rolls and McCabe 2007). These findings fit well with the earlier evidence of exaggerated appetitive responses to chocolate seen in women who eat chocolate to excess compared with those who eat it in moderation (Hetherington and Macdiarmid 1995).

The link between comfort eating and increased responsiveness of the limbic hypothalamic pituitary adrenal (LHPA) axis, leading to greater release of cortisol from the adrenal cortex, may be key to understanding why sweet fatty foods are sought by comfort eaters. There is substantial evidence

Fig. 40.6 Reported changes in intake of various food categories from two samples of students who tend to eat either less, the same, or more overall when stressed. Reported changes in intake of various food categories during stress (*y*-axis; five-point scale), for three groups (*x*-axis): people who perceive eating less overall; those eating the same; those eating more overall under stress. The nonoverlapping lines illustrate a consistent relative pattern in the change in intake under stress for different foods. Note that intake of sweets and chocolate is raised by stress even in the group who perceived their overall intake to be less under stress. (**a**) Data are from a survey of 212 students (Adapted from Gibson 2006. With permission). (**b**) Unpublished data from a survey of 135 students at Roehampton University, London (Gibson and Harris unpublished data)


from animal studies that rats prefer such foods when stressed, and also that those foods have a beneficial effect, by restraining the activity of the LHPA axis, i.e. comfort foods (e.g., chocolate cookies) improve rats' abilities to cope with stress (Dallman et al. 2005). The importance of peripheral (e.g. insulin and endocrine action of adipose tissue) versus central routes for this sort of effect is not clear, though it seems likely that both have a role. Indeed, activation of such brain stress pathways can enhance the incentive salience (thus, wanting) of rewarding food cues, suggesting a critical interaction between stress and reward that could underlie comfort eating (Adam and Epel 2007).

40.4.4 Neurochemical Mediation of Chocolate Comfort Eating

40.4.4.1 Serotonin

This link between stress reactivity, reward sensitivity, and comfort eating raises another possibility – that chocolate is chosen as a comfort food because it may help to correct a deficiency in functioning of the neurotransmitter, serotonin, which is heavily involved in emotional states. Synthesis of the neurotransmitter serotonin (or 5-hydroxytryptamine or 5-HT) depends on dietary availability of the precursor essential amino acid, tryptophan (TRP): uptake into the brain of TRP in turn depends on its ratio to the large neutral, primarily branched-chain, amino acids (LNAA), with which it competes for transport from blood to brain. In brief, insulinogenic high carbohydrate meals, with little protein, raise this ratio and can result in increased serotonin synthesis in the brain (Fernstrom and Fernstrom 1995). There is in fact evidence to support this theory: when participants were divided into high or low stress-prone groups, as defined by a questionnaire measure of neuroticism, carbohydrate-rich/protein-poor meals (which raised plasma TRP/LNAA ratios) prior to a stressful task were found to block task-induced depressive feelings and release of cortisol, but only in the high stress-prone group (Markus et al. 1998). It was argued that, because stress increases serotonin activity, the poor stress-coping of this sensitive group might indicate a deficit in serotonin synthesis that is improved by this dietary intervention. If eaten in sufficient amounts on an empty stomach, chocolate might increase TRP availability to the brain via such a process, and so allow improved mood via enhanced serotonin release.

Macht (2008) has argued that this TRP-dependent mechanism would be too slow acting (probably taking 1–2 h after eating). However, it is still possible that a delayed mood enhancement via increased serotonin could reinforce a learned liking for chocolate (or sweet, fatty foods), and a tendency to choose it during negative emotions: then, merely anticipating the serotonin-dependent improvement in mood could be enough to raise the spirits immediately on eating chocolate. Macht and Mueller (2007) showed experimentally that eating chocolate lessened film-induced negative mood – an effect which occurred immediately after eating the chocolate, provided that the chocolate was palatable to the participant. Even though the mood change was only measured for a few minutes, the effect was greater in emotional eaters. However, there was no relationship to habitual chocolate consumption, so the authors concluded that the cause is more likely due to sensory effects than learned anticipatory ones.

40.4.4.2 Opioids

Another important neurochemical route for emotional effects of sweet, fatty, palatable foods such as chocolate is via stimulation of the endogenous opioid system. Endogenous opioid neuropeptides are released during stress, and are known to be important for adaptive effects such as resistance to pain and induction of positive mood, possibly by relief from aversive memories. They are also involved in motivational and hedonic processes in eating behavior, such as stimulation of appetite by palatable foods (Berridge 2009). Moreover, in animals and human infants, the ingestion of sweet and fatty foods, including milk, alleviates crying and other behavioral signs of distress, and this effect can be blocked by opioid antagonists (Blass et al. 1989). Such a mechanism probably explains why eating highly liked chocolate chip biscuits prior to a finger pressure test resulted in increased pain tolerance in female students, whereas an unliked food was ineffective (Mercer and Holder 1997) (Fig. 40.7). Opioids are also able to suppress the activity of the LHPA axis (Adam and Epel 2007), which suggests another route by which eating chocolate might help to alleviate stress.
Fig. 40.7 Comparison of the impact of chocolate-flavored or nonchocolate foods on tolerance to pain in female students. Tolerance to pain from pressure on the finger after eating either nothing, rice cakes (a hedonically neutral food), chocolate cookies (highly liked food), or black olives (disliked food). The *y*-axis scale represents distance (cm) that a weight on a lever can be moved to exert pressure on the finger before the participant (US female students) can no longer tolerate the pain. Eating chocolate cookies produced higher tolerance than any other condition (*$p < 0.05$ that conditions were equal) (Redrawn from Mercer and Holder 1997. With permission from the authors)

40.5 Chronic Effects of Chocolate on Emotion and Behavior

40.5.1 Can a Chocolate Habit be Good for You?

There seems to be very little systematic research so far on effects of chronic chocolate consumption on emotions and behavior, aside from comparison of chocolate "addicts" or cravers versus non-cravers, as discussed before. One cross-sectional study of interest recruited pregnant mothers who were either regular or infrequent consumers of chocolate, and compared prenatal stress levels as well as their subsequent ratings of their child's temperament at 6 months of age (Raikkonen et al. 2004). Regular chocolate eaters rated their child's responsivity as more positive, and whereas prenatal stress was associated with increased ratings of fearfulness in the infants of low chocolate eaters, this was not seen for mothers who regularly ate chocolate. Such cross-sectional data need to be interpreted cautiously, but could suggest a stress-reducing and/or mood-enhancing action in mothers that transfers at least to the mothers' perception of their infants temperament.

One might expect other behavioral benefits from chronic chocolate consumption, such as improved mental function, given that cocoa (beverage) improves cerebral blood flow in the brain, as well as lowering blood pressure and benefiting cardiovascular health, presumably via action of its antioxidant polyphenol components, especially the flavanols (reviewed by McShea et al. 2008) – such compounds have been suggested to contribute to health and behavioral benefits from other foods (see Chap. 41, Section 41.5). However, the benefit to brain blood flow was not associated with any benefit to mental performance, at least in young adults. Furthermore, a randomized placebo-controlled study of effects of 6-weeks' consumption of chocolate (bar and beverage) by elderly participants failed to find any improvement in cognition, blood pressure, or blood lipids (Crews et al. 2008). Therefore, despite promising preclinical and epidemiological data on the health benefits of cocoa products, it is at present unclear whether long-term consumption of chocolate has measurable psychological benefits.

40.5.2 The Power of the Dark Side?

Central to the issue of beneficial effects of eating chocolate is the question as to whether it matters if the chocolate is milk chocolate or dark (plain) chocolate. At first the answer seems straightforward – both psychoactive and antioxidant or other pharmacotherapeutic effects of chocolate should be greater the more cocoa is present in the chocolate. Therefore, one would expect greater benefit from dark chocolate containing at least 70% cocoa than from milk chocolate. Even so, it is hard to predict whether a particular chocolate will be rich in antioxidant compounds, for example, because their formation depends on complex variables in the processing of the cocoa bean, which are not under close control (McShea et al. 2008). Nevertheless, there is of course increasing commercial interest in developing chocolate products that can claim to be reliably rich in beneficial compounds (Table 40.2). However, this is not the end of the problem, because animal studies suggest that highly palatable sweet or fatty energy-rich foods can help to alleviate stress. In that case, milk chocolate should be capable of producing beneficial effects such as mood enhancement and stress reduction, at least in some people, despite

Table 40.2 Key facts about chocolate

Key points	Facts
The origins of chocolate	Chocolate is derived from the beans of the tropical tree, *Theobroma cacao*, a native of Central and South America. The ancient Mayan and Aztec peoples of Central America fermented, roasted, and ground the cacao beans, and mixed this with spices into a highly valued drink that the Aztecs called *xocolatl*. This rather bitter tasting drink was prized for its energizing, medicinal, and aphrodisiac properties.
Arrival of chocolate in Europe	The Spanish conquistador Hernan Cortés brought cacao beans back to Spain in 1528, where, as a very rare commodity, monks secretly made a sweetened chocolate drink, adding milk and honey to suit the European taste, for the use of a privileged few cognoscenti. From the early seventeenth century, the chocolate drink gradually spread through the royal courts of Europe, and plantation production was established in Central America and the West Indies. The British doctor, Sir Henry Sloane, invented a medicinal milky chocolate drink in Jamaica in 1687, which eventually formed the origins of Cadbury's drinking chocolate. By the eighteenth century, taking a chocolate drink in Chocolate Houses was a regular way to start the day, and to do business, among fashionable urbanites.
First chocolate bars	Following the invention in 1828, by Dutchman Conrad van Houten, of a press to separate cocoa butter from cocoa liquor, creating cocoa powder, Joseph Fry made the first bars of eating chocolate in 1847. In Switzerland in 1875, Daniel Peter and Henri Nestlé added powdered milk to create a milk chocolate bar. The final key development was that of "conching," discovered by Rodolphe Lindt, a process of heating and grinding the cocoa to produce a much smoother texture. In 1905, Cadbury launched their "Dairy Milk" chocolate bar, which remains a favorite of UK consumers to this day. In 1907 in the United States of America, Milton Hershey launched his individual "KISSES" milk chocolates – chocolate for the masses had arrived.
Chocolate consumption	Large-scale chocolate consumption is mainly confined to developed nations with temperate climates. Perhaps appropriately, Switzerland and the UK compete for top spot, consuming about 10–11 kg/year per capita, which is twice the amount consumed in the USA.
Functional future of chocolate	As evidence mounts that cocoa and dark chocolate can have health benefits, such as antioxidant activity that may benefit the cardiovascular system, there is growing industrial interest in developing and promoting such benefits. Some chocolate is already being marketed as a functional food, and this trend looks set to continue at pace.

This table explores the history of the development of chocolate, from medicinal drink to confectionery bar, and its arrival in Europe. Current global consumption and future functional possibilities are also described

lower levels of apparently healthy ingredients. Still, dark chocolate varies hugely in the levels of fat or sugar used, and some brands may have more sugar and fat than milk chocolate; clearly, very bitter chocolate is unlikely to be popular as a comfort food and presumably less effective in producing sensory pleasure for most people, although it would be richer in potentially "active" ingredients.

40.6 Conclusion

Chocolate is a potent nutritional and sensory package. As a result, most people can enjoy a lifting of mood, or positive emotions, by eating chocolate. Furthermore, the combination of energy richness and some psychoactive ingredients tends to promote a liking for chocolate, and reinforce a habit for it. This habit, like others involving sensory pleasure, can lead to intense "wanting" or craving, which is often subconsciously elicited. Some people who seem to be prone to becoming "emotional eaters" (i.e., comfort eaters) show particularly enhanced emotional responses to chocolate, and are more likely to become habitual eaters, using chocolate to regulate their emotions. This habit may clash with their beliefs about possible negative consequences of eating chocolate, such as weight gain, and so lead to feelings of guilt afterwards. This emotional seesaw is attributional in origin and not some unsubstantiated physiological consequence of, for example, changes in blood sugar. This minority of consumers, who sometimes see themselves as chocolate "addicts" who constantly crave chocolate, is more likely to be female; this sex difference may be partly sociocultural, but could also indicate roles for neurochemical and hormonal mechanisms that interact with emotional regulation to promote a chocolate-eating habit. The good news is that cocoa-rich chocolate may be good for us, though long-term psychological benefits remain to be demonstrated.

40.7 Applications to Other Areas of Health and Disease

There is increasing evidence that cocoa-rich chocolate can have beneficial physiological effects, such as reducing blood pressure and markers of cardiovascular inflammation, and improving vascular function including blood flow in the brain (McShea et al. 2008). Fortunately, the fat in chocolate consists primarily of stearic and oleic fatty acids that do not raise harmful cholesterol, although a minority of the fat is palmitic acid which can raise cholesterol. Animal studies also suggest that the antioxidant compounds in chocolate might help to slow the progress of chronic neurological conditions such as dementia and Parkinson's disease; intriguingly, a recent report suggests that chocolate consumption is increased in patients suffering from Parkinson's disease, perhaps implying underlying self-medication (Wolz et al. 2009). Moreover, it is clear that caffeine and theobromine, which occur naturally in chocolate, can improve both mood and mental function. Nevertheless, there is not yet convincing evidence that long-term use of chocolate confers such benefits.

