Bulimia is a psychological eating disorder characterized by intermittent episodes of binge eating behavior followed by episodes of restricted eating. Bulimia was first diagnosed as an eating disorder on its own in the 1980s. Bulimia patients generally exhibit normal body weight (as indicated by their BMI) but their eating habits are far from normal. People with bulimia most often present with normal weight while some may be even overweight. It is often difficult to determine whether one has bulimia because bulimic patients tend to have their binging and food restriction episodes in secret. Bulimia is most common in adolescents and young, adult women.

Studies of eating behavior in patients with bulimia nervosa have demonstrated a diminished responsiveness in satiety-related pathways involving serotonin and other neurotransmitters (Wolfe et al. 1997). Excessive eating during the binge in these patients may potentially affect leptin synthesis and secretion. On the other hand, decreased leptin function may also contribute to reduced satiety responses and large meals in this group of patients. Alteration in leptin function may also contribute to abnormalities in other neuroendocrine systems. It is also worth mentioning that there is some discrepancy in published data with regard to leptin levels in patients with bulimia nervosa, ranging from very low anorexic-like leptin levels to normal plasma concentrations. One possibility is that within the bulimia nervosa group there exists a subset of patients who may hypersecrete leptin.

To test the hypothesis that decreased leptin function may contribute to abnormalities associated with eating patterns in bulimia nervosa patients, Jimerson et al. compared leptin levels in well-characterized outpatients with bulimia and matched control subjects (Jimerson et al. 2000). They reported that bulimic patients had significantly reduced serum leptin concentrations compared to age- and weight-matched controls. An additional finding from this study was that patients who recovered from bulimia still had significantly lower circulating leptin levels (Jimerson et al. 2000). The latter observation perhaps indicates that decreased leptin function in bulimia may be a stable biological trait.

84.7 Future Directions and Applications to Other Areas

Apart from its involvement in the regulation of body weight, leptin appears to be associated with cardiovascular disease. Using data from the West of Scotland Coronary Prevention Study (WOSCPS), researchers investigated whether plasma leptin levels are associated with the risk of a coronary event and if it was independent of BMI, age, lipids, blood pressure, and C-reactive protein, which is a marker of inflammation and a predictor of coronary heart disease (Wallace et al. 2001). Leptin levels were found to be significantly higher in individuals who experienced a cardiac event compared to age- and BMI-matched controls. Leptin also strongly correlated with C-reactive protein levels (Wallace et al. 2001). Based on this set of results, leptin would appear to be an independent risk factor for coronary heart disease.

It is clear that a link exists between obesity and hypertension which may involve leptin. This link is suggested by the observation that mice deficient in leptin have reduced blood pressure, whereas the mice overexpressing leptin have elevated blood pressure (Mark et al. 1999). Furthermore, leptin administered peripherally and, to a greater extent, centrally has been demonstrated to increase the sympathetic outflow to the kidneys, adipose tissue, skeletal muscles, and adrenals (Dunbar et al. 1997; Haynes et al. 1997).

Leptin has been also implicated in neurogenesis. In a study by Pinto published in Science (Pinto et al. 2004), leptin was demonstrated to affect both the architecture and function of neural circuits in the brains of mice: in response to leptin the cells were shown to create new connections. In addition, the researchers found that leptin alters the electrical activity of these connections. The capacity for change of these neural circuits by leptin suggests the possibility that the brain's wiring may differ between lean and obese individuals. Therefore, learning more about the hormone's mechanism of action could be critically important in understanding not only obesity but also other conditions.

Despite the recent advances in our knowledge of the physiology and pathophysiology of leptin, many important questions remain. Regardless of whether leptin has a place in the therapeutic treatment of the twenty-first century, studies on leptin are contributing greatly to our knowledge of the physiology of energy homeostasis and, on this basis, may lead to the development of novel therapeutic approaches to obesity.

Table 84.1 Key features of leptin resistance

1. Leptin is a 167-amino acid protein hormone secreted predominantly by adipocytes into the bloodstream and is present in circulation in direct proportion to the amount of adipose tissue
2. Leptin acts in the central nervous system, particularly in hypothalamus, where it signals satiety
3. Laboratory mice that have mutation in leptin gene become morbidly obese. Leptin administration to these mice normalizes their body weight as well as other metabolic parameters
4. Peripheral administration of leptin to overweight/obese humans has little effect on weight loss in these people. In fact human obesity is characterized by high circulating levels of leptin. As such, humans are thought to be resistant to leptin's weight-reducing effects
5. Several mechanisms may contribute to leptin resistance, including failure of leptin to enter the brain, defects in leptin receptor or leptin signaling pathways
6. Although animals models of obesity and diet-induced obesity are important in understanding how the system works, the differing results from leptin administration studies do suggest that detailed action of leptin in appetite and energy metabolism are different in humans and rodents for instance

This table lists the key facts of leptin resistance

Table 84.2 Key features of leptin discovery

1. *1994*: Leptin gene discovery (Zhang et al. 1994)
2. *1995*: Discovery of leptin receptor (Tartaglia et al. 1995)
3. *1996*: Biotechnology company (Amgen) announces that it began large clinical trials of leptin in humans. This trial fails to demonstrate weight-reducing effect of leptin in overweight individuals dashing hopes that the hormone could treat obesity
4. *1996*: Demonstration of reduced leptin transport into the brain of obese individuals, suggesting a possible mechanism for leptin resistance (Caro et al. 1996)
5. *1997*: First reported case of leptin gene mutation in humans
6. *1997*: First demonstration of an extra-adipocyte source of leptin (Hassink et al. 1997)
7. *1997*: Demonstration of leptin gene mutation in humans (Montague et al. 1997)
8. *1998*: First report suggesting brain as a source of leptin in humans (Esler et al. 1998)
9. *1998*: Demonstration of leptin receptor mutation in humans (Clement et al. 1998)
10. *2004*: Demonstration of leptin-mediated neuroplasticity (Pinto et al. 2004)

This table summarizes key discoveries of leptin

Key Terms

Body mass index: A measure of someone's weight in relation to height (kg/m^2). It is used as an indicator of body fatness for most people and to screen for weight categories that may lead to health problems.

Blood brain barrier: A protective mechanism that serves to separate blood from the central nervous system. The main function of this barrier is to protect the brain from sudden changes in the levels of ions, amino acids, and other substances and as such a key element in the normal functioning of the brain.

Cerebrospinal fluid: Produced by the brain and surrounds and circulates throughout the central nervous system.

Hyperleptinemia: High circulating leptin levels characteristic of obesity.

Leptin resistance: In common obesity leptin loses the ability to signal the brain to inhibit food intake and increase metabolism.

Chapter 85
The Role of Bile Acids in Gut-Hormone-Induced Weight Loss After Bariatric Surgery: Implications for Appetite Control and Diabetes

Rachel E. Roberts, Jamsaid Alaghband-Zadeh, and Carel W. Le Roux

Abbreviations

ARC	Arcuate nucleus
AUC	Area under the curve
BND	Gastric banding
BPD	Biliopancreatic diversion
D2	Type 2 iodothyronine deiodinase
FGF-19	Fibroblast growth factor-19
FXRα	Farnesoid X receptor α
GBP	Gastric bypass
GI	Gastrointestinal
GK	Goto Kakizaki rats
GLP-1	Glucagon-like peptide 1
HbA1C	Hemoglobin A1C
HOMA-IR	Homeostasis model assessment for insulin resistance
MAPK	Mitogen-activated protein kinase
mM	Millimolar
OGTT	Oral glucose tolerance test
PI3K	Phosphoinositide 3-kinase
PYY	Peptide YY
RYGBP	Roux-en-Y gastric bypass
T2DM	Type 2 diabetes mellitus
TGR5	G-protein-coupled receptor TGR5

85.1 Introduction

Obesity is a growing problem, which the World Health Organization predicts will affect 700 million people by 2015 (WHO 2006). The impact of obesity on national health services is unparalleled when considering its cardiovascular, metabolic, neoplastic, reproductive, musculoskeletal,

and psychosocial complications. Bariatric surgery has become an increasingly popular option in the management of obesity and obesity-related complications. Proposed mechanisms for the success of weight loss post bariatric surgery include gastric restriction, mild malabsorption, alterations in neural signals, duodenal exclusion, and early delivery of nutrients to the distal small intestine (Moo and Rubino 2008). These changes may alter secretion of metabolically active gastrointestinal (GI) hormones ghrelin, peptide YY (PYY), and glucagon-like peptide-1(GLP-1) (Korner et al. 2005; Chan et al. 2006). In addition to the success of bariatric surgery in inducing weight loss there is also substantial evidence supporting its efficacy in controlling type 2 diabetes mellitus (T2DM), even before substantial weight loss has occurred. Increased concentrations of GLP-1 may account for the improved glycemic control via its incretin action. The mechanisms of increased PYY and GLP-1 concentrations post bariatric surgery are not clear. Altered anatomy following bariatric surgery accelerates the delivery of nutrient-dense chyme to the distal intestine to stimulate increased secretion of gut hormones. It is possible that co-delivery of bile acids within the chyme enhances the stimulation of gut hormone release.

85.2 Roux-en-Y Gastric Bypass Surgery

Roux-en-Y gastric bypass (RYGBP) is the most frequently performed gastric bypass (GBP) surgery. It involves division of the stomach into a small proximal pouch (which holds about 15–30 mL) and a larger distal portion, which is bypassed (Fig. 85.1). The small pouch is anastomosed to the distal part of the jejunem, which is divided 30–75 cm from the ligament of Treitz. The remaining distal portion of the stomach, the duodenum, and proximal jejunem are reattached to the GI tract at a variable distance from the gastrojejunostomy, usually 75–150 cm, to allow for excretion of GI and pancreatic juices. This results in food bypassing 95% of the stomach, the entire duodenum, and a section of the jejunum (Saber et al. 2008). More than 70% of the small bowel remains in continuity and thus malabsorption of calories does not usually occur. RYGBP results in an initial weight loss of 20–40%, which is largely maintained over at least 15 years (Cummings et al. 2004).

85.3 Mechanisms of Weight Loss and Diabetes Reversal After Bariatric Surgery

The mechanisms of weight loss following GBP surgery are incompletely understood. Several hypotheses have been put forward. Reduced gastric capacity post-RYGBP certainly results in early symptoms of satiety and consequently patients eat smaller meals (Trostler et al. 1995). However, if this were the sole cause of weight loss a compensatory mechanism would come into effect to increase food intake and reduce energy expenditure in response to the weight loss, and patients would increase energy intake by eating more frequently and choosing energy-dense foods (Tadross and le Roux 2009). Instead, it has been found that after RYGBP surgery patients typically eat fewer meals and snacks per day (Halmi et al. 1981; Kenler et al. 1990). Furthermore purely restrictive surgeries, such as gastric banding (BND), require production of smaller gastric pouches than RYGBP before significant weight loss occurs, and BND is less successful in terms of weight loss and appetite control compared with GBP surgery (Biertho et al. 2003). Malabsorption of nutrients has also been proposed as a mechanism of weight loss after RYGBP (Brolin et al. 2002). Although initially this is true once
Fig. 85.1 Schematic representation of the Roux-en-Y gastric bypass (RYGBP). Roux-en-Y gastric bypass (RYGBP) involves division of the stomach into a small proximal pouch and a larger distal portion, which is bypassed. The small pouch is anastomosed to the distal part of the jejunem and the larger distal portion is reattached further down the gastrointestinal (GI) tract to allow for excretion of GI and pancreatic juices

the gut has adapted clinically significant malabsorption measured by serum markers of nutritional status such as albumin, prealbumin, and fecal fat, is not observed (Faraj et al. 2001; MacLean et al. 2001; Brolin 2002). The "dumping syndrome," which is a physiological response to consuming simple sugars, is also a possible mechanism of weight loss post-RYGBP. Following high-carbohydrate meals sugars are rapidly "dumped" into the small intestine, causing an osmotic load, which results in a fluid shift from the blood into the intestine. In some patients, this can cause symptoms of nausea, bloating, colic, diarrhea, lightheadedness, sweating, and palpitations (Hertz 1913). These unpleasant symptoms can promote avoidance of high-sugar foods, which may contribute to weight loss. However, the dumping syndrome is not universally experienced by patients following RYGBP and the severity of dumping correlates poorly with the efficacy of RYGBP (Cummings et al. 2004). It is therefore unlikely that dumping plays a major role in weight loss following RYGBP. Perhaps the most important factor in determining weight loss post-RYGBP is the profound loss of appetite which ensues (Brolin 2002). There is also a significant change in feeding behavior following GBP with patients reporting less frequent episodes of hunger, overeating, guilt about eating, or food preoccupation than morbidly obese control subjects (Rand et al. 1987). Gut hormones are important regulators of appetite and energy expenditure and several studies have shown that changes in gut hormone profiles following bariatric surgery favor an anorectic state, facilitate weight loss, and improve metabolic parameters (Korner et al. 2005).

In addition to the weight loss achieved following bariatric surgery it has also been widely observed that dramatic improvements in glycemic control in subjects with T2DM occur, specifically following RYGBP (Pories et al. 1995). It is estimated that bariatric surgery resolves T2DM in 76% of patients (Buchwald et al. 2004). Weight loss plays an important role in the reversal of T2DM following bariatric surgery but many patients with T2DM have significant improvement in glycemic control, discontinuing all antidiabetic medication and even achieving normal fasting plasma glucose

concentrations before significant weight loss has occurred (Clements et al. 2004). It has been proposed that these immediate improvements in diabetic control may be the result of altered gut hormone profiles following bariatric surgery.

85.4 Contribution of Gut Hormones to Weight Loss and Reversal of T2DM Post Bariatric Surgery

A number of peptides released from the GI tract have been shown to play an integral role in appetite control and food intake. Ghrelin is the only known gut hormone to stimulate appetite while PYY, glucagon-like peptide-1 (GLP-1), cholecystokinin, and oxyntomodulin suppress appetite. These hormones work at the level of the arcuate nucleus (ARC) in the hypothalamus to exert their orexigenic and anorexigenic effects (Schwartz and Morton 2002). The improvements in glycemic control, reduction in appetite, and weight loss following GBP surgery may be the result of changes in circulating gut hormone concentrations.

Several prospective studies of RYGBP have shown an exaggerated postprandial response of PYY compared to placebo (Vincent and le Roux 2008). Both peak and area under the curve (AUC) postprandial PYY concentrations have been found to be increased following RYGBP (Korner et al. 2009). The increased PYY response post-RYGBP is to concentrations previously shown to have appetite-reducing effects in humans (Batterham et al. 2003). The increase in postprandial PYY has been reported to occur as early as 2 days after bypass suggesting that the exaggerated response is secondary to the intervention per se and not to weight loss (Chaikomin et al. 2005). However, once substantial weight loss has occurred after RYGBP, the PYY response to the oral glucose tolerance test (OGTT) is significantly higher than in controls, demonstrating that changes in PYY concentrations following RYGBP persist after weight loss occured (Borg et al. 2006). Interestingly the postprandial response of PYY following RYGBP is strikingly greater than that after BND, perhaps accounting for the greater weight loss seen in RYGBP compared to BND (Korner et al. 2006). A study of matched RYGBP and BND subjects demonstrated that inhibition of gut hormone release by administration of octreotide (a somatostatin analogue) increased appetite and food intake in the RYGBP subjects by 87% but not in the BND patients, further implicating gut hormones in the regulation of food intake after RYGBP (le Roux et al. 2007).

In addition to raised postprandial plasma PYY concentrations, postprandial GLP-1 concentrations are also increased following RYGBP (Borg et al. 2006) although no differences have been found in fasting GLP-1 concentrations (Clements et al. 2004). Furthermore, in a cross-sectional analysis of patients post-RYGBP, AUC of PYY and GLP-1 was greater in "good" compared with "poor" responders (le Roux et al. 2007). GLP-1 concentrations are also raised after jejunoileal bypass (Naslund et al. 1997). Increased concentrations of GLP-1 are thought to contribute to increased insulin sensitivity and improvement in glycemic control as well as to increased satiety following RYGBP (Naslund et al. 1997).

RYGBP was initially shown to suppress serum concentrations of the orexigenic hormone ghrelin compared with stable weight individuals, despite significant weight loss (Cummings et al. 2002). However, subsequent studies have found inconsistent results regarding ghrelin concentrations post-GBP (Copeland et al. 2003; Faraj et al. 2003; Fruhbeck et al. 2004; Couce et al. 2003; Geloneze et al. 2003; Holdstock et al. 2003; Leonetti et al. 2003; Tritos et al. 2003; Vidal et al. 2003; Stoeckli et al. 2004; Vendrell et al. 2004) indicating it is unlikely that ghrelin has a major role in weight loss post-RYGBP.

85.5 Why Do PYY and GLP-1 Concentrations Rise Post-GBP Surgery?

The mechanism of increased PYY and GLP-1 concentrations post-GBP is not entirely understood. PYY and GLP-1 are predominantly secreted by L-cells of the distal gut following nutrient ingestion (Anini et al. 1999). L-cells are the most abundant endocrine cell type in the colon and ileum (Bryant et al. 1983). Altered anatomy post-GBP results in rapid transit of nutrients to the distal gut. This may increase nutrient-dependent stimulation of L-cells and thus greater secretion of GLP-1 and PYY. In addition to nutrients, Bile acids also stimulate PYY and GLP-1 release. In RYGBP surgery, the anastomosis of the bypassed stomach, duodenum, and proximal jejunem to the distal small intestine allows GI and pancreatic juices to be directly excreted into the distal small intestine, bypassing a significant proportion of the GI tract, resulting in increased exposure of L-cells to bile acids, which may represent a second mechanism by which concentrations of PYY and GLP-1 increase following RYGBP.

85.5.1 Hindgut Theory

The "hindgut hypothesis" was first described by Mason (Mason 1999) and proposes that the rapid transit and greater exposure of nutrients to the distal terminal ileum (a common feature of GBP and biliopancreatic diversion (BPD)) is responsible for the improvement in glycemic control after surgery and for the enduring effects on glucose metabolism (Patriti et al. 2004a,b; Patriti et al. 2004, 2005). It has been suggested that increased postprandial GLP-1 concentrations are responsible for the metabolic success of the hindgut hypothesis (Mason 1999; Cummings et al. 2004; Patriti et al. 2004). Ileal transposition (IT) is a surgical manipulation designed to allow assessment of the exclusive role of ileal activation as a mediator of surgically induced weight loss. The procedure involves resecting a 10–20 cm portion of the distal ileum, and then transposing it into the proximal jejunum. Following IT there is premature delivery of nutrient-rich chyme to the ileum, as in jejunoileal bypass, but the total length of the bowel is unaffected and malabsorption is absent. Strader et al. (2005) performed ITs in rats and found that they lost more weight and consumed less food than control rats with intestinal transections and reanastomosis without transposition. Rats with IT also had increased synthesis and release of GLP-1 and PYY. To avoid the effects of postoperative weight loss on insulin resistance and GLP-1 and insulin secretion, Patriti et al. (2005) used a model of nonobese diabetic Goto-Kakizaki (GK) rats, whose weight is not affected by IT. This study showed that glucose tolerance improved during an OGTT 30 days after IT without any effect on weight or food intake. A possible mechanism for the improvement in glycemic control could be the incretin effect of GLP-1 as GLP-1 concentrations were significantly higher in the IT diabetic group compared with the sham-operated rats. Patriti et al. later showed that GLP-1 secretion in GK IT rats was characterized by a more sustained response during OGTT and increased pro-glucagon mRNA expression in the ileum compared with sham-operated or nonoperated controls. However, they found no effect on glucose-stimulated GLP-1 concentrations by 6 months postsurgery (Patriti et al. 2007). Clinically performed IT in patients with T2DM and a mean BMI of 30.1 kg/m^2 showed promising results with mean weight loss of 22% (postsurgery BMI 24.9 kg/m^2) and adequate glycemic control in 86.9% with decreased HbA1C (by 28%), fasting glucose (by 44.6%), postprandial glucose (by 45.3%), and HOMA-IR (by 50%), heralding it as a promising procedure for the control of T2DM (DePaula et al. 2008). Unfortunately, GLP-1 concentrations were not measured in this study.

85.5.2 Bile Acid Theory

Bile consists of bile acids, cholesterol, phosphatidylcholine, and bilirubin. Bile is synthesized in the liver and secreted from hepatocytes into the bile canaliculi. Bile acid synthesis from cholesterol is the principal pathway for cholesterol catabolism. Bile acids constitute a large family of molecules composed of a steroid structure with four rings and a five or eight carbon side-chain terminating in a carboxylic acid. Each bile acid has a specific number and orientation of hydroxyl groups (-OH). The principal primary bile acids in humans are cholic acid and chenodeoxycholic acid. Before bile acids leave the liver they are conjugated to either glycine or taurine, forming bile salts, such as glycocholic acid and taurochenodeoxycholic acid. Bile salts have an enhanced amphipathic nature to enable greater emulsifying activity for more effective dietary lipid absorption in the GI tract. Once in the GI tract intestinal flora can remove glycine or taurine from the bile salts, regenerating primary bile acids. Intestinal flora can then convert some of the primary bile acids into secondary bile acids by removing a hydroxyl group, for example cholic acid becomes deoxycholic acid and chenodeoxycholic acid becomes lithocholic acid. Bile is stored in the gallbladder. When a meal is ingested bile flows via the common bile duct into the duodenum. Ninety-five percent of bile salts are reabsorbed in the terminal ileum. Blood from the ileum flows directly to the hepatic portal vein and returns to the liver where the hepatocytes reabsorb the bile salts and return them to the bile ducts to be re-used (Fig. 85.2). Each bile acid can complete 4–12 cycles between the liver and intestine each day (Cohen 2003). Owing to this efficient recycling of bile salts only a small proportion of the bile acid pool is derived from de novo bile acid synthesis (Champe et al. 2005).

In addition to their role in lipid metabolism and cholesterol homeostasis bile acids act as signaling molecules. Three main signaling pathways activated by bile acids have been described: bile acids activate mitogen-activated protein kinase (MAPK) pathways (Gupta et al. 2001; Qiao et al. 2003), are ligands for the G-protein coupled receptor TGR5 (Maruyama et al. 2002; Kawamata et al. 2003), and activate nuclear hormone receptors such as farnesoid X receptor α (FXRα) (Mangelsdorf et al. 1995; Makishima et al. 1999; Parks et al. 1999), a ligand-activated transcription factor (Mangelsdorf et al. 1995). By activation of these pathways bile acids can regulate their own enterohepatic circulation, as well as cholesterol, triglycerides, energy, and glucose homeostasis, giving bile acids an important systemic endocrine function (Houten et al. 2006).

Bile acids have been shown to prevent high-fat-diet-induced obesity and development of insulin resistance (Ikemoto et al. 1997). Administration of bile acids to mice increases energy expenditure in brown adipose tissues, thus preventing obesity and insulin resistance via induction of the cyclic-AMP-dependent thyroid hormone activating enzyme type 2 iodothyronine deiodinase (D2) (Watanabe et al. 2006). This study also showed that *in vitro* treatment of brown adipocytes and human skeletal myocytes with bile acid increases D2 activity and oxygen consumption. These effects are medicated by increased cAMP production resulting from the binding of bile acids with TGR5. In addition bile acid stimulation of FXRα may also mediate the effects of bile acids on energy homeostasis via fibroblast growth factor-19 (FGF-19) induction, which activates a signaling pathway culminating in improved metabolic rate and decreased adiposity (Tomlinson et al. 2002; Holt et al. 2003; Inagaki et al. 2005).

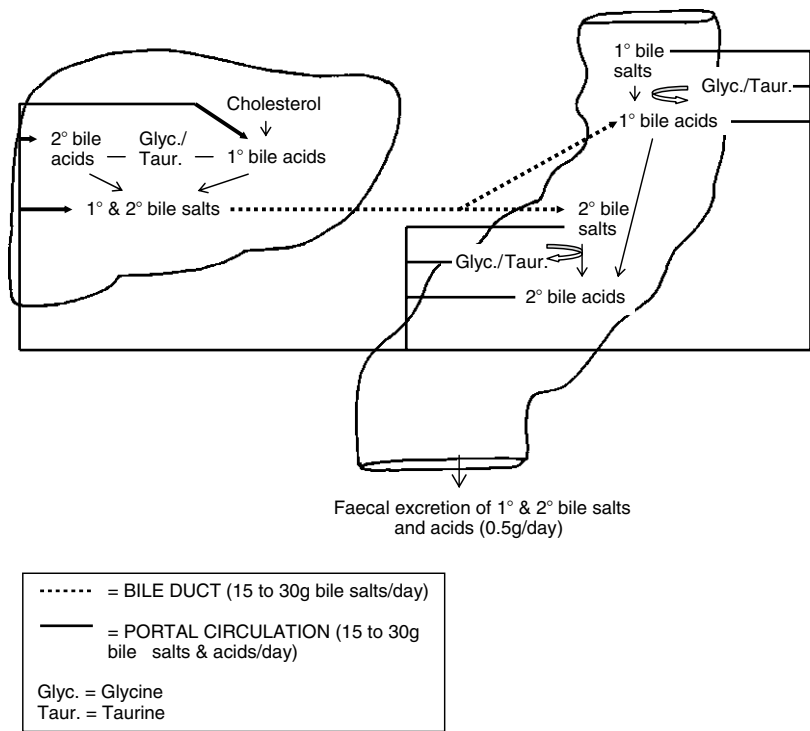
Bile acids play a significant role in glucose metabolism. In humans, circulating bile acid concentrations correlate with measures of insulin sensitivity (Shaham et al. 2008). Modulation of bile acid homeostasis using bile acid sequestrants has been shown to have an effect on glucose metabolism. An assessment of the efficacy and tolerability of cholestyramine in patients with T2DM and dyslipidemia unexpectedly revealed it to also improve glycemic control (Garg and Grundy 1994). More recent clinical trials have shown a similar effect of the bile acid sequestrant colesevelam in


Fig. 85.2 Enterohepatic circulation of bile salts and bile acids. Primary (1°) bile acids are synthesized from cholesterol in the liver. Bile acids enter a complex pathway in the liver and gastrointestinal (GI) tract in order for effective dietary lipid absorption to take place. Ninety-five percent of bile salts are recycled and re-used via this pathway

improving glycemic control (Fonseca et al. 2008; Goldberg et al. 2008). The mechanisms by which bile acids improve glycemic control are likely to be multifactorial. They are largely thought to be FXRα-independent and are instead mediated by binding to TGR5, leading to cAMP generation and activation of the intracellular type 2 thyroid hormone deiodinase (Yamagata et al. 2004). Bile acids also act via the phosphoinositide 3-kinase (PI3 kinase)/AKT pathway, directly promoting insulin signaling and glycogen synthase activation, thus aiding insulin-dependent control of glucose metabolism in the liver (Han et al. 2004). It is also thought that bile acids affect glucose metabolism indirectly via their influence on body weight. As outlined above, bile acids increase energy expenditure in brown adipose tissues and stimulate FGF-19-dependent metabolic control. In addition bile acid activation of TGR5 has been found to stimulate GLP-1 production *in vitro*, which promotes insulin secretion, thus improves glucose metabolism (Katsuma et al. 2005).

A role of bile acids in appetite suppression was proposed as early as 1968 (Bray and Gallagher 1968). Bile acids are known to be strong stimulators of PYY and GLP-1 release with direct infusion of deoxycholate into the colon increasing secretion of enteroglucagon (proglucagon-derived peptide products of the L-cell including GLP-1) and PYY in humans (Adrian et al. 1993). Bile acids also promote GLP-1 release *in vitro* (Katsuma et al. 2005). Several studies have demonstrated the importance of bile acids, in combination with fatty acids, in the stimulation of PYY release. Infusion of fatty acid oleic acid alone was not found to stimulate PYY or GLP-1 release (Soper et al. 1990; Adrian et al. 1993), whereas infusion of a high dose of oleic acid (24%) emulsified with 10 millimolar (mM) of bile acid deoxycholic acid did cause significant PYY and GLP-1 release (Adrian et al. 1993). In isolated perfused rabbit colon, graded doses of oleic acid (0.22–22 mM)

suspended in 10 mM of deoxycholic acid did not cause a concentration-dependent increase in PYY concentrations whereas graded doses of deoxycholic acid (1–25 mM) alone did cause a concentration-dependent release of PYY in the portal circulation (Ballantyne et al. 1989). In canines, intraileal infusion of oleic acid (56.6 mM) alone failed to stimulate a PYY response (Wen et al. 1995), whereas oleic acid combined with taurocholate did stimulate PYY release in dogs (Aponte et al. 1985). These observations indicate that bile acids deoxycholic acid and taurocholic acid combined with fatty acids are more significant than fatty acids alone in stimulating PYY release in the ileum. Bile acid infusions of taurocheodeoxycholate and deoxycholate at 1–25 mM in the isolated perfused rabbit ileum and colon have been shown to increase serum PYY concentrations to more than 400 pmol/L (Ballantyne et al. 1989; Armstrong et al. 1993). In addition, deoxycholate infusion at 1–30 mM in the human colon stimulates PYY release in a dose-dependent manner (Adrian et al. 1993). Importantly, the concentrations of bile acids used in these studies are consistent with the physiological concentrations bile acids found in the intestinal lumen postprandially (Dietschy 1968), supporting a physiological role of bile acids in the stimulation of PYY release. However, not all bile acids have been found to stimulate PYY release. Taurocholic acid and deoxycholic acid, as mentioned, are effective in stimulating PYY release, whereas hyodexycholate (Plaisancié et al. 1996) and ursodeoxycholate (Ballantyne et al. 1989) have shown no effect on PYY release. The reason for differences found in specific bile acid stimulation of PYY release is not clear. It is likely that increased GLP-1 and PYY release is a contributory mechanism of bile acid-dependent appetite suppression.

The multifactorial mechanisms promoting weight loss and improved glycemic control following RYGBP are incompletely understood. As discussed, bile acids can mediate energy homeostasis, glucose metabolism, and appetite by several mechanisms including activation of the G-protein-coupled receptor TGR5 and type 2 thyroid hormone deiodinase enzyme, stimulation of FGF-19, and promotion of PYY and GLP-1 release. It has been proposed that altered upper intestinal tract anatomy post-GBP surgery may affect the enterohepatic circulation of bile acids, resulting in increased serum bile acid concentrations which may contribute to the improved carbohydrate and lipid metabolism observed in patients post-GBP surgery. Total serum bile acid concentrations are demonstrated to be more than twice as high in individuals 2–4 years after GBP surgery than in overweight or severely obese individuals who have not had bariatric surgery (Patti et al. 2009). The increased bile acids included both primary and secondary bile acids, and reached statistical significance for glycochenodeoxycholic (more than a fourfold increase), glycodeoxycholic, glycocholic, and taurodeoxycholic acids. In this study, total bile acid concentrations post-GBP correlated significantly with several key parameters of lipid and glucose metabolism. Total bile acid concentrations positively correlated with plasma adiponectin, a marker of insulin sensitivity, and postprandial peak concentrations of GLP-1 and total bile acid concentrations inversely correlated with 2-hour postprandial glucose concentrations and fasting glucose (Patti et al. 2009). It may be inferred from these data that the resolution of T2DM seen after GBP may be the result of improved insulin sensitivity (as indicated by increased concentrations of adiponectin) and incretin-mediated insulin secretion (as indicated by increased concentrations of GLP-1) although none of the subjects had T2DM before GBP, this needs further investigation. Unfortunately, PYY concentrations were not measured in this study. However, as both PYY and GLP-1 are secreted from the same L-cells in the distal intestine and release of both PYY and GLP-1 is stimulated by bile acids, it is likely that the rise in postprandial concentrations of GLP-1 would be mirrored by rises in PYY. It is therefore likely that bile acid-dependent increases in postprandial GLP-1 and PYY concentrations are partly responsible for the success of GBP surgery in terms of both weight loss and glycemic control.

One cited limitation of this study was that it measured only peripheral serum concentrations of bile acids (Patti et al. 2009). Although serum bile acid concentrations are correlated with portal

venous concentrations (Angelin et al. 1982), they cannot provide direct information about the complex enterohepatic circulation of bile acids. Therefore, it is uncertain whether the increase in bile acid concentration is the result of increased synthesis and secretion by the liver, increased active and passive reabsorption from the small intestine, increased return to the liver via the portal vein, or by more efficient hepatic uptake.

85.6 Conclusion

It is possible that the mechanisms involved in increasing GLP-1 and PYY concentrations post-GBP (increased bile acid concentrations and the hindgut hypothesis) are not mutually exclusive. Together with the rapid transit and greater exposure of nutrients to the distal small intestine, GBP surgery also delivers a more rapid load of bile acids to the distal intestine. Both nutrients and bile acids are known stimulators of endocrine L-cells, which are concentrated in the terminal ileum (Fig. 85.3). Therefore, it may be the cumulative effect of greater bile acid and nutrient delivery to the distal small intestine that causes the rise in gut hormones PYY and GLP-1, and consequent weight loss and reversal of T2DM, which is so well documented after bariatric surgery (Fig. 85.4).

Fig. 85.3 Schematic diagram to show proposed mechanism of increased L-cell stimulation after Roux-en-Y gastric bypass (RYGBP). Following Roux-en-Y gastric bypass (RYGBP) there may be greater exposure of both nutrients and bile acids to the distal terminal ileum resulting in increased PYY and GLP-1 secretion from endocrine L-cells

Fig. 85.4 Summary figure showing the proposed model for mechanisms of type 2 diabetes mellitus (T2DM) remission after GBP. It is likely that there are multiple mechanisms in which gastric bypass (GBP) may improve T2DM. These mechanisms can either work via weight loss or independent of weight loss

85.7 Applications to Other Areas of Health and Disease

Understanding the mechanism of weight loss and improved glycemic control after bariatric surgery has important implications for the future treatment of obesity and type 2 diabetes mellitus (T2DM).

The National Institute for Clinical Excellence (NICE) currently recommends bariatric surgery in patients with a BMI > 40 kg/m² without comorbidities or between 35 and 40 kg/m² in patients with significant comorbidities. In view of its beneficial effects in improving glycemic control, it may be appropriate to offer bariatric surgery to patients with lower BMIs who have comorbid T2DM, especially in cases of significant insulin resistance or when simple weight-loss methods and pharmacological treatment have proved ineffective.

In future pharmacological approaches that mimic the physiological changes seen after bariatric surgery could prove beneficial in treating patients with obesity and T2DM. For example, therapeutic agents based on targeted bile acid delivery to the distal small intestine may reduce appetite, stimulate weight loss, and improve glycemic control in patients with obesity and T2DM. Pharmacological agonists of receptors activated by bile acid-dependent pathways, for example TGR5 and FXRα could be successful in improving glycemic control. Activation of TGR5 increases energy expenditure *in vivo* and in cultured cells (Watanabe et al. 2006) and increases GLP-1 in cell lines (Katsuma et al. 2005). Further work *in vivo* is required to determine whether such agents are efficacious in humans.

One limitation of many studies that demonstrate increased gut hormone concentrations after bariatric surgery is that they have been conducted on nondiabetic subjects. These results have then been used as a possible explanation for the mechanisms of improved glycemic control in diabetic patients after bariatric surgery. Therefore, further research needs to be done directly on diabetic subjects to validate this mechanism in the diabetic population and to investigate the role that duration and severity of diabetes may play in determining the success of treating T2DM with bariatric surgery.

Summary Points

- Gut hormones play an integral role in appetite control and food intake. PYY and GLP-1 act in the hypothalamus to suppress appetite. GLP-1 also has an important incretin effect, thereby improving glycemic control.
- PYY and GLP-1 are both secreted by endocrine L-cells predominantly found in the distal small intestine. Both nutrients and bile acids are known stimulators of PYY and GLP-1 secretion.
- Roux-en-Y gastric bypass (RYGBP) is the most frequently performed and most successful surgery to treat obesity. It results in food bypassing 95% of the stomach, the entire duodenum, and a section of the jejunum. The mechanisms of weight loss following RYGBP are incompletely understood.
- RYGBP can dramatically improve glycemic control in subjects with T2DM. These improvements occur before significant weight loss has occurred. It has been proposed that these immediate improvements in diabetic control may be the result of altered gut hormone profiles following bariatric surgery.
- Following RYGBP PYY and GLP-1 concentrations are increased. It is likely that altered intestinal anatomy following RYGBP enables quicker transit and greater exposure of both nutrients and bile acids to the distal terminal ileum resulting in increased L-cell stimulation and PYY and GLP-1 secretion.
- Understanding the mechanism of weight loss and improved glycemic control after bariatric surgery has important implications for the future treatment of obesity and T2DM. Pharmacological compounds that stimulate bile acid-dependent pathways are a possible therapeutic option in improving metabolic conditions such as T2DM.

Definitions and Explanations of Key Terms and Words

Anorexigenic: Decreasing or inhibiting appetite.

Bariatric surgery: Surgical intervention for the treatment of morbid obesity.

Bile acids: Steroid acids found predominantly in bile. The two major bile acids are cholic acid and chenodeoxycholic acid. The main function of bile acids is to facilitate the formation of micelles, which promotes processing of dietary fat.

Bile salts: Bile acids conjugated to glycine or taurine. In humans, taurocholic acid and glycocholic acid (derivatives of cholic acid) represent approximately 80% of all bile salts. Bile salts have an enhanced amphipathic nature to enable greater emulsifying activity for more effective dietary lipid absorption in the GI tract.

Ghrelin: A 28-amino acid peptide produced predominantly by X/A-like cells of the mucosal layer in the fundus of the stomach. Ghrelin is the only known orexigenic hormone, and plays a role in regulating premeal hunger and meal initiation as well as long-term energy balance. Ghrelin also stimulates growth hormone release, lactotroph and corticotroph secretion, gastric motility and has cardiovascular effects.

Glucagon-like peptide-1: A 30-amino acid peptide, which is cleaved from its precursor preproglucagon. GLP-1 inhibits gastric motility, reduces gastric emptying, and inhibits gastric acid secretion. GLP-1 also has an important incretin effect and suppresses glucagon secretion, enhances glucose disposal, and inhibits food intake.