Chocolate is a well-known comfort food, bringing emotional relief to some people during times of stress, and any alleviation of stress is usually of benefit to health. Nevertheless, this has to be balanced against the potential additional energy intake that a chocolate habit may contribute to. Indeed, there are links between stress and obesity, which may partly be the result of increased comfort eating, as comfort foods are invariably energy dense. Therefore, some people may benefit from retraining their chocolate-eating habits, for example avoiding chocolate when hungry, and perhaps using cocoa-rich chocolate, so that they can curb consumption to levels where the balance shifts in favor of health benefits rather than weight gain.

Summary Points

- Emotions result when we interact with events that might reward or punish us: thus, emotions and eating are often closely linked. We usually experience pleasure from eating, and pleasure is one emotional response that encourages us to eat: this is often especially true for chocolate.
- Chocolate has unique sensory properties that may be innately pleasurable. Yet, it is also energy-rich, often in the form of a sweet fatty food, and a memorable experience. Such foods rapidly become liked and can lead to learning of strong habits, especially if regularly eaten when hungry.
- A feature of such habits is that the brain can motivate us to want to eat chocolate subconsciously, despite our best intentions, i.e. our attempts at cognitive control of our habit. This can lead to a sense of "craving" for chocolate.
- Although psychoactive ingredients in chocolate may not be responsible for forming a chocolate habit or for alleviating its craving, caffeine and theobromine, found naturally in chocolate, do have positive effects on mood and mental function, in doses found in a 50-g bar: this may help form a chocolate habit.
- Chocolate craving is also partly due to having particular beliefs about chocolate being "naughty" (too many calories), which conflicts with the brain's fundamental recognition that chocolate is very "nice." This helps explain why women are far more likely to be cravers than men.
- Two strategies may help reduce craving for chocolate: first, avoid eating chocolate when hungry. If eaten full, the sensory pleasure and energy delivery will have far less impact. Second, if chocolate can be avoided altogether for several weeks, craving will "extinguish" itself because the habit is no longer reinforced.
- Chocolate is a recognized comfort food, i.e. eating chocolate can alleviate stress, reduce negative emotional states, and even increase tolerance to pain. These effects may be the result of activation of brain pathways known to combat stress, process pain, and to regulate emotions.
- Although there is evidence that cocoa-rich chocolate may benefit health in the short-term, it remains to be demonstrated that a long-term habit of eating chocolate improves psychological well-being.

Definitions and Explanations

Functional magnetic resonance imaging (fMRI): A form of magnetic resonance imaging that allows detection of activity in the brain, overlaid on detailed brain structural images, without the use of radioactive isotopes. fMRI uses blood-oxygen-level-dependent (BOLD) changes in magnetic characteristics of blood that reflect the delivery of oxygen from blood to local activated neuronal sites.

Serotonin: A neurotransmitter (chemical signal between nerve cells), also known as 5-hydroxytryptamine (5-HT), present throughout the body, and involved in numerous functions in the brain, including control of blood pressure, pain, sleep, appetite, emotions, and cognition.

Brain opioids: A class of neurotransmitters or neuromodulators whose receptors include those binding opiate drugs. Opioids are found in the periphery as well as the central nervous system, and are particularly involved in mediating pleasure and euphoria, as well as relief of pain and stress.

Amino acid: Molecules containing an amine group (e.g. $-NH_2$), a carboxylic acid group ($-COOH$) and 1 of 20 organic structures. They form proteins and peptides, which are chains of amino acids. In human adults, eight "essential" amino acids, including tryptophan, cannot be synthesized internally and so have to be obtained from food.

Methylxanthines: Methylated (having a chemical group of additional carbon and three hydrogen atoms attached, in place of a single hydrogen) derivative of xanthine, an aromatic organic chemical structure common in nature. Examples include caffeine and theobromine (one less methyl group than caffeine), and typically have mild stimulant properties.

Limbic hypothalamic pituitary adrenal axis: A network in which neurones in the limbic system (emotional circuitry) of the brain, especially the hippocampus, activate neurones in the hypothalamus that in turn control the release of trophic hormones from the anterior pituitary gland. These then stimulate release of e.g. glucocorticoid hormones from the adrenal glands, including cortisol.

Chapter 41
Psychological and Physiological Consequences of Drinking Tea

E.L. Gibson and J.A. Rycroft

Abbreviations

CVD   Cardiovascular disease
EGCG   Epigallocatechin gallate
LDL   Low-density lipoprotein (cholesterol)
DNA   Deoxyribonucleic acid
EEG   Electroencephalography
GABA   Gamma-aminobutyric acid
CFF   Critical flicker fusion test

41.1 Introduction

The beverage tea is second only to water in terms of global consumption of a drink, outstripping all other drinks put together: in the UK, 77% of adults drink tea, averaging nearly three mugs (540 mL) per day, with volume increasing with age (Gardner et al. 2007). Moreover, tea is known to most of the world's ethnic and cultural groups: therefore, putative effects of tea on health or behavior may assume considerable importance for public health. This chapter considers the evidence that tea may affect both these outcomes, through psychological and physiological consequences. There is now a very substantial literature relating tea to health, but there is only space here to summarize the evidence, concentrating in particular on studies in human beings, and the recent consensus. The impact of tea on psychological and behavioral outcomes is less thoroughly researched, but nevertheless several intriguing findings that have emerged in recent years are considered here.

It is important from the outset to define the term "tea" as used in this chapter, since tea can take many forms across the world. Here, tea refers to the most universally recognized form of beverage, a hot drink formed from infusing leaves and leaf buds from the shrub *Camellia sinensis* (familiarly

known as the tea plant) in hot or boiling water (though once cooled, this beverage can be drunk cold, as "iced tea"; extracts of tea also form the basis of bottled or canned forms). These tea leaves can be cultivated, picked, cured, and processed in a variety of ways, resulting in differing fermentation and oxidation, giving several classes of tea beverage, principally (in order of oxidation): white, green, oolong, black, and pu-erh teas (Fig. 41.1). In oriental countries, "red tea" is another (arguably more accurate) term for black tea, although, red tea is also a name used for an infusion of leaves from the South African "rooibos" (red bush) plant, which thus contains no *C. sinensis*, or caffeine. Indeed, infusions of a wide variety of other plants, fruits, and flowers are often referred to as "tea" (or its equivalent in the local language) in many cultures across the globe, and many of these may have both psychological and physiological effects relevant to health and well-being (Pardo de Santayana et al. 2005). However, such effects have not been scientifically or extensively researched for most of these other beverages: indeed, the vast majority of research on tea deals with forms of green or black tea, which are also the most commonly consumed varieties globally (Table 41.1); therefore, this is the nature of the evidence summarized in this chapter.

Nevertheless, restricting the scope of the chapter to infusions of the leaf of one plant does not result in a simple categorization or interpretation of evidence, since the forms of tea from *C. sinensis* vary in biochemical content as a result of cultivation of different varieties of the plant, as well as both preparation of the leaves (Fig. 41.1) and preparation of the infusion (e.g., temperature of the water and length of brewing time; Astill et al. 2001). Moreover, studies of the potential impact of tea on health and behavior have often used processed extracts of tea; this has the advantage of controlling dosage and preparation, but somewhat limits the possibility of generalizing results to any effects of drinking tea as a beverage.

Table 41.1 Key facts about tea

Key points	Facts
Origins of tea drinking	Tea originated in southeast Asia, where it has been drunk for at least 3000 years. However, tea did not arrive in Europe until the early seventeenth century, finally becoming fashionable in Britain in the late seventeenth century, whence it spread to the colonies – the British East India Company established tea plantations in India in the early nineteenth century.
Types of tea	True tea is a drink made by infusing in hot water the leaves from the tea plant, *Camellia sinensis*. These tea leaves can be cultivated, picked, cured, and processed in a variety of ways. However, the main process that differentiates tea is fermentation (oxidation) of the leaves. Thus, white tea (the youngest leaves), a Chinese yellow tea, and green tea are not fermented, but undergo steaming, roasting, and drying, resulting in delicate, light tea. Oolong tea is semi-fermented, giving a tea part way between green and black. Black tea and pu-erh ("shu" type) tea are fully fermented, although there is a variety of pu-erh tea, "sheng," which is unfermented like green tea. Within these broad tea types, there are numerous varieties.
Global tea production and consumption	Most tea is produced in East and South Asian countries, including China, Japan, India, Sri Lanka, Korea, Vietnam, and Indonesia. Other continents produce substantial amounts of tea including East Africa (especially Kenya), Central and South America. Turkey is also a major producer. About 70% of production is black tea, and 22% green tea. These top producers also tend to be big consumers, accounting for at least half of all production: however, the major importers of tea are (from the highest) Russia, UK, Pakistan, USA, Egypt, Japan, and Iran. These countries consume very different forms of tea, in terms of processing, variety, and preparation. Global tea consumption continues to grow, and has more than doubled since 1970.
Tea preparation	Water temperature is important for correct tea preparation, with the more delicate tea needing lower temperatures than the fermented one. Thus, for white, yellow, and green tea, water temperature should range from 66°C to 82°C (coolest for white tea). Oolong tea is best brewed using water at 82–88°C, whereas black and pu-erh tea require water near boiling point (99°C). Tea should always be steeped (brewed) for at least 30 s (which allows all the theanine to be released). If steeping is limited to 2 min or so, then several separate infusions can be obtained from the same leaves; each will have different flavor characteristics, as well as chemical components. Longer brewing, for 3–4 min, maximizes the release of antioxidant polyphenol compounds, although brewing beyond 5 min will tend to produce a bitter tea.
With or without milk?	Adding milk to tea was established early on in its arrival in Europe, although it is practiced elsewhere, such as Manchuria. It is the most common way to take tea in Britain, where the popular tea varieties are quite strongly flavored and astringent. There are mixed findings concerning the impact of milk on tea's health benefits, but it is likely that, when added as less than 10% of the volume, milk will have little impact on tea's effects.

This table gives key facts about the origins and global distribution of tea drinking, its varieties, production, and preparation of the tea drink

The approaches to studying effects of tea, or its components, on health, behavior, and well-being (a sense of positive health that is more than the absence of illness), vary from in vitro studies of chemical activity in "test tube" models, through experimental studies of tea dosing in animals and man, to epidemiological studies of relationships between habitual tea consumption in large populations and psychological and physiological outcomes. These outcomes are varied, but are grouped here as: cardiovascular (heart and circulatory) health; cancer risk; body weight and obesity; mental well-being and mood; and cognitive function or mental performance.

41.2 Cardiovascular Health

> Drinking a daily cup of tea will surely starve the apothecary
>
> (Ancient Chinese proverb)

Earlier epidemiological studies, including prospective studies looking at development of cardiovascular disease (CVD) over several years in large population samples, did not find conclusive evidence of either a beneficial or harmful effect of drinking tea, but instead, inconsistent results, despite experimental evidence that tea contained potentially beneficial chemicals; however, it was acknowledged that this may be due to close associations in some populations between tea drinking and other lifestyle factors that themselves may be detrimental to cardiovascular health (Hollman et al. 1999). In other words, in some populations, for example in the UK, frequent black tea drinking is popular in lower socioeconomic groups in which unhealthy behaviors are also common, and their confounded influence on heart health may not easily be separated, so that in such populations greater tea intake may even be associated with poorer cardiovascular health, at least in unadjusted analyses. However, a recent overall review of many such epidemiological studies, including populations where this behavioral confounding is not apparent, has concluded that (black) tea clearly has a positive association with coronary heart disease, with three mugs per day reducing risk by up to 71%, depending on the study and population (Gardner et al. 2007). Another meta-analysis of the epidemiological studies linking tea consumption to incidence of stroke, using data from nine studies involving 4,378 strokes among 194,965 individuals, also showed that consuming three or more cups of either green or black tea per day may reduce the risk of ischemic stroke by as much as 21% (Arab et al. 2009).

What properties of tea might benefit the cardiovascular system? The most likely candidates are the various plant chemicals found in tea, collectively known as polyphenol flavonoid compounds, as these are known to have antioxidant activity in vitro, which could suppress inflammatory processes that otherwise contribute to CVD. These components of tea include the catechin flavanols, particularly epigallocatechin gallate (EGCG), their oxidation (fermentation) products, the theaflavins, thearubigins, as well as the flavonols, quercetin, keampherol, and rutin (Fig. 41.2). Tea also contains a unique amino acid, theanine, which may have important effects on the brain (see next; refer Fig. 41.3 for structures of catechins and theanine).