Incretins: A group of GI hormones that enhance glucose-dependent insulin secretion from beta cells of the islets of Langerhans after eating, thereby improving glucose tolerance.

L-cells: The most abundant endocrine cell type in the distal small intestine. The apical surface of L-cells has microvilli, which are in contact with the intestinal lumen allowing them to sense nutrients.

The basal surface of L-cells is rich in endocrine granules allowing secretion of hormones into the circulation. L-cells secrete peptide YY (PYY), proglucagon-derived peptides such as glucagon-like peptide 1 (GLP-1), glucagon-like peptide 2 (GLP-2), glicentin, and oxyntomodulin (OXM).

Orexigenic: Increasing or stimulating appetite.

Peptide YY: A 36-amino acid GI hormone, where Y depicts the abbreviation for tyrosine. It is a member of the pancreatic polypeptide family and mediates its effects through G-protein linked NPY receptors. PYY has an important role in appetite control. It stimulates satiety and reduces food intake. It also inhibits transit through the proximal small intestine, delays gastric emptying, and inhibits gallbladder emptying.

Roux-en-Y gastric bypass: Division of the stomach into a small proximal pouch and a larger distal portion, which is bypassed. The small pouch is anastomosed to the distal jejunem. The remaining distal portion of the stomach, the duodenum, and proximal jejunem are reattached to the GI tract distal to the gastrojejunostomy to allow for excretion of GI and pancreatic juices. It is a type of bariatric surgery.

Type 2 diabetes mellitus: A disorder characterized by high blood glucose in the context of insulin resistance and relative insulin deficiency.

Key Facts About PYY

- PYY is a 36-amino acid GI hormone, where Y depicts the abbreviation for tyrosine. PYY exists in two forms – the full-length peptide PYY1-36, which is truncated to the biologically active PYY3-36 by dipeptidyl peptidase-IV. PYY3-36 is the predominant form.
- PYY is a member of the pancreatic polypeptide family, which includes pancreatic polypeptide (PP) and neuropeptide Y (NPY), which mediate their effects through G-protein-linked NPY receptors of which there are several subtypes (Y1R, Y2R, Y4R, and Y5R represent fully defined subtypes).
- PYY is secreted by L-cells of the distal gut, together with glucagon-like peptide and oxynto-modulin. Peripheral neurons, especially enteric neurons, also express PYY, as do a restricted set of central neurons.
- Secretion of PYY in the GI tract is primarily stimulated by the presence of nutrients (mainly lipids and protein) in the gut lumen, and is proportional to the caloric density of the meal ingested. Other stimulants of PYY release include intraluminal bile acids, gastric acid, and cholecystokinin. Peak plasma concentrations of PYY occur in the second hour following food ingestion.
- PYY reduces food intake, inhibits transit through the proximal small intestine, delays gastric emptying, and inhibits gallbladder emptying.
- PYY secretion stimulates vagal and somatosensory afferent fibers arising in the GI tract and terminating at the nucleus tractus solitarius (NTS) of the brainstem, which transmit information pertaining to recent food intake. Neurons from the NTS can then relay this information to the ARC of the hypothalamus, a key component of the forebrain pathway involved in appetite control. PYY can also act directly in the brain via the blood, entering at areas where the blood–brain barrier is deficient.
- In obese humans, plasma concentrations of PYY are reduced. Genetic variations in PYY and NPY receptor Y2R genes may contribute to obesity and are associated with the severe obesity of Pima Indian men.
- In contrast, PYY concentrations have been found to be increased in disease states characterized by significant weight loss, such as anorexia nervosa, celiac disease, inflammatory bowel disease, and cardiac cachexia.

Chapter 86
Orlistat and the Influence on Appetite Signals

Mark Ellrichmann

Abbreviations

AgRP	Agouti-related peptide
Alpha-MSH	Alpha-melanocyte-stimulating hormone
Apo A-IV	Apolipoprotein A-IV
BMI	Body mass index
BNRP	Bombesin/bombesin-related peptide
CART	Cocaine- and amphetamine-regulated transcript
CCK	Cholecystokinin
CCK1R	CCK-1 receptor
CNS	Central nervous system
CRF	Corticotropin-releasing factor
DPP-4	Dipeptidyl-peptidase-4
FFA	Free fatty acid
GHRH	Growth hormone-releasing hormone
GHS	Growth hormone secretagogue
GI	Gastrointestinal
GIP	Gastric inhibitory polypeptide
GIPR	Gastric inhibitory polypeptide receptor
GLP-1	Glucagons-like peptide 1
GLP-2	Glucagon-like peptide 2
kJ	Kilo joule
MCH	Melanin-concentrating hormone
MG	Monoglyceride
NPY	Neuropeptide Y
OLETF	Otsuka-Long-Evans-Tokushima-Fatty rat
OXM	Oxyntomodulin
PP	Pancreatic polypeptide
POMC	Pro-opiomelanocortin
PYY	Peptide YY

THL	Tetrahydrolipstatin
TG	Triglyceride
VAS	Visual analogue scales

86.1 Introduction

Over the past decades, the prevalence of overweight and obesity worldwide has reached epidemic proportions. This has been correlated with various comorbidities, the most relevant ones being diabetes mellitus, arterial hypertension, and cardiovascular diseases. The management of obesity has become a modern challenge since nonpharmacological methods have demonstrated only short-term efficacy. Current obesity guidelines recommend that drug therapy should be considered in conjunction with nonpharmacological strategies for patients with a body mass index (BMI) greater than 30 kg/m^2 or a BMI of 25–30 kg/m^2 with one or more obesity-related disorders (Pi-Sunyer 1998). Antiobesity drugs can be classified into two categories: (1) drugs that suppress appetite, increase satiety or thermogenesis, primarily by modifying central nervous system (CNS) neurotransmitters; and (2) inhibitors of intestinal fat absorption.

86.2 Orlistat

Orlistat, also known as tetrahydrolipstatin (THL), is a covalent inhibitor of digestive lipases derived from lipstatin, a natural product from *Streptomyces toxytricini*. It is an active site-directed inhibitor that reacts with the nucleophilic serine residue from the catalytic center of intestinal lipases. By covalently blocking the active site of lipases, orlistat inhibits the hydrolysis of dietary triglycerides (TG) and thus reduces the intestinal absorption of the lipolysis products monoglycerides (MG) and free fatty acids (FFAs) (Lucas et al. 2001) (Fig. 86.1). The formulation of the drug was licensed by the European Union in 1998 and in the United States in 1999 for the treatment of morbid obesity. At the standard prescription dose of 120 mg three times daily before a meal, orlistat prevents approximately 30% of dietary fat from being absorbed (Zhi et al. 1999). Historically, orlistat has been available by prescription only, whereas nowadays certain formulations of orlistat at a dose of 60 mg have been approved in Australia, the European Union, and the Unites States (Table 86.1). The primary side effects of the drug are gastrointestinal (GI)-related, and include steatorrhea, fecal incontinence, frequent or urgent bowel movements, and flatulence. Side effects are most severe when beginning therapy and may decrease in frequency with time. This is supported by the XENDOS study, which showed that only 36% of people had GI adverse effects during their fourth year of taking orlistat, whereas 91% of the study population had experienced at least one GI-related side effect within the first month of treatment (Torgerson et al. 2004).

A recent meta-analysis by Padwal et al. included 11 orlistat studies with a follow-up period of at least 1 year. These trials comprised a total of 6,021 participants with an average BMI of 35.7 kg/m^2. The dose of orlistat used in all studies was 120 mg t.i.d. according to the recommended standard dose in clinical practice. In all reported studies a greater weight loss was reported in the orlistat group compared to placebo. Pooled results revealed a weight loss of 2.7 kg (95% CI: 2.3–3.1 kg; 11 studies) or 2.9% (95% CI: 2.3–3.4%; ten studies) with orlistat treatment (Padwal et al. 2003).
Fig. 86.1 Orlistat – mode of action. Oral administration of orlistat inhibits intestinal lipase and thus prevents dietary triglycerides (TG) from being hydrolyzed in absorbable free fatty acids (FFA) and monoglycerides (MG). About 30% of dietary TG are excreted undigested

Table 86.1   Key facts of orlistat

Orlistat
• Tetrahydrolipstatin
• Antiobesity drug
• Covalently blocks intestinal lipases
• Reduces hydrolysis of TG in MG and FFA by 30%
• 120 mg t.i.d. prescription dose
• 60 mg t.i.d. over-the-counter dose
• Negligible bioavailability
• Approved in the EU in 1998, in the US 1999

TG triglycerides, *MG* monoglycerides, *FFA* free fatty acids

86.3 Orlistat and Satiety

The regulation of body weight is precisely controlled by a variety of gut hormones and peripheral as well as central signals that influence hypothalamic, limbic, and brainstem circuits controlling appetite and energy expenditure. These include cholecystokinin (CCK), glucagon-like peptide (GLP)-1, insulin, and ghrelin among others (Wren et al. 2007). These and various other hormones contributing to the regulation of hunger and satiety are presented in Table 86.2.

While CCK, YY, and GLP-1 have been shown to enhance satiety and reduce the amount of caloric intake, ghrelin has been identified as an endogenous orexigenic factor (Wren et al. 2007). The hypothalamus also receives mechanical signals indicating distension of the stomach, and signals transmitting smell, sight, and social context of food. In addition, velocity of gastric emptying, pyloric pressure, and antro-pyloro-duodenal motility have been shown to modify appetite and satiety (Chaudhri et al. 2006). The secretion of the GI hormones from enteroendocrine cells is primarily controlled by the absorption of nutrients from the gut and can be modulated by variations in the velocity of gastric emptying (Meier et al. 2005). Therefore, inhibition of intestinal lipase would be expected to have extensive effects on GI hormone levels and gastric emptying. However, there has

Table 86.2 Overview of hormones and peptides regulating energy intake

Hormones/peptides involved in hunger	Hormones/peptides involved in satiety
Ghrelin	CCK
Orexin A and B	PP
NPY	PYY
AgRP	GLP-1
MCH	Leptin
Galanin	OXM
Noradrenalin	Amylin
ß-Endorphin	Enterostatin
Dynorphin	Somatostatin
GHRH	BNRP
	Apo A-IV
	Thyrotropin-releasing hormone
	Calcitonin-gene-related peptide
	Serotonin
	Alpha-MSH
	CART
	POMC
	CRF
	Urocortins

Hormones levels that are attenuated by orlistat administration according to the current data are underlined

NPY Neuropeptide Y, *AgRP* Agouti-related peptide, *MCH* Melanin-concentrating hormone, *GHRH* Growth hormone-releasing hormone, *CCK* Cholecystokinin, *PP* Pancreatic poly-peptide, *PYY* Peptide YY, *OXM* Oxyntomodulin, *GLP-1* Glucagon-like peptide 1, *BNRP* Bombesin/bombesin-related peptide, *Apo A-IV* Apolipoprotein A-IV, *Alpha-MSH* Alpha-melanocyte-stimulating hormone, *CART* Cocaine- and amphetamine-regulated transcript, *POMC* Pro-opiomelanocortin, *CRF* Corticotropin-releasing factor

been some controversy regarding the influence of orlistat treatment on the postprandial levels of CCK, PYY, and GLP-1, with some studies reporting significant reductions in the respective hormone levels and others showing normal or even increased concentrations. In a similar way, the effects of intestinal lipase inhibition on appetite control, food intake, and GI motility have been widely debated within the literature. The reasons underlying these discrepancies are yet unclear.

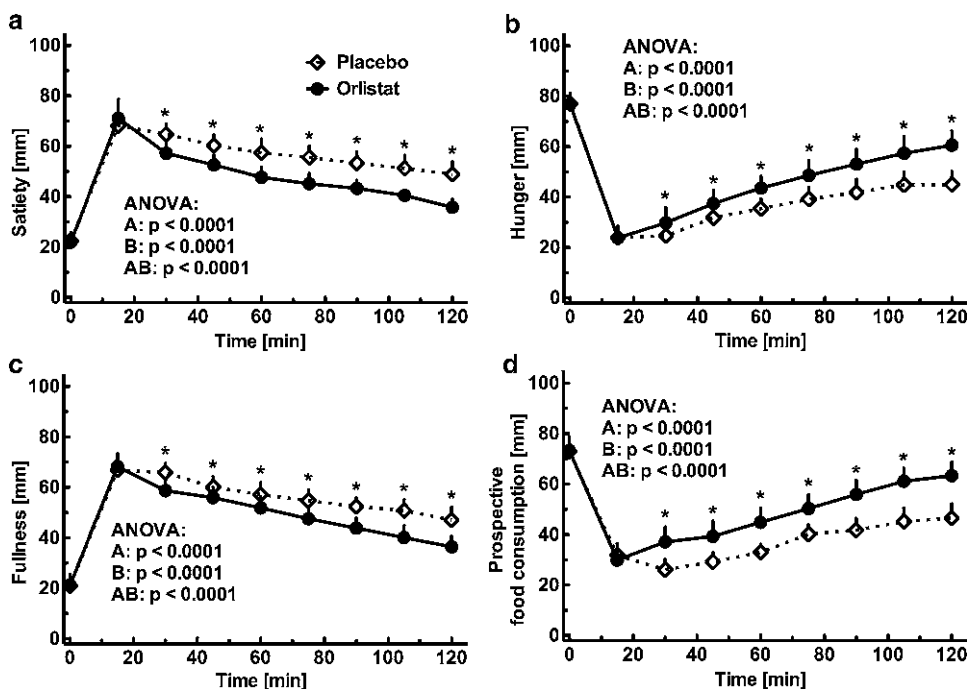
In our own tudy, 25 healthy volunteers were examined with a solid–liquid test meal following oral administration of 120 mg orlistat or placebo in a randomized fashion. Visual analogue scales (VAS) were used to assess feelings of hunger, satiety, fullness, and prospective food consumption over a period of 2 h after meal ingestion. As shown, the feelings of satiety and fullness rose significantly after ingestion of the test meal and declined during the subsequent study period ($p < 0.0001$). Both satiety and fullness were significantly reduced by orlistat administration from 15 to 120 min after the test meal (Fig. 86.2). The mean reduction of satiety by orlistat treatment was 15% ($p < 0.0001$), whereas fullness was lowered by 12% ($p < 0.0001$). Conversely, appetite and prospective food consumption were lowered immediately after meal ingestion and increased subsequently throughout the observation period ($p < 0.0001$). Orlistat significantly increased the mean ratings for appetite and prospective food consumption by 24% or 31%, respectively ($p < 0.0001$) (Ellrichmann et al. 2008). Previous studies have also examined the effects of orlistat on appetite sensations and the corresponding secretion of GI hormones, but conflicting results have been reported. Feinle et al. could show that lipase inhibition prevented the reduction in scores for prospective food consumption and hunger induced by duodenal fat infusion and increased energy intake at a free buffet meal (Feinle et al. 2003). These findings are


Fig. 86.2 Mean ratings for satiety (**a**), hunger (**b**), fullness (**c**) and prospective food consumption (**d**), as determined by visual analogue scales (VAS), after ingestion of a solid–liquid test meal following oral administration of 120 mg orlistat or placebo in 25 healthy volunteers. Data are presented as means ±SEM. *p*-Values were calculated using paired repeated measures ANOVA and denote A: difference between the experiments, B: differences over time and AB: differences due to the interaction of experiment and time. Asterisks indicate significant difference ($p < 0.05$) versus placebo at individual time points (one-way ANOVA)

consistent with other observations that the decrease in hunger and increase in fullness induced by gastric distension are diminished by lipase inhibition (Feinle et al. 2001). Moreover, these data are in line with other studies indicating that the suppression of food intake by duodenal infusion of olive oil is attenuated when fat digestion is inhibited, underlining the importance of the products of fat digestion in the regulation of appetite perception and food intake (Matzinger et al. 2000) (Table 86.3).

In contrast, Goedecke and colleagues found no effect of orlistat treatment on appetite ratings in healthy male subjects. Orlistat did not alter the ratings of hunger, satiety, and prospective food consumption, when examining changes over time in response to a high-fat meal. In addition, there were no differences in post-test meal intake between orlistat and placebo trials. The reasons underlying the discrepant results of some of these studies are difficult to explain, but certainly methodological issues need to be considered. In particular, different meal compositions and the respective routes of nutrient administration (direct intraduodenal infusions versus oral meal ingestion) might have had an impact on the conflicting results (Goedecke et al. 2003). Nevertheless, the majority of studies support the notion that appetite is acutely increased by orlistat treatment, most likely as a consequence of impaired secretion of anorexigenic GI hormones. The significant increase in appetite and prospective food consumption observed in our as well as previous studies (O'Donovan et al. 2003) may counteract the primary therapeutic indication of orlistat, i.e., the treatment of morbid obesity. Against this, intestinal lipase inhibition has proven to efficiently lower body weight in obese patients over chronic treatment durations (Kelley et al. 2002). Furthermore, in a recent prospective trial over 3 years eating behavior was not affected in a negative way by orlistat

Table 86.3 Effects of orlistat administration on gastrointestinal (GI) hormone regulation

Hormone	Study author (year)	Test meal	Change in hormone release	Comment
CCK	Ellrichmann et al. (2008)	Oral administration	↓	25 healthy volunteers, inverse correlation with hunger scores
	Feinle et al. (2001)	Intraduodenal infusion	↓	Intraduodenal infusion of lipids
	Borovicka et al. (2000)	Intraduodenal infusion	↓	Acceleration of gastric emptying, increase in postprandial gastric acidity
	Hildebrand et al. (1998)	Intraduodenal infusion	↓	Intraduodenal infusion of fat, significant CCK suppression by orlistat
GLP-1	Ellrichmann et al. (2008)	Oral administration	↓	Orally ingested test meal, significant suppression postprandial GLP-1 levels by orlistat
	O'Donovan et al. (2004)	Oral administration	↑	Only 8 patients with type 2 diabetes
	Damci et al. (2004)	Oral administration	↑	Increased GLP-1 plasma levels, decreased food intake
	Feinle et al. (2003)	Intraduodenal infusion	↓	Significantly attenuated GLP-1 levels by orlistat
	Pilichiewicz et al. (2003)	Oral administration	↓	Reduced GLP-1 levels after orlistat administration in type 2 diabetes
PYY	Ellrichmann et al. (2008)	Oral administration	↓	Signification attenuation of PYY by orlistat
	Degen et al. (2007)	Intraduodenal infusion	↓	CCK1R blockade reduced postprandial PYY concentrations
	Feinle et al. (2005)	Intraduodenal infusion	↓	Fat digestion required for PYY secretion
	Feltrin et al. (2006)	Oral administration	↓	CCK-8 infusions stimulate PYY concentrations
PP	Feinle et al. (2005)	Intraduodenal infusion	↓	Fat digestion required for PP secretion
GIP	Enc et al. (2009)	Oral administration	↓	Attenuation of GIP, no significant changes of GLP-1, PYY by orlistat
	Pilichiewicz et al. (2003)	Oral administration	↓	Only 7 patients with type 2 diabetes, attenuation of GIP
Leptin	Sahin et al. (2008)	Oral administration	unchanged	No effect of single dose of orlistat on serum leptin levels, 34 patients
	Dimitrov et al. (2005)	Oral administration	↓	Long-term therapy with orlistat reduces leptin leves, mediated by weight loss
Ghrelin	Ellrichmann et al. (2008)	Oral administration	unchanged	Ghrelin unchanged, due to accelerated gastric emptying
	Degen et al. (2007)	Intraduodenal infusion	↑	Effect mediated indirectly via CCK1R
	Feinle et al. (2005)	Intraduodenal infusion	↑	Elevated ghrelin levels by orlistat, intraduodenal lipid infusion
	Mohlig et al. (2002)	Intraduodenal infusion	↑	Elevated ghrelin levels by orlistat, intraduodenal lipid infusion

Overview of current studies evaluating the effect of orlistat on postprandial hormone levels, i.e., cholecystokinin (CCK), glucagon-like peptide (GLP)1, peptide YY (PYY), pancreatic polypeptide (PP), gastric inhibitory polypeptide (GIP), leptin, and ghrelin

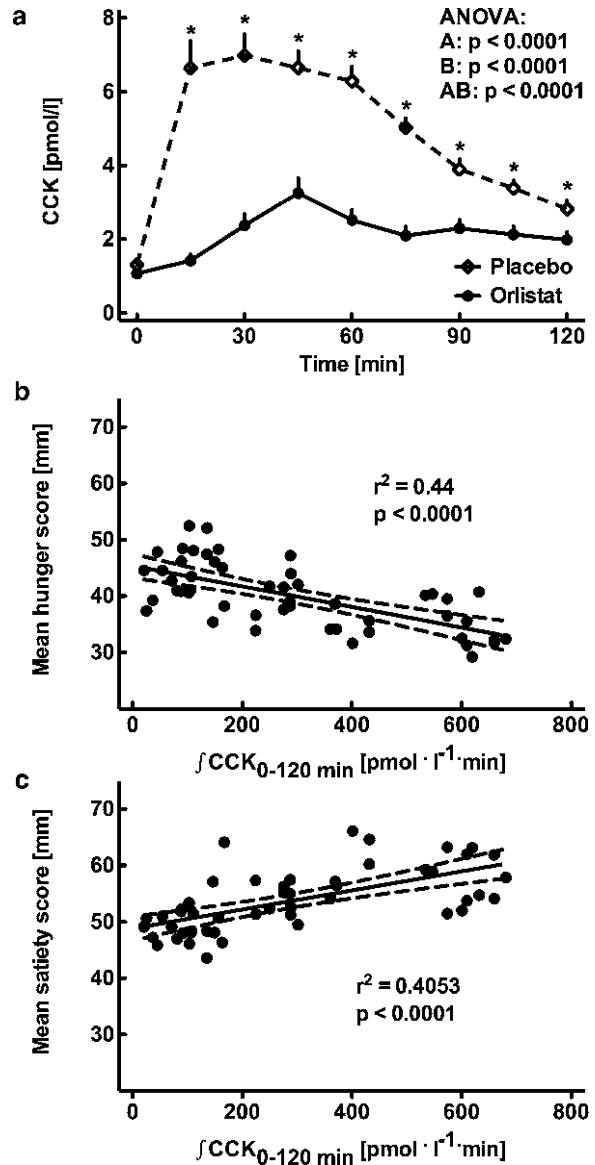
treatment, although hunger ratings were still significantly increased at the end of the observation period. Over 300 obese subjects with a mean BMI of 37.5 ± 4.1 kg/m^2 were randomized to either 120 mg t.i.d or placebo. The scores for hunger were significantly increased in the orlistat group compared to placebo in male subjects after 33 months of treatment. Similar tendencies were observed in women, but did not achieve statistical significance (Svendsen et al. 2008). The acute and long-term effects of orlistat on satiety are mediated by several satiety signals, i.e., GI orexigenic and anorexigenic hormones.

86.4 Orlistat and CCK

Gibbs et al. first demonstrated a dose-dependent effect of exogenous CCK on reducing food intake in rats. This effect was specific to food intake, with CCK having no effect on water intake in water-deprived rats (Gibbs et al. 1973). This finding was subsequently confirmed in humans, in whom an intravenous infusion of the terminal octapeptide of CCK reduced meal size and duration. It has been proposed that the inhibitory effect of CCK on gastric motility might contribute to its inhibitory actions on feeding. CCK may promote excitation of gastric mechanoreceptors, and thus evoke a neural feedback from the gut to appetite centers of the brain (Moran et al. 1988). Similarly, gastric distension in humans was found to augment the reduction of nutrient intake effected by intravenous CCK-8 (Kissileff et al. 2003). CCK also alters food intake through pathways that are independent of its effect on the stomach. While the induction of satiety at higher doses of CCK may be attenuated by surgical removal of the pyloric sphincter, lower doses continue to be effective in inhibiting food intake. Lesioning of the vagus nerve abolishes the effects of CCK (Moran and Kinzig 2004). The induction of satiety by CCK at physiological concentrations may therefore rely on direct activation of vagal afferent fibers. In addition, CCK-1 receptors (CCK1Rs) were found on afferent fibers of the vagus nerve, and also in the brainstem and dorsomedial nucleus of the hypothalamus. The use of specific CCK-1 and CCK-2 receptor antagonists has implicated the CCK1R in the reduction of food intake (Moran et al. 1992). The Otsuka-Long-Evans-Tokushima Fatty (OLETF) rat, which lacks CCK1R, is both hyperphagic and obese, supporting the role of CCK in regulating energy balance (Schwartz et al. 1999).

CCK is released by intestinal I-cells in response to adequate hydrolysis of dietary TG. Hildebrand et al. showed in human studies that endogenous CCK release depends on adequate digestion of dietary fat by pancreatic lipase in the intestinal lumen (Hildebrand et al. 1998). As noted, administration of orlistat covalently inhibits the hydrolysis of dietary TG into MG and FFAs. We have recently established that orlistat significantly impairs CCK release, thereby accelerating gastric emptying and altering ratings of satiety and hunger. In our experiments healthy volunteers were investigated on two occasions, either with orlistat or placebo. Meal ingestion elicited an immediate and pronounced rise in CCK concentrations in the placebo experiments, whereas the increase in CCK levels was largely delayed and significantly blunted after orlistat treatment ($p < 0.0001$). Correlation analysis revealed a positive correlation between integrated CCK serum levels and hunger ratings, and an inverse correlation to satiety levels (Fig. 86.3). We also demonstrated a strong correlation between CCK serum levels and gastric emptying (Ellrichmann et al. 2008).

Borovicka et al. (2000) showed that intragastric administration of orlistat with a stable emulsion of TG, which reduced lipolysis by 75%, inhibited plasma CCK release. When administered intraduodenally, orlistat attenuated the CCK response to a triglyceride emulsion (Hildebrand et al. 1998). These studies are consistent with our findings that intragastric and intraduodenal administration of orlistat attenuates CCK release, via its inhibitory effects on lipolysis.

Fig. 86.3 (**a**) Plasma concentrations of cholecystokinin (CCK) after ingestion of a solid–liquid test meal following oral administration of 120 mg orlistat or placebo in 25 healthy volunteers. Data are presented as means ± SEM. *p*-Values were calculated using paired repeated measures ANOVA and denote A: difference between the experiments, B: differences over time and AB: differences due to the interaction of experiment and time. Asterisks indicate significant difference (*p* < 0.05) versus placebo at individual time points (one-way ANOVA). (**b**, **c**) Linear regression analysis between the integrated incremental plasma concentration of CCK and mean ratings for hunger (**b**) and satiety (**c**) as determined using visual analogue scales (VAS) (*n* = 50). Dashed lines indicate the respective upper and lower 95% confidence interval. r^2 = correlation coefficient squared, *p* < 0.05 statistically significant


86.5 Orlistat and GLP-1

Glucagon-like peptide (GLP)-1 is cleaved from preproglucagon within the intestine, where it is co-localized in the endocrine L-cells of the distal gut with OXM, PYY, and GLP-2. GLP-1 mediates glucose-dependent insulinotropic effects in a number of species, inhibits gastric acid secretion and gastric emptying, as well as suppresses glucagon release and promotes an increase in pancreatic β-cell mass (Meier and Nauck 2005). Consistent with its role as an incretin, GLP-1 is released into the circulation in response to a meal in proportion of calories ingested (Orskov et al. 1994). In common with other gut peptides, GLP-1 works as a neurotransmitter within the CNS. It is present within the dorsovagal complex, the thalamus, and the pituitary, in key areas of the hypothalamus involved

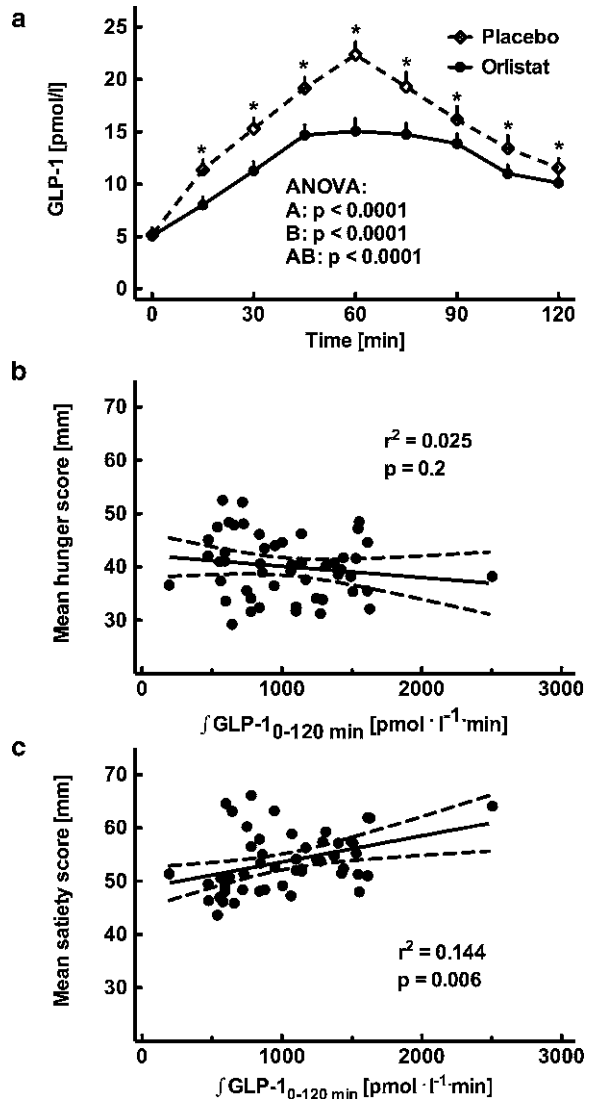
in appetite regulation GLP-1-immunoreactive neurons were found (Larsen et al. 1997). Food intake data from human studies are concordant with animal studies. GLP-1 dose-dependently decreases appetite and caloric intake in lean and obese subjects and in patients with type 2 diabetes (Gutzwiller et al. 1999). A meta-analysis by Verdich et al. concluded that infusion of GLP-1 reduces both appetite and food intake with the magnitude of this reduction being similar in lean and obese men (Verdich et al. 2001).

The impact of orlistat administration on postprandial GLP-1 secretion has been debated in the literature. Damci et al. found that lipase inhibition stimulates the meal-mediated secretion of GLP-1. In this study, only a single blood sample was obtained 60 min after a meal in diabetic patients (Damci et al. 2004). O'Donovan et al. revealed that orlistat administration may exacerbate postprandial glycemia as a result of accelerated gastric emptying (O'Donovan et al. 2004). These observations need to be critically considered. In a study conducted by Feinle et al., the effect of lipase inhibition by orlistat on gastric emptying, antro-pyloro-duodenal motility, satiety, and GLP-1 levels was investigated. Healthy volunteers were given a TG emulsion via 120 min duodenal infusion either with orlistat or placebo. Immediately after the duodenal infusion, food intake at an ad libitum buffet was quantified. Lipase inhibition with orlistat resulted in significantly reduced postprandial GLP-1 levels. In addition, administration of orlistat was associated with markedly higher scores of prospective food consumption and hunger and greater food intake at the subsequent buffet. They conclude that GLP-1 secretion depends on adequate hydrolysis of TG into MG and FFA in the upper part of the small intestine (Feinle et al. 2003). In patients with type 2 diabetes, the ingestion of orlistat together with a liquid meal containing oil and glucose also accelerates gastric emptying and attenuates the postprandial rise in GLP-1 (Pilichiewicz et al. 2003). Furthermore, Beysen et al. demonstrated differential stimulation of GLP-1 release by different types of oral fat (monounsaturated, olive oil; polyunsaturated, softflower oil; saturated, palm stearin). The greatest increase in GLP-1 was observed after fat containing monounsaturated fatty acids (Beysen et al. 2002). These findings are in line with our own data showing that in healthy volunteers peak GLP-1 levels following orlistat treatment were 20% lower compared to placebo. Likewise, the integrated concentrations of GLP-1 were significantly lower following orlistat administration. These lowered GLP-1 levels were associated with reduced satiety ratings (Fig. 86.4).

86.6 Orlistat and PYY

Peptide YY (PYY) is released into the circulation in response to a meal from L-cells of the GI tract in proportion to the calories ingested and in relation to the meal composition (Wren et al. 2007). Higher plasma levels are seen following isocaloric meals of fat compared to meals consisting of protein or carbohydrate. The release of PYY in response to fat in the proximal intestine is atropine-sensitive, raising the possibility that a neural reflex involving the vagus nerve may mediate PYY release (Lin and Taylor 2004). Other stimulants of PYY release include intraluminal bile acids, gastric acid, and CCK (Onaga et al. 2002). PYY3-36 has a central role in the control of appetite in humans as supported by a number of observations. In disease states characterized by weight loss PYY3-36 levels are elevated (Le Roux et al. 2005). Conversely, in obese humans fasting plasma levels of PYY3-36 are reduced in overweight patients having a relative deficiency of postprandial PYY3-36 release associated with reduced satiety (Batterham et al. 2003b).

Degen et al. used orlistat to determine whether inhibition of fat hydrolysis affects the release of PYY. In their study, PYY secretion in response to intraduodenal fat in the small intestine was completely abolished by orlistat administration (Degen et al. 2007). The data are in line with previous

Fig. 86.4 (**a**) Plasma concentrations of glucagon-like peptide (GLP)1 after ingestion of a solid–liquid test meal following oral administration of 120 mg orlistat or placebo in 25 healthy volunteers. Data are presented as means ± SEM. *p*-Values were calculated using paired repeated measures ANOVA and denote A: difference between the experiments, B: differences over time and AB: differences due to the interaction of experiment and time. Asterisks indicate significant difference ($p < 0.05$) versus placebo at individual time points (one-way ANOVA). (**b**, **c**) Linear regression analysis between the integrated incremental plasma concentration of GLP-1 and mean ratings for hunger (**b**) and satiety (**c**) as determined using visual analogue scales (VAS) ($n = 50$). Dashed lines indicate the respective upper and lower 95% confidence interval. r^2 = correlation coefficient squared, $p < 0.05$ statistically significant


studies: suppression of fat hydrolysis by orlistat inhibits the release of PYY (Feinle et al. 2005). The crucial importance of fat hydrolysis on digestive functions is illustrated by the effects of these products on exocrine pancreatic responses in animals and humans. Only duodenal infusion of long-chain FFAs can stimulate maximal pancreatic enzyme secretion, whereas undigested long-chain TG are ineffective (Lin and Taylor 2004). Inhibition of lipolysis by orlistat reduces the amount of FFAs in the small intestine with a subsequent reduction in PYY release. The reduction in PYY release attenuates inhibitory appetite circuits resulting in further food intake. This hypothesis was confirmed by our work. Meal ingestion elicited a significant rise in PYY levels in both experiments, but the increase in PYY levels was significantly attenuated by orlistat treatment. The reduction in PYY responses resulted in increased ratings for hunger compared to control, though correlation analysis failed to reach statistical significance (Fig. 86.5) (Ellrichmann et al. 2008). This indicates that PYY may play a minor role in enteroendocrine appetite regulation.

Fig. 86.5 (**a**) Plasma concentrations of peptide YY (PYY) after ingestion of a solid–liquid test meal following oral administration of 120 mg orlistat or placebo in 25 healthy volunteers. Data are presented as means ± SEM. *p*-Values were calculated using paired repeated measures ANOVA and denote A: difference between the experiments, B: differences over time and AB: differences due to the interaction of experiment and time. Asterisks indicate significant difference (*p* < 0.05) versus placebo at individual time points (one-way ANOVA). (**b**, **c**) Linear regression analysis between the integrated incremental plasma concentration of PYY and mean ratings for hunger (**b**) and satiety (**c**) as determined using visual analogue scales (VAS) (*n* = 50). Dashed lines indicate the respective upper and lower 95% confidence interval. r^2 = correlation coefficient squared, *p* < 0.05 statistically significant

PYY secretion is initiated either directly via luminal contact of nutrients to the endocrine cells or indirectly through neurohumoral signals such as CCK. Since a CCK1R antagonist (Dexlox) completely abolished PYY response to intraluminal FFAs, it is conceivable that the products of fat digestion stimulate CCK release, which in turn regulates PYY secretion via CCK1Rs (Degen et al. 2007).

86.7 Orlistat and PP

Pancreatic polypeptide (PP) is produced largely not only in the PP-cells of the endocrine pancreas, but also in the exocrine pancreas, colon, and rectum. Like PYY, PP is released into the circulation in response to a meal in proportion to the caloric intake. Low levels of PP have been found in obese

patients (Glaser et al. 1988), and high levels in patients with anorexia nervosa (Fujimoto et al. 1997). Both basal and postprandial PP release is subject to control by the vagus nerve as proved by truncal vagotomoy. Both truncal vagotomy and atropine have been shown to reduce meal-induced PP release in humans (Meguro et al. 1995). PP secretion is also controlled by other gut hormones, including ghrelin, motilin, and secretin, all of which stimulate PP release, and somatostatin, which potently inhibits (Gomez et al. 1997).

A recent study evaluating the effects of duodenal infusion of a long-chain TG infusion with or without 120 mg THL revealed that lipase inhibition completely abolishes the postprandial PP release. In response to a subsequent free buffet meal, PP levels were stimulated in both groups with and without application of THL. In addition, the THL group consumed significantly more food at the buffet than the control group. This may suggest that, in contrast to PYY, gastric distension, enhanced by the greater amount of food eaten, may be a more potent stimulus for PP (Feinle-Bisset et al. 2005). Moderate gastric distension with a 600 mL balloon has been shown to cause a substantial increase in PP secretion in healthy volunteers (Koop et al. 1990). Alternatively, it is possible that other macronutrients, carbohydrate and protein, are more potent stimuli than fat. Batterham et al. demonstrated that PP infusion reduces both appetite and food intake in healthy subjects. In addition, inhibition of food intake was sustained, such that energy intake, assessed by food diaries, was significantly reduced both in the evening of the study and the following morning. Plasma levels of PP remain elevated for up to 6 h postprandially suggesting that PP may regulate meal-to-meal intervals (Batterham et al. 2003). Conversely, reduced PP levels induced by orlistat treatment may shorten meal-to-meal intervals and increase food uptake per meal by attenuating satiety signals. Further studies are required to establish these potential mechanisms.

86.8 Orlistat and GIP

The first incretin hormone to be identified was isolated from porcine small intestine and was initially named gastric inhibitory polypeptide (GIP), based on its ability to inhibit gastric acid secretion in dogs. Since the inhibitory effect on gastric acid secretion was only observed at pharmacological doses, whereas its incretin action occurred at physiological levels, GIP was renamed as glucose-dependent insulinotropic polypeptide (Meier et al. 2002). In accordance with its role as an incretin hormone, GIP is released from K-cells of the small intestine in response to glucose and fat ingestion, and thus potentiates glucose-stimulated insulin secretion. While the effects of GIP on insulin secretion have been studied extensively, only limited information is available about its effects on lipid homeostasis. The potent stimulation of GIP secretion after high-fat meals, as well as the observation of increased GIP plasma levels in obesity, suggested a role of GIP as an anabolic regulator of fat metabolism. The anabolic effects of GIP in fat include stimulation of fatty acid synthesis, enhancement of insulin-stimulated incorporation of fatty acids into TG, upregulation of lipoprotein lipase synthesis, and reduction of glucagon-stimulated lipolysis (Meier et al. 2002). Ob/ob mice with a GIP receptor (GIPR) knock-out are resistant to diet-induced obesity and exhibit reduced adipocyte mass. GIPR-/- mice expend more energy and use fat as preferred energy substrate, thereby preventing the accumulation of fat in adipocytes. Food intake is comparable in GIPR-/- and wild-type mice (Miyawaki et al. 2002). In humans, no direct links between GIP and obesity as well as appetite regulation have been demonstrated. Since GIP is released into the circulation in response to fat ingestion, the role of lipase inhibition on postprandial GIP response was investigated by several groups. According to Enc et al., orlistat administration induced profound attenuation of postprandial GIP response. With ingestion of the control mixed meal, plasma GIP levels increased significantly and

remained elevated throughout the experimental period. Orlistat significantly lowered GIP response as expressed by integrated areas under the curve (Enc et al. 2009). Pilichiewicz et al. evaluated the effect of orlistat on gastric emptying and plasma GIP response in patients with type 2 diabetes. This study also showed reduced postprandial GIP secretion and accelerated gastric emptying by orlistat treatment (Pilichiewicz et al. 2003). It is therefore likely that orlistat by its ability to inhibit intestinal lipid absorption attenuates postprandial GIP release. Despite the well-characterized effects of GLP-1 on appetite and food intake, the role of GIP in feeding regulation remains unclear. Peripheral infusion of GIP at a rate shown to elicit supraphysiological plasma concentrations increases feelings of hunger in healthy lean volunteers ($p < 0.05$). Comparing hunger responses between healthy lean subjects and obese patients with type 2 diabetes during GIP infusion, a trend for higher hunger scores was observed in lean subjects, though this trend failed to reach statistical significance ($p > 0.05$). Despite these findings, ad libitum food intake during a buffet lunch at the end of the infusions was similar in the GIP and placebo group (Daousi et al. 2008). Whether these potential effects of GIP on appetite regulation are relevant under physiological conditions remains questionable.

86.9 Orlistat and Leptin

Adipose tissue, once considered to be a relatively passive site of lipid storage, is known to carry a number of complex metabolic and endocrine functions. One important hormonal factor is the protein leptin, which was isolated and synthesized following positional cloning of the gene responsible for obesity in the ob/ob mouse strain. Leptin is synthesized and released from white adipose tissue and circulates to the brain where it binds to its receptor. It acts to decrease weight and adipose tissue mass through reduction in appetite and food intake. Detected synthesis of leptin within the gastric mucosa raised the possibility that it may also play a role in meal termination (Peters et al. 2005). Markedly elevated leptin levels have been shown in obese humans compared to nonobese, conversely leptin levels markedly decline in underweight patients compared to normal-weight subjects (Haluzik et al. 1999). Only two studies have investigated the effect of lipase inhibition on serum leptin levels. Sahin et al. studied the acute effects of orlistat on postprandial leptin levels in nondiabetic obese patients. Although serum leptin levels showed a more horizontal and delayed increase after a mixed meal in patients in the orlistat group than they had in the placebo group, there were no statistical differences between these two groups (Sahin et al. 2008). A long-term, 3-month prospective study was conducted in 40 patients with clinical features of metabolic syndrome either with or without coexisting type 2 diabetes. In addition to a hypocaloric diet, these patients were given orlistat t.i.d. They observed beneficially enhanced weight loss by orlistat accompanied by decreased serum leptin concentrations (Dimitrov et al. 2005). These changes cannot be regarded as direct effects by lipase inhibition but as indirect effects due to the significant weight loss.

86.10 Orlistat and Ghrelin

Ghrelin acts as the endogenous ligand for the growth hormone secretagogue (GHS) receptor secreted primarily by the stomach to the circulation although ghrelin mRNA is present throughout the whole GI tract. Ghrelin is a peripherally active appetite-stimulating gut hormone. Ghrelin levels rise in the fasting state and fall upon eating, which has led to the suggestion that ghrelin may be involved in meal initiation. The postprandial suppression of ghrelin does not require the vagus nerve, but vagal

afferents are necessary for the rise of ghrelin in the fasted state (Wren et al. 2007; Cummings et al. 2001). The exact mechanisms responsible for postmeal suppression of ghrelin are not known. Both carbohydrate and fat, when ingested orally, suppress ghrelin secretion, whereas protein may stimulate ghrelin release or may have no effect (Greenman et al. 2004). Postprandial decline of ghrelin levels significantly depends on the caloric load of the meal: a larger caloric load produces a lower nadir in ghrelin levels after a meal than a smaller one of similar volume (Callahan et al. 2004). Recent evidence in humans suggests that both PYY and oxyntomodulin (OXM) suppress concentrations of ghrelin when given peripherally, PP having no effect (Batterham et al. 2003).

Feinle et al. documented that duodenal infusion of a long-chain TG emulsion potently suppresses ghrelin secretion in healthy young man. This emulsion given with THL completely abolished ghrelin suppression, indicating that ghrelin secretion is sensitive to digested fat, an effect apparently not mediated by an increase in blood FFAs (Feinle et al. 2005). These findings are consistent with the data obtained by Degen et al. Intraduodenal infusion of fat induced a significant inhibition in ghrelin levels ($p < 0.01$) and a significant increase in PYY concentrations ($p < 0.02$). Inhibition of lipolysis by orlistat completely abolished both effects. In addition, administration of a specific CCK1R antagonist together with intraduodenal infusion of fat abolished the effect of long-chain fatty acids on ghrelin and PYY secretion. These authors conclude that fat hydrolysis in the proximal small intestine plays a crucial role for digestive processes. Free fatty acids stimulate the release of CCK, which in turn acts on CCK1Rs thereby initiating a series of digestive functions, including modulation of CCK-1-dependent ghrelin secretion (Degen et al. 2007). The data are contrasted by our own results showing no effect of orlistat on postprandial ghrelin concentrations (Ellrichmann et al. 2008). The size, composition, and route of administration of the respective test meals might explain these inconsistencies.

86.11 Applications to Other Areas of Health and Disease

CCK does not only regulate appetite sensation and gastric emptying but also regulates gallbladder contraction and emptying of bile during the postprandial state by binding to G-protein-coupled CCK-A-receptors on the smooth muscle of the gallbladder thereby mediating gallbladder emptying. As already mentioned, CCK is released by intestinal I-cells in response to an adequate hydrolysis of dietary TG. In addition to the previous studies, we assessed whether oral administration of orlistat inhibits CCK release in response to a test meal. In the same setting, healthy volunteers were given a test meal with 120 mg orlistat or placebo visualizing gallbladder volume by abdominal ultrasound. Orlistat administration resulted in significantly reduced gallbladder emptying through meal-mediated CCK release (Ellrichmann et al. 2008) (Fig. 86.6). Since reduced gallbladder contractility leading to bile stasis is one of the major risk factors for the development of cholesterol gallstones, in a 1-year follow-up Mathus-Vliegen et al. investigated the risk of gallstone occurrence by orlistat administration. After 1 month of diet, obese patients were treated with either placebo or 60 or 120 mg orlistat t.i.d. One month and 12 months after randomization, gallbladder kinetics and CCK levels were assessed. In the 60-mg group, no significant changes of the gallbladder motility were observed, whereas 120 mg orlistat resulted in a significant decrease in gallbladder emptying. The residual gallbladder volumes and percentage of gallbladder emptying are comparable to our findings. After 1 year of treatment, disturbed gallbladder emptying persisted, 16.7% of patients in the placebo group developed gallstones, whereas only 7.1% of gallstone formation was seen in the 60 mg orlistat group. In contrast, no gallstone formation was observed in the 120 mg orlistat group (Mathus-Vliegen et al. 2004). These results were rather unexpected and might indicate that altered gallbladder kinetics is outweighed by other factors, such as a reduction of cholesterol supernaturation and nucleation factors (Fig. 86.7).

Data are presented as means ± SEM. *p*-Values were calculated using paired repeated measures ANOVA and denote A: difference between the experiments, B: differences over time and AB: differences due to the interaction of experiment and time. Asterisks indicate significant difference ($p < 0.05$) versus placebo at individual time points (one-way ANOVA). (**b, c**) Linear regression analysis between the integrated incremental plasma concentration of PYY and mean ratings for hunger (**b**) and satiety (**c**) as determined using visual analogue scales (VAS) ($n = 50$). Dashed lines indicate the respective upper and lower 95% confidence interval. r^2 = correlation coefficient squared, $p < 0.05$ statistically significant

Fig. 86.7 Effects of orlistat administration on postprandial gastrointestinal (GI) hormone levels. Orlistat reduces leptin levels secreted by the adipose tissue. In addition, the secretion of cholecystokinin (CCK), glucagon-like peptide (GLP)1, peptide YY (PYY), pancreatic polypeptide (PP), and gastric inhibitory polypeptide (GIP) from pancreas and the small intestine is attenuated. Ghrelin levels, primarily secreted by the stomach, are elevated. The changes in these GI hormone concentration lead to increased appetite sensation in the central nervous system (CNS) and thus to increased food intake

86.12 Conclusion

In conclusion, intestinal lipase inhibition by orlistat accelerates gastric emptying and markedly reduces the postprandial secretion of the anorexic hormones CCK, GLP-1, PYY, PP, and GIP, whereas ghrelin levels are elevated. Taken together, these alterations in GI hormone concentrations can increase appetite sensations leading to greater food consumption. These findings underline the importance of GI hormones in the central nervous control of energy homoeostasis. Increased appetite sensations, a potentially increased risk of developing gallbladder stones, and alterations in postprandial glucose regulation should be considered as potential side effects when applying lipase inhibitors for the treatment of morbid obesity.

Summary Points

- Orlistat inhibits intestinal lipases and thus reduces hydrolysis of dietary TG in MG and FFAs.
- Orlistat leads to a marked acceleration of gastric motility and to an inhibition of gallbladder emptying.
- Lipase inhibition significantly attenuates appetite ratings and increases food intake.
- Increased appetite induced by orlistat is mediated by changes in GI hormone levels, especially CCK, GLP-1, PYY and ghrelin.
- Changes in enteroendocrine hormone levels regulating appetite counteract the weight-lowering effect of the drug and the treatment of morbid obesity.

Definitions and Explanations of Key Terms

Cholecystokinin (CCK): CCK is derived from a 115-amino acid precursor, pro-CCK. Selective cleavage results in several circulating isoforms; the major forms in man are CCK-58, -33, -22, and -8. Biological activity resides in the amidated C-terminus of the peptide; all active species of CCK share a C-terminal heptapeptide sequence including O-sulfated tyrosine. CCK physiologically mediates gallbladder contraction and inhibits gastric emptying and gastric acid secretion. In addition, CCK induces satiating effects in the CNS.

Glucagon-like peptide (GLP)1: Post-translational processing of preproglucagon in enteroendocrine L-cells yields the peptides glicentin, OXM, GLP-2, and GLP-1. Multiple forms of GLP-1 are secreted in vivo, including GLP-1(1–37) and GLP-1(1–36)NH_2, which are thought to be inactive, and GLP-1(7–37) and GLP-1(7–36), which are biologically active. In humans, the majority of GLP-1 in the circulation is GLP-1(7–36)NH_2. GLP-1 possesses a variety of physiological properties comprising increase in insulin secretion, decrease of glucagon secretion, inhibition of gastric emptying, and attenuation of food intake.

Peptide YY (PYY): PYY is a 36-amino acid linear peptide and is a member of the pancreatic peptide family. The main of PYY is stored and secreted to the circulation as PYY(3–36), which is the N-terminally truncated form of the peptide. PYY is secreted from the endocrine L-cells of the small and large bowel, with high concentrations at the terminal ileum and colon and maximum concentration in the rectum. PYY exerts its action through NPY receptors thereby inhibiting gastric motility and pancreatic secretion. Furthermore, PYY has been shown to reduce to appetite and prospective food consumption via NPY receptor within the CNS.

Pancreatic polypeptide (PP): PP is a 36-amino acid peptide and as well a member of the pancreatic peptide family. It is produced in the endocrine type F cells located in peripheries of the pancreatic islets in response to food ingestion, hypoglycemia, and exercise. The physiological mechanisms of PP still remain unclear. Several studies suggest that vagal nerve activity can be estimated by PP serum levels.

Gastric inhibitory peptide (GIP): GIP is the first incretin hormone to be identified isolated from porcine intestine. Based on its ability to inhibit gastric acid secretion it was named "gastric inhibitory polypeptide." Subsequent studies demonstrated a glucose-dependent stimulation of insulin secretion by GIP. Accordingly, the term "glucose-dependent insulinotropic polypeptide" was proposed to more accurately define the acronym GIP. GIP is synthesized in K-cells of the upper small intestine. The mature bioactive 42-amino acid form of GIP is cleaved from its 153-amino acid proGIP precursor via post-translational processing. GIP is known to stimulate insulin secretion from the endocrine pancreas. It is also thought to have significant effects on fatty acid metabolism by stimulation of lipoprotein lipase in adipocytes.

Leptin: Leptin is a 16 kDa protein that plays a key role in regulating energy intake and expenditure. The ob gene located on chromosome 7 in humans is expressed in adipose tissue and encodes for leptin. In addition for being a biomarker for body fat composition, serum leptin levels reflect individual energy balance. By binding to NPY neurons in the arcuate nucleus leptin induces satiety in the CNS.

Ghrelin: Ghrelin has a 28-amino acid structure, with an octanoylated serine residue at position 3. This unique side chain appears to be essential for the effects on appetite regulation and GH release. The X/A-like cells in the fundus of the stomach are the major source of circulating ghrelin. To date, ghrelin is the only endogenous peripheral hormone that has been show to induce hunger and increase food intake.

Pathology and Abnormal Aspects: Neurological

Chapter 87
Gastrointestinal Disorders in Neurologically Impaired Children

Abbreviations

GER	Gastroesophageal reflux
GERD	Gastroesophageal reflux disease
NIP	Neurologically impaired patients
PEG	Percutaneus endoscopic gastrostomy

87.1 Introduction

There is a saying "Liebe geht durch den Magen" – "The way to a man's heart is through his stomach." In neurologically impaired patients (NIPs), often eating or being fed something gustatorily pleasant is one of the highlights of their life. Despite this need for autonomic or assisted nutrition, problems and disorders of the gastrointestinal tract exist in a high percentage in this special group of patients, reducing their and their caregivers' quality of life.

Motility of the gut is controlled both by extrinsic inputs from the dorsal motor nucleus of the vagus and paravertebral sympathetic ganglia and by local reflexes mediated by intrinsic neurons of the enteric nervous system. Motility of the gastrointestinum results from interplay of a few fundamental mechanisms, including myogenic mechanisms, neurogenic propulsive mechanisms, and migrating neurogenic motor activity. This complex interplay can be interrupted or disturbed by abnormalities of one or more of these mechanisms.

Severe neurologic impairment affects both children and adults considerably. In many cases, severe gastrointestinal problems accompany these children throughout their life (Moore 2008). Failure to thrive, difficulties in oral nutrition, recurrent vomiting, and respiratory tract infections caused by aspiration as well as loss of appetite and abdominal pain are results of frequent associated conditions. Dysphagia is present in 60% of NIPs, gastroesophageal reflux (GER) in 77%, resulting in chronic pulmonary aspiration in 41%; 74% of NIPs suffer from chronic obstipation (Del Giudice et al. 1999).

It is difficult for NIPs to express the pain and discomfort caused by gastrointestinal disorders to their caregivers. Thus, the interpretation of behavior indicating pain experience is a challenge for parents and health care professionals, resulting in late diagnosis.

This chapter attends to the pathogenesis, diagnosis, and treatment of dysphagia, GER, and constipation as three of the main gastrointestinal problems in severe NIPs. Knowledge and understanding of these disorders will lead the way to earlier, timely diagnosis and treatment, thus preventing pain and further damage to the gastrointestinum as well as to the pulmonary system and improving the quality of life in this special group of patients.

87.2 Dysphagia

87.2.1 Background

87.2.1.1 Physiology of Normal Swallowing

The act of swallowing is a complex process and requires the coordination of cranial nerves, the brain stem, cerebral cortex, and 26 muscles of the mouth, pharynx, and esophagus. The main cranial nerves that influence swallowing include the trigeminal (V), the facial (VII), glossopharyngeal (IX), vagus (X), and hypoglossal (XII). These nerves mediate the sensation and movement related to swallowing. Any abnormalities affecting these nerves, the cerebral cortex, mid brain, or cerebellum may have a negative impact on the individual's ability to swallow.

Four phases of swallowing can be distinguished: the oral-preparatory, the oral, the pharyngeal, and the esophageal phases. Dysphagia is characterized by a dysfunction in the sequential oral, pharyngeal, and esophageal phases of the swallowing process. The presence of abnormal movement patterns, for example tongue thrust in children with cerebral palsy, disrupts the normal movement of food from the anterior to the posterior regions of the mouth. Children with dysphagia have trouble in tongue control and bolus manipulation, problems with movement of food from the mouth to the pharynx as well as delayed pharyngeal swallow. Delayed or lack of initiation of the swallowing reflex results in increased risk of aspiration from an unprotected airway.

87.2.1.2 Causes of Dysphagia

Dysphagia can be caused by acute onset of intracranial hemorrhage, cerebral infarction, or traumatic injuries (Schaller et al. 2006). Alternatively, it can be the result of congenital and chronic disorders resp. diseases: intracranial tumors, cerebral palsy, genetic disorders, encephalopathy, or neuropathy.

As can be observed, dysphagia from chronic causes may worsen progressively or remain static. Worsening dysphagia will lead to deterioration of feeding and swallowing skills. In static dysphagia, swallowing skills will remain stable, or there may be a slow improvement.

87.2.2 Signs and Symptoms

Difficulties in swallowing or transporting a food bolus may result in frequent aspirations, especially in fluid intake. Thus, it may eventually lead to pulmonary infections. Refusal of food, pain in swallowing, and inpatient or aggressive behavior of the children can be observed frequently. In some

children, dystrophy might be present. Food intake or feeding can show enormous duration. Excessive drooling, signs of fatigue, and respiratory distress during feeding are often found. Notable oral hypersensitivity to touch with spoon, food, or finger is sometimes present and should lead to further investigation considering dysphagia.

87.2.3 Diagnostics

An understanding of normal and abnormal swallowing patterns as well as other developmental characteristics unique to children is essential for assessment. Identification and assessment of dysphagia is complex and requires the expertise of a multidisciplinary team. A multidisciplinary team can use various assessment methods including the following.

87.2.3.1 History of Feeding

A feeding history obtained from parents or caregivers helps assessing severity of dysphagia considering preferred texture of meals, duration of feeding, and eventually occurring signs of aspiration.

87.2.3.2 Physical Assessment

Physical examination should include clinical bedside evaluation by the speech pathologist and oral motor examination. Look for structural abnormalities of the tongue, palate, and jaw, difficulties in any of the four phases of swallowing or abnormalities in oral, laryngeal, or pharyngeal movement. A neurological examination for presence of dystonia, which might affect the ability to feed, as well as for any indices of other neurological or neuromuscular disorders should be performed.

Upper motor impairments are common in children with neurogenic dysphagia and may affect the ability to control their head, neck, and trunk and thereby the subsequent ability to swallow and ability to self-feed. Presence of dystonia and dyskinesia will affect the patient's ability to chew, manipulate the bolus in the mouth, and swallow. Those suffering from muscular hypotonus may experience poor coordination of posterior tongue resulting in difficulties with the pharyngeal phase of swallowing.

The child's hydration and nutritional status and its growth and development must be assessed. Since GER can be associated with dysphagia, the signs and symptoms of this disorder need to be investigated.

87.2.3.3 History of Medications

Some neuroleptics and medications used to control seizures may reduce alertness and ability to swallow. Muscle relaxants administered to patients suffering from spasticity may affect their ability to swallow.

87.2.3.4 Radiological Examinations

A videofluroscopic modified contrast swallow study may be helpful to assess the type of dysphagia and the individual risk of aspiration.

87.2.4 Therapy

Dysphagia often occurs parallel with many other streams of abnormal or delayed development. This may include impaired cognitive, oral motor, and fine and gross motor skills. A child's developmental age and current level of functional swallowing skills, for example the ability to chew, and/or control and manipulate a bolus, should be considered in any management program. Management of dysphagia requires the expertise and cooperation of a multidisciplinary team. Members of this team include a medical practitioner, a speech therapist, a physiotherapist, an occupational therapist, a dietitian, and nurses as well as pediatric surgeons.

87.2.4.1 Monitoring Nutrition and Hydration

In oral motor dysfunction there may exist an inadequate nutritional intake. This sometimes is even worsened due to difficulties in communicating desire for food and food preferences, inability to self-feed, coexisting GER, and aspiration.

Assessment of the diet may help in maintenance of nutrition. This includes fluid and food intake and loss with consideration of supplemental nonoral feeding. To get a better understanding of this disorder and to find possible ways to improve symptoms, duration of meal times has to be observed.

87.2.4.2 Positioning the Patient

Children with poor head control and poor trunk stability will require appropriate and individualized positioning techniques. The aim of positioning is to maintain a central body alignment.

In children with severe cerebral palsy and feeding problems, feeding position can be dependent on degree of dysphagia and on its occurrence in the oral or pharyngeal phase. The chin tuck and 30° reclining position and flexed hips may be effective in eliminating aspiration in children with major oral phase swallowing problems. In children with minor oral phase but greater pharyngeal phase swallowing difficulties, the erect position with flexed neck and hips was recommended.

87.2.4.3 Diet

Children with dysphagia may have difficulties managing different bolus sizes, flavors, and textures. Modifications will vary according to the needs of each child. Barium swallow studies may be used to determine the safest textures for each child with dysphagia. Children with neuromuscular disorders and weakened or uncoordinated swallowing may swallow a semi-solid consistency more easily as a single bolus.

Thickened fluids are recommended as they assist in reducing the risk of aspiration.

87.2.4.4 Prevention of Complications

Patients must be observed for signs of aspiration (coughing, choking, and respiratory distress). If aspiration is suspected, oral feeding should be stopped until the cause is investigated.
PIC 87.1   Laparoscopic view of a percutaneus endoscopic gastrostomy probe (PEG). The PEG penetrates the skin and the gastric wall to ensure endogastrical feeding

87.2.4.5 Nonoral Feeding

In severe dysphagia, oral feeding can not only become extremely exhausting both for patients as well as for caregivers but can endanger the health of the patients by recurrent pulmonary aspirations. In these cases, enteral feeding through a percutaneous endoscopic gastrostomy (PEG) probe or a button, to which the gastrostomy feeding probe can be fixed is preferred. In severe cachexia, continuous feeding through jejunal tube can be a good answer to this problem (Valletta and Angelini 2004) (PIC 87.1).

87.3 Summary Points

- Dysphagia can be caused by acute onset of intracranial hemorrhage, cerebral infarction, or traumatic injuries. Alternatively, it can be the result of congenital and chronic disorders and diseases: intracranial tumors, cerebral palsy, genetic disorders, encephalopathy, or neuropathy.
- Caring for children with dysphagia is stressful and to some degree exhausting for patients as well as for caregivers or parents.
- Information should be provided to assist caregivers to manage the child's swallowing and feeding difficulties. These include strategies for oral feeding, preparation of nutritious meals, adaptive equipment, positioning techniques, positive interactive behaviors, and child's progression in regaining swallowing skills.
- A multidisciplinary approach with parental involvement in assessment and management of their child's dysphagia is important. In severe dysphagia, enteral feeding through a PEG can be an extremely helpful approach.

87.4 Gastroesophageal Reflux

87.4.1 Background

Gastroesophageal reflux is defined as the return of gastric content into the esophagus. Up to some amount, this condition is normal and is found in each healthy individual. In this healthy context, there are mechanisms preventing an acid or pepsin refluat to overwhelm the intact epithelium: the antireflux barrier and functioning clearance mechanisms of the esophagus.

The antireflux barrier as the first line of mucosal defense consists of the lower esophageal sphincter and the crural diaphragm as well as of the angle of HIS. The latter is formed between the cardia at the entrance to the stomach and the gastric fundus, thus providing a valve which prevents reflux of gastric content from entering into the esophagus. The angle of His is created by the collar sling fibres and the circular muscles around this gastro-oesophagal junction.

The second line of defense consists of the esophageal clearance function, which limits the time of contact between refluate and esophageal mucosa by eliminating esophageal content into the stomach. Salivary secretions from the esophageal glands as well as gravitation in an upright position support this clearing function.

If these mechanisms are not sufficient, cellular defense, or mucosal resistance is discussed as the last line of defense against aggressive refluat (Boix-Ochoa and Ashcraft 2005).

A malfunctioning of these barrier or clearance mechanisms as well as a delayed gastric emptying leads the way to pathologic GER.

When the lower esophageal sphincter shows disturbed function, transient relaxations occur. These relaxations are not associated with swallows, a clearing wave of peristalsis, thus leading to regurgitation of gastric contents (Kawahara et al. 1997). In NIPs, the dysfunction of the esophageal motility causes longer contact of the acid gastric content with the esophageal mucosa leading to esophagitis and gastroesophageal reflux disease (GERD). Additionally these patients often lack upright positioning. Thus, gravity fails to support esophageal clearance function. Another cause for the high occurrence of GER in NIPs is considered the high incidence of epilepsy or spastic disorders elevating the muscular tonus and thereby increasing the intra-abdominal pressure.

To prevent further damage to the esophageal mucosa and the pulmonary system, to ease the pain and discomfort caused by pathologic GER, early diagnosis and treatment is mandatory. Therefore, health care professionals should pay attention to typical signs of GER as well as to behavioral alterations in children with neurological impairment and evaluate the possible causes including GER.

87.4.2 Signs and Symptoms

The diagnosis of GER is based on typical symptoms such as vomiting and regurgitation but is often diagnosed late, especially when symptoms like chronic pulmonary disease, recurrent pulmonary infections, and changes in behavior mislead the diagnosis.

Dental erosions, recurrent laryngitis, and esophagitis reveal the aggressive character of gastric content on extragastric tissue.

Recurrent episodes of uncontrollable singultus, belching, or acid foetor ex ore represent frequently existing and often underestimated symptoms.

In some cases a sudden rotation of the head and neck to one side and the legs to the opposite side in a spastic dystonic mode, typically appearing in the postprandial period may be present. This condition is called the Sandifer syndrome and is associated with GER.

Symptomatic GER presents as GERD and may be associated with recurring pain, thus impairing health-related quality of life (Madisch et al. 2003).

GER and GER-related esophagitis is often detected late due to severe deficits in communication – thus challenging the parents and caregivers abilities to interpret behavior indicating pain experience. It is difficult for NIPs to express the pain caused by acid reflux and esophagitis to their caregivers.

This reflux-related pain in neurologically impaired children has in many cases a significant influence on the behavior of these patients, as it may lead to increased agitation with increased undirected movements, moaning, crying, and difficulties to pacify as well as auto-aggressive behavior. Special attention should be given to changes in behavior indicating pain experience (Figs. 87.1 and 87.2).

In neurologically normal children the prevalence of symptoms associated with GER has been shown to peak at 4 months of age (67%) but decreases to 5% at 12 months of age (Nelson et al. 1997). In contrast, in children with neurological impairment pathological GER is a often lifelong condition.
Fig. 87.1 Correlation of pH-metric time of reflux and changes in behavior. Children with behavioral changes, represented by increased agitation and auto-aggression, showed highly pathologic levels of gastroesophageal reflux here measured in RI with a sign difference to those without behavioral changes
Fig. 87.2 Correlation of degree of inflammation of the esophageal mucosa and changes in behavior. Children with agitation and auto-aggressive behavior showed higher degrees of inflammation (grading after Savary Miller) and thus more severe inflammation than those without behavioral changes

The patients suffering from GER frequently haves difficulties with oral nutrition which may result in weight loss or failure to gain weight.

Delayed diagnosis of reflux and esophagitis not only results in difficult nutrition and recurrent pulmonary infections through aspirations, but also may finally result in mucosal damage leading to esophageal carcinoma arising from Barrett's epithelium.

Symptoms corresponding with pain for patients with severe neurological impairment were used to develop pain evaluation scales (Giusiano et al. 1995; Mc Grath et al. 1998). Despite the attempts to standardize the documentation of pain by medical professionals it has been shown that parents are best qualified to assess a typical behavior indicating that their child is feeling pain (Callery 1997). Therefore, medical professionals should respond to the caregivers' judgment of abnormalities in behavior even if otherwise typical symptoms are missing.

The clear correlation between auto-aggressive and agitated behavior and the severity of GERD shows that pathological GER may induce chronic pain in children with mental disabilities. Auto-aggressive or agitated behavior can be an indicator for GERD in neurologically impaired children and can be considered as a marker for reoccurring or first time diagnosed pathologic GER (Hunt et al. 2003).

Adapted with the permission from the publisher from. Gössler A, Schalamon J, Huber-Zeyringer A, Höllwarth ME, Gastroesophageal reflux and behavior in neurologically impaired children. J Pediatr Surg. 2007 Sep; 42(9):1486–90.

87.4.3 Diagnostics

87.4.3.1 Physical Assessment

A thorough examination of the patient should be performed to assess signs of GER or related conditions.

It is important to know if the patient is ambulatory or nonambulatory, if he prefers upright or prone position. Knowing this may lead to better understanding at which position the child suffers from more pathologic reflux and in which position each single child is feeling more comfortable. There is a healthy circulus, which is lacking in children who are bound to the wheel chair or the bed. The patient must be ambulatory, thus both increasing intestinal mobility and preventing obstipation. This is especially important, since the latter causes increased abdominal pressure which is associated with a higher incidence of GER.

Movement patterns should be observed as well as markers of auto-aggressive behavior like scratches or hematomas or bite marks.

Nutritional status as well as skin hydration should be examined; ideally, the development of weight and height should be stated.

Examination of the teeth to detect possible erosions from acid refluat should be included in the examination.

Auscultation, palpation, and percussion of the abdomen have to be performed to assess peristalsis, possible abdominal tumors, or hernias of the abdominal wall.

87.4.3.2 History

In most cases, a typical history of symptoms can be found. A thorough interview with patients and/ or caregivers is mandatory.

87.4.3.3 Sonography

Sonography is performed to investigate occurrence of GER, gastric emptying, and to exclude abdominal masses as the cause of increased abdominal pressure or barrier of intestinal movement.

87.4.3.4 Contrast Study

A contrast study of the upper gastrointestinal tract is performed to assess anatomy, gastric emptying, possible hiatal hernias, or esophageal strictures. In some patients, gastroesophageal reflux can be observed during this study, showing the heights of return of gastric content into the esophagus (PIC 87.2).

87.4.3.5 24-h pH Monitoring

pH is monitored to assess the total as well as the percentage time of acid refluat into the esophagus as well as the number and duration of occurring refluxes and the clearance function of the esophagus. Since this investigation monitors only acid refluat, a 24-h combined impedance and pH monitoring is now standard for investigation of acid and nonacid refluat (Del Buono et al. 2006) (PIC 87.3, PIC 97.4).

87.4.3.6 Endoscopy

Esophagogastroduodenal endoscopy is performed to assess or rule out mucosal damages. Esophagitis is assessed according to Savary and Miller. Ulcers, strictures, or Barrett mucosa can be found in

PIC 87.2 Upper gastrointestinal contrast study. Contrast study showing gastroesophageal reflux up to the upper half of the esophagus
PIC 87.3 Measurement of gastroesophageal reflux by impedance pH monitoring. Impedance pH monitoring shows reflux of acid gastric content in the esophagus. Note drop of pH (lowest line) during reflux, the beginning and ending of which is marked with vertical lines

endoscopic examinations. Biopsies have to be taken, especially since in up to 48% of inflammation of the esophageal mucosa this has not been seen under macroscopic examination. During endoscopy, possibly occurring hiatal hernias can be observed.

87.4.3.7 Esophageal Manometry

Manometrically, the tonus, resting pressure, length, and transient as well as swallow-induced relaxations of the lower esophageal sphincter can be documented. The common cavity phenomenon with equalization of gastric and esophageal pressure is the manometric equivalence of reflux.

Esophageal peristalsis and occurrence of GER can be investigated.

87.4.4 Therapy

87.4.4.1 Conservative Treatment

A special diet which consists of less acid, low fat, and not too spicy food should be administered. Elevation of the head of the bed and, especially in children with frequent aspirations, thickened feedings will support gravity's part of esophageal clearance.
PIC 87.4 Positioning control of the impedance probe. Radiographic control of the endoesophageal position of the impedance probe

Reduction of acid refluat may permit healing of the esophageal mucosa in cases of mild to moderate GER. Thus both a better distal esophageal peristalsis and fewer transient lower sphincter relaxations may result, disrupting the circulus vitiosus of GER leading to esophagitis enhancing GER.

The superior efficacy and safety of proton pump inhibitors (PPIs) have changed the diagnostic and therapeutic recommendations. PPIs belong to a group of chemically related compounds whose primary function is the inhibition of acid production in the final common metabolic pathway of gastric parietal cells. The suppression of gastric acid secretion achieved with H2 receptor antagonists has proved to be suboptimal. PPIs have been shown to be more effective than them (Vandenplas, *Current Concepts in the Medical Therapy of GER in Children*).

In combination with mucosa protecting drugs like sucralfat, these mediations effectively may lead to healing of reflux-associated esophagitis.

In some cases motility enhancing, prokinetic drugs (cisapride, erythromycin) can be helpful. Cisapride is a prokinetic mainly acting via indirect release of acetylcholine from the myenteric plexus.

87.4.4.2 Surgery

How can the surgeon help?

GERD has been shown to occur with an increased incidence in neurologically impaired patients, representing a major factor in the long-term care and management and life in these patients.

Reduction of gastric acid production can improve symptoms of GERD. But while some improvement after healing of esophagitis may be present after some weeks or months of medication in mild GER, conservative therapy does not help with the natural history of development of gastroesophageal reflux disease. Reflux-depending symptoms and pathological oesophageal findings show recurrence in up to 80% within the first year. Thus, severe cases might require a long-term or even lifelong administration of medications (Stanghellini 2003).

In cases of severe GER, anatomic anomalies, failure to thrive, and recurrent pulmonary infections, fundoplication will lead to an impressive overall improvement of symptoms, health, and quality of life (Ceriati et al. 2006; Spitz and McLeod 2003).

87.5 Summary Points

- Pathologic GER is the result of malfunction of the barrier function and of the esophageal clearance.
- If left untreated or unrecognized, GERD can lead to damage of the esophageal mucosa or the pulmo by recurrent infections, failure to thrive, and changes in behavior like auto-aggression and agitation.
- Treatment includes special diet, acid suppressing medications, and surgery in severe cases.

87.6 Obstipation

87.6.1 Background

87.6.1.1 Physiology

The function of the colon is modulated through several separate systems, including neural, endocrine, and luminal factors.

There are two kinds of nervous systems controlling the colon – the intrinsic colonic nervous system and the extrinsic colonic nervous system. While the intrinsic nervous system consists of nerve cell bodies and endings that are located between the circular and the longitudinal muscle coats in the submucosal ganglia (Meissner's plexus) and the myenteric ganglia (Auerbach's plexus), the extrinsic acts through sympathetic and parasympathetic functions.

Stimulation of parasympathetic fibers increases the overall activity of the gastrointestinal tract. It initializes peristalsis, increases local blood flow and intestinal secretion, and promotes the defecation reflex. The sympathetic innervations of the gastrointestinal tract show an inhibiting effect on noradrenalin on the enteric nerves. It is supposed to regulate the contraction of the internal anal sphincter.

The external sphincter is innervated via branches of the pudendal nerves, as is sensation from the perianal area and perineum, whereas tension and stretch in the rectal wall and proximal part of the anal canal is carried in the pelvic nerves.

Through mass movements of the distal colon, feces are pushed into the otherwise empty rectum prior to defecation. The resulting distension and filling of the rectum initiates the sensation of the need

to defecate. Now relaxation of the internal anal sphincter and voluntary relaxation of the external sphincter promote defecation.

Defecation can be delayed by voluntary contraction of the external anal sphincter and the urge to defecate gradually decreases in intensity over a period of minutes.

The central nervous system contributes to the regulation of bowel function, and is involved in the timing and initiation of defecation.

Asides from neurologic function, three elements are important for normal bowel function: dietary bulk, fluid intake, and exercise (Winge et al. 2003).

Any factor that influences neurologically induced peristalsis or these three elements may cause bowel dysfunction and chronic constipation.

Chronic constipation is a common problem in children. And it is particularly common in children with disabilities.

Other possible causes of constipation include the disregard of the impulse to defecate, emotional conflicts, overuse of laxatives, or prolonged dependence on enemas as well as it can result as a side effect of some commonly used medications, especially antiepileptic drugs or sedative.

There is frequently a delay in the recognition and adequate treatment of constipation in children. Difficulties in communication make it nearly impossible for neurologically impaired children to express the extreme discomfort caused by constipation. This leads to existence of problems and symptoms for months or years before their importance is understood.