Fig. 41.2 A comparison of the flavonoid contents of typical green and black tea. Pie charts showing the proportions of different classes of flavonoid compounds in average cups of green and black tea (% = % dry weight) (Based on data from Lakenbrink et al. 2000 and Astill et al. 2001. flavonols (10%)

catechins (8%)

Average cup of black tea = 135 mg per 200 ml

thearubigins (70%)
Fig. 41.3 The chemical structures of catechin and theanine. The chemical structures for two key components of tea: (**a**) the basic catechin structure and (**b**) the structure of the amino acid, theanine (an analog of glutamate and glutamine). Both structures were downloaded from Wikimedia Commons (http://commons. wikimedia.org/ – public domain images)
In many European populations, tea is the dominant source of flavonoids such as catechins – in the UK, accounting for as much as 80%, though rather less in the USA – although these are also found in red wine, chocolate, and apples, for example. It has been estimated that average intake of flavonoids in Western countries is about 65–250 mg/day (Erdman et al. 2007). Tea's importance in contributing catechins to the diet was illustrated by findings from a prospective study of elderly Dutch men, in whom high habitual dietary catechin intake reduced risk of dying from coronary heart disease by about 50% compared with low catechin intake; in contrast, once the contribution of tea had been statistically removed, the risk reduction was down to 20% and was not statistically significant (Arts et al. 2001).

In determining likely mechanisms for the impact of tea on cardiovascular health, experimental studies of tea, or its components, have revealed beneficial effects on vascular physiology that support probable health benefits of drinking tea on the cardiovascular system, in in vitro laboratory and animal models, and in clinical trials in human participants (Vita 2005). Several clinical studies have investigated two aspects in particular: (1) activation of blood platelets (assessed as aggregation of platelets with white blood cells or activated by factors such as adenosine diphosphate), which indicates risk of clot formation and inflammation of arterial walls, and is a key event leading to coronary heart disease; (2) responsiveness of the vascular endothelium (cellular lining of blood vessel walls) to changes in blood flow (i.e., dilatation vs constriction), which is thought to be an important indicator of the health of the cardiovascular system. In patients with established CVD, 4 weeks of drinking 900 mL of black tea per day did not reduce platelet aggregation compared to water, despite increased plasma flavonoid content, although the design cannot rule out an interaction with change in caffeine intake. In contrast, this same group did find that this tea "treatment" improved endothelial function in these patients (reviewed by Gardner et al. 2007). By comparison, in a recent double-blind, placebo-controlled study in a larger sample of healthy men, where caffeine intake was equated between treatment groups, 6 weeks of drinking four mugs of black tea per day was shown to inhibit platelet activation (aggregation with white blood cells), as well as lowering plasma levels of C-reactive protein, usually regarded as a general indicator of chronic inflammation (Fig. 41.4; Steptoe et al. 2007a).

Similar evidence is available from studies of effects of green tea, which is higher in levels of catechins, especially EGCG, than black tea (although the amount consumed will depend on how the tea is brewed). In epidemiological studies, where potentially confounding lifestyle and other factors are controlled for, an inverse association has been described between green tea consumption and CVD, including stroke and hypertension, in oriental populations (Tanabe et al. 2008). Clinical studies have been short term, but beneficial effects on vascular inflammation and blood lipids, including
Fig. 41.4 Change from pretreatment baseline in measures of platelet activation and C-reactive peptide after drinking four mugs of black tea per day for 6 weeks, or a tea placebo (means adjusted for baseline values). Measures: "Mono-platelet aggr" = monocyte-platelet aggregation; "Neutro-platelet aggr" = neutrocyte-platelet aggregation; "Leuko-platelet aggr" = leukocyte-platelet aggregation. *$p < 0.05$ for significant differences between tea and placebo treatments (Based on data from Steptoe et al. 2007a. With the authors' permission)

reduced oxidation of low density lipoprotein (LDL) cholesterol, have been reported. Indeed, particularly impressive results were found in a recent randomized, double-blind placebo-controlled study administering decaffeinated green tea extract capsules for 3 weeks to healthy volunteers aged from 21 to 70: the green tea treatment reduced blood pressure, inflammation and oxidative stress (a cellular process that can damage DNA), and total and LDL cholesterol (Nantz et al. 2009).

However, there is still a need for longer-term placebo-controlled clinical studies. Moreover, it should be noted that recent ex vivo experimental assessment of tea flavonoid effects on vascular endothelium vasodilatation found that highly fermented black tea was equally as potent as green tea, suggesting that the theaflavins and thearubigins in black tea, to which green tea catechins are converted by fermentation, also have beneficial effects on endothelial function (Lorenz et al. 2009). Similarly, a very recent study showed that black tea dose-dependently improved flow-mediated dilation (a noninvasive measure of endothelial function) in healthy male volunteers (Grassi et al. 2009). These beneficial cardiovascular effects of tea are reminiscent of similar effects, including lowering of blood pressure, seen for diets high in fruit and vegetables: similar mechanisms may be involved and continue to be intensively researched.

41.3 Prevention of Cancer

The ability of components of tea to have physiological activity that benefits cardiovascular health, either by reducing inflammation or improving arterial vasodilatation, makes it possible that drinking tea will have other health advantages; key among these could be a reduction in the risk of cancer. Several mechanisms might account for tea's anticancer properties, but the principal ones are likely

to be reduction of DNA damage by oxidative stress, e.g. by scavenging (deactivation) of reactive oxygen species (free radicals) and binding of metals, metabolism and detoxification of carcinogens, modulation of carcinogenic gene expression, and lowering the rate of cell replication (Lambert et al. 2005). In addition, recent evidence suggests that flavonoids in tea may be able to induce apoptosis, i.e. a process of cell death important in regulating cell proliferation and thus cancer, as well as altering biochemical intracellular signaling pathways (de Mejia et al. 2009). Furthermore, even theanine may have anticancer activity (Liu et al. 2009).

Nevertheless, most laboratory studies use higher flavonoid concentrations than those likely to occur from normal tea drinking. Thus, it is important that this mechanistic evidence should be supported by evidence of inverse associations between tea consumption and cancer risk at a population level, i.e. epidemiological studies, where other potentially confounding influences are statistically adjusted for (Lambert et al. 2005). Although there are promising results from some studies showing such inverse associations, others have not supported those findings. For example, in prospective studies in older populations used to assess relations between dietary flavonoid intake and death from cancer, an inverse association was found in a Finnish cohort but not in two Dutch cohorts (Hollman et al. 1999). Gardner et al. (2007) recently reviewed epidemiological studies of associations between specifically black tea and cancer, and concluded that there was little evidence of a consistent protective effect. For example, in a large sample of Canadian men, no association was found between (mainly black) tea drinking and prostate cancer (Gardner et al. 2007). Moreover, a recent report from a very large sample of North American women aged over 45 found no association between total or site-specific cancer incidence and dietary intake of flavonols and flavones (Wang et al. 2009b). However, it should be noted that, in this population, tea is likely to be only a minor contributor to the intake of these flavonoids. In another sample from the USA, no association was found between tea intake and colorectal cancers (Gardner et al. 2007). In a Japanese sample, frequency of green tea intake was also not associated with gastric cancer (one of the most common cancers in Japan; Tsubono et al. 2001).

Conversely, green tea was associated with almost a 50% reduction in risk of gastric cancer in a Chinese population (Setiawan et al. 2001), and black tea was strongly protective against gastric cancer in an Indian population (Rao et al. 2002). Moreover, in a Japanese population, drinking more than ten cups per day of green tea reduced the risk of developing any cancer in both men and women by at least 40%, and onset of cancer was delayed, compared with low intake of green tea (Nakachi et al. 2000). These studies are dependent on accuracy of information concerning both tea intake and confounding factors: importantly, in a prospective study of Chinese men, urinary tea polyphenols were measured to estimate tea intake; high tea intake protected against gastric and esophageal cancers, but only in men who had a low intake of carotene, suggesting low consumption of vegetables (Sun et al. 2002). This could suggest that any protective effect of tea against cancer may be obscured if the diet is generally healthy. Such complex interactions are also indicated by a study of Dutch men and women, where protective effects of dietary flavonoids against colorectal cancers depended on the body size of participants, i.e. protection was only evident in overweight men and normal weight women (Simons et al. 2009), which suggests subtle interactions with other lifestyle, and perhaps genetic, factors.

In summary, despite very promising evidence from mechanistic laboratory studies suggesting that tea flavonoids could reduce the risk of cancer, epidemiological studies of relations between tea (or dietary flavonoid) intake and cancer incidence have produced inconsistent findings. The US Food and Drug Administration previously assessed all the epidemiological data available on green tea and cancer prevention and concluded that it is highly unlikely that green tea reduces the risk of prostate cancer and that there is no credible evidence to support a relationship between green tea consumption and a reduced risk of gastric, lung, colon/rectal, esophageal, pancreatic, ovarian, and combined cancers (FDA 2005). One reason could be that, to protect against cancer, tea intake may need to be both high and in populations that eat relatively low amounts of fruit and vegetables.

41.4 Body Weight, Appetite, and Obesity

> Tea's proper use is to amuse the idle, and relax the studious, and dilute the full meals of those who cannot use exercise, and will not use abstinence.
>
> > Samuel Johnson (1757) "Essay on tea."

Anecdotally, tea has long been believed to alter appetite; however, scientific evidence has been scarce until recently. Laboratory studies investigating potential cardiovascular benefits of black and green tea flavonoids revealed physiological effects that could be of benefit to obese humans at risk of insulin resistance and unhealthy blood lipid profiles (Ramadan et al. 2009). Consistent with this, the green tea flavanol EGCG, was found to promote postprandial insulin secretion in human beings (Weber 2004): this latter result is particularly interesting, as insulin is known to promote satiety and so constrain food intake (see Sect. 1.3 and 1.7 of this publication). In addition, short-term administration of green tea extract plus caffeine to ten healthy men increased fat oxidation and energy expenditure, through stimulation of the sympathetic nervous system (probably by inhibiting enzymatic degradation of the neurotransmitter noradrenaline), whereas caffeine alone was ineffective (Dulloo et al. 1999). Likewise, in 12 healthy men performing a 30-min cycling exercise, green tea extract (without caffeine) increased fat oxidation rate compared with placebo (Venables et al. 2008).

Eleven long-term clinical studies have recently been reviewed and meta-analyzed by Hursel et al. (2009): some of those are summarized here (but not cited, if included in that review). In a study of 104 obese Dutch men and women undergoing severe energy restriction for weight loss, the effect of green tea on weight regain after the restricted period was compared to placebo: there was no difference between groups; however, there was evidence that caffeine may reduce weight regain in habitually low consumers of caffeine. This shows that it is important to design studies that distinguish between effects of caffeine and the flavonoid components of tea. In another study by these same investigators, caffeine was standardized to 300 mg/day for both a green tea extract treated group and a placebo group, during a weight loss diet in women. There was no benefit from green tea on weight or fat loss; in fact, the women given green tea actually became hungrier than those on placebo.

However, in normal and overweight Japanese men and women, taking a drink containing green tea catechins twice or thrice a day for 12 weeks resulted in greater weight and fat loss than placebo (Kajimoto et al. 2005). During this period, participants were asked to maintain their usual diet; even so, the catechin drink also reduced total and LDL cholesterol. Similar results were found in a study of Japanese men comparing 12 weeks of drinking either oolong tea once per day or the same tea supplemented with green tea extract; body weight and fat loss, and reduction in LDL cholesterol, were greatest for the green tea extract group. Furthermore, in obese Thai men and women on a calorie-controlled diet (8.4 MJ/day) for 12 weeks, green tea treatment reduced body weight and increased resting energy expenditure compared to placebo. By comparison, in Taiwanese obese women taking green tea extract or placebo capsules for 12 weeks, there was no difference in weight loss, but blood cholesterol profiles were markedly improved by the tea extract. Despite these somewhat mixed findings, a meta-analysis of such studies concluded that evidence supports a small effect of green tea or catechins (or combined with caffeine) in enhancing weight loss or weight maintenance (Hursel et al. 2009).

Since then, another study monitored the effects of green tea consumption on body weight, body fat mass, as well as the distribution of fat (Wang et al. 2009a). A total of 182 moderately overweight Chinese subjects, aged between 18 and 55 years, were divided into four groups, with each group allocated a regular dose of green tea containing a different quantity of catechins. Amounts consumed ranged from 30 mg to almost 900 mg; an average cup of green tea contains between 50 and 100 mg of catechins. Participants in the study drank their designated tea divided in two daily doses. On days 0, 30, 60, and 90, measurements of body composition were taken to assess the effects that the prescribed tea had on body mass and fat.