87.6.2   Signs and Symptoms

Constipation is defined as small, infrequent, or difficult bowel movements. But what is infrequent? Constipation always must be regarded in relation to the single patient. When defecation costs extreme effort, hurts and produces hard stool, constipation is present.

In most cases, constipation might just be a minor annoyance. But sometimes it presents as an acute abdominal condition with massive pain and respiratory distress caused by extreme metoristic abdomen and elevation of the diaphragm.

Adequate treatment of constipation provides relief for the child and impressively leads to an improvement in appetite and sometimes behavior.

If left untreated, chronic constipation may lead to painful fecal impaction. It can result in hemorrhoids, fissures, and abdominal pain. Additionally, elimination of hardened stool can become extremely difficult and painful. Pseudo incontinence can occur, when only fluid or softened stool can pass around hard and impacted stool without possibility to control this.

Many patients loose their appetite and refuse their meal, caused by nausea, pain, or simply the feeling of metoristic and "full" abdomen and frequent episodes of abdominal cramping.

Chronic obstipation can lead to an acquired afunctional distention of the colon with reduced or poor colonic peristalsis. As a secondary result of excessive use of laxatives, in some patients fluid and electrolyte depletions occur.

Especially in the neurologically impaired, this discomfort without possibility to communicate their problems can lead to an increase in auto-aggressive behavior as well as in disquietness and aggression.

Chronic obstipation is frequently associated with gastroesophageal reflux. A possible cause for this is found in the increased abdominal pressure as well as in the frequently additionally delayed gastric emptying.

87.6.3 Diagnostics

87.6.3.1 Physical Assessment

Especially in the neurologically impaired, an entire physical examination should be performed.

The abdomen should be auscultated to determine absence or presence of peristalsis as well as to determine the kind of peristalsis. Check the patient's abdomen for visible signs of distension or abdominal wall hernias, which may interfere with the necessary amount of abdominal pressure during defecation.

Palpation of the abdomen can show masses of hardened stool as well as abdominal tumors. In many cases, left lower quadrant pain can be found in severe acute constipation.

In many patients, signs of healed or yet active anal fissures or hemorrhoids can be found. Less frequently, anal polyps or rectal prolapse may be present. To some amount, sonography can assist in determining the rectal distension in patients in whom a rectal examination cannot or can only be performed with difficulty.

A thorough neurologic examination concerning anal, cremasteric, and abdominal wall reflexes should be performed.

Labor chemistry should be performed with special regard to the electrolyte status and thyroid status to rule out hypothyroidism in patients whose symptoms proved to be refractory to dietary management.

87.6.3.2 Radiology

Always a screening sonography should be performed to evaluate peristalsis, exclude abdominal or retroperitoneal tumors, and show rectal distension (PIC 87.5).

An abdominal X-ray can be useful in both indicating the nature of the problem and assessing the degree of constipation and, hence, the appropriate treatment.
PIC 87.5 Transabdominal sonography of the rectum. Sonography showing rectal distension by stool masses

87.6.4 Therapy

The degree of neurologic involvement and abnormalities in defecation dynamics will guide in developing an appropriate management plan. A cleaning phase of the colon followed by medical and dietary management as well as changes in life style – if possible – is often successful. Since continence may not always be a realistic possibility in people with severe disabilities, the goal of therapy in these cases is to soften the stool so that it is painless to pass.

87.6.4.1 Treatment of Acute Constipation

To prevent abdominal cramping pain and to lead the way to an effective use of laxatives, the entire colon and rectum should first be emptied. This is achieved by use of enemas. In less severe cases, some suppositories can be used alternatively. These normally consist of CO_2-supps to achieve a sensation of filled rectum, which results in rectal peristalsis. Glycerin supp can soften the distal stool masses to assess easier passage. In severe cases, digital disimpaction under anesthesia by a physician may be necessary, including use of irrigation to clean the colon. It should not be performed ambulatory, since freedom of pain has to be assured during this otherwise hurting and unpleasant procedure. After this cleaning phase, oral medications are administered.

87.6.4.2 Management of Chronic Constipation

It should be aimed for frequent, at least each other day, effortless and – and this should not be underestimated – painless defecation. Especially in children with many physical and sometimes psychological problems, alleviation if not freedom of pain has to be achieved to improve their and consequently their caregivers' quality of life.

The need for patience has to be explained to caregivers, since sometimes medication and treatment can be necessary for several months to years.

Laxatives and fiber therapies may be effective in improving bowel movement frequency.

In less severe cases, adequate fluid and fiber intake alone may lead to adequate improvement. If the physical condition of the neurologically impaired child allows, some physical training should be performed.

Since some medications are known to worsen colonic peristalsis, anticholinergics, opiates, antacids, and antiepileptics as well as sedatives should be reduced as possible.

If these modifications alone fail to be effective, medication to ensure soft and easy-to-pass stool should be administered.

For a short period, lactulose can be useful. In cases of extreme dilatation of the colon caused by prolonged, sometimes yearlong delay in defecation and tailback of stool masses, we found dihydro-ergotamin to be a good choice.

Often used and very helpful is macrogol, which ensures the transport of softer, more voluminous stool masses. Medications such as pyridostigmin are also known to be effective in chronic constipation. Before administering these drugs, it has to be checked for contraindications.

Enemas and suppositories can relieve constipation temporarily. Still, they should be used only for a short period of time and not regularly. Inflammations, interfere with natural bowel muscle control and last, but not least, the discomfort caused for the patients should lead to an use only prior to oral antiobstipation medication.

When basic understanding of this training can be achieved, biofeedback techniques may be of some help in patients who initiate contraction of the external anal sphincter during the attempt to defecate. Biofeedback shows these children how they can change voluntarily the striated muscle contractions.

How can the surgeon help?

If changes in lifestyle, diet, and medication treatments fail to be effective, surgical therapy can improve bowel emptying and soften stress caused by this problem:

– Rectoscopy with anal dilatation or myotomy.
– Appendicostomy (Malone procedure) (Malone et al. 1990; Roberts et al. 1995; Zerhau et al. 2008) with antegrade continence enema (ACE).
– Colostomy.

87.7 Summary Points

- Obstipation is caused by immobility, inadequate fluid and fiber intake, and disturbed neuronal control of the colon as well as by some frequently used medications.
- If left untreated, it can lead to severe abdominal pain, anal fissures and refusal of food. The discomfort sometimes is shown by agitation and disquietness.
- Changes in diet, and physical training pave the way to improved colonic function.
- Laxatives, enemas, and stool softening medications help improve the symptoms and maintain regular stool passes.
- Surgical treatments like dilatation of the anal sphincter or, in severe cases, the Malone procedure may be very helpful treatments.

87.8 Surgical Therapy

87.8.1 PEG in Dysphagia

How can the surgeon help these patients?

Nutritional support is often an integral part of patient management in this group of children.

In patients where tube feeding is supposed to be of short duration, a nasogastric tube can be considered. There are three principal access routes used for nutrient delivery: oral, enteral, and parenteral. If oral intake is inadequate or contraindicated, then enteral tube feeding is preferable. Still, there are a number of problems associated with the use of the nasogastric tubes over the longer-term. A gastrostomy or jejunostomy is often the only way to secure the daily caloric need of the body in patients with a failure to thrive. Gauderer and Ponsky introduced a PEG 30 years ago. It is a safe and effective method for adequate enteral nutrition. The main indication for this is the inability to swallow or recurrent aspirations during the process of swallowing in children and adult patients with dysphagia as well as in extremely dystrophic or cachectic patients with GER. Their nutritional status as well as their quality of life improves sometimes impressively from the benefits of enteral feedings via gastrostomy or PEG (PIC 87.1).

Since neurologically impaired children pose the main indication and frequently suffer from additional GER, this condition has to be evaluated prior to gastrostomy.

Button: The major advantage of the PEG is that it allows a great number of patients to be discharged into family care. The simple button-gastrostomy tube is a next benefit in these cases.

87.8.1.1 Laparoscopy

Laparoscopy in pediatric surgical practice has become a reality. Laparoscopy in children requires a special care and provides a special caring.

Generally, low pressures about 6mmHg are used in children up to 8 years. We use instruments and ports no larger than 2 to 5 mm in diameter, thus providing very small wounds and minimal scarring.

Advantages of the laparoscopic approach are easily understood: there is a cosmetically better outcome, less tissue dissection, and disruption of tissue planes. Postoperatively, younger and older patients show less pain and overall there is a low intraoperative and postoperative complication rate.

Laparoscopic-assisted PEG: In patients with V-P shunt or generally in patients after another surgical procedure of the epigastric region a laparoscopy with 3mm camera is performed for visualization of the intraperitoneal part of the V-P shunt or for visualization of the adhesions between the stomach and the peritoneum (PIC 87.1).

Laparoscopic gastrostomy: Laparoscopic gastrostomy is indicated when a PEG cannot be performed or is contraindicated (obstruction of the esophagus, colon or omentum are overlaying the stomach). In these patients, the laparoscopic gastrostomy is the best opinion.

Laparoscopic jejunostomy eliminates the risk of aspiration associated with gastrostomy feeding. It will help assessing a healthier nutritional status in patients prior the further abdominal surgery.

In severely malnutrition, a jejunal tube can be inserted via the gastrostomy catheter for continuous enteral feeding in contrast to bolus feeding via the gastrostomy tube. It is posed under endoscopic surveillance into the jejunum.

87.8.1.2 Contraindications of PEG

Absolute contraindications for this procedure are:

Malignant obesity
Acute inflammation process of the abdominal wall
Peritoneal dialysis
Malignant ascites
Tumors of abdominal wall
Tumors of the left lobe of the liver with stomach dislocation
Peritonitis
Pancreatitis
Portal hypertension
Coagulation disorders
Relative contraindication: Displacement of the stomach (e.g., scoliosis).

87.8.1.3 Complications

Seldom, but possible complications are gastric and bowel perforation, gastric bleeding, migration of the gastric tube or wound infection, and abscess of the abdominal wall.

87.8.2 Fundoplication and Pyloroplasty in GERD

How can the surgeon help?

87.8.2.1 Pyloroplasty

In delayed gastric emptying, a pyloroplasty can be performed. In most cases, this surgery will be performed together with an antireflux procedure to ease emptying of the stomach.

When conservative treatment fails, or age, existing anatomic anomaly or severe symptoms make it necessary, surgery can present help against symptoms and GER-associated problems.

87.8.2.2 Fundoplication

In fundoplication, a complete or partial wrap of the fundus around the intra-abdominal esophagus is performed. Thus transient lower esophageal relaxations, which pose one major mechanism of pathologic GER, can be reduced successfully. Additionally the reconstruction of the angle of HIS prevents complete relaxation of the lower esophageal sphincter via elevation of the intragastric pressure. The diaphragmatic crura are narrowed to prevent the fundoplicate from slipping into the thorax as well as to reduce a hiatal hernia (PIC 87.6).

This surgery can be performed laparoscopically or in open access surgery.

The 360° wrap or Nissen fundoplication has been used much more frequently than other antireflux operations. For this wrap, the intra-abdominal esophagus is mobilized to assure an adequate length. Then a stomach cuff is created by passing the fundus dorsally around the distal esophagus. Anteriorly the left and right margins of this fundic wrap are sutured together in a "floppy" way. This wrap reacts as a valve, when gastric pressure is transmitted to the distal esophagus, raising the lower esophageal sphincter pressure (PIC 87.7).

In dorsal or ventral semifundoplications, the alternative surgical aim is to correct anatomic anomaly while permitting a physiologic amount of GER.

The wrap is created similarly. A partial – 180°–270° wrap is constructed and sutured to the esophageal wall.

Fundoplication can be a life-saving procedure in those patients who have severe manifestations such as recurrent aspiration or extreme failure to thrive.

PIC 87.6 Laparoscopic view of the narrowing of the diaphragmatic crura. Note the sutures to the diaphragmatic crurae which strengthen the distal esophageal sphincter and prevent the yet-to-be prepared fundoplicate from slipping into the thorax
PIC 87.7 Laparoscopic view
of the fundoplicate.
Laparoscopic achieved
fundoplication after Nissen.
Note the 360° fundic wrap
around the distal esophagus
Antireflux surgery in the neurologically impaired carries a higher risk for wrap failure than in the neurologically normal patients. The most significant association of recurrent reflux in our own study was found with the state of preoperative dystrophy as an indicator of a catabolic status (Goessler et al. 2007).

An optimal, continuously anabolic preoperative nutritional status in NIP is important for the success of surgical treatment. This condition should be achieved by adequate enteral and/or parenteral therapy before any surgical procedure is planned (Falcão 2002; Kudsk et al. 2003).

The results of our own analysis showed that the surgical procedure results in significantly reduced GER-related symptoms and, as reported by the caregivers, a striking improvement of the quality of life (Teixeira et al. 2009) considering the often most difficult situation of caring and adequate feeding. Furthermore, an impressive reduction of agitation and auto-aggressive behavior was reported by the caregivers.

87.8.2.3 Complications

Seldom, but possible complications can be intraoperative injury to the gastric, intestine, or esophageal wall as well as lesions of liver or spleen. While performing the wrap, in cases with inadequate viability, the vagal nerve can be hurt, thus posing a risk for functioning gastric emptying. Other possible complications would be disruption of the fundoplicate, slipped fundoplicate, or to narrow wrap with postoperative need of bouginage or reoperation.

87.8.3 Anorectal Myectomy or Malone Procedure in Chronic Pbstipation

How can the surgeon help?

87.8.3.1 Anorectal Myectomy or Sphincter Dilatation

In some patients failing to correspond to the aforementioned conservative treatment of obstipation, the removal of a strip of rectal muscular wall can ease the process of defecation. This removal starts right below the dentate line and extends upwards to the level of the puborectalis muscle. The lowest part of the internal sphincter is not to be divided.

In less severe cases, anal sphincter dilatation during anesthesia can be a helpful procedure.

87.8.3.2 Malone Procedure

The Malone Procedure is easily understood when considering that it is just another way to administer an enema. In patients with neurological disorder, this can be extremely helpful not only because the enema runs through more efficiently when it is administered to Malone's site but also is easily accessible.

It consists of a special appendicostomy. The appendix is open or laparoscopically connected to the umbilicus or to the skin in right hypogastrium. The appendix is invaginated into the coecum or embedded submucosally after an incision of taenia libera. Thus, a valve mechanism is created.

If an appendectomy has been performed prior, a continent neo-appendicostomy can be created with a flap from the wall of the coecum.

The antegrade continence enema has met wide acceptance in the treatment of intractable fecal incontinence or for the use of repeated enemas in chronic intractable obstipation.

87.9 Summary Points

- In severe or distressing problems, surgery can be helpful, lead to less pain, and thus increase patients' and caregivers' quality of life.
- In dysphagia, gastral feeding via a PEG or jejunal continuous feeding via a jejunal tube can lead to a shortened duration of feeding and improvement of the nutritional status.
- In GER, a fundoplication or semi-fundoplication reduces the risk of damage to the esophagus and the pulmonary system and eases pain and reflux-associated symptoms.
- In obstipation, the Malone procedure is an easy access to perform frequent enemas.

87.10 Applications to Other Areas of Health and Disease

Dysphagia, GER, and obstipation present frequently existing conditions in neurologically impaired children. Understanding these conditions, knowledge of their signs and symptoms, especially of their tendency to lead to changes in behavior, will lead to earlier recognition and thus to earlier intervention and therapy. This poses extreme importance to caregivers, parents, nurses, doctors, and all therapists who perform training with this special group of patients.

Definitions

Dysphagia: In dysphagia, the transport of the fluid or food bolus from mouth to pharynx to esophagus is disturbed.

Gastroesophageal reflux: In GER, gastric content returns into the esophagus via a disturbed barrier function

Gastroesophageal reflux disease: Pathologic gastroesophageal reflux with damage to the esophageal mucosa or severe symptoms

Obstipation: Obstipation is characterized by chronic infrequent, difficult passage of hardened stool.

Key Facts of gastrointestinal problems in neurologically impaired patients (NIPs)

In 60% of NIPs, dysphagia is present

Up to 77% of NIPs suffer from pathologic gastroesophageal reflux, resulting in chronic pulmonary aspiration in 41%.

74% of NIPs show typical signs and problems of chronic constipation.

Due to deficits in verbal communication, the pain and discomfort resulting from these conditions is difficult to be expressed to caregivers and parents, resulting in late diagnosis and treatment.

Knowledge of signs and symptoms is mandatory to achieve earlier, timely diagnosis and therapy, thus
    improving quality of life of neurologically impaired children.

88.1 Introduction

Swallowing dysfunction is a frequent complaint in older individuals (White et al. 2008), particularly if they have underlying dementia or a neurologic conditions (Easterling and Robbins 2008). Disordered swallowing or dysphagia can be classified as a primary (i.e., stroke) or secondary problem (i.e., radiation fibrosis) with many causes and complications. Age-related changes also accompany normal swallowing (Barczi et al. 2000; Humbert and Robbins 2008).

Dysphagia can significantly affect the health, quality of life, and nutritional status of those affected. The ramifications are serious and extremely concerning, especially in the elderly population, often overwhelmed by other medical conditions and social isolation and in whom swallowing difficulty is usually neurologically mediated (Humbert and Robbins 2008). There are many challenges when caring for these individuals. Changes in mental status, deficiencies in immunologic reserve, poor nutrition, and end-of-life issues increase medical complexity (White et al. 2008). As the population over age 65 increases, swallowing disorders and their impact on quality of life are of great importance.

88.2 Epidemiology

In the United States, about 15% of community dwelling individuals over age 65 have some type of swallowing dysfunction; whereas in hospitals, the prevalence is around 13–14% (Humbert and Robbins 2008; Dray et al. 1998). In institutionalized settings, the rates rise; affecting up to half of all individuals (Easterling and Robbins 2008). Gilmore et al. (1995) evaluated 290 individuals residing in a nursing facility and demonstrated that of those eating less than half their meals, 30% had dysphagia and were unable to maintain adequate nutrition or an optimal weight with oral feeding. Groher and McKaig (1995) found that out of 740 individuals living in an institutionalized setting, 31% were receiving a modified meal. Of those studied, dementia was the most common underlying medical condition (53%) followed by stroke (25%).

88.3 Physiology of Swallowing

Swallowing is a finely regulated, intricate process that requires cortical and subcortical input from various regions of the brain to move food and/or liquid from the mouth to the stomach without compromising the airway (White et al. 2008). The physical act of swallowing can be divided into four discrete stages: oral preparatory, oral propulsive, pharyngeal, and esophageal (Matsuo and Palmer 2008). A normal swallowing videofluorographic sequence is described in Fig. 88.1.

In the oral phase, the bolus is prepared and then propelled under voluntary control with the assistance of the tongue to the back of the oral cavity and pharynx (Gonzalez-Fernandez and Daniels 2008). Once the bolus reaches the pharynx, the pharyngeal phase begins, consisting of a series of coordinated movements that drive the bolus to the upper esophageal sphincter. The esophageal stage starts as the bolus moves through the upper esophageal sphincter, esophagus, lower esophageal sphincter, and finally into the stomach. The pharyngeal and esophageal phases are not voluntarily controlled. Dysphagia can occur as a result of problems in one or more of these phases or locations (Matsuo and Palmer 2008). Key features of swallowing are detailed in Table 88.1.

88.4 Dysphagia

Many conditions can lead and/or increase susceptibility to dysphagia; making the identification process challenging, particularly in older individuals (Schindler and Kelly 2002). Nonetheless, neurologic disorders are the most common cause of swallowing disorders. Problems with sensation, muscle function/coordination, and behavioral issues are paramount and are usually related to a multifactorial rather than an isolated trigger (Easterling and Robbins 2008).

Oropharyngeal disorders are typically characterized by impairments in swallow initiation and food propulsion to the esophagus and are strongly linked to aging (Gleeson 1999; White et al. 2008). Associated findings include difficulty in chewing and manipulating the quantity of material consumed, sensation that the swallowed bolus is trapped (globus sensation), coughing, choking, dysphonia (wet-sounding vocalization), or passing of contents backwards through the nose or mouth (Schindler and Kelly 2002; White et al. 2008). Tongue pressure also declines with increased age contributing to disordered pharyngeal phase function (Schindler and Kelly 2002). In contrast, esophageal phase dysfunction is the result of esophageal pathologies which restrict or slow food entry or passage (i.e., esophageal strictures, carcinoma, and diverticulae; Dray et al. 1998).
Fig. 88.1 Normal swallowing sequence eating a soft food (banana with a barium coating) on lateral projection videofluoroscopy. (**a**) Food is placed in the mouth. (**b**) Chewing starts. (**c**) Food that is of the appropriate size and consistency is moved posteriorly while chewing continues. (**d**) Food reaches the valleculae while chewing continues. (**e**) The remaining food from the mouth is moved posteriorly. (**f**) Swallowing ensues. (**g**) Upper esophageal sphincter opens to allow food passage. (**h**) Upper esophageal sphincter closes as food continues down in the esophagus

1. Swallowing is the basic process that allows passage of food from the mouth to the stomach.
2. Swallowing can be divided into four discrete stages: oral preparatory, oral propulsive, pharyngeal, and esophageal.
3. Normal swallowing requires cortical and subcortical input from various regions of the brain to move food and/or liquid from the mouth to the stomach.
4. Failure to protect the airway during swallowing may result in aspiration.
5. Gastroesophageal reflux can result in aspiration after the swallow.
6. Dysphagia rehabilitation can improve swallowing and may allow patients to continue oral feeding.

This table lists the key factors of swallowing including swallowing phases, neural control, and major consequences of swallowing dysfunction
Fig. 88.2 Cervical spine osteophytes causing dysphagia. This lateral projection radiograph abstracted from a videofluorographic swallowing study illustrates a large cervical anterior osteophyte (bony prominence) causing mechanical obstruction of the foodway resulting in dysphagia. The dark black material is barium contrast passing by the obstruction

Orthopedic changes in the cervical spine associated with osteoarthritis (bony projections or osteophytes) cause decreased neck range of motion, thus hindering swallowing efficacy (Gleeson 1999; Achem and Devault 2005). Osteophytes in the cervical spine can push forward on the posterior pharyngeal wall creating a physical barrier to overcome in order to swallow (Fig. 88.2).

Other causes include polypharmacy and generalized age-related changes with breathing, gustation, sensation, and motor function of the tongue, face, neck, pharynx, and larynx (Gleeson 1999; Schindler and Kelly 2002; Leslie et al. 2005; Humbert and Robbins 2008).

In general, with aging, all processes operate at a reduced pace. In fact, studies have demonstrated a reduction in oropharyngeal and hypopharyngeal peristalsis along with a decline in the range of laryngeal movements (Leslie et al. 2005). Most importantly, and physiologically, vocal fold adduction secures the airway and must be coordinated with the speed of content passage in order to prevent aspiration (Fig. 88.3). If the sequencing of these processes is not timely, the airway can be compromised (Ren et al. 1993; Leslie et al. 2005).

Fig. 88.3 Aspiration of thin liquids. Lateral projection videofluoroscopy. Following administration of liquid barium contrast (*dark gray*) and a swallowing attempt, incomplete opening of the upper esophageal sphincter (*UES*) caused spillage of liquid into the pharyngeal vestibule (*open arrow*), through the vocal folds (*solid arrow*), and into the trachea (*white arrow*)
Swallowing safety is critical and is of utmost importance in preventing complications such as weight loss, fluid status deficits, malnutrition, and aspiration pneumonia (Easterling and Robbins 2008). Changes in mental capacity, diminished immune system function, and end-of-life issues amplify medical complexity and pose multiple care challenges in the elderly (White et al. 2008).

88.5 Neurologic Causes of Dysphagia

Parkinson's disease (PD), amyotrophic lateral sclerosis (ALS), multiple sclerosis (MS), dementia, and traumatic brain injury (TBI) are neurologic conditions associated with swallowing dysfunction of which stroke is the most common (Easterling and Robbins 2008; Gonzalez-Fernandez and Daniels 2008; Miller et al. 2008; Ward et al. 2007).

In fact, neurologic disease accounts for three-quarters of dysphagia during the oropharyngeal phase (Ertekin and Aydogdu 2003). Incidence in stroke varies based on assessment methods, but can be as high as 90% (Gonzalez-Fernandez and Daniels 2008; Miller and Chang 1999). Stroke patients with dysphagia have longer duration of hospitalization and more difficulties with hydration and nutrition (Gordon et al. 1987; Axelsson et al. 1989; Kidd et al. 1995). A threefold increase in pneumonia has been documented in stroke patients with dysphagia (Martino et al. 2005); the risk is even higher in patients with confirmed aspiration (Teasell et al. 1996). Reports indicate that dysphagia in this population results from impairments in muscle control, tongue function, sensation (larynx and pharynx), and cough (Dray et al. 1998).

Dysphagia is also an important consideration in TBI and is associated with the severity of brain injury, time span for cognitive recovery, tracheostomy placement, and duration of mechanical

ventilation (Ward et al. 2007). Swallowing problems in this population are multifaceted and can be a result of impaired swallow response or lingual, pharyngeal, laryngeal, or cricopharyngeal dysfunction (Mayer 2004). Cognitive and executive dysfunctions, aberrant behavior, problems with speech production, and/or comprehension along with motor abnormalities are major constraints to intervention and airway protection (Mayer 2004). In TBI, these findings may be more problematic with regard to swallowing safety than the underlying pathologic swallow (Mayer 2004).

As opposed to PD and ALS in which the disease course continues to advance, stroke and head injury-induced swallowing problems usually improve or resolve (Dray et al. 1998; Broadley et al. 2005; White et al. 2008). In stroke, dysphagia resolves in up to 90% of patients (Broadley et al. 2005; White et al. 2008).

The rate of swallowing dysfunction in those with PD is variable (18–100%; Miller et al. 2008). Solid textures have been shown to be more challenging for these individuals (Edwards et al. 1992). Disordered swallowing usually occurs as a result of problems with mastication; most evident during the oral phase (Calcagno et al. 2002; Hartelius and Svensson 1994; Merson and Rolnick 1998; Thomas and Wiles 1999).

In MS, dysphagia occurs less frequently (33–43%) and often remains unrecognized by the individual until later in the disease course, despite acknowledgment by others (Dray et al. 1998; Gonzalez-Fernandez and Daniels 2008; Pasquinelli and Solaro 2008). For this reason, identification tends to be delayed (Schindler and Kelly 2002). Features include decreased bolus movement through the pharynx and inability to trigger a pharyngeal swallow response (Dray et al. 1998). As well, dysphagia for liquids and solids may be exacerbated by low energy levels, especially in the beginning phases (Dray et al. 1998).

ALS is a progressive neurodegenerative disease that destroys both upper and lower motor neurons specifically in the brainstem and spine along with the associated pathways. Dysphagia usually occurs at later stages of the disease but can be present at onset (Higo et al. 2004). Findings include protracted swallow responsiveness to the bolus and increased upper esophageal sphincter activity and pressure (Achem and Devault 2005). Oral phase difficulties, manifests soon after onset and in many cases, leads to increased time for food consumption and inability to tolerate textures that are not softened (Dray et al. 1998).

Dementia is a common cause of dysphagia and is likely the result of disease effects superimposed on age-related alterations in sensation, muscle function, and coordination (Easterling and Robbins 2008). Horner et al showed disordered swallowing in approximately 28% of those examined with Alzheimer's disease based on videofluoroscopic assessment (Horner et al. 1994). Another reason for disordered swallowing in this population is deterioration in olfaction (Easterling and Robbins 2008). Given the interdependence of smell and gustation, food tends to be less palatable and desirable; likewise nutritional status can become compromised (Easterling and Robbins 2008).

88.6 Swallowing in the Elderly

Growing old, in general, causes a host of changes – thinning of muscles, weakness, decline in bone quality, slower nerve conduction (loss of myelin) – and can affect virtually all bodily functions (Gleeson 1999). Global features include performing activities at a reduced pace, decrement in body processes, weakness, decreased stamina, and impairments in dexterity (Gleeson 1999). Swallowing is not exempt. In fact, Robbins et al demonstrated that swallowing velocity is reduced as early as 45 years of age and will continue insidiously thereafter so that by 70 years, the changes are more pronounced than those seen at 45 years (Robbins et al. 1992).

Adaptations in deglutition that are a result of the natural aging process are termed presbyphagia (Robbins et al. 1992; Leslie et al. 2005). While dysphagia refers to disordered swallowing, the alterations whether structural, instinctive, compensatory, and/or emotional are not considered to be pathologic (Humbert and Robbins 2008). For this reason, it is becoming increasingly more important to be able to make this distinction in order to manage these individuals appropriately (Humbert and Robbins 2008).

88.7 Nutritional Implications

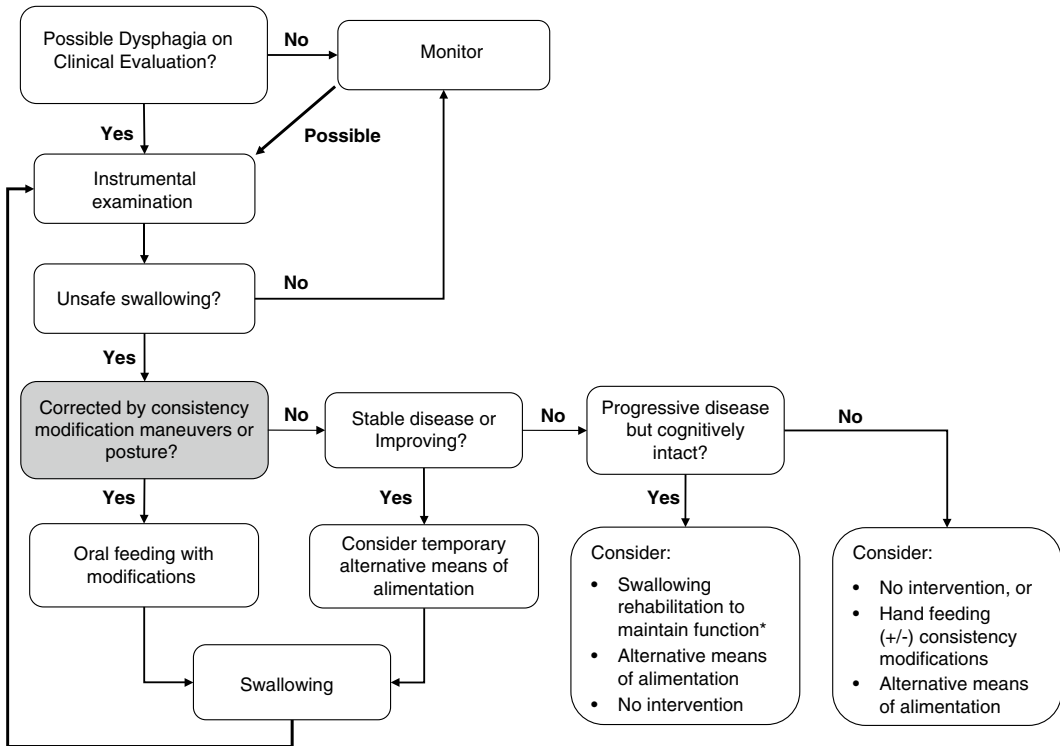
Malnutrition is one of the major sequelae of dysphagia. If not promptly recognized, the clinical outcome may be significantly compromised (Curran 1990). Malnutrition can occur either as an early complication of swallowing dysfunction or late in progressive cases (Pasquinelli and Solaro 2008). Despite the cause or time of onset of dysphagia, elderly individuals are at risk because of social isolation, medical comorbidities, decreased mobility, fatigue, poor cognition, diminished awareness, impaired vision, and inability to cook, clean, and/or self-feed (Gariballa and Sinclair 1998; Leslie et al. 2005). Side effects of medications and mood disorders can also adversely impact nutritional status by retarding appetite (Cole et al. 2000). In addition, foods may be selected based on underlying swallowing impairments. For example, in PD softer foods are preferred (Lorefalt et al. 2006).

When the body is unable to maintain adequate nourishment and meet its inherent demands, the consequences can be devastating (Pasquinelli and Solaro 2008). Insufficient intake, malabsorption, and/or abnormal output are the usual culprits (Pasquinelli and Solaro 2008). Problems with olfaction (less palatable food) and memory (not remembering to eat) are major threats to sustaining sufficient intake (Easterling and Robbins 2008). Often, this is compounded by mealtime anxiety, general noncompliance, and an unwillingness to eat, especially in cases of dementia (Biernacki and Barratt 2001). More devastating are impairments in mastication and oral control, which necessitate adjustment in oral intake consistency, albeit not without drawbacks and/or nutritional risk (Easterling and Robbins 2008). In contrast, deglutition can also be worsened by malnutrition; inflicting further regression in an already impaired but safe swallow (Leslie et al. 2005).

Nutrition is an important factor not only for preservation of overall health and vigor, but also for convalescence (Gariballa and Sinclair 1998). Managing dysphagia appropriately can facilitate feeding in a situation that can be extremely stressful and complicated for caregivers who feel compelled to keep the patient alive. Consumption can be improved by providing food that is safe (from a swallowing standpoint), pleasurable, and/or self-selected on a frequent, yet, desired basis in addition to already scheduled times (Biernacki and Barratt 2001). Supervision and/or help with feeding may also be of benefit (Pasquinelli and Solaro 2008).

88.8 Management of Swallowing Dysfunction

A systematic and individualized approach is important in the management of swallowing dysfunction. In cases of dysphagia associated with neurological dysfunction it is important to consider the nature of the disease and the patient's wishes (Fig. 88.4).

The goal of dysphagia treatment is to ensure safe swallowing while concurrently avoiding complications; most worrisome being aspiration pneumonia. As a result, food and fluid consistencies


* Exercise might be contraindicated in certain diseases such as ALS.

Fig. 88.4 Dysphagia evaluation and management of the neurologic disease patient. *Exercise might be contraindicated in certain diseases such as ALS. (From Gonzalez-Fernandez and Daniels 2008). This algorithm describes the decision-making process in evaluation, management, and treatment of dysphagia in patients with neurologic disease

may be adjusted (Vivanti et al. 2009). Although consistency modification can be important to prevent passage of contents into the airway, these dietary restrictions can be rather displeasing (Humbert et al. 2009). In fact, this can cause more difficulty at mealtimes as intake, manipulation, and movement of food and fluid becomes more time consuming; and may result in nutritional or hydration problems (Vivanti et al. 2009).

It is extremely important that clinicians are able to identify swallowing dysfunction and coordinate appropriate treatment. Swallowing can be assessed clinically, with bedside screening tools such as the 3-oz water swallow test or the Mann assessment of swallowing ability, among others (Carnaby-Mann and Lenius 2008; DePippo et al. 1992; Easterling and Robbins 2008). Instrumental examination using videofluoroscopy (VFSS), in which X-ray beams are used to detect the course of specialized, contrast-labeled food products during swallowing and/or fiberoptic endoscopy is important to determine the underlying cause of dysphagia (Schindler and Kelly 2002). Although fiberoptic endoscopic evaluation of swallowing (FEES) is superior for direct evaluation of the pharynx and larynx, it is invasive and does not allow for visualization of the oral and esophageal phases. VFSS remains the most used method (Schindler and Kelly 2002).

The mainstay of dysphagia treatment includes compensatory and rehabilitative techniques (Table 88.2). Compensatory techniques (chin-up, chin tuck, head turn, head tilt, and reclining

Table 88.2 Common interventions for dysphagia management

Feeding modifications	Postural maneuvers	Rehabilitation[a]
Thickened liquids	Chin tuck	Oral exercises
Nectar thick liquids	Head tilt	Range of motion
Honey thick liquids	Head rotation	Strength exercises
	Neck extension	Lingual exercises
Processed solids	Reclining position	Masako maneuver
Pureed		Shaker exercises
Mechanical soft		Effortful swallow
		Glottal attacks
Volume control		Pushing and pulling exercises
Teaspoon feeding		EMG biofeedback
Special utensils		

[a]Lingual exercises – Aim is to augment multidirectional tongue movements, sucking and swallowing in order to improve oral control. Masako maneuver – Tongue-holding technique designed to facilitate tongue contact with the pharyngeal wall. Shaker exercises – Strengthening exercise for muscles located below the chin to facilitate upper esophageal sphincter opening and prevent pharyngeal food retention. Effortful swallow – A strategy in which a forceful swallow is encouraged increasing the oral/pharyngeal pressures to clear the bolus, from the vallecular space. Glottal attacks – Specialized adduction exercises in which the vocal folds are powerfully drawn toward midline prior to phonation increasing laryngeal muscular tension to enhance voice control. These can improve vocal cord adduction and closure during swallowing. EMG biofeedback – Adjunct therapy that allows visualization of muscle activity, in this case, visualization of submandibular or anterior neck muscles. It can allow greater control of those muscles and facilitate rehabilitation efforts

positioning, texture modification) serve to optimize bolus movement into the pharynx by altering head and/or chin positioning or improving bolus control (Logemann 2008). Rehabilitative efforts may include exercises to increase neck mobility and strengthen oral, lingual, pharyngeal, and laryngeal muscles and neuromuscular electrical stimulation (Logemann 2008). Postural maneuvers and texture modifications should be trialed during VFSS, FEES, and therapy sessions (Schindler and Kelly 2002). Other therapeutic strategies include sensory training, which targets gustation, and temperature accommodation (Logemann 2008).

When eating is not an option, enteral feeding can be considered via percutaneous endoscopic gastrostomy tube (PEG) or, for short-term purposes, with use of oral or nasogastric feeding tubes (Easterling and Robbins 2008). The underlying disease-causing swallowing dysfunction is critical in considering nonoral feeding. In cases with dementia, feeding through PEG tubes has not been associated with improved survival, functional status, patient comfort, or reduced complications (Finucane et al. 1999). The decision to use non-oral feeding requires the input of the patient (when possible), family, treating physicians, and speech language pathologists to determine if the benefits of nonoral feeding outweigh possible complications.