The results showed that, relative to the control group consuming no green tea catechins, body weight, waist circumference, intra-abdominal fat, and the total lean mass all decreased after 90 days in the group that drank the tea with the highest concentration of catechins. The authors concluded that regular consumption of green tea with very high catechin content can, over a 90-day period, reduce body weight, body fat mass, and waist size in moderately overweight Chinese individuals.

41.5 Mental Well-being and Mood

If you are cold, tea will warm you; if you are too heated it will cool you. If you are depressed, it will cheer you; if you are excited, it will calm you.

W. E. Gladstone (British Prime Minister 1865)

In many cultures, it is an accepted folklore that drinking tea can acutely improve one's state of well-being, especially the ability to calm oneself, to relax, and escape for a moment from life's many pressures. However, there has been very little scientific investigation to support this notion. Of course tea normally contains caffeine, and, as described in the next section, this explains some, but not all, of the arousing potential of a regular cup of tea (Hindmarch et al. 2000). Yet, other aspects of tea may have important effects on mood: for example, drinking tea, but not coffee, was associated with feeling more relaxed, for women with high social support at work (see Steptoe et al. 2007b). Furthermore, the amino acid, l-theanine, unique to tea, has been shown to increase a psychophysiological measure of relaxation in human beings, i.e. increased electrical alpha-wave activity on the brain surface, as detected by electro-encephalographic (EEG) recording of brain electrical potential changes, or "brain waves" (Nobre et al. 2008), and to improve relaxation during restful conditions (Lu et al. 2004). However, another study measuring EEG after theanine-enriched green tea intake found evidence of increased attention but not relaxation (Dimpfel et al. 2007). Furthermore, several studies have found that theanine and caffeine can interact in affecting mental function (see below), and one study reported that theanine can ameliorate the increase in blood pressure seen after acute caffeine intake (Rogers et al. 2008).

If theanine aids relaxation, one might expect theanine to be of benefit during stress, as seems anecdotally to be the case for tea. There is evidence that this is indeed the case: thus, in participants who were acutely stressed by having to complete a difficult mental arithmetic task, theanine reduced the heart rate response to stress, and also reduced a well-known stress-sensitive response, a rise in salivary immunoglobulin A antibody levels, compared to placebo (Kimura et al. 2007).

One study has looked at the impact of drinking black tea (without milk) four times a day for 6 weeks on responses to stress in healthy men (Steptoe et al. 2007b). This was a randomized double-blind placebo-controlled study, where effects of caffeine were controlled by equating caffeine levels between tea and placebo drink groups. Participants underwent stressful laboratory tasks (role-play speech and mirror tracing tasks) at baseline, after a 4-week wash-out phase on placebo tea, and finally after 6 weeks on either active or placebo tea: 75 men completed the study. Blood samples were taken before and after the stress; heart rate and blood pressure were measured continuously during each session, and the hormone cortisol, known to increase under stress, was measured at several time points in saliva samples. The main findings were that, compared to placebo (a) tea treatment did not alter the stress-induced increases in heart rate and blood pressure; (b) tea drinking resulted in a faster poststress recovery of the cortisol response (Fig. 41.5); (c) participants given the active tea were more relaxed after stress than those given placebo (Fig. 41.6). Thus, drinking tea for 6 weeks did not alter the acute physiological responses during stress, but improved the hormonal and psychological recovery from stress.

If tea benefits mood and coping with stress, it might be expected to show some ability to protect against depression. There is indeed some support for this: a cross-sectional study of over 2000
Fig. 41.5 Changes in salivary cortisol before, after, and during recovery from, stressful tasks, after either 6 weeks of drinking black tea or a placebo drink. Levels of the stress hormone, cortisol, in saliva samples taken before and after performing psychologically stressful tasks, and during subsequent poststress recovery. Cortisol levels fell more rapidly during recovery from stress (50 min later) for the group drinking black tea for 6 weeks (*solid line*), compared to the group drinking placebo tea (*dashed line*) (The figure is reproduced from Steptoe et al. 2007b. With the permission of the authors.)

Fig. 41.6 Effect of 6-week tea drinking vs. placebo on change in relaxation from before performing stressful tasks to after post-task recovery. Change in rated relaxation from before performing stressful tasks to after posttask recovery, 50 min later. Participants were less relaxed after stress following placebo treatment (*dashed line*), but more relaxed after drinking active tea for 6 weeks (*solid line*) (The figure is reproduced from Steptoe et al. 2007b. With the permission of the authors)
Finnish people found that respondents reporting daily tea drinking were significantly less depressed than those drinking tea less frequently, and there was no depression among those drinking five or more cups per day (Hintikka et al. 2005). This finding may also be relevant to the evidence that tea has neuroprotective effects (see next). A similar finding has been reported for a Japanese population, in relation to green tea and psychological well being (Hozawa et al. 2009): in over 42,000 Japanese over 40 years old, those drinking green tea at least five times per day were 20% less likely to report being psychologically distressed than those drinking tea less than once a day, after controlling for other lifestyle and demographic factors.

What could be the mechanisms by which tea benefits mood and psychological well-being? Animal studies have shown that the catechins in tea can act in the brain via type-A receptors for

gamma-aminobutyric acid (GABA-A), a major inhibitory neurotransmitter known to be involved in the calming, sedative, and anti-anxiety actions of benzodiazepine drugs like Valium (Vignes et al. 2006). Moreover, these catechins have recently been found to inhibit activity of neurones in the brain stem nucleus, the locus coeruleus (Chang et al. 2009). As the locus coeruleus is involved in brain arousal systems, this might indicate a mechanism for the calming effects of tea, although it is not clear that catechins absorbed from drinking tea could affect the brain in this way. Theanine also appears to act in the brain via another inhibitory amino acid transmitter, glycine, and via modulation of dopamine release (involved in attention and motivation, as well as motor control). Theanine is a structural analog of glutamate and glutamine, two neurotransmitters involved in excitatory brain transmission. As such, theanine is able to compete with glutamate and glutamine for their transporters, receptors, and metabolizing enzymes. By attenuating the action of glutamate and glutamine, theanine might affect cognitive function, or mood (Bryan 2008). There remains much to be learnt about the potentially complex mechanisms by which tea may modulate brain activity and so mental well-being.

41.6 Cognitive Function

My dear, if you could give me a cup of tea to clear my muddle of a head, I should better understand your affairs.

Charles Dickens (1894)

This section will consider two sorts of evidence in relation to tea and brain function: (a) that tea can acutely modulate cognitive function, i.e. as assessed by mental performance after short-term dosing with tea or its components; (b) that drinking tea, or ingesting its components, is associated with neuroprotective effects, i.e. effects on neuronal structure and function that prevent or ameliorate neurodegeneration and associated cognitive decline or dementia.

41.6.1 Acute Effects on Cognitive Function

More than a decade ago, it was shown that drinking black tea improved alertness acutely (within 10 min; Critical Flicker Fusion test, CFF) – an effect that was not matched by 100 mg caffeine and was more reliable than the effect of coffee on repeated testing over the day (Hindmarch et al. 1998). Nevertheless, that study also found no acute benefit of tea, coffee, or caffeine on tests of short-term memory. Subsequently, in a comparison of tea and coffee over a day, tea improved alertness (CFF) more than coffee (which had twice as much caffeine), whereas coffee showed some additional benefit for reaction times in a choice reaction time task (Hindmarch et al. 2000). Additionally, both these caffeinated drinks delayed and disrupted sleep, although tea less so than coffee. Finally, there are preliminary reports that black tea may improve focused attention, i.e. the ability to select and process only relevant sensory information from among multiple stimuli, although it is not clear to what extent that effect is independent of caffeine (Lipton Institute of Tea Factsheet, "Black tea and mental performance," 2009, Unilever; de Bruin et al. unpublished data).

Thus, there is some evidence that beneficial effects of tea on alertness may differ from those of caffeine per se. It is also worth noting here that there is increasing evidence that apparently beneficial effects of caffeine may largely be due to removal of cognitive impairment following overnight withdrawal from caffeine. Thus, unlike the positive effects seen in overnight withdrawn participants, no beneficial effects of caffeine on performance were found in participants who had abstained from

caffeine for 3 weeks prior to testing, and among those receiving placebo, these long-term withdrawn participants performed better than overnight withdrawn participants (Rogers et al. 2005). However, it is not known whether beneficial effects of tea, as distinct from caffeine, depend on acute withdrawal.

How might tea improve alertness and attention, other than via caffeine? One possibility is via the activity of theanine: as already mentioned, EEG recordings of brain activity after theanine administration suggest that it is able to produce a relaxed state without drowsiness that might improve sustained attention (Nobre et al. 2008; Gomez-Ramirez et al. 2009). One group examined the impact on performance of caffeine (150 mg) or theanine (250 mg) alone or in combination (Haskell et al. 2008). As expected, caffeine improved performance on several measures; however, theanine alone did not, and even impaired performance on a demanding mental arithmetic task, as well as increasing headaches 90 min later. Yet, the combination of caffeine and theanine improved performance above caffeine alone on more complex verbal tasks, and also caused the greatest increase in alertness. However, these effects on mood were not replicated by another group who used 250 mg of caffeine and 200 mg of theanine, alone or in combination (Rogers et al. 2008). In that study, theanine seemed to prevent the increase in alertness caused by caffeine, as well as the increase in blood pressure. The authors noted that this might help to explain why tea is often perceived to be more relaxing than coffee, and it is in line with changes in EEG activity described above. However, it is important to note that these doses of theanine and caffeine are considerably greater than would normally be found in a cup of tea. Nevertheless, when lower doses of caffeine (50 mg) and theanine (100 mg) were tested in another study, the combined treatment showed some improvement in attention and memory over caffeine alone and placebo (theanine was not tested alone), whereas the caffeine-related increase in alertness was again weaker in the presence of theanine (Owen et al. 2008). The effects of these same doses of caffeine and theanine have subsequently been shown to improve attention on a switch task but not to improve intersensory attention or subjective alertness (Einöther et al. 2010).

Could the flavonoid components of tea, especially the catechins, also contribute to any acute effects of tea on cognitive function? It may be plausible, given the animal evidence discussed in the previous section that catechins do alter brain neurotransmitter systems – indeed, the inhibition of locus ceoruleus neuronal activity by catechins (Chang et al. 2009) would be compatible with a more relaxed frame of mind after tea, though not obviously with improved attention – though they may not reach the brain in sufficient amounts. Furthermore, catechins and other flavonoids could improve blood flow in active areas of the brain via their vascular epithelial effects (see above). There are also several studies in rodents demonstrating that chronic consumption of catechins improves memory and other aspects of neuronal function (de Mejia et al. 2009), as well as promising results from human interventions administering some types of dietary flavonoids (mainly isoflavones) for weeks or months (Macready et al. 2009). Nevertheless, there do not appear to be any studies demonstrating short-term effects of tea flavonoids on cognitive performance, so the question of their contribution to any such effects from tea remains open.

41.6.2 Chronic Effects on Cognition and Brain Function

There is growing evidence from animal studies that various flavonoids, including tea catechins, can benefit neuronal growth and function, and furthermore act as neuroprotective agents, counteracting neurodegenerative processes, such as oxidative stress, that otherwise lead to dementia, Parkinson's disease, etc. (de Mejia et al. 2009; Macready et al. 2009). Moreover, theanine also appears to have neuroprotective effects in animals (Il Kim et al. 2009). To date, there do not appear to be any controlled interventions examining the impact of chronic tea intake (or tea components) on cognitive function in human beings.

Nevertheless, there are several epidemiological studies that have examined relationships between long-term tea consumption and brain or cognitive function. In a cross-sectional study of elderly

Japanese, higher green tea consumption, but not coffee, was associated with lower cognitive impairment (Kuriyama et al. 2006). In an elderly French population, risk of dementia after 5 years was reduced by 51% in those having the highest intake of dietary flavonoids at baseline (Commenges et al. 2000). In an American population, drinking two or more cups of tea per day was associated with a reduced risk of Parkinson's disease, independently of smoking or coffee drinking (Macready et al. 2009). In Chinese adults aged 55 or over, tea (mainly black or oolong) consumption at baseline was clearly associated with lower cognitive impairment or decline 1–2 years later (Ng et al. 2008). Finally, in 70–74-year-old Norwegians, habitual intake of tea, wine, and chocolate (all of which are rich in flavonoids including catechins) was dose-dependently and additively associated with better cognitive performance (Nurk et al. 2009). Taken together, these findings support beneficial effects on brain function from habitual consumption of tea.

41.7 Conclusions

It is becoming increasingly clear that tea, the beverage made from infusions of leaves from *C. sinensis*, can have both physiological and psychological effects that may benefit health. Tea contains plant chemicals known as flavonoids that have antioxidant properties and have been shown to benefit indicators of cardiovascular health in laboratory studies measuring effects on inflammation and vascular function, and in clinical trials administering fixed doses of tea or tea extracts. Population-based studies also, on balance, support a positive relationship between tea drinking and cardiovascular health.