88.9 Application to Other Areas of Health and Disease

Eating is essential to the operation of virtually every body system; dysphagia can have a significant impact on an individual's ability to eat and meet its nutritional needs. As previously discussed, nutritional status can deteriorate with senescence; dysphagia can have an additional detrimental effect on nutrition. Malnutrition can have a major impact on overall functioning and disease susceptibility and can

Table 88.3 Key points of dysphagia

1. Neurologic disease is one of the most common causes of dysphagia.
2. Dysphagia associated with neurologic disease can affect any of the stages of swallowing.
3. Malnutrition is one of the most serious sequela of dysphagia.
4. Physical, cognitive, and behavioral changes can impact food preferences and contribute to swallowing difficulties in the elderly.
5. Age-related changes can increase the probability of developing dysphagia after neurologic events.
6. Early comprehensive dysphagia evaluation and treatment is essential for best outcomes.

This table lists the key facts of dysphagia including cause, swallowing stages, sequela, and age-related changes

result in growth and gonadotropic hormone insufficiency, decreased insulin uptake, hypothyroidism, immune system deficits, impaired gastrointestinal absorption, osteoporosis, psychiatric disorders, altered sleep hygiene, age-related and/or nutritional anemia, muscle mass loss, and vitamin deficiencies (Lytras and Tolis 2007; Carmel 2008)

Nutritional deficiencies can impair sensorimotor and cognitive functioning (Biernacki and Barratt 2001; Espeland and Henderson 2006). Endocrinologic and immune system alterations interfere with kidney output, nutrient uptake/processing, and generalized performance (Lytras and Tolis 2007). Physical impairments amplify associated medical risks leading to decubitus ulcers and pneumonia (Almirall et al. 2000; Gariballa and Sinclair 1998; Langmore et al. 2002). Thus, it is extremely important that clinicians understand the ramifications of malnutrition, its association with dysphagia, and other medical conditions/impairments in the aging population.

88.10 Final Points

Dysphagia is common, associated with neurologic disease and senescence. Depending on the primary pathology, the course is rather variable. However, when present, the complications can be extremely devastating substantiating the need for aggressive diagnosis, management, and treatment. With a better knowledge and awareness of the swallowing process including its relation to the existing disease state, complication risk, and importance of rehabilitation services, care can be coordinated effectively to improve overall health, wellbeing, and quality of life. Key points of this chapter are described in Table 88.3.

Summary Points

- Dysphagia is a common problem, particularly in older individuals and is primarily associated with dementia and neurologic disease.
- Depending on the primary pathology, the course of dysphagia is variable.
- Malnutrition, dehydration, weight loss, and aspiration pneumonia are frequent, yet serious complications associated with disordered swallowing.
- Older individuals are at greater risk for malnutrition due to medical comorbidities, decreased functional mobility, limited self-care capacity, and social isolation; which is exacerbated by underlying dysphagia.
- Proper diagnosis, management, and treatment are essential to the care of patients with disordered swallowing.
- Dysphagia therapy focuses on compensatory techniques and exercises for neck, facial, lingual, pharyngeal, and laryngeal muscles.
- Enteral feeding should be considered when safe oral feeding is not possible.

Key Terms

Dysphagia: Disordered swallowing.

Deglutition: The act of swallowing.

Presbyphagia: Age-related, nonpathologic changes in swallowing function.

Videofluoroscopic swallow study (VFSS): X-ray beams are used to detect the course of specialized, contrast-labeled food products during swallowing.

Fiberoptic endoscopic evaluation of swallowing (FEES): Passage of a small, flexible scope attached to a camera, through the nose and into the pharynx and larynx in order to visualize swallowing during the oral and esophageal phases.

Traumatic brain injury: Intracranial injury due to traumatic forces causing injury to the head.

Chapter 89
Neuropsychological Aspects of Eating Disorders – A Focus on Diagnostic Criteria

Jennie C. Ahrén

Abbreviations

AN	Anorexia nervosa
BN	Bulimia nervosa
BED	Binge eating disorder
CSF	Cerebrospinal fluid
ED	Eating disorders
EDNOS	Eating disorders not otherwise specified
fMRI	Functional magnetic resonance imaging

89.1 Introduction

Eating disorders (ED) are severe psychiatric disturbances with psychosomatic complications, mainly affecting young women (Treasure 2008; Palmer 2008). The long-term effects of starvation and deviations in eating behaviors are devastating, from a psychological as well as a physiological perspective. ED is stated as one of the leading causes of disease burden in terms of years lost through disability or death in industrialized countries and recent work shows that they are increasing (Mathers et al. 2000; Hay et al. 2008). The mortality rate is higher than any other psychiatric disorder (Kaye et al. 2009).

The interest in neurological correlates of behavior has increased during the last decades. Modern neuropsychology assumes that intellectual capacities and cognitive processes are complex functions that depend on several interrelated systems in the brain. But even though our knowledge on neural networks and behavior has developed drastically, the classification in anatomical areas according to Brodmann in the early twentieth century is still frequently used and continually updated (Kandel 2000). The connection between brain and behavior as a key aspect of anorexia nervosa (AN) was introduced several years ago (Braun and Chouinard 1992) but new techniques have made it possible to evaluate and observe behaviors in ways that were not anticipated earlier. Functional magnetic resonance imaging (fMRI) is one of the latest methods in brain imaging, revealing patterns of neural activity and resulting in new insights on how the brain functions. fMRI is a specialized MRI scan

e-mail: jennie.ahren@chess.su.se

where the neural activity in the brain or in the spinal cord is measured by the blood flow. It has come to dominate in the field of brain imaging, mainly due to the low radiation exposure.

The relationship between behavioral changes in ED on the one hand and alterations of the brain on the other can be divided into two categories as suggested by a recent review on AN (Kaye et al. 2009). The first one is based on the assumption that there is a genetic component involved; that premorbid traits make an individual more vulnerable to develop AN. Secondly, it is possible that malnutrition causes alterations in the brain and thereby reinforces and helps to maintain the behavior.

The overarching focus of this chapter was to describe subtypes of ED from a neuropsychological perspective. In order to establish how different functions are connected to behavior, definitions of ED will be presented rather detailed. The first section is a short overview of different subtypes of ED with a short description of the etiology of these conditions and comorbid symptoms. This is followed by a brief overview on neuropsychological functions in relation to ED. Furthermore, different parts of the brain involved in eating pathology are briefly described.

89.2 Etiology of ED

The etiology of ED remains unclear, multifactorial models are best applied to increase our understanding on how different factors interact in the development of disorders such as AN and bulimia nervosa (BN). An ED does not only involve deviations in eating behavior, but typically include somatic complications due to starvation and decreased psychosocial functioning. ED often occur during adolescence, a developmentally critical period. The functions of the brain are important clues in understanding behavioral changes in puberty, the relationship between genetic vulnerability, endocrine changes, and environment are overlapping (McAnarney 2008). The rapid change in body composition during this period requires flexibility in regulating weight and hunger; this may be associated with an increased vulnerability in the appetite regulation systems, including hypothalamic structures (Connan et al. 2003). The interaction between genetic, environmental, and psychological factors is complex and demands integrated perspectives (see Fig. 89.1).

Certain personality traits have been described as typical for different types of ED. AN is characterized by high constraint, constriction of affect, perfectionism, conformity, and obsessive-compulsive behavior (Bulik et al. 2003; Kaye 2008). One of the central traits in patients with ED is the need for control. Controlling food intake is sometimes described as a way of controlling a life situation that is overwhelming (Fairburn et al. 1999). For BN impulsivity, sensation seeking and low self-esteem are often stated as predisposing traits (Fairburn et al. 1999; Jacobi et al. 2004). The comorbidity between ED and personality disorders is high. A recent methodological review states that obsessive-compulsive personality disorder shares many of the same features as AN (Lilenfeld et al. 2006). Anxiety disorders are frequent in ED patients and previous research indicates that those might be interpreted as predisposing traits (Swinbourne and Touyz 2007).

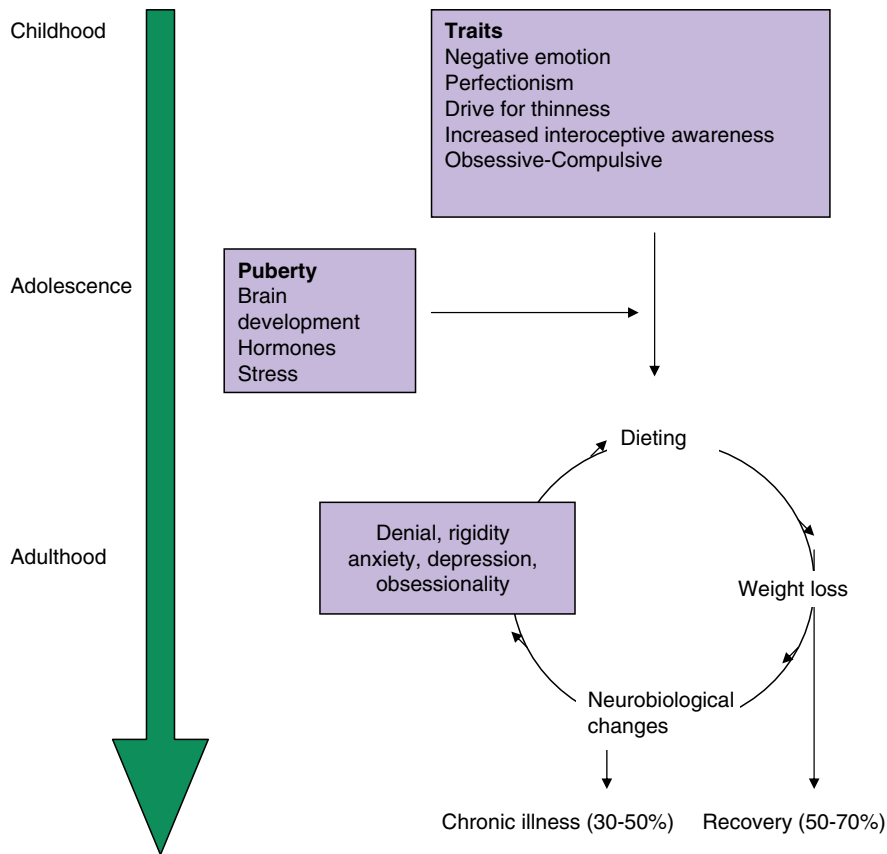
Individual differences are likely to influence cognitive style and different aspects of problem-solving strategies. Certain traits that have been described as central for ED, such as obsessive or compulsive behavior, may actually be a result of neuropsychological impairments following the disorder. Starvation leads to a range of psychosocial consequences in the same way as physiological functions are affected. The well-known work by Keys et al. (1950) studied the effects of starvation in a group of healthy men during the mid-forties in Minnesota, USA. Thirty-sex men, described as intelligent, psychologically sound, and physically healthy had their food intake strictly limited during 6 months, resulting in significant weight loss. Interestingly, most of the men showed behavioral patterns similar to those described in patients with ED. Symptoms such as increased apathy, depression,


Fig. 89.1 The time course and phenomenology of anorexia nervosa (From Kaye et al. 2009)

and increased neuroticism were reported by most of the men. Furthermore, they showed an increased interest in food and were preoccupied with thoughts of food and became more socially withdrawn. They reported impaired concentration, comprehension, and bad judgment. Six months of semi-starvation also brought on other physical and cognitive problems, such as decreased motor control, impaired sleep, and visual disturbances.

The effects of starvation or binge-eating are obviously devastating from a physiological point of view, but neuropsychological aspects provide important clues in the development and maintenance of ED and need to be further explored.

89.3 Definitions of ED

According to DSM-IV (American Psychiatric Association 1994) ED are divided into the diagnoses AN, BN, eating disorders not otherwise specified (EDNOS), and binge-eating disorder (BED). The life-time prevalence in women for full and partial AN range from 0.9% to 4.3% (Hudson et al. 2007; Wade et al. 2006). Prevalence for full and partial BN range from 4% to 7% in women (Favaro et al. 2003). For BED the lifetime prevalence is 3.5%. The corresponding figures for men are 0.9% for AN, 0.5% for BN, and 2.0% for BED (Hudson et al. 2007). Most of the studies cited in this text are exclusively based on women, and the main perspective will therefore be on women.

It is commonly stated that AN and BN are modern phenomena, but a glance in historical descriptions shows that these conditions are not new. This particularly applies to AN, or "nervous consumption," as described by the British physician Richard Morton as early as in 1689. In 1868 Sir William Gull, physician to Queen Victoria, presented his three case studies under the title "Anorexia Nervosa" and the diagnose was given its name (Pearce 2006).

The essential feature of AN is low body weight and self-starvation. Diagnostic criteria according to the American Psychiatric Association (1994) are as follows (Table 89.1).

BN mainly refers to recurrent binge-eating and compensatory actions such as vomiting or using laxatives. The diagnosis was first applied in 1979 and was included in the psychiatric classification in 1980. Diagnostic criteria for BN according to DSM-IV (American Psychiatric Association 1994) are listed in Table 89.2.

The EDNOS category is for disorders of eating that do not meet the criteria for any specific ED. This does not imply that they are less severe; several features are the same as those stated in the diagnostic criteria for the other subtypes. Examples include the following (Table 89.3).

Table 89.1 Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) criteria (APA 1994) for anorexia nervosa (AN*)*

(A) Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected)
(B) Intense fear of gaining weight or becoming fat, even though underweight
(C) Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight
(D) In postmenarchal females, amenorrhea – the absence of at least three consecutive cycles (a woman is considered to have amenorrhea if her periods occur only following hormone (e.g. estrogen) administration)

Types:
- Restricting type: During the current episode of anorexia nervosa, the person has not regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas)
- Binge-eating/purging type: During the current episode of anorexia nervosa, the person has regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas)

Table 89.2 Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) criteria (APA 1994) for bulimia nervosa (BN)

(A) Recurrent episodes of binge-eating. An episode of binge-eating is characterized by both of the following: • Eating, in a discrete period of time (e.g., within any 2-h period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances • A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
(B) Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise
(C) The binge-eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months
(D) Self-evaluation is unduly influenced by body shape and weight
(E) The disturbance does not occur exclusively during episodes of anorexia nervosa

Types:
- *Purging type*: during the current episode of bulimia nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas
- *Nonpurging type*: during the current episode of bulimia nervosa, the person has used other inappropriate compensatory behaviors, such as fasting or excessive exercise, but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas

Table 89.3 Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) criteria for eating disorder not otherwise specified (EDNOS)

(A) All diagnostic criteria for anorexia nervosa are met, except the menstrual cycle is normal
(B) All diagnostic criteria for anorexia nervosa are met, except weight is normal for height and age even after considerable weight loss
(C) All diagnostic criteria for bulimia nervosa are met, but the frequency of binges is less than twice weekly and for a duration of less than 3 months
(D) There are recurring efforts to compensate (such as self-induced vomiting) for eating only small amounts of food, but body weight is normal for height and age
(E) Regularly chewing and spitting out large quantities of food without swallowing
(F) Binge-eating disorder – regular episodes of binge eating, but with no recurring efforts to compensate, such as purging or excessive exercise

Table 89.4 Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) criteria for binge eating disorder (BED)

(A) Recurrent episodes of binge-eating: an episode of binge-eating is characterized by both of the following:
(1) Eating, in a discrete period of time (e.g., within any 2-h period), an amount of food that is definitely larger than most people would eat in a similar period of time under similar circumstances
(2) The sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
(B) Binge-eating episodes are associated with three (or more) of the following:
(1) Eating much more rapidly than normal
(2) Eating until feeling uncomfortably full
(3) Eating large amounts of food when not feeling physically hungry
(4) Eating alone because of being embarrassed by how much one is eating
(5) Feeling disgusted with oneself, depressed, or very guilty after overeating
(C) Marked distress regarding binge-eating is present
(D) The binge-eating occurs, on average, at least 2 days a week for 6 months
(E) The binge-eating is not associated with the regular use of inappropriate compensatory behavior (e.g., purging, fasting, excessive exercise, etc.) and does not occur exclusively during the course of anorexia nervosa or bulimia nervosa

BED was first described by Stunkard in 1959 (Mathes et al. 2009). Binge-eating refers to overeating to the extent that you have none or little control over your food intake. This is followed by feelings of disgust and guilt. People suffering from BED often eat alone or late at night to hide their behavior. BED is distinguished from BN by the absence of purging or compensatory after binge-eating. BED is more common in obese or overweight individuals. The criteria for BED are included for clarification of eating pathology, but will not be developed further in the text (Table 89.4).

89.4 Neuropsychological Functioning in ED

Earlier research proposes that neuropsychological deficits in various cognitive domains may serve as an underlying factor in the development of ED (Lena et al. 2004). A large study of women with AN showed that half of the patients studied had mild cognitive impairments and that more than one-third failed two or more neuropsychological tasks (Bayless et al. 2002). However, it is not clear whether malfunctions in cognitive processes are predisposing or stand as a consequence of the ED. In a review of cognitive functioning in patients with ED, Duchesne and co-workers (2004) reported that AN was associated with difficulties in executive functions, visuospatial abilities, and psychomotor

speed, BN was more connected to impairments in selective attention and executive functions. They conclude that ED in general is associated with neuropsychological dysfunctions, although there is no consensus on exactly what functions are affected. Executive functioning was studied in AN showing that performance worsened at the presence of obsessive behavior, depression, and starvation (Wilsdon and Wade 2006).

Neuropsychological assessment in a group of ED inpatients as compared with healthy controls showed that the performance level on tasks measuring attention demands and problem-solving abilities was impaired. Re-tests after recovery indicated that AN and BN were characterized by similar neuropsychological deficits, and that these malfunctions seemed to be reversible (Lauer et al. 1999). Gillbergs' research group did a follow-up study of AN patients 10 years after onset of the ED. They found no major neuropsychological deficits in the group (Gillberg et al. 2007).

It has been suggested that a weak central coherence is predisposing for AN. The focus on details and difficulties in assessing the "whole" are related to several core features of AN such as rigidity and impairments in cognitive flexibility (Gillberg et al. 1996; Tchanturia et al. 2004). Other studies have showed that people with ED have difficulties in global processing (Lopez et al. 2008a).

The inconsistency in these findings points at the need for identification of neuropsychological deficits, their relation to clinical symptoms, and potential relationships with personality and biological measures (Tchanturia et al. 2005). It also addresses issues of state versus trait, and shows the need for future studies assessing whether neurological abnormalities are predisposing in ED or if these dysfunctions are secondary to the condition (Kaye et al. 2009; Schmidt 2003).

89.5 Neurological Correlates of Eating Pathology

Recent neuro-imaging studies in AN have shown specific and persistent neuropsychological deficits associated with neurological abnormalities (Agrawal and Lask 2009). Earlier studies show that individuals with ED have reduced brain mass. Reductions in grey and white matter and increased levels of cerebrospinal fluid (CSF) has been found in both AN and BN subjects (Swayze et al. 2003; Giordano et al. 2001). A study on individuals who had recovered from their ED showed that both CSF and total volume of white and grey matter was restored (Wagner et al. 2006). This indicates that brain tissue abnormalities might be reversible after long-term recovery.

It has recently been suggested that a disconnection between structures in the brain leads to features typical for AN (Agrawal and Lask 2009). Nunn et al. (2008) suggest certain cortical structures in connection with AN; frontal, somatosensory and parietal cortices and sub-cortical amygdala, hippocampus, hypothalamus, and the striatum. Another study demonstrated a bilateral reduction in hippocampal volume in women with AN, although these were not associated with any impairments in cognitive functions (Connan et al. 2006). A medial prefrontal response to symptom-provoking stimuli was identified as a common feature in both AN and BN. Neural correlates thus indicate that there might be transdiagnostic features for ED (Uher et al. 2004).

Different parts of the brain have been put in connection with food intake. Two regions are located in the hypothalamus; one in the ventromedial part, and the other one in the lateral region. Further, the part of the cortex referred to as the insula, located in between the temporal lobe and the frontal lobe, is involved in regulation of appetite (Koh et al. 2003). Dieting is often stated as a major triggering factor in ED, even though the underlying reasons for this behavior can be multiple. The responses to taste stimuli in the insula and adjacent structures in the prefrontal cortex were stronger in the phase of fasting, especially in women as showed by Uher et al. (2006). Neurobiology of binge-eating has been compared to substance abuse behavior (Mathes et al. 2009). Dopaminergic neurons within the

nucleus accumbens, often described as an important part in the "reward system" in the brain, are stimulated by food intake. Repeated activation of this center in an attempt to relieve stress has been linked to binge-eating (Koob and Le Moal 2008).

Disgust and fear in response to images of food has been found in ED patients (Ellison et al. 1998). A study of changes in cerebral blood flow in BN patients showed that the right temporal lobe was activated after being exposed to images of the own body. This response was interpreted by the authors as caused by threat-related events (Beato-Fernandez et al. 2009). Similar results were found in a study on patients with AN. Body distortion was connected to activation of the amygdala, often stated as the brain's center for fear (Seeger et al. 2002). Uher et al. (2005) showed that patients with ED had less activity in neural networks connected to processing of female body shapes. The patients consistently rated body shapes in all categories as more aversive than did controls. This suggests an inability to evaluate the body in a realistic way. The authors conclude that illness duration most likely has an impact on body image disturbances.

89.6 Applications to Other Areas of Health and Disease

New insights into how the brain functions and develops have led to a better understanding on neurological aspects of eating pathology. This, in turn, renders new knowledge on how these conditions affect individuals, leading to better diagnoses and better opportunities for early treatment. Neuropsychological feedback has successfully been integrated in treatment suggesting that information-processing styles can be used for patients to develop a more balanced strategy in the relationship toward food and weight (Lopez et al. 2008b). For AN, impairments in cognitive flexibility have implications for rehabilitation, for example a focus on rigidity that goes beyond eating behaviors (Tchanturia et al. 2004). Older studies, pointing at deficiencies in visuospatial ability and difficulties in assessing the "whole" (Gillberg et al. 1996) are confirmed by recent work on information processing in AN strengthening the assumption that these patients often focus on details, indicating a weakness in central coherence (Southgate et al. 2008). Cognitive remediation therapy (CRT) which deals with processes rather than content of thoughts has been incorporated in the treatment of patients with AN (Agrawal and Lask 2009). Several studies on neuropsychological functions and neurological correlates of ED are currently ongoing. Insights into underlying mechanisms of disordered eating will evolve in the near future; this in turn will result in new perspectives on treatment and prevention of these severe disorders.

Summary Points

- ED are severe psychiatric disturbances resulting in impaired psychosocial functioning and physiological complications.
- AN, BN, and BED are the main diagnoses.
- The etiology of ED remains unclear; psychological, biological, and social perspectives need to be considered when assessing risk factors and clinical course.
- Neuropsychological functioning is impaired in patients with ED; chronic states of the disorder further complicate cognitive malfunctions.
- There are several inconsistencies in differences in cognitive ability between subtypes of ED and future studies need to assess how different functions in the brain are associated with deviations in eating behavior.
- The limbic system, insular cortex, and hypothalamus are the neurological structures that seem to be of most relevance in eating pathology.

Definitions

White matter (substantia alba): Composed of myelinated axons; nerve fibers.

Grey matter (substantia grisea): Tissue in the brain and the spinal cord that contains cell bodies.

Hypothalamus: Located above the brain stem under the thalamus and controls the autonomic system, endocrine, and motor functions. It also regulates food and water intake, body temperature, the sleep and wake cycle, and emotions. Involved in controlling behaviors such as hunger, thirst, sleep, and sexual response.

The insular cortex: Often referred to as the insula (the island in Latin), located between the temporal lobe and the parietal lobe. Involved in emotion, regulation of body homeostasis perception, motor control, and cognitive functioning.

Limbic system: The limbic system is often described as the center of emotions, learning, and memory. Included in this system are the cingulate gyri, hypothalamus, amygdala (emotional reactions), and hippocampus (memory).

Chapter 90
Lexical-gustatory Synesthesia and Food- and Diet-related Behavior

90.1 Introduction

Synesthesia is a multivariant condition that gives rise to fundamental differences in sensory and cognitive functions. For people with synesthesia – known as synesthetes – everyday activities such as reading or listening to music, give rise to extraordinary experiences such as colors, tastes, smells, and other sensations. The condition is characterized by the co-activation of two (or more) functions when only one is stimulated. In other words, synesthetes experience two (or more) phenomenological sensations when only one would be felt by the average person. For example, when synesthete JW hears a 370-Hz single piano note, she experiences it not only as a sound, but also as a darkish off-yellow color (Ward et al. 2006). Synesthetic sensations often feel perceptually "real," and can be phenomenologically almost identical to real-world experiences. However, they are not considered hallucinations because the synesthete is almost always aware that these perceptions are not part of the outside world. For example, synesthete JS experiences letters and digits in color (and this is known as grapheme-color synesthesia), and those colors are seen projected onto the written typeface when he reads. However, JS is fully aware that the print itself is black on white. In other words, synesthetes are aware that their sensations are produced by their own mind, although they often assume that these sensations are experienced by all people.

Synesthesia has been a curiosity to psychologists for several hundred years, although the last decade has seen a considerable explosion of interest. Over 50% of all articles written on synesthesia during the last 100 years have been written within the last 5 years alone, and interest in the condition is higher now that at any previous time (see Fig. 90.1 for a statistical history of synesthetic reports over the last century).

Fig. 90.1 History of synesthesia research. The number of research articles on the topic of synesthesia over the last 100 years, 1909–2009 (Web of Science; www.wos.mimas.ac.uk)

Very early treatments of synesthesia in the last century were hampered by the behaviorist movement in the psychological sciences which emphasized behavior over mental experience, and effectively knocked synesthesia out of scientific consciousness for almost 80 years. Public knowledge remained low, and this was compounded by the fact synesthetes rarely mention their unusual experiences, believing that everybody shares them. At the end of the twentieth century, however, improved methodologies and the advent of brain imaging (see next) re-introduced synesthesia into empirical study, and it has since found its way into the scientific main-stream. As a result, synesthesia studies no longer focus on simple tests of genuineness, as they did in the nineteenth and twentieth centuries, but instead, use a range of methodologies to reveal the complex system of cognitive, neurological, and sensory processes that underlie the condition. In turn, improvements in the public understanding of science, and the usefulness of the World Wide Web in bringing together large populations of synesthetes, have further transformed the field. Next, I give details of what has been learned about variants of synesthesia that involve food, taste, flavor, and diet, focusing particularly on *lexical-gustatory synesthesia*, the most well-understood food-related variant, in which flavor sensations are triggered by words. First, however, I give a brief overview of synesthesia, describing its prevalence, inheritance, genetic roots, and neurological basis.

90.2 Synesthesia: A Background

Synesthesia is an umbrella term that describes many different manifestations, according to the particular type of synesthetic *inducer* (i.e., triggering stimulus) and the particular type of synesthetic experience (or *concurrent*; Grossenbacher 1997). For synesthetes who experience synesthetic colors from sounds, for example, the inducer and concurrent are sound and color, respectively. However, at least 50 different variants have been attested to date (Day 2005). The most common type of synesthetic inducers are language units, such as letters, words, and digits, and these account for around 88% of all synesthesias identified in one recent large-scale assessment of prevalence (Simner et al. 2006).

For example, synesthetes may experience the word *Tuesday* as a pale yellow color, or the name *Phillip* as tasting of oranges. The fact that many variants are triggered by language units such as these shows that synesthesia can involve higher level processing, and is more than simply a "merging of the senses." Indeed, many studies now provide empirical evidence of a range of nonsensory synesthesias, involving personality constructs (e.g., Simner and Hubbard 2006), abstract word meanings (Simner and Ward 2006), and other language features (e.g., Simner et al. 2006a). Such nonsensory attributes are often acquired during childhood development (e.g., during literacy training), and this provides important evidence that synesthesia is sensitive to environmental influences. Next, we shall see that synesthesias involving taste are sensitive to the dietary environment of the synesthete.

The most common synesthetic concurrent is color, and so the most prevalent type of synesthesia overall is the involuntary and automatic pairing of linguistic units (such as days of the week, letters, and digits) with colors. In contrast, the chemical senses are comparatively *under*-represented (see Fig. 90.2, which shows the proportion of synesthesias whose inducer or concurrent involves the chemical senses, compared with other variants; Simner et al. 2006b). Nonetheless, there have been a number of reports of synesthesias involving gustation, olfaction, and flavor. Day (2005) describes a variant in which the flavor of foods in the mouth triggers the visual perception of color. These colored photisms appear in the visual field in response to the flavors of food in the mouth. Flavors in the mouth can also give rise to haptic sensations of touch against the skin. This particular variant was first described in detail by Richard Cytowic's *The Man who Tasted Shapes* (Cytowic 1993). His synesthete experiences geometric shapes triggered by flavors in the mouth, and these shapes can be felt against the skin, as well as seen in the mind's eye. As the taste develops on the tongue, the form of these shapes apparently changes (e.g., from round to pointed), and the case was verified by consistency over time, and by reduced cortical blood flow in Xenon SPECT imaging (Cytowic 1993; Cytowic and Wood 1982). Taste and flavor can also arise as the synesthetic concurrent, and one recent example has been attested by Beeli et al. (2005). Beeli and colleagues report a synesthete who experiences both pure tastants, and complex flavors when hearing musical tone intervals. For example, hearing a minor sixth interval triggers the sensation of cream, while hearing a major third triggers the pure sensation of sweetness. However, perhaps the most well-understood variants involving the chemical senses is known as lexical-gustatory synesthesia in which words trigger sensations of flavor in the mouth. This variant is described in detail in the present article, after further information about the general characteristics of synesthesia.
Fig. 90.2 Synesthesia and the chemical senses. The proportion of synesthesias identified in random sampling ($n = 500$) which involve the chemical senses as either inducer or concurrent, compared with other senses (including nonsensory variants involving language) (Data adapted from Simner et al. 2006)

Although synesthesia exists in many different forms, all variants have a number of characteristics in common. First, synesthesia appears to be typified by the consistency of the inducer-concurrent pairings over time. In other words, the type of synesthetic experience tied to any given trigger (e.g., the particular color of a letter) tends to remain constant throughout the synesthetes' life-time. For example, if the letter *a* is deep carmine red for any given synesthete, it will have been red for as long as that synesthete can remember, and will continue to be red throughout her life-time. (Some letters can have two colors, although again, these two colors are consistent over time.) This same consistency is found across synesthesias involving taste and flavor. For example, if hearing the name *Phillip* triggers the flavor of unripe oranges, it will always trigger that exact same association. The assumption of consistency has been a fundamental tool for synesthesia researchers, who use this characteristic as a diagnostic for the condition. Specifically, all studies tend to include an obligatory description of how the synesthete has been verified as genuine: the synesthete is first asked to provide her sensations for a set of stimuli (e.g., to list her colors for the letters of the alphabet), and is then given a surprise retest many months, or even years later. Synesthetes tend to perform at least 90% consistent over considerable time intervals, while non-synesthete control participants perform very badly. Controls are asked to invent comparable associations (e.g., to invent colors for letters) and then to recall these associations in a retest, which they do very poorly, even after a far shorter time interval. For example, synesthetes tested across a year will significantly out-perform controls tested after only a week, and this pattern remains even when controls (but not synesthetes) are prewarned about the retest, and even if controls are given financial incentives to perform well (Ward and Simner 2003). Due to its ubiquitous use, the test of consistency is now considered the "behavioral gold standard" test of genuineness for synesthesia (e.g., Rich et al. 2005). It may yet be possible that a small number of synesthetes have associations that are *not* consistent over time, and this may be most likely where their experiences are mediated in some way by emotion (e.g., some synesthetes report colors influenced by how they *feel*). However, there has been virtually no study of such synesthetes in the literature, perhaps given the difficulties encountered in establishing genuineness in the absence of the behavioral gold standard test of consistency.

Across all variants, synesthesia is found in at least 1 in 23 people, making a prevalence of at least 4%. Moreover, this figure is likely to be an underestimate, given that several novel variants of synesthesia have been identified since this seminal prevalence study took place (in 2005; reported in Simner et al. 2006b). For example, recently identified novel variants include *mirror-touch synesthesia*, in which tactile sensations are felt against the body in response to watching *others* being touched (Banissy and Ward 2007). The introduction of additional variants into the synesthesia literature means that a prevalence study carried out today would likely identify a yet higher proportion of synesthetes than was found previously. Another area that has seen development in recent studies is the estimate of female:male ratios among synesthetes. Older studies suggested that synesthesia was predominantly a female trait, because early methods for assessing prevalence found up to six times more female synesthetes than male synesthetes (e.g., Baron-Cohen et al. 1996). However, these studies relied on self-referral in their count of synesthetes, and it has since been shown that the self-referral methodology may artificially inflate the count for women (Simner et al. 2006b). This is because, across a range of different psychological phenomena, women are more likely to *report* atypical behavior than are men. Hence, female synesthetes may simply be more likely to identify themselves in self-report compared with male synesthetes. When prevalence was subsequently assessed without reliance on the self-referral method, approximately the same number of female and male synesthetes was found (Simner et al. 2006b). As such, the condition is likely to affect women and men in equal numbers (or perhaps women in only very moderately greater numbers; see Simner et al. 2006b).

Synesthesia is known to run in families (e.g., Ward and Simner 2005) and one recent whole genome scan of grapheme-color and music-color synesthetes found evidence of linkage to chromosomes 2q24, 5q33, 6p12, and 12p12 (Asher et al. 2009). Hence, the condition has a genetic basis which has now been identified, at least for some variants. This genetic inheritance is assumed to give rise to neuro-developmental differences in the brain maturation of synesthetes. The brains of adult synesthetes show increased structural connectivity, and this hyperconnectivity has been identified using a methodology known as diffusion tensor imaging (DTI; Rouw and Scholte 2007). The DTI technique identifies pockets of hyperconnectivity in the white matter of the brain, by tracking the movement of water molecules. Where white matter fiber bundles are more dense or more coherent, water moves in an anisotropic fashion (i.e., with restricted movement along some plane). In the brains of synesthetes, DTI imaging shows that pockets of hyperconnectivity are found in regions associated with the synesthesia. For example, synesthetes reporting colored letters showed increased connectivity (inter alia) in regions near to those implicated in the processing of letters and of colors (Rouw and Scholte 2007). Other areas implicated are those involved in the *binding* of features: i.e., areas responsible for the combing of featural information such as color and shape in the recognition of objects, for example. The role of these regions in synesthesia suggests that the condition may represent a type of *hyperbinding* – a propensity to combine features that are not present in the outside world. In addition to structural differences, synesthetes' brains also show functional differences, using functional magnetic resonance imaging (fMRI). The fMRI technique tracks oxygenated blood flow and indicates which brain regions are likely to be active in certain tasks. Studies using fMRI to identify the regions implicated in synesthetic experiences show that synesthetic sensations activate the same regions as those that support veridical perception. For example, synesthetes reporting color sensations (e.g., from graphemes) show activation in color-selective regions (e.g., human V4) when hearing or reading graphemes (e.g., Nunn et al. 2002; for a review of functional imaging data in synesthetes, see Hubbard and Ramachandran 2005). Put differently, imaging patterns showed evidence of color processing, where no color was present in the outside environment. Similar patterns are found in synesthesias involving flavor perceptions. Parslow et al. (unpublished, see Ward and Simner 2003 for report) generated fMRI data from a single lexical-gustatory (word-to-flavor) synesthete, and showed activation of Brodmann's area 43 when he listened to words (but not tones, while controls showed no such activity at all). This area is within the primary gustatory cortex, and provides strong evidence that the flavor experiences of lexical-gustatory synesthetes are, to some extent, perceptual in character.

In all imaging studies, synesthetes' patterns of neurological data are compared with those of the control participants, and these types of comparison show systematic differences in both structure and function across groups. But imaging studies have also shown differences *within* groups of synesthetes, and these differences correspond to the ways in which synesthetes experience their sensations. Dixon et al. (2004) identified a distinction between *projector* and *associator* synesthetes: projector synesthetes report that their synesthetic concurrents (e.g., colors) are experienced in a similar way to veridical perception, outside the body; for example, color may be seen superimposed onto the written type face. In contrast, associator synesthetes report that their sensations exist in "the mind's eye" only; for example, that colors are "seen" only on an "internal screen." This distinction is demonstrated not only in phenomenological reports and behavioral tasks, but is also seen in different patterns of fMRI activation. Hubbard et al. (2005) showed that both projector and associator synesthetes have significantly more activation in color-selective regions than control participants, but that projectors show most activation of all. These type of data provide neurological support for differences in the phenomenological reports of synesthetes, and validate the range of experiences they report. Next, we shall see that the same projector/associator distinction can be applied to synesthesias involving food, taste, flavor, and diet, and we turn to this subset of synesthesias now.

90.3 Lexical-gustatory Synesthesia

Previously we saw that each of the many different variants of synesthesia is characterized by the pairing of a particular type of synesthetic inducer with a particular type of synesthetic concurrent, and that taste/flavor can serve in either capacity. One of the best understood variants of the food-related synesthesias is lexical-gustatory synesthesia. In this variant, the inducer and concurrent are words and flavors, respectively. So for lexical-gustatory synesthetes, hearing, saying, or reading words gives rise to associated food experiences (Ward and Simner 2003; Ward et al. 2005; Simner and Ward 2006; Simner and Haywood 2009). For synesthete JIW, for example, the word *this* tastes of bread soaked in tomato soup, while the name *Philip* tastes of unripe oranges (Ward and Simner 2005). Equally, synesthete MM has sensations of flavor which flood her mouth whenever she hears proper names (e.g., *John* tastes of cornbread). Table 90.1 shows other examples of flavor sensations reported by lexical-gustatory synesthetes.

As in other variants of synesthesia, the condition is characterized by the consistency of inducer-concurrent pairings over time. Hence, the particular flavor associated with any given word tends to remain highly constant across the synesthete's life-time. In one extreme example, the consistency of word–food experiences of a lexical-gustatory synesthete was verified as being unchanged across almost 30 years. In this study, Simner and Logie (2007) presented a number of consistency tests to lexical-gustatory synesthete, JIW, including a retest of word–flavor associations first elicited in 1979. JIW was given a questionnaire in 2006 containing the target words from the original 1979 list in a randomized order, and was asked to write his synesthetic flavor associations, some 27 years after these had been initially elicited (by a third-party associate of JIW). JIW's performance in this task was compared with a group of ten non-synesthete age-matched controls. Control participants were given the same list of words and were asked to invent analogous associations (i.e., they were asked to pair each word with any food name of their choice). Controls were forewarned that they would be immediately retested as soon as they had generated the last of their word–taste pairings, and that they should make their associations as easy to recall as possible (e.g., if the target word were *Christmas*, they should write turkey). Controls were around 48% consistent in their immediate retest after only 10 s. JIW scored 100% consistent in his associations over 27 years. In other words, JIW significantly out-performed controls, notwithstanding the considerable difference in retest intervals. Simner and Logie concluded that JIW's performance was achieved by something other than the conscious, episodic retrieval of paired associations. Indeed, JIW reports that his score was simply the result of reporting exactly the flavors that flooded his mouth as he heard each word, and that these flavors simply do not change.