Laboratory studies suggest that tea and its components, especially catechins, can have effects on cellular processes that might reduce the risk of developing cancer. However, results from population-based studies have been inconsistent, and currently it is not possible to conclude that tea reliably reduces cancer risk.

There is some evidence that high doses of catechins from green tea may promote weight loss, potentially by stimulation of fat oxidation. In terms of psychological effects, tea can improve cognitive function acutely, and to some extent independently of its caffeine content. One reason may be due to effects on the brain of the amino acid, theanine, which has been shown to alter brain electrical activity. Theanine seems to improve relaxation and aspects of attention, without overstimulation. Possibly related, tea can also ameliorate physiological responses to stress and help poststress relaxation. This might explain population evidence that links tea drinking with resistance to depression.

Finally, laboratory and animal studies suggest that tea and its components, both flavonoids and theanine, can have neuroprotective effects, suggesting resistance to neurodegeneration. This possibility is further supported by prospective epidemiological evidence indicating that populations drinking tea regularly show slower declines in cognitive function, or less risk of dementia with aging, while cross-sectional studies have found a positive association between tea consumption and cognitive function in the elderly.

In conclusion, there have been a large number of scientific studies investigating physiological and psychological effects of drinking tea. Overall, a number of health benefits may arise from tea, but the strongest evidence is for cardiovascular and neurological health.

41.8 Applications to Other Areas of Health and Disease

Gardner et al. (2007) have recently reviewed areas of health that may be affected by drinking tea, in addition to those discussed before.

41.8.1 Dental Health

The tea plant naturally accumulates fluoride from the soil, and so drinking tea can contribute to the beneficial effect that fluoride can have on preventing or treating damage to teeth enamel caused by dental caries, for example. The high levels of catechins in green tea may also protect against caries by inhibiting growth of oral bacteria.

41.8.2 Bone Health

It has been suggested that compounds in tea including fluoride, phytoestrogens, and caffeine may influence bone mineral density, especially in older people. There is limited evidence that drinking four or more cups per day may increase bone mineral density, and reduce the risk of hip fractures, independently of whether milk is added – although adding milk clearly contributes a significant amount of calcium in regular drinkers.

41.8.3 Hydration

Although high doses of caffeine can be diuretic, i.e. stimulating the kidneys to increase secretion of water, eventually leading to dehydration, there is no evidence that such an effect occurs at the levels of caffeine normally drunk in tea. On the contrary, it has been demonstrated that tea has a beneficial effect on hydration.

41.8.4 Iron Status

Polyphenols in tea can inhibit the absorption of iron from non-heme sources (i.e., plants). This appears only to be of concern to those who may already be at risk from low iron status: in such cases, drinking tea should be avoided within 1 h of meals.

Summary Points

- From a health point of view, the key components of tea are likely the flavonoid group of chemicals, including catechins, such as EGCG (high in green tea), their metabolites the theaflavins and thearubins (high in black tea), and the flavonols, as well as the amino acid, theanine.
- The flavonoids have antioxidant, as well as other biochemical effects, and these reduce inflammation and improve blood vessel dilatation, which may lead to better cardiovascular health.
- Despite laboratory evidence suggestive of cancer preventive properties of tea components, findings from population-based studies have been inconsistent, so it is not clear whether chronic tea drinking reliably reduces cancer risk.
- Green tea catechins, at least at high doses, appear to aid weight loss in overweight people, probably by increasing oxidation of fat.
- Tea can relieve effects of stress, and help with poststress recovery, both physiologically and psychologically.

- Tea can benefit acute cognitive performance, possibly by the action of theanine in the brain, where it appears to aid relaxation but also improves some forms of attention.
- Tea may protect the brain against degeneration: tea components are neuroprotective in the laboratory, and tea drinking is associated with less dementia in the elderly.

Key Terms

Polyphenol antioxidants: A group of chemicals based on a polyphenolic substructure, widely available in fruits and vegetables. These compounds show strong antioxidant activity in laboratory tests, although the extent to which dietary sources reach target sites in sufficient concentrations is debated. They may benefit health by deactivating reactive oxygen species (free radicals), so reducing inflammation and cell damage.

Flavonoids: A subclass of polyphenol antioxidants, some of which are common in tea, especially the catechins (strictly, flavonols) such as EGCG.

Reactive oxygen species: Often called free radicals, these are small molecules that are highly reactive due to the presence of oxygen ions with unpaired (free) electrons. They are a normal byproduct of oxygen metabolism in cells, but if levels rise (a state known as oxidative stress), reactive oxygen species can damage cell structures including DNA.

Electroencephalography: Recording of brain surface electrical activity through electrodes placed around the scalp. The electrical potentials reflect the sum of activity of millions of neurones, and result in rhythmic activity (brain waves) with frequencies between 1 and 20 Hz; these are classified (in increasing frequencies) as delta, theta, alpha, beta, and gamma waves, reflecting different brain states.

Cortisol: A steroid hormone produced in the cortex (outer shell) of the adrenal glands, in response to activation of the hypothalamic–pituitary–adrenal–neuroendocrine axis. Cortisol levels in blood or saliva rise rapidly in response to psychological stress, although they also display an underlying circadian rhythm (high in the early morning and low in the evening).

42.1 Introduction

Caffeine is the most widely consumed drug in the world; it is found in foods such as coffee, tea, cocoa, and cola. In many countries, coffee is the beverage that the largest proportion of adults reports consuming over the day other than water. The first population that used coffee as a beverage in the history was in the highlands of Ethiopia and possibly also some populations in nearby highland areas of Sudan and Kenya. Anyway, coffee was effectively cultivated by Arabs since the fourteenth century and was introduced in the New World and in much of the rest of the tropics since the seventeenth century (Smith 1985). Today it is cultivated in many of the moist tropics and subtropic areas including Puerto Rico, the Virgin Islands, Guam, and Samoa (Burkill 1997).

The annual amount of coffee consumed per person is 8–12 kg in the Scandinavian Countries, 4.2 kg in USA, and 2.8 in UK, as reported in Fig. 42.1. A recent epidemiological study regarding beverage consumption of Canadian adults reports the consumption of coffee at different ages (Garriguet 2008): 50 years old or older men were more likely to report having had coffee rather than water; the exception to this trend toward coffee consumption was in 19- to 30-year-old people, who were more likely to report having had milk the previous day and also preferred soft drinks rather than coffee. Among those who drank coffee, consumption peaked at ages from 31 to 50, with an average annual intake of caffeine of 639 g for men and 586 g for women; by age 71 or older, this intake was considerably lower (489 and 398 g respectively). Coffee accounts for about 80.6% of the caffeine intake in adults, while tea and soft drinks account for 12.3% and 5.9%, respectively. Key fact of coffee influences on nervous system are reported in Table 42.1.

CONSUMPTION OF COFFEE
Fig. 42.1 Consumption of coffee. Annual consumption of coffee per capita. These data are referred to 2007, as reported by Euromonitor International

Table 42.1 Key facts of coffee influences on nervous system

1. The caffeine content of a cup of coffee ranges from 65 to 360 mg depending on the type of coffee and the type of preparation.
2. Coffee influences general sleep quality.
3. Coffee improves short-term memory and speeds up reaction times.
4. Coffee modifies the activity of the autonomic nervous system.
5. Coffee reduces the prevalence of some neurodegenerative diseases, including the Alzheimer's and the Parkinson's diseases.
6. Coffee can be considered a functional food.

This table lists the principal properties of coffee

This table indicates the neuro-vegetative modifications induced by subjects, which utilize coffee beverage

The caffeine content of a cup of coffee ranges from 65 to 360 mg, whereas the caffeine content of a cup of decaffeinated coffee is less than 10 mg, as reported in Table 42. 2. The main effects of caffeine include a variety of stimulatory effects on the central nervous system; caffeine increases respiratory rate, produces bronchodilatation, lipolysis, and diuresis. It can cause gastrointestinal disturbances, palpitations and, sometimes, even cardiac arrhythmias (Chou and Benowitz 1994; Mehta et al. 1997). It has been suggested that caffeine may be potentially hypertensive (Nurminen et al. 1999). Caffeine is a natural alkaloid, methylxanthine. About 99% is absorbed after oral ingestion, the blood concentration peaks 1–1.5 h after the ingestion, and its half-life in adults is 3–6 h. Caffeine is metabolized by the cytochrome P450 hepatic enzyme system (Monda et al. 2009).

Caffeine is the most widely consumed central nervous system stimulant. Three main mechanisms of action of caffeine on the central nervous system have been described. Mobilization of intracellular calcium and inhibition of specific phosphodiesterases only occur at high, unusual, concentrations of caffeine. The most likely mechanism of action of methylxanthine is the antagonism of adenosine receptors. Caffeine increases energy metabolism throughout the brain but at the same time decreases cerebral blood flow, inducing a relative brain hypoperfusion. Caffeine activates noradrenaline neurons and seems to affect the local release of dopamine. Many of the alerting effects of caffeine may be related to the action of methylxanthine on serotonin neurons. Methylxanthine induces dose–response

Table 42.2 Caffeine content of coffee drinks

Type	Volume (mL)	mg of caffeine
Starbucks Grande Coffee	500	330–360
Drip	250	115–175
Brewed	250	80–135
Instant	250	65–100
Brewed decaffeinated	250	4–5
Espresso	50	70–100

The caffeine content of a cup of coffee ranges from 65 to 360 mg, while the caffeine content of a cup of decaffeinated coffee is less than 10 mg, as reported by US Food and Drug Administration

increases in locomotor activity in animals. Its psychostimulant action on man is, however, often subtle and not very easy to detect. The effects of caffeine on learning, memory, performance, and coordination are mainly related to methylxanthine actions on arousal, vigilance, and fatigue. Caffeine exerts evident effects on anxiety and sleep which vary according to individual sensitivity, and children, in general, do not appear to be more sensitive than adults. The central nervous system does not seem to develop a great tolerance to the effects of caffeine although dependence and withdrawal symptoms have been reported (Nehlig et al. 1992).

42.2 Effects on Sleep

Caffeine is a widely used stimulant with marked variability in the behavioral response between individuals. Positive behavioral responses may include increased alertness and physical activity, although these may represent a withdrawal reversal mechanism operating in habitual caffeine users (James and Gregg 2004; Roger et al. 2003; Yeomans et al. 2002), whereas responses such as heightened nervousness and sleep disturbance would be considered negative (Hughes et al. 1991; Heath et al. 1998). Some people experience no effects whatsoever of caffeine ingestion. Significant individual differences in the extent of wakefulness (i.e., delay of sleep onset) and soundness of sleep due to caffeine have been observed in subjects who were blind to placebo or caffeine administration 1 h prior to bedtime (Goldstein et al. 1965).

Luciano et al. (2007) have reported that individual differences in coffee-attributed sleep disturbances depend on additive genetic and environmental factors, and that these factors were distinct from those influencing general sleep quality and dimensions such as anxiety and depression. Interestingly, the chromosomal region 2q is significantly correlated to coffee-attributed insomnia in both sexes; other regions of interest, but falling short of the significant criterion, are on regions 17q, 5q, 10q, 13q, and 6p.

Sin et al. (2009) have recently reported a systematic review about the effectiveness of caffeine abstinence on the quality of sleep. The authors browsed several electronic databases and reference lists of articles regarding the correlation between caffeine consumption and sleep deprivation. They selected the articles according to predefined inclusion and exclusion criteria. Two reviewers assessed the quality of trials, which were selected according to the Jadad quality assessment scale, and they included those trials scoring 3 or above; three randomized control trials fulfilled the selection criteria among which two trials scored at least 3 on the Jadad scale, so they included these two trials in the systematic review. The design and outcome measurements of these two trials were not homogeneous, so they did not combine the results but they conducted a critical appraisal. In one trial, caffeine abstinence was associated with significant lengthening of sleep duration and better sleep quality; in the other trial, subjects had less difficulty falling asleep when they drank decaffeinated coffee. This result showed

that caffeine abstinence for a whole day could improve sleep quality, so health practitioners are recommended to include caffeine abstinence in the instructions for sleep hygiene.

42.3 Effects on Memory

Coffee improves short-term memory and speeds up reaction times by acting on the brain prefrontal cortex, according to a recent study by Koppelstaetter et al. (2008), in which functional magnetic resonance imaging (fMRI) was used to determine what areas of the brain were activated by coffee. Prior to testing, the group under examination fasted for 4–6 h and abstained from caffeine and nicotine for at least 24 h. They were then given either a cup of coffee (containing 100 mg of caffeine) or a caffeine-free placebo drink. After 20 min all participants underwent fMRI scans while carrying out a memory and concentration test. Few days later, the experiment was repeated under the same conditions but each subject received the other drink. During the memory tests, a fast sequence of capital letters was shown to the participants; a single letter was then flashed on screen and subjects had to quickly decide whether this letter was the same one which appeared second-to-last in the earlier sequence. They had to respond by pressing a "Y" for yes or "N" for no. All subjects showed an activation of the working memory part of the brain, but those who received caffeine had a significantly greater activation in parts of the prefrontal lobe, particularly the anterior cingulate gyrus. These areas are involved in "executive memory," attention, concentration, planning, and monitoring. This type of memory is used when, for example, you look up a phone number in a book and then mentally store it before dialing. These results suggest that caffeine modulates neuronal activity in those brain areas associated with executive and attentive functions during a working memory task.

42.4 Effects on Anticipatory Processes

Tieges et al. (2006) studied the effects of moderate amounts of caffeine on task maintenance or task switching, using single-task blocks (AAAA, BBBB) or mixed-task blocks (AABB), in which participants were switched predictably between two tasks; in these experiments, switch cost was the longer reaction times on task-switch trials (e.g., AB) compared to task-repeat trials (e.g., BB), while mixing cost was the longer reaction times in task-repeat trials compared to single-task trials. In a double-blind, within-subjects experiment, two caffeine doses (3 and 5 mg/kg body weight) or a placebo were administered to 18 coffee drinkers; both caffeine doses reduced switch costs compared to placebo. Event-related brain potentials revealed a negative deflection developing within the preparatory interval, which was larger for switch than for repeat trials; caffeine also increased this switch-related difference. These results suggest that coffee consumption enhances task-switching performance by enhancing anticipatory processing such as task set updating, presumably through the neurochemical effects of caffeine on the dopaminergic system.

42.5 Effects on Degenerative Brain Diseases

Alzheimer's disease is a common problem in occidental elderly population. Although research is leading to improvements in our understanding of the underlying biology, we still have little understanding of

the environmental risk factors associated with this disorder. Caffeine, an easily modifiable environmental factor, may have a protective effect on the likelihood of developing Alzheimer's disease. Although epidemiological studies reported that a regular consumption of coffee seemed to be protective for Alzheimer's disease in Canadian people (Lindsay et al. 2002), further investigations are needed to determine whether caffeine consumption could have a major affect on the development of Alzheimer's disease or on age-related cognitive decline (Rosso et al. 2008).

The results of case-control studies and of prospective investigations in men suggest that the consumption of coffee could also protect against the risk of Parkinson's disease, although the effective constituent of coffee for this effect is not clear. To address the hypothesis that caffeine is protective against Parkinson's disease, Ascherio et al. (2001) examined the correlation between the risk of this disease and coffee or caffeine consumption among participants in two ongoing cohorts: the Health Professionals' Follow-Up Study and the Nurses' Health Study. This study population comprised 47,351 men and 88,565 women who were free of Parkinson's disease, stroke, or cancer at baseline. A comprehensive life style and dietary questionnaire was completed by the participants at baseline and updated every 2–4 years. During the follow-up (10 years for men, 16 years for women), a total of 288 new cases of Parkinson's disease was documented. After adjustment for age and smoking, the relative risk of Parkinson's disease for men in the top one-fifth of caffeine intake compared with those in the bottom one-fifth was 0.42 (95% CI: 0.23–0.78; p for trend < 0.001). An inverse correlation was also observed with coffee consumption (p for trend = 0.004), with caffeine intake from noncoffee sources (p for trend < 0.001), and with tea consumption (p for trend = 0.02) but not with decaffeinated coffee consumption. Among women, the relationship between caffeine or coffee intake and the risk of Parkinson's disease was U-shaped, with the lowest risk observed at moderate intakes (1–3 cups of coffee/day). The correlation between caffeine intake and the risk of Parkinson's disease was similarly observed in both fast and slow caffeine metabolizers, in agreement with evidences from animal models showing that both caffeine and its major metabolite, paraxanthine, are neuroprotective (Tan et al. 2007). These data support a possible protective effect of moderate doses of caffeine on the risk of Parkinson's disease.

42.6 Effects on the Autonomic Nervous System

Espresso is the main type of coffee drink in most of southern Europe. It is also popular throughout much of the rest of Europe and in Argentina, Brazil, Cuba, and in the urban centers of North America, Australia, and New Zealand. Espresso is a coffee beverage brewed by forcing steam or very hot water under high pressure through finely ground, darkly roasted coffee beans. Monda et al. (2009) have studied the effects of coffee on the autonomic nervous system in young, healthy people. This study analyzed the effect of a cup of espresso coffee on the power spectral analysis of the heart rate variability (HRV), which is a method to evaluate the activity of the sympathetic and parasympathetic nervous system. In young, healthy, sedentary subjects, the HRV-power spectrum was evaluated over a period of 5 min before and 150 min after the administration of espresso coffee (75 mg of caffeine) or decaffeinated coffee (<10 mg of caffeine) in the supine or in the seated position. The absolute values of the spectrum were summed in the low (LF) and high frequencies (HF). The LF and HF values were used to estimate the sympathetic and parasympathetic activity, respectively. In the supine position, coffee increased HF, while decaffeinated coffee caused little modifications of HF (Fig. 42.2). In the seated position, HF was not modified by coffee or decaffeinated coffee. Coffee and decaffeinated coffee did not induce any modification of LF in both positions (Fig. 42.3). This experiment demonstrated that espresso coffee influences the parasympathetic activity in the supine position, underlining the effects of coffee on the activity of the autonomic nervous system.

Corti et al. (2002) demonstrated that coffee induces comparable increases in sympathetic activity and blood pressure in nonhabitual coffee drinkers, whereas habitual coffee drinkers exhibited lack of blood pressure increase despite sympathetic activation due to coffee. Because in that experiment decaffeinated coffee also increased blood pressure and sympathetic activity in nonhabitual drinkers, ingredients other than caffeine could be responsible for the cardiovascular activation.

Anyway, the restriction of coffee or caffeinated beverages is no longer indicated in the seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) guidelines for the treatment of hypertension. In fact, no clear association between coffee and the risk of hypertension, myocardial infarction, or other cardiovascular diseases has been demonstrated. In contrast to early studies, recent research indicates that habitual, moderate coffee intake does not represent a health hazard (Sudano et al. 2005).

42.7 General Considerations

Dórea and da Costa (2005) reported the association between coffee-drinking and health benefits that support the concept of coffee as a functional food; definitions of functional foods vary but are essentially based on foods' ability to give some positive effects of the quality of life, or physical and mental performance, of regular consumers. The worldwide use of coffee for social engagement, leisure, enhancement of work performance, and well-being is widely recognized. Depending on the

Fig. 42.3 Low frequency power. Low frequency power in supine or seated subjects after administration of a cup of espresso coffee or decaffeinated coffee at time 0. The low frequency is an index of the sympathetic activity. No statistical difference was noted between coffee groups and decaffeinated groups
quantities consumed, it can affect the intake of some minerals (K, Mg, Mn, Cr), niacin, and antioxidant substances. Epidemiological and experimental studies have shown positive effects of regular coffee-drinking on various aspects of health, such as psychoactive responses (alertness, mood change), neurological (infant hyperactivity, Alzheimer's and Parkinson's diseases) and metabolic disorders (diabetes, gallstones, liver cirrhosis), and gonad and liver function. Anyway, most reviews do not mention coffee as fulfilling the criteria for a functional food. Unlike other functional foods that act on a defined population with a special effect, the wide use of coffee-drinking impacts a broad demographic (from children to the elderly), with a wide spectrum of effects.

42.8 Applications to Other Areas of Health and Disease

The influences of coffee consumption on the functions of the peripheral and the central nervous system can also influence the mechanisms of the diseases affecting other systems, including the cardiovascular system, the renal system or the gastro-intestinal system. Thus, further investigations are needed to better clarify when and to what extent a greater or a reduced coffee intake can have preventive effects or can ameliorate the symptoms or the evolution of specific pathologies. The modifications due to coffee consumption on biological functions should obviously be extended also to the many other caffeine-containing foods and soft drinks.

Key Terms

Coffee: Brewed beverage prepared from roasted seeds of the coffee plant, commonly called coffee beans. Today, coffee is one of the most popular beverages worldwide.

Caffeine: Bitter, white crystalline xanthine alkaloid that is a psychoactive stimulant drug. Caffeine was discovered by a German chemist, Friedrich Ferdinand Runge, in 1819.

Sleep disturbance: Modification of normal pattern of sleep due to different possible causes, including the use of psychoactive substances, such as caffeine.

Memory systems: These include working memory, explicit long-term memory, and implicit long-term memory; they are stimulated by coffee consumption.

Neurodegenerative diseases: Progressive dysfunction and death of neuronal cells in selected areas in the nervous system, leading to alterations of some of the brain functions; the Alzheimer's and the Parkinson's diseases are two of the most important neurodegenerative diseases.

Autonomic nervous system: This comprises the sympathetic nervous system and the parasympathetic nervous system. It is part of the nervous system responsible for the control of involuntary muscles, e.g. heart and other viscera such as bladder, bowels, and so on, meaning that it regulates body functions that are not consciously directed.

Chapter 43
Selective Attention as a Mediator Between Food Motivation and Disposition to Act

Jaime A. Pineda and David S. Leland

Abbreviations

ERP	Event-related potential
fMRI	Functional magnetic resonance imaging
IFG	Inferior frontal gyrus
IPL	Inferior parietal lobule
LC	Locus coeruleus
MNS	Mirror neuron system
NA	Nucleus accumbens
OFC	Orbitofrontal cortex
PF	Parietal frontal
PFC	Prefrontal cortex
PMv	Premotor ventral
PPC	Posterior parietal cortex
PWS	Prader-Willi syndrome
RT	Reaction time
SMA	Supplementary motor area
STS	Superior temporal sulcus
VTA	Ventral tegmental area

43.1 Introduction

Food is a primary motivator of behavior. It is a fundamental physiological requirement for all animals and, in humans and other social species, central to a host of social interactions, such as hunting, foraging, shared meals, and trade, which can yield other tangible and social rewards. In order to successfully acquire food, one must make effective use of relevant cues, for example colors indicating ripe fruit. This is complicated, however, by the fact that the physical and social environments offer a near-limitless supply of information, only some of which is useful to the pursuit of food. This over-abundance of information, coupled with limitations on time and neural resources, provided evolutionary pressure for brain mechanisms enabling selective attention toward motivationally salient

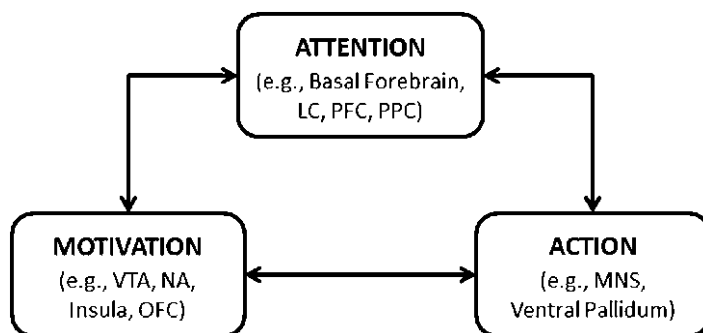

Fig. 43.1 Attention as mediator between motivation and action. Brain regions that attribute motivational salience to incentive stimuli can trigger action through relatively direct connections but also via their influence on attentional networks, allowing more flexibility and control over behavior. Movement and attention toward these appetitive stimuli also can have reciprocal effects, increasing motivational salience by facilitating the sensory and evaluative processes that identify and empower them as incentives. *LC* locus coeruleus, *MNS* mirror neuron system, *NA* nucleus accumbens, *OFC* orbitofrontal cortex, *PFC* prefrontal cortex, *PPC* posterior parietal cortex, *VTA* ventral tegmental area

information. That is, there is a bias toward enhanced processing of goal-related information at the expense of other information. Attentional biases toward food-related stimuli afford them preferential access to perceptual and cognitive resources, prioritizing learning and decision-making related to food and facilitating action to acquire and consume food. This chapter explores the psychological and neural underpinnings of selective attention toward food-related stimuli in the context of its mediation between motivation and action (Fig. 43.1), providing a framework for understanding the multidimensional factors that contribute to normal and disordered eating.

43.2 Motivation

43.2.1 Subcortical Mechanisms

Motivation is the goal-oriented force in behavior, contributing to its initiation, direction, intensity, and persistence in the face of obstacles. Motivation to seek and consume food arises in part from internal cues generated by homeostatic processes that monitor and regulate nutritional status and immediate energy needs. A significant amount of motivation-related neural circuitry lies below the cerebral cortex. The hypothalamus, in particular, is an important region for regulating neural and endocrine systems. Discrete nuclei of the hypothalamus play significant roles in the control of homeostatic signals relating to eating, drinking, and temperature regulation (Garcia-Segura et al. 2008). Electrical stimulation of these areas leads to an enhancement or inhibition of the corresponding behavior, while lesions produce the opposite results. The hypothalamus and related structures regulate homeostatic processes using chemical signals in the form of neurotransmitters, neuromodulators, and neurohormones.