Lexical-gustatory synesthesia is rare, even within the rarity of synesthesia overall, although 10–15 cases have now been reported in the contemporary literature (Cytowic 1989; Ward and Simner 2003;

Table 90.1 Synesthetic flavors. Examples of flavor concurrents reported by lexical-gustatory synesthesia in a selection of historical and contemporary reports

Source	Inducer word	Concurrent description	Quality
Simner and Haywood (2009)	*Safety*	"Lightly buttered toast"	Food item
Simner and Ward (2006)	*Tambourine*	"Crumbly biscuit"	Food item including texture
Ward and Simner (2003)	*Jail*	"Cold, hard bacon"	Food item including texture and temperature
Pierce (1907)	*Ethel*	"A thimble on the tongue"	Texture only
Ferrari (1907, 1910)	*Alessandro*	"Taste of fried potato and smell of burnt wool"	Food items such as flavor and smell
Simner and Haywood (2009)	*Spluk*	"Yoghurt"	Food item from nonword
Ward et al. (2005)	*Beef*	"Overcooked, dried out beef"	Food item-matching inducer

Ward et al. 2005; Simner and Ward 2006; Simner and Haywood 2009) as well as four cases from historical sources (Ferrari 1907, 1910; Pierce 1907). The rareness of the condition is attested by the fact that no cases at all were found in the *n* = 500 population recruited for one recent prevalence study based on random sampling (Simner et al. 2006b), which otherwise found 38 different instances of synesthesia. This suggests that the prevalence of lexical-gustatory synesthesia is less than 0.2% of the population, and may be considerably lower. In investigating this unusual condition, we can consider in turn the nature of the concurrent experience, the nature of the inducing stimulus, and the processes by which these become associated, and we address each in turn in the following.

90.3.1   The Synesthetic Concurrent: Issues of Flavor, Food, and Taste

Previously we saw that synesthetes can be divided into projectors and associators, according to their phenomenological experience of the concurrent. We saw that projector grapheme-color synesthetes, for example, experience their colors as similar to veridical perceptions, subjectively located out in the word. In contrast, associator synesthetes see colors only in their "mind's eye," by association rather than with "real-world type" perception. The same projector/associator distinction has been made for lexical-gustatory synesthetes, who can be divided into the same two broad groups, this time according to the nature of their concurrent flavor experiences. For projector synesthetes, flavors are subjectively located in the mouth; synesthetic flavors are similar to veridical perceptual experiences and have the same reported phenomenology as those generated by food substances. For example, synesthete JIW reports that the only difference between his synesthetic flavors, and those he experiences while eating, comes from the fact that the former do not involve substances that can be rolled on the tongue. All other sensations, he reports, are phenomenologically identical (e.g., also see the subsequent part regarding texture and temperature). In a similar way, synesthete MM (Simner and Ward 2006) reports that her mouth is flooded with the taste of baked cornbread when she encounters the name *John*. In contrast, 'associator' lexical-gustatory synesthetes do not experience perceptual flavors in the mouth; instead, the food concurrent represents a type of cognitive association, a "mental link" to a food-type, which automatically enters into consciousness when the inducing word is encountered. Synesthete PS, for example, has the overwhelming notion of orange-flavored jelly when he hears, reads, or says the word *shoulder*. Although their subjective experiences differ, both associator and projector synesthetes represent the same, single type of synesthesia, with a shared cognitive basis, and with what is likely to be a shared neurological cause (see next).

In all cases of (projected/associated) lexical-gustatory synesthesia, food experiences are complex sensations, rather than generic tastes of bitter/sweet, etc. The flavors themselves are highly specific and extremely rich in detail, and the synesthetes often go to considerable trouble when describing them (Ward and Simner 2003). For synesthete JG for example, the name *Adrian* tastes of dressed salad, but not just any type of dressed salad: specifically, it is lettuce coated with Caesar salad dressing, and cannot (to her mind) be anything else. Equally, synesthete CS tastes the word *part* as a type of soup: specifically, chicken noodle soup and no other (Ward et al. 2005). Associations can incorporate temperature and texture as well as taste, and so the variant might be more properly described as "lexical-flavor" synesthesia (L.E. Marks, personal communication). For synesthete JIW for example, the word *jail* generates the experience of bacon that is cold and hard (Ward and Simner 2003), while *tambourine* is a biscuit with a crumbling texture. Some lexical-gustatory synesthetes have also reported olfactory experiences, although it is difficult to draw strong conclusions from this (Ward et al. 2005). Taste and smell are difficult to separate subjectively, and the rated intensity of taste sensations in the mouth is increased in the presence of olfactory cues (Murphy et al. 1977).
Fig. 90.3 Synesthetic flavor concurrents. Summary of synesthetic flavor associations of synesthete JIW, elicited by 1195 target words (Reproduced from Simner 2007)

However, in one historical case (Ferrari 1907) the lexical-gustatory synesthete reported that the same word triggered different food experiences in the gustatory versus olfactory domains (e.g., *Alessandro* gave the smell of burned wool, but tasted of fried potatoes). This historical report suggests that concurrents may indeed extend across both flavor and smell, and can do so independently.

Studies have shown the influence of diet and eating behavior in the nature of lexical-gustatory experiences. Analyses of synesthetic concurrents have shown that certain flavors tend to dominate, while others are conspicuous in their absence. In particular, common synesthetic flavors are for sweets (candy) and chocolate, while alcohol and other "adult tastes" tend to be absent. The synesthetic flavor concurrents of synesthete JIW are shown in Fig. 90.3, which illustrates that some flavors are present in greater proportions than others.

It is clear from Fig. 90.3 that certain food types dominate as synesthetic flavors, while others are less dominant, and studies have shown that these patterns are related to the dietary environment of the synesthete. The frequency of synesthetic flavors is correlated with the frequency with which the corresponding food is encountered in the synesthete's diet: commonly eaten foods are significantly more likely to occur as synesthetic concurrents (Ward and Simner 2003). Moreover, the dietary environment is most influential during development: synesthetic tastes are statistically more likely to reflect the diet eaten during childhood compared with adulthood. For instance, although the adult JIW is now a heavy coffee drinker, he did not drink coffee as a child, and consequently, coffee is almost entirely absent from his synesthetic flavors. Indeed, the only time it occurs is in "child-friendly" form, as coffee-flavored chocolates which he may have encountered at a young age. Ward and Simner (2003) confirmed this link between environment, development, and synesthetic experience, by administering dietary questionnaires to both JIW and to his mother; the former was questioned about foods in his current diet, and the latter, about foods in JIW's childhood diet. Both types of dietary information predicted his synesthetic flavors, although the most dominant influences came from his childhood eating patterns. Indeed, Simner (2007) points out that foods consumed during JIW's childhood are 10 times more likely to occur as synesthetic concurrents, compared with those encountered only in later life. This dominance of early foods suggests that synesthetic associations are formed during childhood development, and that they are resistant to change after adolescence. Figure 90.3 shows that a small number of synesthetic flavors are nonfoods. These include bodily inedibles such as earwax, and synthetic inedibles such as plastics. It is possible that these tastes were experienced as part of early exploratory eating behaviors in childhood.

90.3.2 The Synesthetic Inducer: Words, Phonology, and Meaning

Synesthetic flavors are triggered by words, and are influenced by phonemes (i.e., speech sounds), since similar sounding words tend to taste alike (e.g. for JIW, the words *message and college* both taste of sausage meat). Linguistic and statistical analyses show that each synesthetic flavor can be traced to a particular phoneme (or phonemes). For example, words containing the sound /k/ tend to taste of egg for synesthete JIW, and this is true whether the phoneme /k/ is spelt with a *k* (e.g., *York*), *c* (e.g., *accept*), *ck* (e.g., *chuck*), or *x* (e.g., *fax*) (Ward and Simner 2003). Some phoneme "triggers" have been shown to derive from food names. For example, for JIW, words containing the phonemes /I/, /n/, and /s/ (e.g., *prince*, *cinema*) trigger the flavor taste of mince, and the name of this food itself also contains these same three phoneme (*mince* = /mIns/). However, other phoneme relationships have less obvious roots: words containing the phoneme /f/ are significantly likely to taste of sherbet, although there is nothing in the name of this food to suggest why this particular phoneme might be important. However, the semantic associations to the word *fizz* /fIz/ may play a role, given the effervescence experienced in the mouth from sherbet food stuff, and given too, other semantic associations which are known to dictate the mappings. For example, for JIW, the word *blue* tastes "inky," the word *bar* tastes of "chocolate," and the word *newspaper* tastes of chips (French fries, which are traditionally served wrapped in newspaper in the United Kingdom). In other words, both the meaning of a word, and its sounds, can determine the nature of the synesthetic mapping between word and flavor.

It is known that synesthetic tastes can be triggered even when the synesthete is entirely unaware of how the word sounds. Simner and Ward (2006) placed lexical-gustatory synesthetes into *tip-of-tongue* states. Tip-of-tongue is the familiar experience in which a word is known but temporarily cannot be recalled from memory. This arises when the word's meaning, but not its spelling or phonemes, has been retrieved. Simner and Ward placed synesthetes in tip-of-tongue states by asking them to name pictures of uncommon objects (e.g., metronome, platypus). In tip of tongue, synesthetes began to taste the word before they could say it. One woman, for example, tasted Dutch chocolate while struggling to retrieve the word *phonograph*, which is her synesthetic flavor for that word. This study shows that synesthetic tastes can be triggered by word meaning alone, even when sound and spelling are temporarily inaccessible. Finally, synesthetes can taste foods from words they have never heard before, and from words that have no meaning at all. Simner and Haywood (2009; also Ward and Simner 2003; Ward et al. 2005) showed that synesthetes experiences tastes from nonsense words (e.g., *noik*), although these taste less intensely than real words. Figure 90.4 shows the self-rated intensity of synesthetic flavors from nonwords and real words, and illustrates the reduced strength of flavor in the former.

90.4 Applications to Other Areas of Health and Disease

Synesthesia is not recognized as a disease in any of its manifestations, but rather, as an alternative form of perception. Indeed, the widely held view is that synesthesia is something of an asset, which is known to be linked to improved memory, for example (e.g., Yaro and Ward 2007; Smilek et al. 2002). On closer inspection, however, the condition has a rather complex profile of costs and benefits, depending on the variant. In *sequence-space synesthesia*, for example, in which sequenced units such as numbers are seen projected into particular spatial arrays, synesthetes are significantly slower at certain aspects of mental calculation (known elsewhere to involve spatial processes; Ward et al. 2009). Other costs come in collateral experiences: synesthetes report a sense of malaise and discomfort when viewing perceptual objects that conflict with their synesthetic sensations. For example, a synesthete with a red letter *a* might feel discomfort when viewing the letter *a* printed in green
Fig. 90.4 Real words and nonwords. Self-rated intensity of synesthetic sensations of flavor from nonwords (e.g., noik) and real words (Data adapted from Simner and Haywood 2009)

(Callejas et al. 2007). These are fairly mild afflictions however, and overall, most synesthetes report positive experiences and even pleasure from their synesthetic sensations. One very notable exception, however, are those synesthetes who experience flavor in the mouth. Lexical-gustatory synesthete JIW, for example, has described his synesthesia as causing problems at both work and home. He has trouble concentrating during meetings or on the phone, since over half of every word he encounters every minute of every day triggers sensations of strong flavors that flood the mouth. Sometimes these flavors are distracting in their intensity, and other times they are distracting in their unpleasantness (e.g., tastes of earwax, vomit, and other bodily inedibles). Some flavors are particularly strong and persistent, and can last until overridden by a subsequent taste. For these reasons, projector lexical-gustatory synesthetes often regard their synesthesia as a source of irritation, and one that makes it difficult to concentrate. In contrast, associator lexical-gustatory synesthetes are more likely to find their experiences a source of interest of pleasure.

As in all variants of synesthesia, problems sometimes also arise in early childhood, when synesthetes first express their sensations to others, and are often met with disbelief and even ridicule (Day 2005). What is clear, however, is that synesthesias involving the chemical senses (especially in a projected form) appear in some way more noticeable to the synesthete, or more intrusive in daily life. First-person reports also suggest that taste-related synesthesias can have an impact on digestion and diet. Projector synesthetes have reported anecdotally that they encounter digestive discomfort, because their stomach is always anticipating foods that never arrive. Synesthetic tastes certainly appear to cause salivation, for example, and this may be tied to other physiological processes usually involved in food consumption. In addition, associator synesthetes have reported difficulties in maintaining a healthy weight. Associator synesthetes are constantly reminded of foods when speaking, hearing, or reading, and this, they suggest, triggers food-seeking behaviors. A common question from associator synesthetes is whether their condition has been linked to obesity, or weight-maintenance problems. However, no empirical work on this issue has yet been conducted.

Lexical-gustatory synesthesia is a condition of unique interest to neuroscientists and psychologists, but is yet to be explored in any detail by those in the dietary sciences. The gustatory and olfactory "reality" of synesthetic tastes, textures, temperatures, and odors allow us to see, in a very direct

Table 90.2   Lexical-gustatory synesthesia: key points

1	Inducer = heard, read, spoken, or subvocalized words
2	Concurrent = flavors, including taste, texture, temperature, and olfaction
3	Phenomenology = flavors are experienced either as veridical perceptions in the mouth (in projector synesthesia) or as an automatic cognitive association (in associator synesthesia).
4	Associations are automatic and cannot easily be repressed
5	Associations are highly consistent over time
6	Flavors are influenced by dietary experience, and frequently consumed foods generate the common synesthetic experiences. Childhood diet is particularly influential
7	Flavors can also include organic and synthetic inedibles, such as vomit, mucous, earwax, stones, plastics, and flowers. These were likely experienced at a young age through exploratory eating behaviors
8	Projector lexical-gustatory synesthetes report irritation, distraction, or sometimes discomfort from their experiences. Associator synesthetes report difficulties in weight maintenance

way, that the qualia of flavor perception are the result of internal processes, rather than external stimuli. Conditions such as lexical-gustatory synesthesias show us that flavor sensation is the product of a psychological reality which can be constructed in the absence of the usual external stimulation from food (Table 90.2).

Summary Points

- Synesthesia is a condition that gives rise to a merging of sensory and/or cognitive functions.
- Synesthetes experience two or more sensations when only one is stimulated.
- Synesthesia has a range of different manifestations, depending on the particular triggering stimulus (inducer) and the particular type of synesthetic experience (concurrent). The most common inducer is language and the most common concurrent is color.
- Taste and flavor can be either synesthetic inducers of synesthetic concurrents.
- The best understood variant of synesthesia involving flavor/taste is lexical-gustatory synesthesia, in which words trigger complex sensations of flavor.
- Lexical-gustatory synesthesia can produce flavor concurrents that are experienced as veridical sensations in the mouth (in projector synesthesia) or as automatic cognitive associations (in associator synesthesia).
- Synesthesia has a complicated profile of costs and benefits, although synesthesias involving tastes are most often reported as problematic.

Definitions and Explanations of Key Terms

Synesthesia: An inherited neurological condition that gives rise to the merging of sensory and/or cognitive functions.

Synesthete: A person with developmental or inherited synesthesia.

Phoneme: The minimal contrastive unit in the sound system of a language; substituting one phoneme for another changes the meaning of a word (e.g., /t/ vs /n/ because /bat/ differs in meaning to /ban/).

Grapheme: The minimal contrastive unit in the writing system of a language (e.g., *t* vs *n*).

Inducer: Stimulus that triggers the synesthetic sensation.

Concurrent: The particular sensation triggered during synesthesia, in addition to usual perceptions (e.g., in music-color synesthesia; music triggers the synesthetic concurrent of color, in addition to auditory perception).

EAT   Eating attitudes test
EDNOS   Eating disorder not otherwise specified

91.1 Introduction

Do eating disorders exist on a continuum? This question has been debated theoretically and empirically in both the clinical and scientific domains for over four decades (Gleaves et al. 2004; Polivy and Herman 1987; Williamson et al. 2005). This debate is not specific to eating disorders; rather it resonates throughout much of the past and current scientific inquiries into the nature of all psychopathology (Gangestad and Snyder 1985; Watson and Clark 2006; Widiger and Samuel 2005). Nearly 100 years ago German psychiatrist Emil Kraepelin (1913) argued that while personality dimensions were the basic underlying constructs necessary for development of any psychological disorder, mental illness itself was qualitatively distinct from ordinary human behavior.

Kraepelin's (1913) fundamental theories on the etiology and diagnosis of psychiatric disorders in the 1900s formed the foundation for the classification system later devised by the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders (DSM) first published in 1952. With the inclusion of eating disorders as a diagnostic category in the third edition of the DSM (American Psychiatric Association 1980), controversy sparked over whether eating disorders should be considered along a continuum. Many theorists argued that eating disorders were best conceptualized as existing along a continuum of severity, ranging from 'healthy normals' (no weight preoccupation) to mildly weight-preoccupied individuals (with or without disordered eating behaviors), to subthreshold eating syndromes, and finally to the more severe clinical manifestations evidenced by those meeting diagnostic criteria for anorexia nervosa and bulimia nervosa (Button and Whitehouse 1981; Fries 1977; Garner et al. 1993, 1983; Polivy and Herman 1987; Rodin et al. 1984; Striegel-Moore et al. 1986).

A continuum model of eating disorders presumes, in part, that abnormal eating is linearly related to normal eating and that differences are a matter of degree or severity. It also presumes that the individual features or symptoms of an eating disorder can be found across all groups to varying degrees, and are not specific to clinical populations. Furthermore, a continuum model assumes a range of variability in symptoms from least pathological in nonclinical populations to most pathological in clinical populations.

There are several problems with this logic however. First, weight preoccupied individuals may be on a continuum with individuals with an eating disorder with regards to the psychological symptoms, such as fear of fat, but they are not on a similar continuum with regards to the behavioral symptoms, namely, the bingeing, purging, and restricting behaviors of an eating disorder. In fact, most people who have some level of body shape/weight preoccupation are not engaged in any clinically relevant abnormal eating behaviors (Miller 2008). Second, not all abnormal eating behaviors found in clinical eating disorder populations are found among nonclinical populations. Purging behaviors are extremely rare in noneating disordered groups and found only infrequently among high risk or subclinical groups, as we will show later in this chapter. Third, not all eating disorder behaviors can be expressed on a continuum ranging from low pathology to extreme pathology. Extreme exercise, a compensatory behavior described in the DSM definition of anorexia nervosa restricting subtype, does not lend itself to a continuum very easily. Extreme exercise, a frequent and intense regimen of exercise, is not necessarily pathological. Consider elite athletes who would necessarily fall at the most extreme end of a continuum of exercise behaviors because of their profession, and yet for this very reason it would be difficult to consider this behavior to be pathological. Purging behaviors are another good example of an eating disorder behavior that does not conform to a continuum approach. At what point along a continuum would self-induced vomiting be considered normal and not pathological? Even at low frequencies, self-induced vomiting is abnormal and the distinction between normal and abnormal is very clearly drawn at the *onset* of vomiting behaviors. If purging behaviors can be classified as abnormal based on whether they are present or absent this is support for a categorical model of eating behaviors. In fact, some researchers and clinicians have disputed the notion of an eating disorder continuum all along and instead argued for fundamental differences in clinical eating disorders compared to the mild syndromes of weight preoccupation (Bruch 1973; Crisp 1965; Ruderman and Besbeas 1992). However over the last two decades, fewer research studies have been put forth in support of a discontinuous model of eating disorders. It seemed the field was making a shift toward a more continuous approach to understanding normal and abnormal eating behaviors.

More recently there have been a number of research studies using advanced statistical methods (i.e., taxometrics) which have reintroduced the notion of a categorical model of eating disorders. These studies do not contradict the prevailing theoretical perspective of an eating disorder continuum, but rather, they provide evidence for simultaneously employing a dimensional and a categorical model (Lowe et al. 1996; Gleaves et al. 2000a, b) as the two are not mutually exclusive (Wilfley et al. 2007).

Following the lead of recent taxometric studies, we present in this chapter an argument for a combined categorical-dimensional model of eating disorders. The focus of this model is on the relation between normal and abnormal populations for the *symptoms* of the eating disorder, but not the eating disorders as a whole. We propose a continuum of eating disorder thoughts (e.g., I am terrified of gaining weight, I think about vomiting after eating, I am dissatisfied with the shape of my body) and a discontinuum of eating disorder behaviors (severe and chronic restriction, vomiting, laxative abuse, bingeing, excessive exercise resulting in weight loss, etc.).

Toward this aim, we discuss three areas of eating disorder research that will (a) provide evidence to support a dimensional view of eating disorder thoughts and a categorical view of eating disorder behaviors (see Fig. 91.1); and (b) demonstrate the importance of distinguishing between psychological and behavioral symptoms in the assessment and measurement of eating disorders.
Fig. 91.1 A continuum/discontinuum model of eating disorders. What differentiates clinical from nonclinical groups is the presence of eating disordered behaviors and not extreme eating disordered thoughts. Once a person begins to engage in pathological compensatory behaviors (*broken vertical line* and *solid vertical line*) they are, in our opinion, at a subclinical or clinical level of an eating disorder

First, we discuss research indicating that many individuals (primarily females) in nonclinical populations experience the psychological symptoms of eating disorders and often at levels that closely approximate weight and shape concerns in clinical eating disorder groups. Yet the behavioral components of eating disorders are not necessarily present. In other words, it is possible to have elevated levels on the psychological criteria for an eating disorder with none of the behavioral features. Thus it seems that in nonclinical populations the psychological symptoms can present independent of an eating disorder. In contrast, while low levels of eating disorder behaviors may be present in nonclinical populations, they do not occur without psychological symptoms – suggesting that these groups may in fact be an undiagnosed subclinical or clinical population.

Second, we review recent studies that have tested the latent constructs of eating disorders using taxometric methods and draw attention to the fact that both categorical and dimensional models of eating disorders seem to fit the data, but these results vary depending on whether the targeted indicators are behavioral symptoms or psychological symptoms and also whether the composition of the sample is clinical or nonclinical.

Third, we examine the literature on treatment and recovery, and observe that behavioral recovery can often occur independent of psychological symptom recovery and recovery is most often defined by the absence of behavioral symptoms. The relevance of this literature is that it will highlight the fact that psychological symptoms of an eating disorder (i.e., the fear of fat and extreme body dissatisfaction) fail to clearly distinguish not only clinical and nonclinical populations, but also cannot clearly distinguish clinical and recovered populations.

We conclude this chapter with a summary of the implications for theory and research in the prevention and detection of eating disorders and offer recommendations for improving detection and diagnosis in epidemiological studies of eating disorders (Table 91.1).

91.2 The "Normative Discontent"

In 2004, Cash, Morrow, Hrabosky and Perry (2004), published a critical and systematic review of body image among college women and men using 22 studies – all published between 1983 and 2001. Using data from nonclinical samples they found 29% of white women, 17% of black women, and

Table 91.1 Key points in the argument for a categorical model of eating disorder behaviors

Main argument: The clinical behaviors of eating disorders are categorical ("I vomit after eating") while the cognitive/psychological symptoms are continuous ("I am terrified of being fat").

Evidence presented in this chapter:

1. Psychological symptoms of an eating disorder (body dissatisfaction, fear of being or becoming fat, or gaining weight) are present at both low and high levels in nonclinical and in clinical populations.
2. Behavioral symptoms of eating disorders are present at low and high levels in clinical populations only; when they are recorded in nonclinical samples they are accompanied by psychological symptoms of eating disorders and most likely reflect an undiagnosed subclinical or clinical subgroup.
3. Empirical studies of the latent factor structure of eating disorders show dimensional models when using psychological indicators, but categorical models when using behavioral indicators.
4. Psychological symptoms poorly discriminate between recovered and nonrecovered patients and it is the cessation of behavioral symptoms which most often defines recovery.

16% of white men reported *extreme* body dissatisfaction. Body dissatisfaction, which entails an intense disparagement toward specific body regions, as well as a general dissatisfaction with one's shape and weight (American Psychiatric Association 1994), is increasingly common among non-clinical populations and is often associated with significant psychopathology (Polivy and Herman 2002). In conjunction with the overvaluation of shape/weight and fear of fat, body dissatisfaction has been described as the most prominent risk and maintenance factor in pathological eating (Striegel-Moore et al. 1986; Polivy and Herman 2002), the most robust predictor of bulimic symptoms (Stice 2002); and the core psychopathology of both bulimia and anorexia nervosa (Fairburn et al. 2003). Yet despite the prominent role of these cognitions in clinical eating disorders, their increasing prevalence in nonclinical populations has reduced the specificity of these symptoms in identifying eating disorders in epidemiological research studies.

In the years following Cash et al.'s (2004) review of body dissatisfaction, a number of large epidemiological studies have demonstrated a similar level of discontent with weight and shape among females of varying ages. Approximately 46% of girls and 26% of boys are dissatisfied with their bodies according to recent statistics from Project EAT (Eating Among Teens), which to date is one of the largest ($N = 4746$), most comprehensive and ethnically diverse epidemiological studies of middle and high school students' eating behaviors (Ackard et al. 2007). In a review of epidemiological studies of partial syndrome eating disorders from 1980 to 2003, Chamay-Weber, Narring, and Michaud (2005) found 46–80% of adolescent girls in the United States reported intense body dissatisfaction. McVey, Tweed, and Blackmore (2004) sampled 2279 females, 10–14 years of age, from 42 Canadian schools and found 31.3% of the sample felt "too fat" and 29.3% stated they were currently trying to lose weight. Two epidemiological studies on the prevalence of disordered eating using a national Canadian sample (N=36 984), found 26% of women aged 15–24 responded "yes" to having a *strong fear* of being too fat in the past 12 months (Piran and Gadalla 2006). Extending this age range to women aged 15–65 years, Park and Beaudet (2007) found one in five women (19%) responded "yes" to the same question of having a strong fear of being too fat in the past 12 months and this fear was associated with negative self-esteem, body image preoccupation, and food obsession.

High weight preoccupation, however, is not necessarily associated with eating disorder behaviors. For example, Ackard et al. (2007) reported that 26.7% of girls and 20.4% of boys from Project EAT had severe body disparagement without any accompanying eating disorder behaviors (see Fig. 91.2). Bulik, Sullivan, and Kendler (2000) identified a subgroup of women who experienced preoccupied thoughts about weight and shape, but who had not engaged in behaviors associated with a clinical diagnosis of an eating disorder. Cooper and Goodyer (1997) found significant weight and shape concerns among 14.5% of 11–12 year olds, 14.9% of 13–14 year olds, and 18.9% of 15–16 year
Fig. 91.2 Extreme body dissatisfaction among adolescent girls and boys in the USA. These statistics are based on Project EAT (Eating Among Teens), a large (N = 4746), and ethnically diverse epidemiological study of middle and high school students' eating behaviors (Ackard et al. 2007)

olds. However, only the 15–16 year olds showed any significant presence of behavioral pathology. Miller, Vaillancourt and Hanna (2009) compared eating-disordered thoughts to eating-disordered behaviors using items from the Eating Disorder Inventory (EDI; Garner et al. 1983) in a large sample of 1816 female university students and found that several of the items that tapped extreme body dissatisfaction were endorsed by over 50% of the sample whereas items that tapped eating disorder behaviors were rarely endorsed. Further comparing thoughts to behaviors, Miller et al. found that five groups could be identified on the basis of how often women worried about their weight and body image and how often they engaged in pathological compensatory behaviors such as vomiting or extreme food restriction. The most important finding from this study was that in general, behaviors did not occur without psychological symptoms, but psychological symptoms did occur without behaviors. Figure 91.3 illustrates that a significant number of women endorsed moderate to high levels of body dissatisfaction and fears of gaining weight (41%) without endorsing any restricting, binge eating, or purging behaviors. In contrast there were no individuals who endorsed moderate or high levels of restricting, binge eating, or purging behaviors without also endorsing the psychological symptoms. And while there was a sizeable group of women who endorsed moderate to high levels of eating disorder behaviors, it was always in conjunction with a parallel endorsement of the psychological symptoms of an eating disorder. Thus, these results highlight that pathological compensatory behavior is inextricably linked to fears of weight gain and body dissatisfaction, as indicated by the *absence* of a group characterized by eating disorder behaviors without psychological symptoms of an eating disorder. Importantly, these results were replicated in a national epidemiological sample of Canadian females aged 15–34 years (N = 1,627; Miller 2008).

Other studies have reported similar results. For example, Garner, Olmsted, Polivy, and Garfinkel (1984) compared patients with anorexia nervosa to weight-preoccupied and not-weight-preoccupied women drawn from a female college sample and a female sample of ballet students. The weight-preoccupied group displayed similar mean levels of body dissatisfaction and weight preoccupation as the patients with anorexia nervosa. However, only a portion of the weight-preoccupied women were engaged in clinical eating disorder behaviors. A cluster analysis of the weight-preoccupied group revealed one group of women who were elevated on all subscales of the EDI (Garner et al. 1983) and in fact scored as high as or higher than the anorexia nervosa group on dieting and weight preoccupation, but the second cluster was elevated only on scores of body dissatisfaction, drive for

Prevalence of Eating Disorder Symptoms by Type
(Behavioral or Psychological)
Fig. 91.3 Prevalence of eating disorder symptoms by type (behavioral or psychological). These data are based on results from Miller et al. (2009). No symptoms = 13.1%; Psychological symptoms only = 41%. This includes moderate to high levels of endorsement of body dissatisfaction and fears of gaining weight; Behavioral symptoms only = 0%; Psychological and Behavioral symptoms = 44%. This group includes individuals who endorsed moderate to high levels of psychological symptoms with moderate to high levels of behavioral symptoms. Note that only 2.2% of the sample endorsed both high levels of psychological and high levels of behavioral symptoms

thinness, and perfectionism. This weight-preoccupied-only group had low scores on all other EDI subscales including the bulimia subscale which contains items pertaining to binge eating and purging (core eating disorder behaviors).

Although these results by Garner et al. (1984) suggest that eating disorder behaviors were low or absent in this second cluster of weight-preoccupied women, it is important to note that binge eating and purging do not represent all eating disorder behaviors and these women may have been elevated on other eating behaviors, such as caloric restriction leading to weight loss. Indeed, both clusters of weight-preoccupied women scored high on the drive for thinness subscale which includes eating behaviors related to dieting and/or restriction of food intake. However, it is important to keep in mind that measures of dieting do not necessarily represent or capture the caloric restriction that leads to weight loss in anorexia nervosa. The relation between dieting and restriction is addressed in more detail at the end of this section.

Garner et al. (1984) concluded that their results supported the notion that some weight-preoccupied women resemble individuals with clinical eating disorders, and are likely a subclinical variant of a clinical syndrome, but that not all weight-preoccupied women resemble eating disorder populations. In fact, Garner and colleagues (1984) were the first to point out that the pursuit of thinness is not necessarily associated with psychopathology. The main difference between weight-preoccupied women who do and who do not resemble an eating disorder population is in whether or not they engage in clinical eating disorder *behaviors*. This is difficult to establish by examining existing research because measures of eating disorder symptoms have never clearly differentiated thoughts from behaviors. Even the studies by Garner et al. do not distinguish between behavioral and psychological factors since they measured symptoms using the EDI, where thought and behavior items are mixed within the same subscale.

Eating disorder behaviors do occur in non-clinical populations, albeit at low frequencies, and in conjunction with the psychological symptoms of an eating disorder. For instance, quoting the same research studies as before, statistics from Project EAT note 9.4% of girls and 13.5% of boys engage

Table 91.2   Key features of a continuous-discontinuous model of eating disorders

1. Subclinical and clinical eating disorders are on a continuum with one another with respect to the behavioral and psychological features of an eating disorder. In other words, they are different only in degree of symptoms but not in the kind of symptoms.
2. Subclinical and clinical eating disorders are discontinuous with nonclinical populations on the behavioral criteria of an eating disorder, but continuous with nonclinical populations with respect to the psychological symptoms of an eating disorder.
3. Subclinical and clinical eating disorders are discontinuous with partially recovered and recovered populations on the behavioral criteria of an eating disorder, but on a continuum with partially recovered and recovered populations with respect to the psychological symptoms of an eating disorder.

in recurrent purging behaviors such as vomiting, laxative abuse, or excessive exercise (Ackard et al. 2007); Chamay-Weber et al. (2005) report purging behaviors (vomiting, laxatives, and diuretics) between 5% and 16%; and McVey et al. (2004) found 3.9% of their sample endorsed binge eating and 1.5% endorsed self-induced vomiting. Importantly, while studies have reported high percentages of individuals who endorse the psychological symptoms of an eating disorder without the behavioral symptoms, there are no studies that have reported high percentages (or low percentages) of individuals who are engaged in eating disorder behaviors without the psychological symptoms. We would argue that the presence of these pathological eating disorder behaviors in the samples described by Ackard et al., Chamay-Weber et al., and McVey et al. are signaling an undiagnosed subclinical or clinical eating disorder.

According to Stice, Ziemba, Margolis, and Flick (1996), the discontinuity perspective of eating disorders would be supported if research were to show that the same variables that distinguish nonclinical groups from subclinical groups fail to distinguish between subclinical and clinical populations. There is ample research evidence to support behaviors failing to distinguish subclinical and clinical populations. Subclinical and clinical groups both engage in eating disorder behaviors, and even though they may differ in the frequency with which they engage in these behaviors, current research does not support evidence of any meaningful distinction between those engaged in behaviors once a week versus twice a week (Crow et al. 2002; Garfinkel et al. 1995). In fact, the accompanying pathology of those exhibiting subclinical symptoms of eating disorders has been shown to resemble the pathology observed in individuals with a full-blown eating disorder (Garfinkel et al. 1995; Fairburn et al. 2007; Zaider et al. 2000). And, the preponderance of those meeting criteria for a diagnosis of "eating disorder not-otherwise-specified" (EDNOS; approximately 60% of cases) suggests that the frequency level of eating disorder behaviors is less critical than *the actual presence of eating disorder behaviors* (Table 91.2) (Fairburn and Bohn 2005; Fairburn and Cooper 2007; Wade et al. 2006).

91.3 The Dieting Conundrum

We have argued that the behaviors outlined in the DSM criteria for eating disorders are the behaviors that are discrete – food restriction or food avoidance, binge eating, and compensatory or noncompensatory strategies. However, how these behaviors are defined and measured are critical aspects of understanding the continuous or discontinuous nature of these symptoms. Dieting and exercising are prime examples of the difficulty in applying a categorical framework to eating disorders. Dieting and exercising are both behaviors that are not necessarily pathological although they can be and the frequency of the behavior is not a good indicator of whether this behavior is pathological. Dieting, like exercise, does not necessarily increase in pathology the more you engage in the behavior and although

it is unhealthy to be constantly going on and off of a diet, it is not pathological unless it occurs with or leads to other clinical behaviors such as binge eating, significant weight loss, or other psychological aspects such as distress, dysfunction, or disability. Dieting is considered a clinically relevant behavior for two reasons; its role as a risk factor and its potential role as a restricting feature of an eating disorder, and often the distinction between the two becomes blurred by inconsistent definitions of what constitutes a "diet."

Both prospective and cross-sectional research indicates eating disorders commonly begin with behaviors that "resemble" normal dieting (Fairburn and Harrison 2003; Jacobi et al. 2004b). In longitudinal studies, dieting is most clearly demonstrable as a variable risk factor and maintenance factor to the onset of bulimia nervosa and anorexia nervosa binge-purge subtype because of its purported relation to binge eating (Jacobi et al. 2004b; Polivy and Herman 1985). The temporal precedence between dietary restraint and the onset of binge eating supports this assumption (Patton et al. 1990, 1999).

For the restricting type of anorexia, dieting is presumed to be a forerunner to the more severe caloric restriction and starvation that produces the abnormally low body weight exhibited by those with anorexia. But dieting is not synonymous with restriction nor is it sufficient in producing the abnormally low body weight typical of anorexia nervosa. If dieting were on a continuum with the restriction characteristic of an eating disorder, rates of anorexia nervosa would be higher, especially given the prevalence of self-reported dieting. In reality, anorexia restricting type is the rarest form of eating disorder (Hoek 2006). In addition, the majority of dieters do not go on to develop an eating disorder, offering support to the role of dieting as a risk factor, rather than a symptom/feature of an eating disorder (Patton et al. 1990, 1999).

The relation between dieting and restriction in the eating disorders depends on how dieting is defined. Chronic dieting resulting in consistent caloric restriction accompanied by weight loss is consistent with clinical features of anorexia nervosa, and thus, in this sense, dieting appears to be interchangeable with restriction. Research by Lowe et al. (1996) indicates that dieting is related to eating disorder behaviors (e.g., binge eating) only when accompanied by food restriction and weight loss. In contrast, dieting practices accompanied by "normative" body dissatisfaction may lead to emotional distress, but are not indicative of eating pathology (Lowe et al. 1996). The DSM definition of anorexia nervosa does not describe which eating behaviors are considered abnormal or clinically relevant in terms of what leads to the "refusal to maintain minimally normal body weight." Weight loss is referred to loosely as the result of a reduction in total food intake and this reduction is often preceded by the exclusion or restriction of certain foods from one's diet (American Psychiatric Association 2000).

Restriction in anorexia nervosa, by definition, always includes caloric deprivation and weight loss – in comparison, dieting can mean cognitive or behavioral deprivation, with or without weight loss. Dieting is most often defined and interpreted as a method of weight control, yet it is not always associated with weight loss (Brownell and Rodin 1994). In fact dieting is a notoriously ineffective means of achieving weight loss according to some researchers because 95% of those who lose weight will regain the weight within a few years and many will gain more than they originally lost (Grodstein et al. 1996; National Institutes of Health Technology Assessment Conference Panel 1993). The term dieting is also used in reference to cognitive restraint or the desire to lose weight and for this reason it seems clear why numerous research studies have found self-reported dieting to be negatively related to actual reductions in caloric intake or weight loss (Lowe 1993). Herman and Polivy (1984) have suggested that dieters may be best characterized by their *attempts* to lose weight than by actual weight loss.

It is possible that subjective measures of dietary restraint do not correspond well with objective measures of weight loss because the dieting attempts have failed. For instance, an individual may engage in dieting behaviors by restricting food intake or lowering caloric intake during the first half of the day, and this we would consider "engaging in dieting behavior." However, if in the latter half

of the day, when the food restriction has left the dieter feeling hungry and they begin to consume more calories than if they had eaten normally throughout the entire day, this overeating in the second half of the day compensates for the lowered food intake earlier in the day and in the end, the balance of the calories taken-in is either the same or possibly more. In this case, objective measures of weight, such as daily or weekly weighing of participants or even more precise assessments of caloric intake recorded during a single meal would fail to correlate with subjective reports of dietary restraint because overall, there has not been any weight loss. This is not the same as saying the individual is not dieting. They are engaged in dieting behaviors but these behaviors have failed to result in weight loss because they were not maintained. Thus if asked to complete a measure of dietary restraint these individuals would likely score high because from their perspective they are in fact dieting. What is not being accounted (objectively) in self-report measures of dieting is whether the dieter has suc-ceeded or failed in their dieting attempts.

Restriction in anorexia nervosa is unhealthy and pathological – but dieting is not necessarily unhealthy or pathological. Dieting is a heterogeneous term that includes both healthy (eating less fat, eating more fruits and vegetables, exercising) and unhealthy behaviors (e.g. skipping meals, fasting). According to Lowe and Timko (2004) dieting is neither beneficial nor harmful, but simply ineffec-tive for most individuals in the long-term. Dieting may have beneficial effects if the purpose of the diet is to counteract a predisposition to overeat or gain weight (Lowe and Timko 2004). Studies have found long-term low-calorie diets to be effective in decreasing binge eating in obese individuals with and without an eating disorder with length of follow-up varying from 3 to 24 months post-treatment (for a review, see Stice 2002). Even in a normal weight population, Presnell and Stice (2003) found that when college students lost a small amount of weight in a weight-loss program, their level of bulimic symptoms were reduced not increased after a 3 month follow-up. Lowe and Timko (2004) state that the merits of dieting are inconclusive without first clearly defining what is meant by the term, specifying the purpose of the diet, and toward which population it is intended.

These differences between the interpretation of and consequences to dieting versus restriction suggest the two are not synonymous with one another and that despite any overlap in behaviors across those who engage in normative dieting and those who engage in clinical restriction, dieting should not be used as a proxy for restriction unless the instruments used to measure dieting take into account cognitive versus behavioral restraint in conjunction with abnormally low body mass index or measured weight loss. If the purpose is to detect restrictors rather than dieters, it is necessary to separate out the small percentage of successful dieters – 5%, from the unsuccessful dieters – 95% (Grodstein et al. 1996).

91.4 Empirical Tests of the Latent Factor Structure of Eating Disorder Symptoms

Most research on the continuous–discontinuous debate of eating disorders has come from cross-sectional investigations using cluster analysis, latent class analysis, discriminant function analysis factor analysis, and most recently, a series of taxometric investigations (see Table 91.3).

Taxometric analyses specifically test for dimensional versus categorical constructs in a dataset (Waller and Meehl 1998). A taxon is an underlying entity that drives the relations between common indicators of a disorder, and while the common indicators are dimensional, similar to a latent vari-able in factor analysis, a taxon indicates a discrete category. Thus, a taxon does not preclude dimen-sional aspects; however it does indicate a qualitative difference between its underlying construct and other constructs. The utility of this analytic technique has spurred a number of taxometric investiga-tions in the field of eating disorders over the last 5 years.

Table 91.3 Summary of empirical studies on the continuum of eating disorders

Statistical test	Description	Published studies (peer reviewed)
Cluster analysis	• Assignment of a set of observations or objects into clusters/subsets • Requires an a priori assumption of the number of clusters/subsets in order to perform the statistical test • Distance between objects used to determine assignment to clusters	Garner et al. (1993), Hay et al. (1996), Stice and Agras (1999), Westen and Harden-Fischer (2001), Williamson et al. (1992)
Latent class analysis	• Assignment of a case or subject to a group (i.e., latent class) • There is an a priori assumption that the latent variables are discrete • Conditional probabilities are used to determine the likelihood that the set of observed, discrete variables or "cases" will fall into a particular latent class • Observed variables within a class are statistically independent	Bulik et al. (2000), Duncan et al. (2007), Keel et al. (2004), Striegel-Moore et al. (2005), Sullivan et al. (1998a, b), Sullivan and Kendler (1998), Wade et al. (2006)
Discriminant function analysis	• Purpose is to predict group membership or discriminate between two or more mutually exclusive groups from a set of predictors • The dependent variable is group membership	Stice et al. (1996), Lowe et al. (1996), Franko and Omori (1999), Goldner et al. (1999), Stice et al. (1998), Tylka and Subich (1999)
Factor analysis	• Determine the number of subsets (latent factors) that a set of variables can form • Subsets are largely independent of one another • Variables within a subset are related to one another	Gleaves and Eberenz (1993, 1995), Gleaves et al. (1993), Tobin et al. (1991), Vanderheyden et al. (1988), Williamson et al. (2002)
Taxometric analysis	• Determine whether the latent structure contains a taxon/a class in addition to its underlying dimension • There is no a priori assumption about the dimensional or categorical nature of the latent structure (see description in text)	Williamson et al. (2005), Gleaves et al. (2000a, b), Tylka and Subich (2003)

91.4.1 Taxometric Analysis in Clinical Samples

Williamson et al. (2002) examined three latent features of eating disorders derived through a series of exploratory and confirmatory factor analyses; binge eating, fear of fatness/compensatory behaviors, and drive for thinness. These latent scores were then used as indicators in a series of taxometric analyses comparing individuals with clinical eating disorders to obese persons without an eating disorder and to a normal weight comparison group. Binge eating disorder and bulimia nervosa were judged to be qualitatively distinct (taxonic) from both the normal-weight comparison group and the obese comparison group. In contrast, taxometric analyses did not reveal strong support for anorexia nervosa being qualitatively distinct from normalcy (i.e., not taxonic). Excluding noneating disorder groups, Williamson et al. went on to compare the categorical versus dimensional characteristics

within the eating disorders (i.e., anorexia nervosa, bulimia nervosa, and binge eating disorder) and concluded that while there was mixed support for a categorical model of eating disorder subtypes, some of the *features* appeared categorical and some appeared dimensional. Taken together, the taxometric results reported by Williamson et al. support bingeing and purging disorders being taxonic (i.e., categorical), especially when using a mixed sample (clinical and non-clinical), while anorexia nervosa appears to be more dimensional. These findings, that certain features of eating disorders are discrete from nonclinical populations while others are continuous and certain features within the eating disorders are discrete while others are continuous, are consistent with the three existing taxometric studies conducted on eating disorder populations to date (Gleaves et al. 2000a, 2000b; Tylka and Subich 2003).

How might we interpret these findings? If we examine these results from a framework of continuous eating disorder thoughts and discontinuous eating disorder behaviors we can make clearer the inconsistencies reported across taxometric studies. Bingeing and purging disorders (bulimia nervosa and anorexia nervosa binge-purge subtype) may appear taxonic especially in mixed samples because the central characteristic of these disorders are binge eating and purging which incidentally, occur at exceedingly low base rates in nonclinical populations. Bingeing and purging are extreme behaviors that are specific to eating disorder populations; thus when comparing clinical and nonclinical groups, rates of bingeing and purging will be very high in clinical populations and very low in normal populations, increasing the likelihood of detecting a taxon.

In contrast, restricting behaviors (anorexia-restricting subtype) are often measured using dieting items (e.g., Drive for Thinness subscale of the EDI) which are common among nonclinical populations (Chamay-Weber et al. 2005). In general, when restriction is measured in terms of dieting there will be more people in both clinical and nonclinical populations who will endorse items such as, I eat diet foods, than items related to bingeing or purging, (i.e., I vomit after I have eaten). The range of restricting behaviors will be reflected by a more continuous process in taxometric analyses compared to bingeing and purging where the limited variability will result in stronger evidence for a taxon. Williamson et al. (2005) proposed a three-dimensional model that argued for binge eating being taxonic while fear of fatness/compensatory strategies, and drive for thinness were continuous. However, these results may be an artifact of including restricting items that range from somewhat normative behaviors (skipping breakfast, periods of fasting, eating diet foods) to more extreme behaviors (prolonged periods of starvation and chronic lowering of caloric intake) in taxometric studies. We suspect that if Williamson et al. were to re-specify their model by only including extreme restricting items that reflect weight loss, they may find restricting behaviors to appear taxonic. In addition, the continuous nature of this fear of fatness-compensatory strategies may be confounded by the combination of thought and behavioral items in these analyses. For example, latent factors for fear of fatness have typically combined items pertaining to thoughts (preoccupation with weight and shape) with items of behaviors (caloric limitation) within the same latent class (e.g. Keel et al. 2004). Therefore, conclusions regarding the continuous nature of restricting behaviors may be premature.

91.4.2 Taxometric Analysis in Nonclinical Samples

Taxometric analyses on noneating disordered populations can also be understood within a thought-behavior framework. Tylka and Subich (2003) examined the latent structure of eating disorders by performing taxometric analyses on a sample of 532 college women. They included items representative of nonbehavioral features of eating disorders such as body dissatisfaction, and found five distinct factors, all indicative of a dimensional solution. Specifically, taxometric analyses revealed no presence of

a taxon in the data, although importantly, Tylka and Subich did not include *any* behavioral indicators of eating disorders in their model. These authors argue that much of the opposing findings in the literature surrounding the existence of a continuous versus a discontinuous model of eating disorders results from the fact that different indicators are used by different researchers. While some researchers use behavioral indicators (binge eating, purging, restricting) with nonbehavioral indicators (interoceptive awareness, maturity fears, or body dissatisfaction), other researchers use one but not the other. When researchers utilize more behavioral indictors of eating disorders than nonbehavioral indicators, results support categorical models of eating disorders (Gleaves et al. 2000a, b; Tylka and Subich 2003; Lowe et al. 1996), whereas studies that use more nonbehavioral indicators find more evidence for dimensional models of eating disorders (Tylka and Subich 1999, 2002, 2003).

Tylka and Subich (2003) argue that bingeing and purging should not be included in research aimed at uncovering the latent structure of eating disorders because these indicators may either inflate the notion of a categorical model or mask the presence of dimensional models of eating disorders. These authors suggest that one reason for this inflation may be that some researchers classify females in their sample as clinical or nonclinical based on bingeing and purging behaviors only to turn around and use these *same* behaviors as the criterion variable. Evidence in support of a taxon in the data may be artificial because of confounding indicators with the criterion (2003). However, while Tylka and Subich suggest excluding behavioral symptoms of eating disorders, behavioral indicators are fundamental attributes of individuals with eating disorders and must be considered in the continuum debate. Evidence for both categorical *and* dimensional models in taxometric studies are not conflicting findings; they are in fact telling us something critical about the nature of eating disorders.

91.5 Psychological Versus Behavioral Symptoms in Recovery from an Eating Disorder

A number of researchers have found the rate and timing of eating disorder recovery to vary depending on the presence or absence of psychological criteria in the definition of recovery (Cogley and Keel 2003; Couturier and Lock 2006; Fennig et al. 2002; Saccoman et al. 1989; Strober et al. 1997). In general, psychological recovery occurs more slowly, extending years beyond the cessation of behavioral symptoms and as a result, rates of recovery vary depending on the length of remission studied and the variables included in definitions. Saccoman et al. (1989) found that when only the physical aspects of an eating disorder (restricting, bingeing, purging) were considered, 79% of those with anorexia in their study had recovered. Yet when the psychological criteria were examined, this recovery rate fell to 48%. Strober et al. (1997), report recovery rates based on normal weight and regular menstruation to be 86% occurring on average 57.4 months from illness onset. But in the same study, recovery based on psychological criteria was only 76%; occurring an average of 79.1 months from illness onset. Similarly, Fennig et al. (2002) found the psychosocial recovery to take on average 6 years longer than the physical (i.e., behavioral) recovery from an eating disorder.

Bachner-Melman, Zohar, and Ebstein (2006) compared women behaviorally but not cognitively (i.e., lack of body image distortion or fear of weight gain) recovered from anorexia nervosa to a group of women recovered both cognitively and behaviorally and found that the symptoms and personality profile of the behaviorally recovered group showed residual features of anorexia whereas the cognitively and behaviorally recovered were indistinguishable from controls. It seems that while behavioral recovery is critical for initial symptom remission, psychological recovery is necessary for

Table 91.4   Key differences in behavioral versus psychological recovery from an eating disorder

1. Behavioral recovery occurs earliest.
2. Recovery rates are highest when recovery is defined by the absence of the behavioral symptoms (i.e., amenorrhea, bingeing, purging, restricting).
3. Psychological recovery (the absence of extreme weight and shape overevaluation and body dissatisfaction, and fears of weight gain/being fat) occurs slowly, and takes an average of 2 years longer than behavioral recovery.
4. One-third of those with anorexia nervosa will continue to struggle with the psychological symptoms for many more years post-treatment.
5. The presence of psychological symptoms at post-treatment is the best predictor of relapse.
6. Approximately 30–50% of those with bulimia nervosa will continue to struggle with a high degree of body shape and weight concerns following treatment.

longer-term maintenance of recovery from eating disorders (Couturier and Lock 2006; see Table 91.4). In a similar study, Cogley and Keel (2003) evaluated the concurrent validity of requiring remission of "undue influence of weight and shape on self-evaluation" in defining recovery from bulimia nervosa. Three groups were compared: 31 women fully recovered from bulimia, 28 women behaviorally recovered only, and 59 matched controls. Participants completed measures of mood, anxiety, psychosocial functioning, and body dissatisfaction. Results showed no differences between matched controls and the fully recovered individuals with bulimia on any measures, while the behaviorally recovered only group showed significant pathology across all reported measures.

Of particular importance in the distinction between behavioral and psychological recovery are the findings by researchers that body dissatisfaction and overvaluation are the *best* predictors of relapse. For instance, Fairburn, Peveler, Jones, Hope, and Doll (1993) and Freeman, Beach, Davis, and Solyom (1985) found the residual level of shape concern that remained at the end of "successful" treatment was the strongest predictor of relapse among patients with bulimia nervosa. These findings are disconcerting given the high rate of shape concern remaining among individuals who have completed treatment successfully; as many as 30–50% according to some estimates (Farrell et al. 2005). Keel, Dorer, Franko, Jackson, and Herzog (2005) found similar results in their prospective study of predictors of relapse. Specifically, Keel et al. report that body image disturbance was the best predictor of relapse at 9 years post-treatment across both bulimia and anorexia, and this was across a range of relapse predictors including behavioral, psychological, and Axis I and II comorbid conditions.

The overvaluation of shape and weight appears among individuals in nonclinical populations, clinical populations, and recovered or partially recovered populations. In contrast, behaviors are absent in nonclinical groups, acutely present in clinical groups, and absent or remitted in recovered or partially recovered groups. This ongoing battle for psychological recovery across the course of the eating disorder offers support for a continuum of psychological symptoms, while disordered behaviors are more specific to the active phase of the illness where individuals are still meeting diagnostic criteria for an eating disorder.

91.6 Summary

The aim of this review was to offer support toward the notion of a combined categorical-dimensional model of eating disorders by demonstrating that it is the psychological symptoms of eating disorders that are dimensional and the behavioral symptoms that are categorical. Three areas of research were reviewed to offer support for this hypothesis: (1) eating disorder thoughts are so prevalent that they

poorly discriminate between nonclinical and clinical groups; but behaviors are excellent markers of clinical groups because they are specific to clinical populations; (2) empirical studies of the latent factor structure of eating disorders show dimensional models when using psychological indicators, but categorical models when using behavioral indicators; (3) recovery rates for eating disorders are highest when defined by the absence of behavioral symptoms and lowest when defined by psychological symptoms, as the psychological symptoms fail to distinguish recovered individuals from ill or partially recovered individuals. Now we turn our attention to the potential implications of a categorical model of eating disorder behaviors.

91.7 Clinical and Research Implications

Advancing our understanding of the continuum of eating pathology has both research and clinical implications. First, understanding the nature of the relationship between disordered eating and eating disorders advances the theoretical underpinning of eating disorder research, as classification of mental illness is at the heart of all psychiatric diagnoses and subsequent treatment protocols. Establishing valid categories for eating disorders is clinically important as it enables accurate diagnostic instruments to be used and creates standards for diagnosis which is an essential part of interpretation and communication among clinicians and researchers. Addressing the question of continuity versus discontinuity in eating disorders will inform our measurement of eating disorder symptoms in at-risk groups. Improving our measurement in epidemiological research will help reduce the number of false positives in two-stage screening studies, increasing efficiency in research protocols, reducing costs from unnecessary testing, lessen participant burden incurred by lengthy interviews, and free up valuable professional resources that can be directed toward prevention and treatment (Miller 2008).

91.8 Applications to Other Areas of Health and Disease

91.8.1 Personality and Individual Differences in Eating Disorders

It is important to highlight that we are not suggesting eating disorder behaviors are the only difference between clinical and nonclinical populations, rather we would argue in a similar vein to Crisp (1965) and Bruch (1973), and as well Polivy and Herman (1987), that those with eating disorders have fundamental differences in personality, such as ego deficits or psychopathology such as comorbid mood disorder. Engaging in bingeing, purging, or restricting behaviors is both mentally and physically painful, and individuals who are able to engage in these aberrant behaviors likely have underlying personality features and/or brain neurochemistry that are very different from those who do not engage in these behaviors (e.g., Miller et al. 2006). For instance, impulsivity, characteristic of some individuals with bulimia (Bulik et al. 1995) may facilitate the disinhibited eating of a binge. Impulsivity is also associated with substance abuse, and the use of alcohol or other drugs among individuals with eating disorders has been linked to frequency of binges and purges (Davis and Claridge 1998). Concurrent mood disorder may facilitate restricting or bingeing behaviors as a result of changes to brain neurochemistry which can disrupt appetite and/or feelings of satiety (Halmi and Sunday 1991). Additionally, neuroticism has been linked to

symptoms of eating disorders (Davis and Claridge 1998; Miller et al. 2006), with the suggestion that fear of weight gain may enable the highly neurotic individual to restrict food intake more easily than those low in neuroticism.

Herman and Polivy's (1984) boundary model of eating behavior postulates that individuals with anorexia and bulimia have a lowered hunger boundary that allows them to tolerate greater degrees of food deprivation than normal. This "hunger boundary" may explain the ability of individuals with anorexia (restricting type) to maintain consumption at such stringent levels (Herman and Polivy 1984). Although, the authors concede that the degree to which this hunger boundary is imposed by environmental factors, a genetic predisposition, or both, is uncertain.

Individuals who purge may differ from those who restrict because of biological differences that may drive the choice of a particular coping mechanism (the behavior) in dealing with the shared psychopathology (the thoughts: overvaluation of shape and weight) of eating disorders. Thus, it may be beneficial to focus future research on understanding potential executive functioning deficits associated with the behaviors of an eating disorder. For example, reward deficiency syndrome has been put forth as an explanation for other compulsive, impulsive, and addictive disorders based on a common genetic deficiency in the dopamine D_2 receptor (Blum et al. 1996). Dopamine is not the only neurotransmitter implicated in the reward system, serotonin is also known to be involved (Blum et al. 1996) and there is already evidence to support the role of serotonin imbalances in the eating disorders, bulimia nervosa in particular (Steiger et al. 2003).

91.8.2 Measurement of Eating Disorders

Early identification of eating disorders is critical, as mortality rates increase linearly with duration of illness (Hoek 2006) and recovery rates are linked to symptom severity at the onset of treatment (Bulik et al. 1999). In general, recovery rates vary depending on the definition of recovery, but a substantial number of individuals, especially those with anorexia, will remain chronic, will relapse following treatment, or will continue to struggle with psychological symptoms (e.g., fear of weight gain, body dissatisfaction) despite achieving physical recovery (Strober et al. 1997). For these reasons, prevention and early detection is critical.

Detection of undiagnosed cases of eating disorders in community settings requires epidemiological research; however the usefulness of such studies is highly dependent on valid measures and clearly defined indicators of risk. The most rigorous method for identifying cases of eating disorders in those who do not seek medical treatment voluntarily is to employ a two-stage screening study. A two-stage screening study is considered the gold standard in epidemiological research on eating disorders (Jacobi et al. 2004a). The two-stage screen typically involves administering a questionnaire, such as the Eating Attitudes Test (EAT-26) to a large sample of at-risk individuals (e.g., adolescent females) and identifying the subset of individuals who score above a predetermined threshold on the questionnaire (e.g., 20 or above on the EAT-26) to return for the second stage of the screen: the clinical interview.

The EAT is the most widely used screen for detecting eating disorders in epidemiological studies, although its primary use has been for the detection of cases of anorexia nervosa, and not bulimia nervosa (Jacobi et al. 2004a). However, relying on screening measures such as the EAT for detecting undiagnosed eating disorders will be costly and time consuming because most existing screening tools, including the EAT, contain far more normative weight concern items and dieting items than clinically significant eating disorder behaviors and, importantly, it is the eating disorder behaviors which are pathognomonic. The presence of clinically significant eating

disorder behaviors is the best indicator that the disorder is present. While the psychological symptoms of an eating disorder will always identify all true cases of eating disorders, as long as the criteria for an eating disorder continues to be partially defined by disturbances in body image and fears of weight gain, the psychological symptoms will also identify far too many noncases because these symptoms are normative. Given the level of normative discontent concerning weight and shape in our culture it would seem prudent to examine other measures of eating pathology that have higher specificity.

91.9 Conclusion

The goal of this chapter was to introduce a new framework for understanding the inconsistent findings surrounding the continuous or discontinuous nature of eating disorders. If we scrutinize the many studies conducted over the last few decades that have found evidence in favor of either discrete or continuous models of eating disorders, we see that the competing results of most studies are accurate when we consider the sample composition and the features of eating disorders that were examined. Tylka and Subich (2003) argued that many studies find evidence for categorical models when using behavioral features of eating disorders and more dimensional models emerge when using nonbehavioral features; we would agree since it is precisely the behavioral features that appear categorical, not the disorder itself. When researchers examine clinical populations, or mixed samples, there will be more evidence for categorical models because the clinical groups will have more of the disordered behaviors, whereas a truly nonclinical population will mostly be comprised of a continuum of disordered thinkers who do not engage in disordered behaviors (Table 91.5).

Regardless of whether future research supports or refutes the notion of taxonicity in disordered behaviors and/or continuity in disordered thoughts, it is important to highlight the significance and utility of examining the role of psychological symptoms in the eating disorders independently from the behavioral symptoms, as this distinction holds both practical and theoretical implications to the field as a whole.

Table 91.5 Population-based screening of eating disorders: best practice recommendations

1. Body dissatisfaction, fear of fat, or other items that tap body image concerns (psychological symptoms) should not be used to screen for the presence of anorexia nervosa or bulimia nervosa given the high level of endorsement made by women who do not have an eating disorder. Screening with these psychological symptoms will result in too many false positives (poor specificity).

2. If psychological symptoms are included in population-based screening for eating disorders, an extreme threshold should be used as a cut-off point and they should be measured and interpreted separate from the eating disorder behaviors (i.e., psychological symptoms should have a separate total score form behavioral symptoms).

3. Items that assess pathological eating behaviors such as purging (vomiting, laxative/diuretic abuse), restricting, and binge eating will have the highest diagnostic accuracy (specificity and sensitivity).

4. Dieting questions should not be used to assess restricting behavior (e.g., "I eat diet foods" from the EAT-26) because it will increase the number of false positives.

5. Binge eating questions should include a definition of a "binge" (e.g., see the Eating Disorder Examination Questionnaire; EDE-Q) and be assessed along with relevant compensatory behaviors, given the subjective interpretation of binge eating. In the absence of compensatory behavior, such as in binge eating disorder, screening for binge eating behavior will be very difficult and requires further research to understand how and what to ask when screening for binge eating behaviors.

Summary Points

- Addressing the issue of a continuum of eating pathology is necessary because understanding the nature of the relation between disordered eating and eating disorders advances the theoretical underpinning of eating disorder research (i.e., the etiology of eating disorders).
- Understanding whether eating disorders exist on a continuum or are discontinuous informs our measurement and assessment of eating disorders.
- It is important to distinguish between psychological and behavioral symptoms in the assessment and measurement of eating disorders. Screening instruments that rely heavily on psychological indicators of eating disorders will yield high rates of false positives and will suffer a trade-off of low specificity for high sensitivity.
- The presence of clinically significant eating disorder behaviors is the best indicator that an eating disorder is present. It is the behavior which is pathognomonic.
- Because weight discontent is so normative in western culture, it is problematic, from a measurement standpoint, to use these normal features to screen for an abnormal syndrome.
- Screening for eating disorders using instruments such as the EDI or the Eating Attitudes Test (EAT-26) will be a costly and time-consuming effort because both measures contain far more normative weight concern items and dieting items than clinically significant eating disorder behaviors.

Definitions and Explanations

Behavioral symptoms: The behavioral symptoms of an eating disorder, as outlined in the DSM-IV include: a) binge eating and b) compensatory behaviors to prevent weight gain such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.

Psychological symptoms: The psychological symptoms of an eating disorder, as outlined in the DSM-IV include intense fear of gaining weight or becoming fat, even though underweight; disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, denial of the seriousness of the current low body weight.

Population-based screening: Population-based screening for eating disorders is a method used in epidemiological research where a large and ideally representative sample of people from a nonclinical population are administered a short survey or interview that identifies those who are at-risk of having an eating disorder. Those who are determined to be at-risk are followed up with a more in-depth interview to determine whether they meet diagnosis for a clinical eating disorder.

Sensitivity: Sensitivity of an eating disorder measurement tool or diagnostic test refers to how good a test is at correctly identifying people who have an eating disorder.

Specificity: Specificity of an eating disorder measurement tool or diagnostic test refers to how good a test is at correctly identifying people who do not have an eating disorder.

Taxon: A taxon is like a category; it indicates a discrete group where in/out classifications can be made. However, the presence of a taxon does not mean there is no dimensional aspect. With eating disorders, if eating behaviors were taxonic, they could be measured on a continuum. The discrete part of the behavior comes when we compare clinical to nonclinical populations. A "dimension' of eating behaviors exits in the clinical sample (dimensional aspect), but this dimension is only present in the clinical sample; it is unique or specific to the clinical population. This is the categorical aspect.

92.1 Introduction

Obesity, defined as an unhealthy amount of body fat, is a major health problem that is increasing dramatically worldwide; figures show a current overweight and obesity prevalence of more than 60% in the USA and UK, and comparable statistics are documented for many other countries in the world (Wadden et al. 2002). In 2005, it was estimated by the World Health Organisation (WHO) that at least 400 million adults were obese and 1.6 billion people of over the age of 15 were overweight (World Health Organisation 2009). WHO further predicts that by 2015, about 2.3 billion adults will be overweight and more than 700 million will be obese. WHO refers to these figures as the obesity epidemic.

The ultimate cause of obesity and overweight is an energy imbalance between calories consumed and calories expended. The main reasons for the energy imbalance are a shift in diet towards increased intake of energy-dense foods that are high in fat and sugars and decreased physical activity. Highly palatable energy-dense foods are widely available and difficult to resist. However, not everybody grows obese, so some people are better able to handle the temptations of the current environment than others. Understanding how people handle temptations is necessary to develop prevention strategies or to strengthen interventions for obesity. Why are some people better able to resist the "toxic" environment than others?

A difference between normal eaters and overeaters might be related to the automatic responding of one's body to appetitive cues as a consequence of learning. Overeating is associated with increased

A. Jansen (✉)

e-mail: a.jansen@maastrichtuniversity.nl

cue reactivity, that is, increased appetitive responding to food cues (Jansen 1998; Jansen et al. 2003; Jansen et al. 2008). When overeaters are confronted with a diverse range of tasty food cues that are predictive of food intake – like the smell, taste, and sight of palatable high calorie foods – they show increased appetitive or cephalic phase responding, like salivation and the release of insulin, followed by increased food intake (Jansen 1998; Jansen et al. 2003; Wardle 1990; Woods 1991). Cephalic phase responses are responses that prepare for food intake: the greater the appetite, the more intense the response (Powley 1977). Signals that cause the cephalic phase response originate in the cerebral cortex, amygdala, and hypothalamus and are transmitted to the stomach. The cephalic phase or appetitive responding is believed to be experienced as an urge to eat, making it more difficult for people to refrain from eating. As a consequence, healthy eating in a "toxic" environment is much easier without than with these appetitive responses. Learning theory states that appetitive responses decrease and extinguish when exposure to foods remains *systematically* unreinforced, that is, when palatable high-calorie foods are seen or smelled but not eaten. In other words, being able to resist palatable high-fat food temptations and maintaining a regular and healthy diet even if exposed to the "toxic" environment, leads to a decrease and eventually extinction of the automatic urges to eat, which in turn makes it easier to refrain from eating high-fat foods for a longer period of time. In contrast, dieters who intermittently or always give in to the urge to eat, keep reinforcing the learned appetitive responding, ending up in increasingly stronger urges to eat the highly palatable foods (Jansen 1998). In the present chapter, it is argued and demonstrated that food cues might elicit almost reflex-like irresistible food cravings that could sabotage a healthy diet. It will also be shown that there are ways to decrease the abnormal food cue reactivity and overeating and it is suggested that cue exposure with response prevention should be used more often in the treatment of overeating.

92.2 Cue Elicited Eating

The intake of food activates physiological responses. A large number of studies show that the physiological responses brought about by food intake, e.g. insulin release, blood sugar increase, and salivation, can be brought under the control of any stimulus predictive of food intake, like odors, time of the day, eating-related situations, seeing, smelling, tasting, and even thinking of food (see for an overview Jansen 1998; Siegel 1972; Woods 1991). Any time food is ingested, there is an opportunity to associate the food with cues that are present at the time (Bouton et al. 2006; Havermans et al. 2007). The place where the food is eaten, the people with whom it is eaten, the food preparing rituals, the smell and taste of the foods – they may all become signals for eating and when this happens, classical conditioning occurs (see Fig. 92.1).

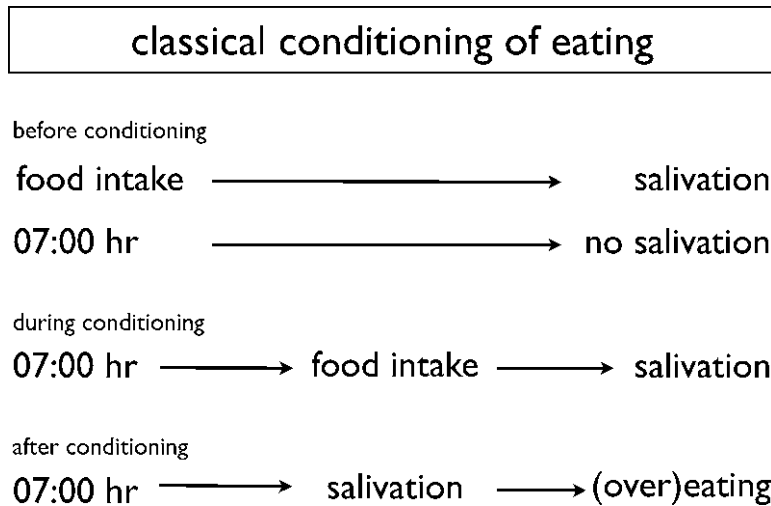
The conditioned responses (CRs) prepare the organism for food intake and contribute to the body's internal homeostatic regulation. Food intake may, in terms of classical conditioning, be considered an unconditioned stimulus (US), whereas its metabolic effects are unconditioned responses (URs). Cues that reliably signal food intake, such as the sight, smell, and taste of food, or even the context in which one eats, may start to act as conditioned stimuli (CSs) that easily trigger cue reactivity (CRs). In short, it is theorized that cues that are (nearly) always and almost exclusively present at the time of eating will, in the long run, acquire the ability to *predict* the eating and its effects. One might think of both proximal cues, e.g., the sight, smell, and taste of the food, intake rituals such as the preparation of food, and interoceptive cues (e.g., affective states or typical palatable food-related cognitions), but also distal cues like context cues (e.g., the room where usually is eaten, time of eating). From the very moment that these cues reliably signal food intake and classical conditioning occurs, the cues or conditioned stimuli (CS) acquire the ability to elicit special food intake related


Fig. 92.1 The classical conditioning model of (over)eating. Any time food is ingested, the food intake is associated with the cues that are present at that time. For example, when breakfast is always eaten at 07:00, this time will be associated with food intake. At the moment 07:00 is a reliable predictor of food intake, the time alone elicits responses that prepare for intake, like salivation

responses in the organism, like insulin release, blood sugar decrease, and the subjective experience of food cravings or appetite. These responses are calledCRs or cue-reactivity. It is assumed that food cravings or appetite reflect the subjective experience of these learned responses (Jansen 1998).

The acquired responses (CRs) might have specific features. Deutsch (1974) showed that an initially neutral taste cue is able to elicit a glycometabolic effect in rats after pairing the taste with glucose administration in a classical conditioning paradigm; the rats learned that sugar would come and when they tasted the formerly neutral taste, they prepared for the glucose with a preparatory decline in blood sugar. In the same way, rats learned to respond with a decline in blood sugar to a placebo after they were repeatedly injected with glucose. Conditioned hypoglycemia was also demonstrated in dogs and humans after injections with intravenous glucose (Overduin and Jansen 1997; Overduin et al. 1997). Conversely, after repeated intravenous injections of insulin (which are usually followed by a decline in blood sugar level), rats learned to respond with a rise in blood sugar level to a placebo (Siegel 1972, 1983). Also eating behavior can be triggered by cues that were systematically associated with food consumption: rats that had already eaten till satiation were found to eat again when exposed to a tune that was previously associated with food consumption (Weingarten 1983). More recently, it was found that rats consumed significantly more (less palatable) chow when exposed to context cues that were earlier paired with the intake of highly palatable foods (Boggiano et al. 2009). Various context cues were used, e.g., different types of bedding or wallpaper. Boggiano et al. concluded that context-cues associated with palatable food intake might drive overeating in rats, even in sated rats and even when a less-preferred food (chow) was used in the test phase. The authors also report that the cue-conditioned overeating was quickly learned and appeared to be particularly strong when the taste of a palatable food was used to make cue-associations.

In humans, it has been found that the mere anticipation of food and sham feeding (i.e. the sight, smell, taste, chewing, or swallowing of food without it entering the gastrointestinal tract) as well as cognitive processes (such as the thought of food or even hypnotic suggestion of food) elicit responses which prepare the organism for the digestion of food, such as insulin release and salivary responses (Mattes 1997; Nederkoorn and Jansen 2002; Nederkoorn et al. 2000; Power and Schulkin 2008; Powley 1977; Rodin 1985).

In sum, it is well documented that exposure to food cues evokes cephalic phase responses. The cephalic phase responses gear up the body and serve the efficient use of nutrients. The classical conditioning model of food intake states that, after systematic association of cues (CS) and food intake (US), the cues will reliably signal the food intake effects. The moment the cues are good predictors of eating, they acquire the ability to elicit physiological responses that prepare for intake and are called cue reactivity. Appetite or craving is the subjective experience of cue reactivity. A main prediction flowing from this cued eating model is that the CRs or cue reactivity increase the likelihood of food intake and easily leads to overeating.

92.3 Cue Elicited Overeating

Imagine that you are in a wedding party: in that situation you will definitely eat more than when you are at home on a weekly day. Presumably, you will also eat more than you need to: you overeat. Overeating is quite normal; many people overeat once in a while, depending on the context or situation. But there are also people who do overeat on a regular basis, almost habitually. They will gain weight and might become overweight or obese. Some other people, mostly young females, are frequent binge eaters. Binge eating refers to the eating of an objectively large amount of food in a discrete period of time, while experiencing a loss of control over intake (APA 1994). Mostly, palatable high-calorie foods are eaten during a binge and the food usually is stuffed into the mouth. Binge eating occurs in the (sub)clinical eating disorders Bulimia Nervosa, Anorexia Nervosa, and Binge Eating Disorder (APA 1994), and it is also been found to occur in about 12% of a normal female population sample (Bruce and Agras 1992) as well as 15–50% of the obese participating in weight-control programs (Marcus et al. 1985). The obese usually do not compensate for the extra calories that they eat during a binge, whereas the underweight and normal weight binge eaters do compensate by e.g. self-induced vomiting, use of laxatives, exercising, and dieting.

The most frequently mentioned triggers of binge eating are negative emotions – like feeling depressed, hopeless, worried and dissatisfied – and appetitive cues that elicit craving – like the sight, smell, and taste of highly preferred foods (Jansen et al. 2008). Tasting or smelling palatable foods, being in a low mood, anxious or emotionally upset, thinking of eating; all these binge precursors could, hypothetically, be conditioned to the excessive intake of food. After systematic association of these cues with binge food intake, the cues reliably signal the food effects. The moment the cues are good predictors of intake, they will elicit physiological responses that are subjectively experienced as craving or appetite, which almost reflexively increase the likelihood of overeating.