External cues are another major influence on food motivation, and they, too, exert their influence through chemical signaling (see Table 43.1). The mesolimbic dopamine pathway is a key neurotransmitter circuit for motivation that responds to food and food-related cues. It originates in the ventral tegmental area (VTA) of the midbrain and projects to the nucleus accumbens (NA) of the striatum and other forebrain limbic targets. This neural system is important not only for food motivation but

Table 43.1 Major neurotransmitters and their roles in food-related behavior

Neurotransmitter	Roles in food-related behavior
Glutamate	Food-cue association learning
GABA	Disinhibition of circuits for food-directed attention and action
Acetylcholine	Attention to food stimuli; control of muscles for eating
Dopamine	Food-related reinforcement, cognition, and movement
Norepinephrine	Food-related arousal and attention
Serotonin	Appetite and food-related mood effects

Listed in this table are six of the central nervous system's major neurotransmitters. Each has a wide variety of functions, some of which pertain to appetite, food acquisition, and eating as indicated

for other conditioned and unconditioned reinforcers, including sex, addictive drugs, and money. As a natural (unconditioned) reinforcer, food generally increases the probability of behaviors that lead to its acquisition and consumption. Through associative learning, stimuli associated with food can become conditioned reinforcers in their own right.

Positive reinforcers are commonly referred to as "rewards," and because rewards of various kinds cause a release of dopamine in the NA, many researchers once concluded that dopamine serves as a common denominator for pleasure in the brain. This hedonic theory of mesolimbic dopamine has been challenged over the past several years and is being replaced by a set of theories focusing on cognition and disposition to act rather than subjective feelings, as a way to more specifically account for how dopamine activity contributes to goal-directed behavior (Schultz 2006; Salamone et al. 2007; Berridge 2009). The evidence for this new perspective comes in large part from studies of food motivation. For instance, when mesolimbic dopamine function is compromised by lesions or dopamine blockers, animals still prefer and will seek larger food rewards if they do not require substantially more effort to obtain than smaller ones (Salamone et al. 2007), and will still produce hedonic facial expressions when force-fed sweet solutions, even when they will not work to obtain them (Berridge 2009). Berridge has argued that there are distinct but functionally integrated circuits mediating food "liking" (hedonia) and "wanting" (incentive salience), with mesolimbic dopamine more closely (but not exclusively) tied to the latter. Furthermore, VTA dopamine neurons have been observed to shift their response from presentation of actual food rewards to presentation of the cues that predict them over the course of instrumental learning (Schultz 2006). Computational modeling and empirical findings suggest that VTA neurons signal a violation of reward expectancy and are important in learning to predict rewards on the basis of associated cues.

43.2.2 Cortical Mechanisms

Food-related cues, both environmental and social, along with affective states, also contribute to appetitive behavior. While subcortical circuits account for basic aspects of food motivation and are relatively well-conserved across species, mammals in general and primates especially have cortical mechanisms that allow for more complex motivations. Examples of this include flexible and relative preferences between food alternatives, inhibition of appetitive urges, and social facilitation of eating. These more recently evolved mechanisms have not replaced the subcortical ones, but are anatomically and functionally integrated with them, such that subcortical circuits serve as a foundation while cortical elements allow for an expanded repertoire of motivations, behaviors, and subjective experiences.

Wang et al. (2004) showed that at least two cortical regions in particular, the insula and orbitofrontal cortex (OFC), appear to play such a role and are critically involved in processing food-related stimuli and influencing the appetitive behavior of humans.

The insula represents certain sensory qualities of food such as taste and texture (exteroceptive cues; Rolls 2006). It is especially important, however, for the sensation of internal physiological states such as hunger (interoceptive cues) and appears to play a role in conscious awareness of these states (Craig 2003). The insula receives inputs from areas that include the amygdala, somatosensory cortex, and various thalamic nuclei. The OFC receives projections from the insula as well as the amygdala, eating-related subcortical nuclei (e.g., lateral hypothalamus), and multimodal sensory regions (Rolls 2006). Functional neuroimaging in humans shows that visual stimuli associated with the taste of glucose and pictures of foods, as compared to pictures of locations, activate the OFC and some interconnected areas (Simmons et al. 2005). OFC activity is not related directly to the primary stimulus properties of food; it instead shows highly flexible responses reflecting context-specific motivational and affective value. For instance, monkey OFC neurons that initially respond to multiple foods will reduce their response to those that have been consumed to satiation but not to others, suggesting a neural basis for food-specific satiety (Rolls 2006). The OFC also contains a number of neurons that respond to reward-predicting stimuli in a manner similar to that of dopamine neurons in the VTA (Schultz 2006).

The insula and OFC can be thought of as limbic-related cortices, given their functional roles and dense interconnections with limbic structures such as the amygdala, which influences behavior by linking sensory properties of a stimulus with its incentive value. All of these regions carry out their reward functions in conjunction with the dopamine system, including its sources (VTA and substantia nigra) and target structures (e.g., striatum, anterior cingulate cortex). Together, this circuitry allows for the evaluation of context-specific relative reward value and for the learning and prediction of reward contingencies.

The effect of motivation on disposition to act is mediated in part by subcortical efferent connections from the NA to the ventral pallidum and hypothalamus, which in turn can trigger overt eating behavior. Likewise, the OFC is important for preparation of more complex motor action via its connections to regions such as premotor cortex, which is involved in the simulation of action (Cavada et al. 2000). Motivated behaviors are, however, distinct from reflexive ones in that they do not involve fixed, obligatory motor patterns. Rather, goal-directed behavior is adaptive to changing internal and external conditions, and as such requires cognitive processes to provide flexibility of approach. Selective attention is one of the key components of the cognitive apparatus that provides such flexibility and that is recruited in the pursuit of food and other goals.

43.3 Selective Attention

43.3.1 Theories of Selective Attention

Selective attention (see Table 43.2) is one of the most studied topics in cognitive neuroscience. One traditional view of attention is as a unitary, supramodal mechanism subserved by anatomical circuits distinct from those involved in information processing (Posner and Petersen 1990). Posner and colleagues (Posner and Dehaene 1994; Posner and Rothbart 2007) have proposed a modern version of this idea by suggesting a triarchic model consisting of orienting, alerting, and executive attention subsystems. The orienting or posterior system appears to subserve spatial attention with or without

Table 43.2 Key features of selective attention

1. Selective attention is a process by which certain information receives increased cognitive processing at the expense of other information
2. Attention helps guide the sensory organs (orienting), increase the perceived intensity of stimuli (alerting), organize and control the flow of information (executive attention), and prepare the body for action (premotor attention)
3. The triarchic model of attention focuses on brain structures thought to produce attention-specific effects that are separate from other information processing
4. The premotor theory suggests that attention is the result of brain activity for sensory and motor processing that is under inhibition to prevent action until that inhibition is released
5. Attention can be directed to regions of space (spatial attention) even without movement of the sensory organs, making it possible to isolate and study attention effects (e.g., by having subjects keep their eyes fixated at one location while they pay attention for events at others)
6. Tools such as functional magnetic resonance imaging (fMRI) and event-related potentials (ERPs) can be used to detect the neural processes underlying attention
7. Behavioral studies, brain imaging, and neuroanatomy indicate that selective attention is controlled in part by motivational processes, consistent with its role in facilitating goal-directed behavior

This table lists key facts about selective attention, including some of its theories, purposes, and means of investigation

movement of the eyes toward attended stimuli, and is associated primarily with areas in the superior parietal cortex, temporal–parietal junction, frontal eye fields, and superior colliculi. The alerting system involves the noradrenergic-locus coeruleus (LC) system and the right frontal as well as parietal cortices. Finally, the executive or anterior attentional system appears to be involved in attentional recruitment and control of brain areas in order to perform complex cognitive tasks. This anterior system primarily involves the anterior cingulate, lateral ventral prefrontal cortex (PFC), and basal ganglia. Although consistent with a great deal of observations, the existence of such unique and anatomically circumscribed neural systems devoted specifically to attention has been criticized (Corbetta and Shulman 2002). One alternative that is potentially more consistent with the disposition to act as presented in this chapter is the premotor theory of attention. In this perspective, attention derives from activation of the same circuits that process sensory and motor information. For example, selective attention for spatial locations would result from the activity of circuits involved in the computations necessary for eye movement, arm reaching movements, walking, and other motor activities (Eimer et al. 2005), while selective attention for object recognition would derive from activity in cortical areas responsible for object property processing (Duncan and Nimmo-Smith 1996). According to this view of attention, the difference between selective spatial attention and overt actions directed toward a target in space is that in both cases a motor plan is prepared but only in the latter case is that plan executed.

Evidence in favor of the premotor theory of attention derives primarily from findings that some parietal and frontal cortical areas appear to incorporate and share systems for spatial representation, action control, and attention (Graziano and Gross 1998). Damage to these areas can produce inattention (neglect) to particular regions of space and deficits in movement directed toward those regions of space, as well as motor deficits for effectors (e.g., the hand) represented in the damaged areas. The cortical areas that program spatially specific movements are influenced by other cortical areas (e.g., presupplementary motor area or pre-SMA) and by subcortical centers (e.g., basal ganglia). These centers are thought to exert inhibitory control that, when released, allows movement to occur. Without such a release, the portion of the spatial map activated by the intended movement nonetheless gains a selective attention advantage over other locations for information-processing resources (Rizzolatti et al. 1987).

43.3.2 Attention to Motivational Targets

Selective attention toward motivationally salient stimuli may result as a natural consequence of the mesolimbic dopamine activity associated with them. "Wanted" stimuli are those that acquire incentive salience, becoming "attractive" and "attention-grabbing" (Berridge 2009, p. 538), which helps them compete with other stimuli for cognitive processing and the triggering of action. VTA neurons increase their baseline firing in response to the earliest unexpected reward or cue predictive of reward (Schultz 2006), suggesting that these cues may garner selective attention as the animal learns reward associations and prepares for action. One way this may occur is through disinhibition of basal forebrain cholinergic neurons, which potentiate sensory cortex activity and may underlie attention shifts and motor preparation in the PFC (Parikh et al. 2007) and posterior parietal cortex (PPC; Reep and Corwin 2009). These cholinergic neurons are under inhibitory control by GABAergic neurons in the NA, which in turn are inhibited by dopaminergic VTA neurons. Thus, disinhibition of basal forebrain cholinergic activity by mesolimbic dopamine may constitute a neural substrate for the preferential allocation of attentional resources toward motivationally salient stimuli such as food cues.

43.3.3 Attention to Food Stimuli

Selective attention toward food-related stimuli has been demonstrated behaviorally in humans, primarily using modified Stroop and spatial attention paradigms (see "Features of Selective Attention Tasks" at the end of this chapter). A Stroop bias toward food-related words has been demonstrated in subjects with normal eating patterns following food deprivation (Channon and Hayward 1990; Formea and Burns 1996; Francis et al. 1997; Braet and Crombez 2003) and in some cases even without (Lavy and Vandenhout 1993; Overduin et al. 1995). A spatial attentional bias toward the location of food stimuli has been shown as well in normal subjects who are especially hungry (Mogg et al. 1998) or have fasted (Placanica et al. 2002), and again in some cases whether or not subjects fasted (Leland and Pineda 2006). Most food attentional bias studies have focused on groups with eating disorders and dietary restraint. Dobson and Dozois (2004) conducted a meta-analysis of modified Stroop studies and concluded that bulimics but not anorexics or dieters exhibit a greater food word Stroop effect than controls (although both bulimics and anorexics did demonstrate a larger Stroop effect for words related to weight and body image). One spatial attention task has demonstrated bias toward food images that is greater in those with eating disorders (Shafran et al. 2007), while another found, in a nonclinical sample, greater bias among those who report that external cues (e.g., food stimuli) have a particularly large influence on their motivation to eat (Brignell et al. 2009).

Mohanty et al. (2008) used functional magnetic resonance imaging (fMRI) in their study of food-related attentional bias. In hungry but not satiated subjects, cues predicting the location of food image targets activated the amygdala, posterior cingulate, LC, and substantia nigra more than did cues predicting the location of nonfood (tool image) targets. PPC and OFC activations, meanwhile, were correlated with speed of attentional shifts. This study grouped food image trials and tool image trials into separate blocks, which can produce carry-over effects from trial to trial within each block. Thus, the food block effects could be due to general arousal as opposed to selective spatial attention, but the results are consistent with expected spatial attention effects, particularly in the PPC, given its association with visuospatial processing.

   The finding of increased activation in the LC is of particular interest as that area, the primary source of norepinephrine signals in the central nervous system, projects to limbic and cortical structures and appears to mediate attention effects indexed by the P3 component of the electrophysiological event-related potential (ERP; Foote et al. 1991). Various factors influence the amplitude and latency of the P3, including attentional focus. Kok (2001) has suggested that the P3 reflects allocation of attentional resources in the categorization of important events. In our study of food words as cues in a spatial attention task (Leland and Pineda 2006), we found a P3-type component with greater amplitude evoked by food words than neutral words (Fig. 43.2). This appeared to be an effect of selective attention and not general arousal since food- and neutral-word trials were randomly mixed within each block. Attention-related ERP effects also have been found in response to food odor stimuli in normal eaters although not restrained eaters, which may reflect a motivation to suppress attention to food-related stimuli (Kemmotsu and Murphy 2006). Furthermore, attention-related ERPs to images of food varying in degree of suitability for human consumption (e.g., sanitary versus contaminated) appear to differentiate controls from individuals with Prader-Willi syndrome (PWS; Key and Dykens 2008). The ERPs of PWS patients, who are characterized by intellectual deficits and hyperphagia (abnormally increased appetite for and consumption of food), may reflect the impact of maladaptive food cue salience on selective attention. Attending excessively to food quantity and/or not enough to food quality/safety may be an important contributor to this and other eating disorders.
Fig. 43.2 Spatial attention task using words as cues. Each trial of this task begins with visual fixation at a central cross and masks (*filler letters*) at top and bottom locations. The mask is replaced by a word at one of the two locations (50% chance each; word/mask color also counterbalanced). After a variable delay, the box outline surrounding either the word or the mask briefly flashes magenta (shown with a *dashed line* above), signaling the subject to respond by pressing a button. The target surrounds the cue 75% of the time (valid trials) and surrounds the mask 25% of the time (invalid trials), creating an attentional set whereby subjects tend to focus attention on the frequently predictive cue location. Responses to validly cued targets are faster than those to invalidly cued targets (the "validity effect"), reflecting the costs/benefits of attention. Effects of emotion and motivation on attention can be studied by comparing salient and neutral cue word conditions (e.g., food words versus school/art supply words) and testing for a difference in the validity effect (Adapted with permission from Leland and Pineda 2006, p. 70)

43.4 Action

43.4.1 A Feedback Loop for Eating

The mesolimbic dopamine pathway associated with motivation projects to areas such as the ventral pallidum and hypothalamus, which in turn can activate brainstem circuits for eating. One manner in which selective attention can mediate the guidance, initiation, and intensity of eating behavior is by successively narrowing the range of decisions and behaviors toward food-related stimuli (including food itself). The orienting effects of selective attention can lead to shifts of sensory organs toward attended stimuli, for instance movement of the eyes so as to place cues in the center of the visual field. Attended stimuli have greater sensory salience and detectability, which may in turn facilitate their identification and evaluation as incentives. Siep et al. (2009), for instance, found that focusing attention on food images during fMRI modulated food reward processing activity in the OFC and amygdala. Thus, motivation, attention, and action may work together in a positive feedback loop until physical proximity and motivational salience are sufficient to trigger food consumption. A feedback loop of this sort would be consistent with the reciprocal connectivity of the VTA, which receives excitatory inputs from nearly all of its direct and indirect cortical targets, and it is consistent with contemporary views of mesolimbic dopamine as playing a role in incentive salience (Berridge 2009), reward learning (Schultz 2006), and behavioral activation (Salamone et al. 2007).

43.4.2 Social Eating and the Mirror Neuron System

Higher level cognitive mechanisms may help explain the power of food cues in the social context, in particular the impact of seeing others eat. People tend to eat more at meals shared with others (de Castro and de Castro 1989), which may be due in part to mimicry of others' behavior. Mirror neurons in the frontal and parietal cortices show increased firing rates during not only execution of action but also during observation of the corresponding action performed by others and may be a substrate for this influence (Rizzolatti and Craighero 2004). The mirror neuron system (MNS; Fig. 43.3) has been widely defined as consisting of three interrelated regions: ventral premotor area (PMv) of the inferior frontal gyrus (IFG; area F5 in monkeys), parietal frontal (PF) in the rostral cortical convexity of the inferior parietal lobule (IPL) of the PPC, and the superior temporal sulcus (STS). Since the MNS is involved in both motor representation/execution and visuomotor representation, it is hypothesized to be important for observational learning, empathy, and mimicry. The MNS has often been thought of as reacting automatically in a bottom-up fashion to observed action, but neuroimaging and behavioral studies show that top–down influences, including selective attention, increase MNS activity and facilitate subjects' responses that are congruent with observed actions (Chong and Mattingley 2009). Furthermore, selective attention may be drawn to stimuli not only endogenously through top-down control but exogenously by the motivational salience of stimuli, as suggested in the previous section.

In fact, Gallese et al. (1996) noted that when macaques observed actions oriented toward food-related stimuli, mirror neurons in the premotor cortex were reliably activated whereas the response to similar actions toward non-food items had a tendency to habituate. Similarly, Fogassi et al. (2005) found mirror neurons in the inferior parietal cortex that would respond differently to grasping (executed or observed) for the purpose of eating as compared to the purpose of placing an object in a container. In fact, a majority of those parietal neurons studied were influenced by the ultimate goal
Fig. 43.3 Event-related potentials (ERPs) to food and neutral cue words. Words serving as spatial cues in a selective attention paradigm (see "Features of Selective Attention Tasks" at the end of this chapter) evoked brain electrical activity that differed based on semantic category. A positivity peaking approximately 420 ms after stimulus onset (shown with gray background) had greater amplitude in response to food words (e.g., "PIZZA") than a control set of school/art supply words (e.g., "PAINT"). This P3-like positivity may reflect enhanced attention as a consequence of motivational salience. Waveforms represent grand averages (*n* = 20). *F3* left frontal, *F4* right frontal, *C3* left central, *C4* right central, *P3* left parietal, *P4* right parietal (Adapted with permission from Leland and Pineda 2006, p. 77)

of the action even during the time period in which the grasping motions were identical. Studying humans with fMRI, Cheng et al. (2007), reported that hunger enhanced activation in response to food-related stimuli in the parahippocampal formation, OFC, and amygdala, consistent with their motivational salience, but also that hunger increased activation in areas of the MNS, including IFG and PPC. Indeed, IFG and amygdala activations were positively correlated with self-reported hunger. These studies demonstrate a special influence of food-related cues and intentions on MNS activity that could be mediated by selective attention mechanisms. As described previously, forebrain acetylcholine plays a role in selective attention and is disinhibited by mesolimbic dopamine. These cholinergic projections target various parts of the cortex, including specifically PPC, one of the MNS areas activated in the Cheng et al. study. Thus, consistent with more general findings that selective attention influences the MNS and motor-matching behavior, eating more with others could reflect in

part a chain of events in which food stimuli activate motivational systems that focus attention on visuomotor stimuli serving as a model for one's own potential eating behavior.

Human behavior in uncertain environments, particularly with respect to food, appears to be grounded in flexible actions. Evidence shows not only that action is biased toward food but that such actions may be prepared but not executed in a type of virtual simulation, in accordance with the premotor theory of attention. The ability to interrupt and cancel these types of preparatory responses to external events would confer flexibility and adaptability on individual behavior. The human MNS is one mechanism that allows for such preparation of actions toward food. More broadly, mechanisms both subcortical and cortical, evolutionarily old and new, enable the formation of dynamic goal states that can shape equally dynamic behaviors via the influence of selective attention.

43.5 Applications to Other Areas of Health and Disease

Much of the attentional bias work reviewed in this chapter has been conducted using participants with eating disorders. The framework presented suggests that it might be prudent to consider differences in motivation, attention, and action, as well as the connections between them psychologically and neurologically, in exploring the etiology of eating disorders (see Table 43.3). For example, it has been suggested that dopaminergic differences constitute a risk factor for obesity in the form of increased sensitivity to reward (e.g., Davis et al. 2007). Peciña et al. (2003) have shown increased motivation and effort to obtain food (wanting) but no increase in orofacial expressions suggesting increased hedonia (liking) in mice genetically engineered to have abnormally high dopamine levels. Motivation to eat is not synonymous with nor necessarily caused by increased pleasure from eating, in much the same way that drug craving is by no means equivalent to or consistently related to drug-induced pleasure. On that point, it is noteworthy that all of the research approaches covered in this chapter with respect to food also have been applied to the study of drug use and drug dependence, and the implications are essentially the same for how motivation, attention, and action appear to interact to produce drug-seeking and consumption behavior.

Table 43.3 Questions for theory, research, and treatment

1. How separable are pathways for food motivation versus other rewards? What impact might pharmacological treatment targeting food motivation in eating disorders have on other goal-directed behaviors? How about effects of treatment for drug dependence on food motivation?
2. What roles do controlled (conscious) and automatic (unconscious) processes play in the links between food motivation, attention, and action? Can raising individuals' awareness of these links help treat disorders involving compulsive eating?
3. How do neural pathways for food motivation interact with circuitry underlying cognitive processes other than attention (e.g., perception, memory, and decision-making) to ultimately influence normal and disordered eating behavior?
4. If the mirror neuron system plays a role in facilitating eating and other consumptive behaviors, can it also play a role in behavioral treatments aimed at inhibiting or otherwise changing such behavior through modeling and imitation?

The role of attention in food motivation and behavior is one small piece of a larger puzzle involving other cognitive mediators and other motivations. Addressing the questions in this table will be important for furthering our understanding of both normal and disordered behaviors, food-related and otherwise

43.6 Features of Selective Attention Tasks

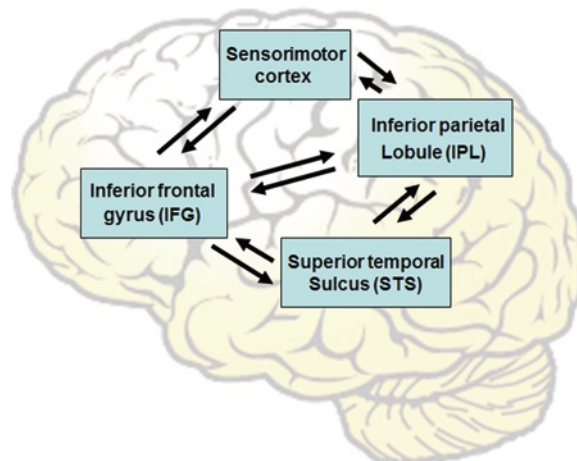
In a *modified Stroop task*, one assesses whether subjects take longer to name the color of words with emotional or motivational salience (e.g., food-related words) than nonsalient control words. Such a difference in reaction time (RT) is presumed to result in part from added difficulty in shifting attention from the semantic properties of salient words to the color in which those words are displayed, although other sources of response conflict can produce RT differences. Attentional biases also have been investigated using modified tests of visual spatial attention. For instance, in the classic "Posner paradigm" subjects respond to visual targets (e.g., dots) that are preceded by nontarget cues (e.g., boxes). Cues that correctly indicate the location of subsequent targets (e.g., a box surrounding the area where the dot will soon appear) are considered "valid" while cues associated with another location (usually the opposite hemifield) are considered "invalid." The "validity effect" refers to the RT benefit for target responses on validly as opposed to invalidly cued trials. By directing attention to the correct location, valid cues are thought to facilitate detection and response, while invalid cues impair detection and response by diverting attention from the correct location. Ordinarily, cues in this paradigm convey spatial information but have no other meaning. The task is easily modified, however, by using emotionally or motivationally salient stimuli, such as food-related words (Fig. 43.4), as cues. Since the subject's task is simply to respond to targets, the semantic content of the cues is irrelevant, yet those stimuli with special salience may nonetheless increase the focus of attention to their location, magnifying the validity effect by increasing the benefit of valid cueing and/or increasing the cost of invalid cueing. A similar spatial cueing task that is used more commonly to assess attentional bias is the *visual probe* (or dot probe) task. In this paradigm, two cues appear simultaneously (one in each hemifield), followed by a target at one or the other location. One of the two cues is an emotionally or motivationally salient stimulus while the other cue has no such salience. If RT is faster to targets appearing at salient cue locations than neutral cue locations, the effect is interpreted as reflecting increased attention as a result of the emotional or motivational content of the cue stimulus, just as it is in the Posner paradigm.


Fig. 43.4 The mirror neuron system (MNS). Schematic of areas in the human brain, such as inferior frontal gyrus (IFG) and inferior parietal lobule (IPL), that contain mirror neurons. Along with the superior temporal sulcus (STS), these make up the "core" of the mirror neuron system (MNS). Additional areas, such as sensorimotor cortex, comprise an "extended" mirror system

Summary Points

- Food is a primary motivator of behavior because it is both a physiological necessity and a central element of much social activity.
- Motivation is based not simply on a pleasure principle but on neural systems involved in predicting rewards and directing attention and behavior toward them even in the absence of pleasure.
- Selective attention is important for motivation because it prioritizes the processing of goal-relevant information and allows for adaptive responses to a changing environment rather than mere reflexive eating.