This model hypothesizes that classically conditioned associations between cues that predict food intake and actual eating behavior are stronger in overweight than in normal-weight children since parents of overweight children more frequently prompt their children to empty their plate and overweight children show higher external eating styles, meaning that their intake is more often triggered by food cues like seeing or smelling food. Both increase the probability that a food cue is followed by food intake, which strengthens the bond between cues and intake and makes smell and taste more predictive of intake in overweight than in normal-weight children. In line with the model it was found that overweight and normal weight 8–12 year old children ate comparable amounts when they were not tempted by food cues (Jansen et al. 2003). However, when they were tempted by cues that signal eating, like the smell and taste of highly palatable foods, the overweight children overate. They ate more in response to food cues than without, whereas the normal weight children did the opposite: they ate less in response to food cues than without these cues. Cue reactivity (salivation) was related to food intake but only in the overweight children: they showed a highly significant correlation between

Table 92.1   Key points of cued overeating

1. The intake of food activates physiological responses
2. When food intake systematically is preceded by internal or external cues, classical conditioning occurs
3. During confrontation with the cue that predicts food intake, the body anticipates eating
4. Cues predictive of food intake are for example the smell, taste, and sight of palatable foods
5. These food cues bring about responses that prepare for intake, like salivation and the release of insulin
6. The anticipative appetitive responding increases appetite or the urge to eat
7. The anticipative appetitive responding increases intake

This table lists the key points of cued overeating including the required systematic association between cue and food intake that leads to a process of classical conditioning. Being confronted with a cue that predicts eating prepares the body for food intake by anticipative appetitive responding

caloric intake and salivary flow after food cue exposure ($r = 0.62$), whereas this relation was almost absent in the normal-weight group ($r = 0.05$).

The abovementioned study shows that overweight children eat normal amounts when tempting food cues are lacking. But when they are tempted by the taste or intense smell of palatable food, they fail to regulate their intake. This vulnerability to cued overeating in overweight children might follow from a learned association between the tempting cues and increased intake. The cue-elicited salivary response of the overweight sample was significantly related to their increased intake. Clearly, the cues elicited reactivity-related overeating in the overweight sample and not in the normal-weight sample, a finding that supports the idea that classically conditioned associations between cues that predict food intake (smell, taste) and actual eating behavior are stronger in overweight than in normal-weight children (Table 92.1).

92.4 The Role of Mood and Restraint

Risk factor models for eating disorders have put forward that negative mood states are key triggers of overeating in samples with eating disorders (Stice et al. 2008). In some recent studies, eating disorders were subtyped along dimensions of negative affect and these studies showed that increased negative affect signaled a stronger vulnerability to disinhibition (Stice et al. 2008). In our lab, we showed that a specific state-trait interaction facilitated overeating: the high negative affect overweight/obese subtype was more vulnerable to overeating in the presence of a disinhibiting cue (negative mood induction or food exposure) than the overweight/obese subtype that was low in negative affect (Jansen et al. 2008). The data show that individual differences might play a critical role in the way overweight/obese people handle the temptations of the current "toxic" environment: negative affect makes it more difficult for the overweight/obese to resist modern temptations (see Fig. 92.2).

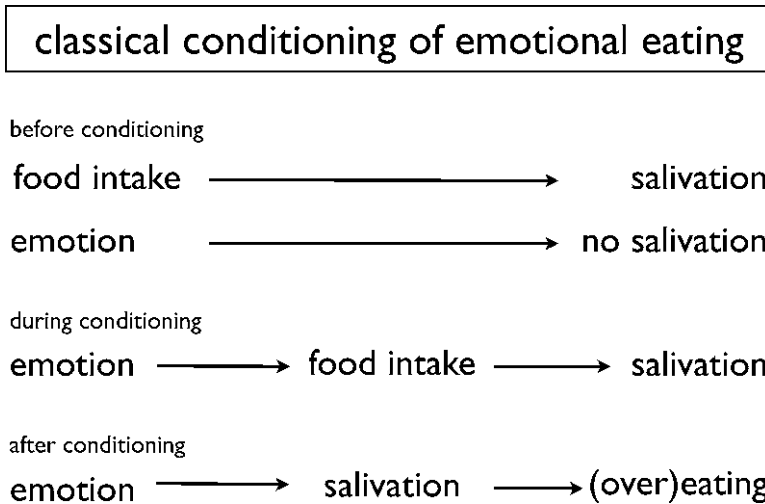
Another trait that plays a role in the way people handle toxic temptations is restraint. Restrained eaters try to restrict their intake, mostly because they want to lose weight. But a substantial part of the restrained eaters usually alternates between restrained and overeating episodes: a very common eating pattern is that in the absence of tempting food cues, the so-called restrained eater succeeds in resisting highly palatable high calorie foods until a cued overeating episode announces itself. It should be noted that such an eating pattern facilitates classical conditioning: deprivation in the absence of cues and eating large amounts of high calorie palatable foods (strong USs) within a limited and specific range of cues (CSs) implies that the contingency between CS and US, and thus classical conditioning, will be strong (Bouton et al. 2006). Strong conditioning is reflected in strong CRs or cue reactivity including appetite or craving. Experimental studies indeed show that dieters overeat after exposure to cues that typically predict food intake, like tasting a priming dose (appetizer


Fig. 92.2 The classical conditioning model of emotional eating. If snack foods are always eaten when emotionally upset, feeling upset will be associated with snack food intake. At the moment being emotionally upset is a reliable predictor of snack food intake, the emotion alone elicits responses that prepare for intake, like salivation

or preload; see for a classic experiment Herman and Mack 1975) and in other studies it was found that they overeat after mere exposure to the smell of binge food (e.g., Jansen and van den Hout 1991). The exposure to food cues (tasting, eating, or smelling the food) elicited a strong desire to eat in people that tend to alternate overeating and restrained eating.

92.5 Successful Dieting

Some dieters never overeat and they might be called successful dieters. Although it is not precisely clear how many people are successful in dieting, it is estimated that about 20% of the obese are capable of reducing to a normal weight and to maintain this reduced weight for at least a year (Wing and Phelan 2005). It is however not at all clear why some people are better able to stick to their diets for a long period of time in the context of a "toxic" environment than others. Successful dieters report to especially refrain from eating palatable high calorie fat foods; they say they are strict dieters who eat little fat and show little variety in their diets (Gorin et al. 2004; Raynor et al. 2005; Wing and Hill 2001). The classical conditioning model of cued overeating would predict that if exposure to tasty high fat foods remains unreinforced in successful dieters, this will lead to the extinction of cue reactivity (including craving) during confrontation with the cues. The extinguished cue reactivity makes it easier to maintain one's diet. In line with the cued overeating model, decreased salivary responding during exposure to palatable high fat food cues was found in postobese successful dieters, whereas unsuccessful obese dieters showed increased salivary responding during exposure to the same cues (Jansen et al. 2009). It was proposed that strict dieting extinguishes cue reactivity. In its turn, the extinction of cue reactivity will make dieting easier (see Fig. 92.3). Strict dieting is however quite difficult for many dieters, especially in the beginning of the dieting, and it might take much time before learned cue reactivity is extinguished. There are also dieters who do not expose themselves to high calorie foods but avoid them, for example because they only consume diet shakes for

Fig. 92.3 The relation between the way of dieting, food cue exposure, food cue reactivity, and extinction or the success of dieting. If exposure to tasty high fat foods remains unreinforced this will lead to the extinction of cue reactivity and makes dieting easier

Fig. 92.4 The relation between the way of dieting, food cue exposure, food cue reactivity, and extinction or the success of dieting. If the dieter avoids the exposure to tasty high fat foods, this will not lead to an extinction of cue reactivity and sabotages dieting

periods of time. They are expected to remain cue reactive, which makes it more difficult for them to maintain the lost weight (see Fig. 92.4). It was further argued that the extinction of cue reactivity is necessary for successful dieting. Dieters that avoid highly palatable food cues, like the dieters that follow a specific shake-diet or another limited diet, do not enable their cue reactivity to extinguish. Likewise, in dieters who intermittently keep overeating high-calorie high-fat palatable foods, cue reactivity will not disappear because the CS is followed repeatedly by the US, which makes it difficult to learn that the CS does not predict the US anymore (see Fig. 92.5). For successful dieting and a reduction of overeating it seems necessary that dieters enter a vicious circle of strict dieting and decreased cue reactivity (see Fig. 92.3). Dieting appears to be difficult. Can we help overeaters to decrease cue reactivity, to facilitate dieting? (Table 92.2).

Fig. 92.5 The relation between the way of dieting, food cue exposure, food cue reactivity, and extinction or the success of dieting. If the dieter intermittently overeats on tasty high fat foods, this will not lead to an extinction of cue reactivity and sabotages dieting

Table 92.2 Key points of successful dieting

1. When the body anticipates eating and prepares for consumption, appetite or the urge to eat is intense
2. When the cues are not followed by eating, the anticipative appetitive responding decreases and appetite or the urge to eat as well
3. After a series of nonreinforced exposures to the cues without eating, the cues do not predict eating anymore
4. When cues do not predict eating anymore, they will stop eliciting preparatory responses
5. Successful dieters confront themselves with the cues that predict food intake without eating
6. The preparatory responses in successful dieters are extinguished making it easier to refrain from foods

This table lists the key points of successful dieting including the required extinction of the systematic association between cue and food intake. Being confronted with a cue without eating extinguishes the anticipative appetitive responding and makes dieting easier

92.6 The Reduction of Cue Reactivity

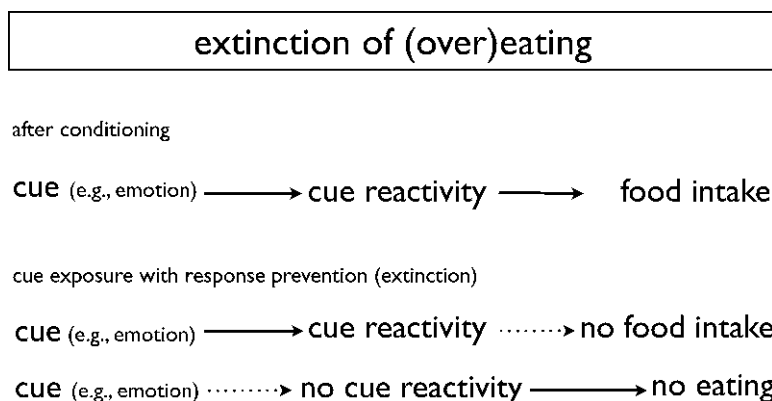
The classical conditioning model of overeating states that cue reactivity follows from probabilistic CS (cues)–US (overeating) contingencies. Cues will elicit craving as long as they are reliable predictors of food intake or, to put it differently, as long as the CSs are systematically reinforced by the US. The model predicts that craving will extinguish when the CS–US bond is broken. This bond will be broken by prolonged and repeatedly nonreinforced exposure to the cues that predict overeating (CS). Strict dieting in the current "toxic" environment is a form of continuous nonreinforced exposure to palatable food cues. However, many dieters try to avoid the palatable food cues in order to make it easier to keep their diets. The toxic environment is however everywhere, so they will never succeed in always avoiding palatable food cues. The link between cues that indicate that overeating is forthcoming and the actual overeating might be eliminated by cue exposure with response prevention. During cue exposure with response prevention the subject is exposed to the craving-eliciting highly palatable food cues and eating is prevented. Individually customized sets of highly palatable food cues are the best to use; the more likeness the cues have to the favorite foods, the better the reactivity is. This means for the exposure to food cues, that all of the cues and contexts that play a part in the overeating should be included in the most perfect exposure: the exposure takes place at the customary overeating spot and with the most favorite foods for overeating. Special attention must be paid to


Fig. 92.6 The extinction of overeating through cue exposure with response prevention. The emotional eater is exposed to the emotion (e.g., by inducing emotions) and responds with cue reactivity including a strong desire to eat the foods (or craving). But the emotional eater is prevented from eating. After several sessions of exposure with response prevention, the emotion is no longer predictive of overeating. The cue reactivity including the desire for eating or craving is extinguished

moods and thoughts that accompany the overeating. For many overeaters, negative moods are important cues that elicit craving; inducing a negative mood might magnify the urge to eat. The goal of the exposure is to elicit a strong craving for the palatable high-calorie food. The overeater touches the food, feels around in it, grabs it, holds it to the nose and smells it – but never eats; the CS–US bond will be broken. Craving will increase until it is experienced as almost irresistible. But if the exposure lasts long enough, the craving for food will slowly die down despite all attempts to keep it as strong as possible; CRs (cue reactivity and craving) will extinguish (see Fig. 92.6).

Pilot studies show that cue exposure with response prevention elicits craving – the craving typically increases gradually until it is high, and then it extinguishes slowly in patients with bulimia nervosa (Jansen et al. 1989; Jansen et al. 1992; Toro et al. 2003; Martinez-Mallén et al. 2007). Extinction was found both within and between the exposure sessions (cue reactivity started lower each session). The exposure was not only highly effective in the reduction of cue reactivity and craving, also the binge frequency of the bulimia nervosa patients decreased significantly.

Another study was, however, less positive (Bulik et al. 1998; Carter and Bulik 1994). It was examined whether the effectiveness of short cognitive behavior therapy (CBT) could be increased through adding food cue exposure with response prevention. All bulimia nervosa patients were first treated with eight sessions of CBT, and then eight exposure sessions followed. The exposure did not improve the results of the short cognitive behavior therapy. However, CBT was already extremely effective; an 80% reduction of binge eating was reached and 40% of the sample was abstinent, i.e. did not binge eat anymore. These excellent results touch the sore spot; the cognitive behavior therapy reached a ceiling effect – the design of the study did not permit the exposures to be successful.

All in all, the positive findings from pilot studies suggest that cue exposure might be an effective treatment for binge eaters. Note, however, that although the data are promising, they were derived from pilot studies with small subject samples. The only large controlled clinical trial that was published is not positive about the contribution of cue exposure with response prevention to CBT in the treatment of binge eating. We pointed to several methodological shortcomings of that study. Further, as far as the authors know, the effects of cue exposure are yet only documented for bulimia nervosa patients. It remains to be seen whether nonbinging overeaters will also benefit from cue exposure with response prevention.

Apart from the extinction of cue reactivity that is strived for by the cue exposure to highly palatable food cues, the olfactory stimulation during the exposure to palatable food cues might have induced

olfactory sensory-specific satiety. A short period of olfactory stimulation (i.e., smelling) produced decreased pleasantness of the smell of the food, which is called olfactory sensory-specific satiety (Rolls and Rolls 1997). Thus, smelling foods may induce satiety. It was suggested by Jansen et al. (2003) that overeaters and people that show a tendency to overeat are characterized by a slowing down of the sensory-specific decrease in neural activity. Indirect evidence for this idea is given in studies on the extinction of craving in binge eaters; binge eaters show increased craving after they started smelling binge foods (without eating it), and the highest of their craving is after about 20 min, after which craving gradually declines. In normal eaters the highest of craving is reached earlier and craving extinguishes more rapidly.

Relating these findings to the cue reactivity model, it might be hypothesized that tasting or intense smelling of palatable food works as a prime that elicits cue reactivity especially in overeaters who are used to eat after being confronted with these cues. Normal eaters show sensory-specific satiety responses to the highly palatable foods. Note that the priming cues will elicit reactivity as long as they are reliable predictors of intake. The model predicts that the cue reactivity will lead to overeating until the cue–intake bond is broken by prolonged and repeated nonreinforced exposure to the cues. During cue exposure, the participant is exposed to the cues (smell, taste) and prevented from intake, leading to reduced reactivity and craving (Jansen 1998). Cue exposure with response prevention might be a promising new treatment intervention for overeaters. It might help to reduce cue reactivity and craving more quickly compared to when one is merely strict dieting. Thus, the first blow is half the battle; a successful start of the diet that frees the body of its cue reactivity will make dieting easier and more successful.

92.7 Applications to Other Areas of Health and Disease

The learning model of excessive consumption was originally formulated for addictive behaviors; many studies showed that the craving and substance intake of addicts is cue-controlled. Cue exposure with response prevention seems to be a useful therapy for addictive behaviors as well (see e.g., Havermans et al. 2007). Cue-elicited overeating might also be present in some anorexia nervosa patients, suggesting that cue exposure with response prevention is indicated for anorexia nervosa as well. Therapists are however strongly advised against using cue exposure with response prevention in anorexia nervosa. A main characteristic of anorexia nervosa is the low body weight and cue-induced (over)eating might be a mean to consume at least some calories. As long as they are underweight, anorexia nervosa patients should not be treated with strategies that do decrease intake.

92.8 Conclusions

The present model of cued overeating states that cues that reliably signal highly palatable food intake, such as the sight, smell, and taste of highly palatable foods, or even the context in which the overeating takes place, may start to act as conditioned stimuli that trigger cue reactivity and craving. It is assumed that learned cue reactivity increases the probability of overeating. Numerous experiments demonstrated that overeaters specifically overeat after confrontation with cues that predict the intake of highly palatable foods.

It was further argued that the extinction of cue reactivity is necessary for successful dieting. Dieters that avoid highly palatable food cues, like the dieters that follow a specific shake-diet or another limited diet, do not enable their cue reactivity to extinguish. Likewise, dieters who intermittently keep eating high-calorie high-fat palatable foods will remain cue reactive. Only dieters who expose themselves to highly palatable food cues without eating them are expected to show the desired

extinction of cue reactivity. This might however take a long time. The extinction of cue reactivity can be accelerated by cue exposure with response prevention. There have been a number of pilot studies suggesting that cue exposure with response prevention is an effective intervention to reduce binge eating. Whether cue exposure with response prevention is also suitable for overeaters and an effective intervention to reduce overeating remains to be studied.

Studies on the effectiveness of food cue exposure should be encouraged. Is cue exposure with response prevention beneficial to help people reaching the extinction sooner? Will dieting become easier and more successful when cue exposure with response prevention sessions are introduced quickly after or even before the start of the dieting? It would be highly relevant to find out how long it takes for learned cue reactivity to extinguish, in dieters who expose themselves to highly palatable high calorie foods without eating them and in dieters who do not expose themselves or to a lesser degree. The cued overeating model predicts that the first blow is half the battle. Experimental studies are needed to find out whether this is true.

Summary Points

- Obesity (partly) follows from overeating.
- Overeating follows from classically conditioned appetitive responding to food cues.
- The food cues elicit irresistible food cue reactivity including cravings that might sabotage a healthy diet.
- If overeating systematically follows negative emotions, the negative emotions will become cues for overeating.
- Cue exposure with response prevention decreases the abnormal food cue reactivity.
- Successful dieting requires the extinction of food cue reactivity.

Key Terms

Obesity: This refers to an unhealthy amount of body fat. Obesity usually is defined by a Body Mass Index (BMI = kg/m^2) of 30 or more.

Classical conditioning: It is a form of associative learning during which the organism learns that stimulus A predicts the occurrence of stimulus B, for example the smell of food (stimulus A) predicts eating (stimulus B).

Food cues: Cues that are predictive of food intake like the smell, taste, and sight of food, but also place, time, or emotions and thoughts if they are predictive of food intake.

Appetitive responding: Bodily responses that prepare for food intake, like salivation and insulin release, and the experience of appetite or urge to eat.

Cue reactivity: Increased appetitive responding to cues that predict food intake.

Extinction: The new learning that stimulus A does not predict stimulus B by presenting stimulus A without stimulus B.

Cue exposure with response prevention: A treatment procedure in which the cues that predict eating (e.g., the smell and taste of foods) are presented without the actual eating until the urge to eat is decreased. After several exposure sessions without eating it is learned that the cues do not predict food intake anymore and at that very moment they will not induce any appetitive preparatory responses and appetite anymore.

Successful dieting: The process by which dieters were successful in losing weight and in maintaining the weight loss.

Abbreviations

PWS   Prader-Willi syndrome
OFC   Orbitofrontal cortex
MRI   Magnetic resonance imaging
PET   Positron emission tomography
FTD   Frontotemporal dementia

93.1 Introduction

Prader-Willi syndrome (PWS) is a neurodevelopmental disorder occurring in approximately one out of 15,000 live births and is the most well-known genetic cause of marked obesity. PWS is characterized by a distinctive behavioral phenotype, including food-related and food-unrelated behaviors. The first report of PWS, published in 1956 by pediatricians Prader, Labhart and Willi, described a syndrome characterized by obesity, short stature, lack of muscle tone during infancy, impaired sexual development, and mental retardation (Prader et al. 1956). Important contributions to the understanding of the clinical features of PWS were made over the following 20 years, and the physical characteristics (Hall and Smith 1972), clinical traits (Holm et al. 1993; Cassidy 1997), and behavioral patterns (Dykens et al. 1996; Dimitropoulos et al. 2001) were characterized better. Figure 93.1a and b show typical individuals with PWS. As for details of general clinical features and genetic background of PWS, please refer to other chapters relevant to PWS.

    In this chapter, we review behavioral features of PWS and discuss the symptoms of PWS in relation to the dysfunction of the frontal lobe, especially the orbitofrontal cortex (OFC) (Fig. 93.2).

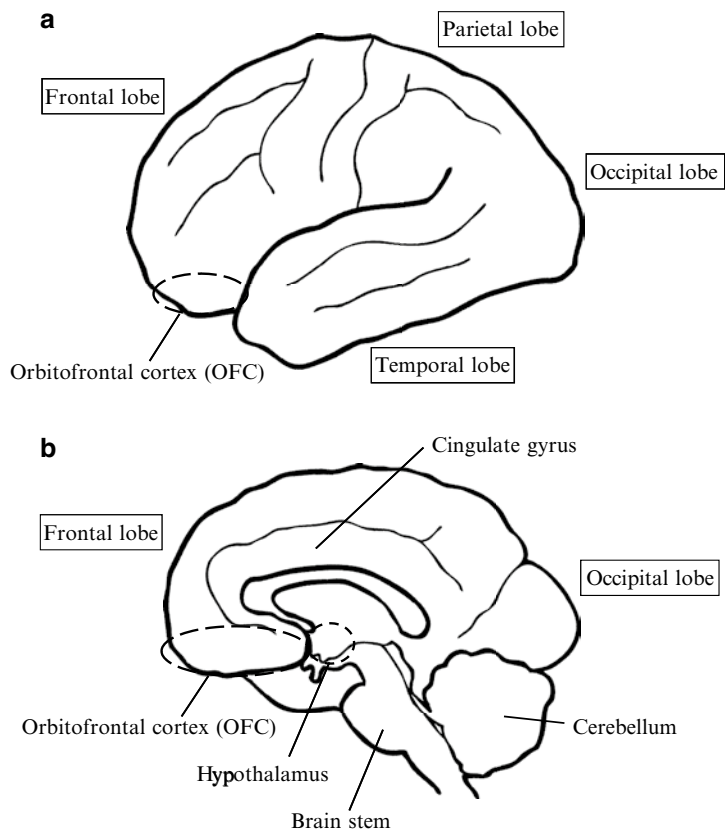
An 1 year-and-9 months old girl with PWS.

Typical adults with PWS.
Fig. 93.1 Individuals with PWS. (**a**) An 1-year-and-9-month old girl with PWS. She cannot stand up yet, because she has muscular hypotonia for her age. (**b**) Typical adults with PWS. Two individuals standing in a front row are Japanese adults with PWS (a male pictured in the left and a female in the right) and a person in a rear rank is a healthy adult male. Two individuals with PWS have typical features: short stature, central obesity, low muscular volume, and typical facial feature with narrow bifrontal diameter, small appearing mouth with thin upper lip, and down turned corners of mouth. In addition, their hands and feet are small (Published with permission)

93.2 Eating Behavior in PWS

Abnormal eating behavior is the most striking feature of behavioral traits in PWS (Holm et al. 1993; Dimitropoulos et al. 2000). Persons with PWS show an intense preoccupation with food, hyperphagia, and incessant food seeking. Their fixation on foods sometimes strikes us as extraordinary. For instance, their families frequently report behavior such as food-stealing, scavenging, and eating raw or frozen food. The abnormal eating behavior is universal in children and adults with PWS, and the absence of it suggests an incorrect diagnosis (Holm et al. 1993; Dimitropoulos et al. 2000). The feature, however, is not present from birth. Individuals with PWS typically show failure to thrive in infancy, followed by the onset of obesity at the age of 18–36 months (Ehara et al. 1993). Infants with PWS are hypotonic, and have a poor suck, typically requiring tube feeding. During infancy they seem to have no interest in a feed. In early childhood, they develop an excessive interest in food and also in associated food seeking behavior, and they begin to gain weight excessively well above the 50th percentile for weight (Greenswag 1987). Hyperphagia and obesity are sustained into their adulthood. It is also shown that the abnormal body composition of those with PWS and their associated reduced energy-use contribute to their physical appearance and to the difficulty in preventing obesity they experience

Fig. 93.2 Schematic drawings of the brain. (**a**) The left cerebral hemisphere viewed from the lateral aspect and (**b**) The right cerebral hemisphere viewed from the medial aspect


(Theodoro et al. 2006). Because the resulting obesity is highly likely to lead to serious health problems and untimely death, it is a major problem to be concerned about (Greenswag 1987).

It is generally stated that persons with PWS will continue to consume food as long as it is available and will search extensively for food when it is not available. In an experimental situation, individuals with PWS were shown to eat continuously, only a minority of them showing any reduction in their food intake over time (Zipf and Berntson 1987). Hyperphagia in PWS seems to be associated with an aberrant satiety response, particularly a delay in satiety (Holland et al. 1993). The food-related abnormal behavior have been attributed to a hormonal aberration caused by hypothalamic dysfunction, because those with PWS show other hypothalamic abnormalities, including growth-hormone deficiency, hypogonadism, and an inability to regulate their body temperature (Swaab 1997). Decreased numbers of oxytocin-secreting neurons were found in autopsy materials from individuals with PWS (Swaab et al. 1995).

In addition to hyperphagia, persons with PWS often show aberrant eating behaviors. Holm and Pipes (1976) reported that individuals with PWS have a propensity to consume products that are commonly considered as unappealing or unappetizing (e.g., dog food, garbage, sticks of butter, and decayed apples). Adults with PWS show a preference for sweet foods rather than salty, plain, or sour foods (Caldwell and Taylor 1983). Fieldstone et al. (1997) reported that individuals with PWS preferred high carbohydrate foods over high protein foods, and high protein foods over high fat foods. Anecdotal reports from parents and caregivers of persons with PWS suggest that those with PWS show a particular eating routine or ritualistic behavior during mealtime. These aberrant eating behaviors suggest that it is unlikely that eating behavior in PWS is simply attributable to the hypothalamic dysfunction.

93.3 Other Behavioral Features in PWS

Other behavioral characteristics in PWS are also distinctive, and they include temper tantrums, rigid thinking, uncontrollable impulse, aggressive behavior, lability of mood, and compulsive behavior (Holm et al. 1993; Dykens et al. 1996; Cassidy 1997; Dimitropoulos et al. 2001). Among them, the compulsive behavior has been of major interest to researchers investigating the PWS phenotype. The characteristic behaviors that are commonly seen in PWS include insistence on routines, repeating rituals, ordering and arranging objects, repetitive speech, and collecting behavior (Dykens et al. 1996). Repetitive behavior is common in early childhood among those with PWS. Children with PWS exhibit severer ritualistic behavior than typically developing children but not other children with developmental delays (Dimitropoulos et al. 2006). Older children and adults with PWS exhibit statistically significant elevations on the compulsivity subscale of the Yale-Broun Obsessive Compulsive Scale (Dykens et al. 1996). Dykens et al. (1996) found that individuals with PWS showed similar levels of symptom severity of compulsions when compared with those with obsessive-compulsive disorder who were matched for age and gender. They also found that the collecting behavior (see Table 93.1) was a salient symptom in PWS, and it was seen in more than half of the subjects. Recently, it is mentioned that compulsive manifestations is related to the severity of hyperphagia among individuals with PWS (Dimitropoulos et al. 2006).

93.3.1 Pathological and Neuroimaging Studies of the Brain in PWS

Despite the observation of serious neurobehavioral symptoms associated with PWS, little is known about the neurobiology and brain development of individuals with PWS. At present, there are only several case studies examining brain structures in individuals with PWS. Postmortem anatomical and histopathological studies have revealed enlarged lateral ventricles, cortical atrophy, abnormalities in cerebellar dentate nucleus, disorganization of neuronal cell layer, neuronal cellar loss, and neuronal heterotopia in the cerebral white matter and brain stem (Hattori et al. 1985; Hayashi et al. 1992; Stevenson et al. 2004). Structural magnetic resonance imaging (MRI) studies have also shown nonspecific morphological abnormalities including ventriculomegaly, cortical atrophy, asymmetry of the Sylvian fissures, a small brainstem, and an abnormal folding pattern of cerebral gyri (Leonard et al. 1993; Hashimoto et al. 1998; Yoshii et al. 2002; Titomanlio et al. 2006; Miller et al. 2007a).

Table 93.1 Key concepts of collecting behavior

- Collecting is the tendency to obtain and retain objects, and is commonly seen among both children and adults, in modern as well as primitive societies
- Abnormal collecting behavior is a symptom that involves acquiring things extensively, retaining objects even when they are of no immediate use, and resisting discarding the collected items even if they are excessive relative to the individual's circumstances or they are of little or no value
- The abnormal collecting behavior can appear as a manifestation of obsessive-compulsive disorder, autism, schizophrenia, anorexia, Tourette's syndrome and various types of dementia
- Little is known regarding its neurobiological mechanisms. It is deduced that the drive to collect would be initiated from subcortical and cortical mesolimbic structures involved in homeostatic regulation, and modulated by prefrontal and mesial temporal cortices
- Damage to prefrontal cortex has been associated with an inability to organize and carry out goal-directed behavior, decision-making, planning and anticipating future consequences, and this may contribute to the failure in normal discard behavior

This table lists the key concepts of abnormal collecting behavior and its neuronal substrates

Recently, some neuroimaging studies have reported that individuals with PWS had changes in regional activity in some brain regions. Shapira et al. (2005) reported a functional MRI study showing that, after glucose administration, three individuals with PWS showed delayed signal reduction in the hypothalamus, the OFC, and nucleus accumbens, with signal increase in the dorsolateral prefrontal cortex and insula. Other two functional MRI studies comparing individuals with PWS with healthy controls have also demonstrated increased activity in the medial prefrontal cortex, which involves the OFC in response to food stimuli (Holsen et al. 2006; Miller et al. 2007b). A positron emission tomography (PET) study showed that neural response to food intake in the OFC differed between a PWS group and a non-PWS group (Hinton et al. 2006). Kim et al. (2006) reported that cerebral glucose metabolism at rest differed in the OFC, middle and inferior frontal gyri, anterior cingulate gyrus, temporal pole, and uncus between PWS individuals and controls. Lucignani et al. (2004), using [^{11}C] flumazenil and PET, found possible functional changes of cerebral gamma-aminobutyric acid receptor in the insula, cingulate gyrus, and frontal and temporal neocortices in six adults with PWS. These findings suggest that there may be a specific relationship between neurobehavioral symptoms and functional abnormality in the OFC in persons with PWS.

93.3.2 Possible Relationship Between Behavioral Features in PWS and the Dysfunction of Orbitofrontal Regions

From a viewpoint of symptomatology, the behavioral features in PWS are strikingly similar to behavioral symptoms of patients with frontal pathologies affecting the OFC. For instance, patients with frontotemporal dementia (FTD), a progressive neurodegenerative disorder affecting the frontal and anterior temporal lobes, often show early alterations in behavior and personality (Neary et al. 1998). Behavioral symptoms in FTD include mental rigidity, impulsivity, mood changes, abnormal eating behavior, and compulsive behavior. The abnormal eating behavior and compulsive behavior are the factors that best distinguish FTD from other etiologies of dementia (Bozeat et al. 2000; Ikeda et al. 2002). Recent studies have highlighted the high prevalence of alterations in food preference (e.g., escalating desire for sweet food), appetite, and eating behaviors in FTD (Neary et al. 1998; Bozeat et al. 2000; Ikeda et al. 2002). A significant weight gain has been reported to occur in from 30% (Ikeda et al. 2002) to 70% (Bozeat et al. 2000) of patients with FTD. Stereotypic eating behaviors, such as wants to cook or eat exactly the same foods each day and tends to eat foods in the same order, were often observed in FTD (Ikeda et al. 2002). The compulsive behavior and collecting behavior are also often emerged in FTD. The compulsive behavior in FTD shows a spectrum of complexity, with simple motor mannerism and verbal repetitions at one end and complex behavioral routines and repetitive conversational themes at the other (Bozeat et al. 2000). For instance, Mendez et al. (1997) reported that patients with FTD showed repetitive checking, recurrent cleaning rituals, wearing clothes of specific colors only, compulsive self-injurious biting and hair-pulling, and collecting coupons entering multiple contests.

93.3.3 Frontal Behavioral Symptoms in PWS

We took particular note of behavioral similarities between PWS and FTD, which may be caused by shared neural dysfunction. To investigate how frequently individuals with PWS manifest frontal behavioral symptoms, we surveyed the prevalence of eating and noneating behavioral features in PWS by using assessment tools developed originally for patients with FTD and with frontal lobe

injury (Ogura et al. 2008). The questionnaire consisted of 35 questions related to three categories of behavior: eating behavior (with four domains: appetite, food preference, eating habits, and other oral behaivior), stereotyped behavior (with four domains: roaming, speaking, movements, and daily rhythm), and collecting behavior. It was administered in Japan to the parents of 250 individuals aged between 1–42 years with a clinical diagnosis of PWS. A parent was asked whether her/his child had the symptoms or not. If caregiver indicated that abnormal behavior was present, she/he was asked to rate its frequency and severity on a scale of one-to-three (where 1 is occasionally and 3 is frequently) and that of one-to-five (where 1 is slight and 5 is very marked), respectively. Then, a severity score was derived as the product of its frequency and severity. The results revealed that prevalence rates of all these behavioral categories were high for the individuals with PWS (Fig. 93.3 and Table 93.2). The overall prevalence rate was in good agreement with those in the previous reports for PWS (Caldwell and Taylor 1983; Holm et al. 1993; Dykens et al. 1996; Dimitropoulos et al. 2000), and it was comparable to those reported for FTD (Neary et al. 1998; Bozeat et al. 2000; Ikeda et al. 2002). Furthermore, the severity score of each domain in the eating behavior was significantly correlated with those in the stereotypy and the collecting behavior (Fig. 93.4).

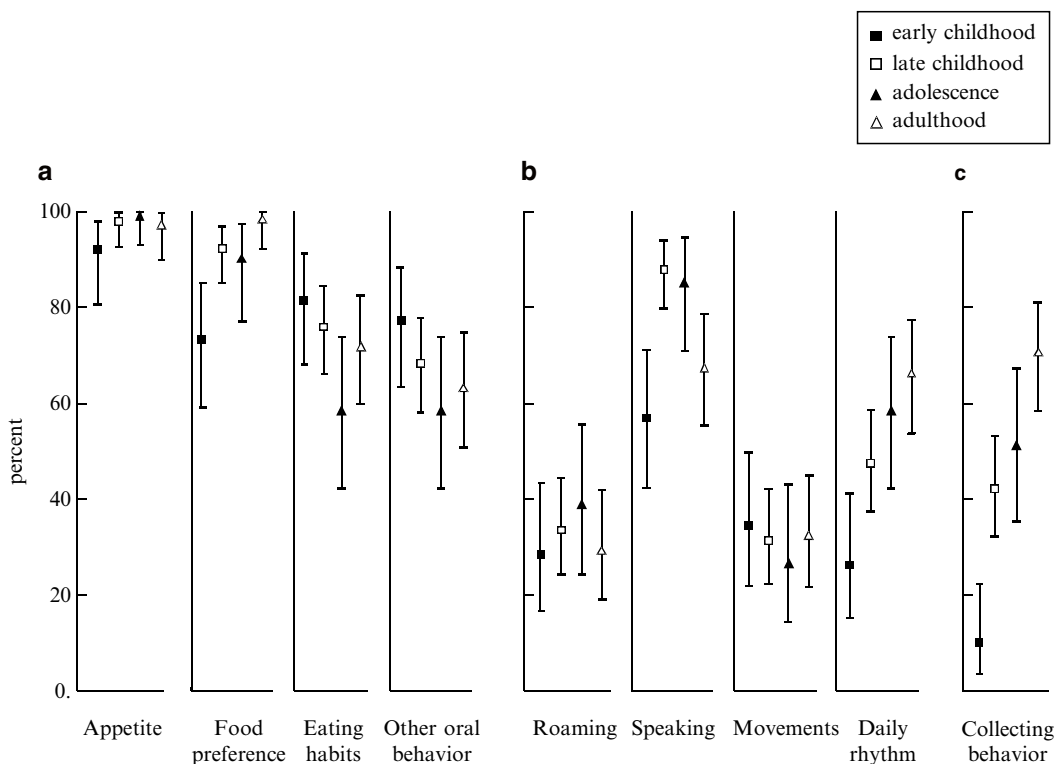
The findings mentioned above suggest that the behavioral features in PWS are associated with a dysfunction of the frontal lobe, especially that of the OFC. The OFC is thought to play a crucial role


Fig. 93.3 The prevalence of symptom domains in each age group. The participating individuals were divided into four groups based on age: early childhood (aged 0–5 years), late childhood (aged 6–11 years), adolescence (aged 12–17 years), and adulthood (aged over 18 years). The overall prevalence of abnormal behaviors and the prevalence rates of each domain and of each item among the age bands were analyzed using the Chi-square test. (**a**) The prevalence of abnormal eating behaviors was extremely high in all age bands. (**b**) Stereotyped behaviors were also common, particularly stereotyped speaking and daily rhythm stereotypy. (**c**) The greatest group differences in prevalence were noted for collecting behaviors. Symbols indicate the prevalence and bars indicate 95% confidence intervals (Ogura et al. 2008: 472, Elsevier)

Table 93.2 Prevalence rates of items in the eating behavior

	Prevalence rate (95% confidence intervals) (%)				
	Early childhood	Late childhood	Adolescence	Adulthood	*p* value
	<6 years	6–11 years	12–17 years	>17 years	
Appetite					
Loss of appetite	2 (0–11)	5 (2–14)	7(2–20)	3 (0–10)	NS
Increase in appetite	53 (38–67)	60 (49–70)	71 (54–84)	72 (60–82)	NS
Seeks out food between meals	49 (34–64)	66 (56–76)	71 (54–84)	87 (76–94)	<0.001
Overeat at meal times	53 (38–67)	74 (64–83)	78 (62–89)	84 (73–92)	0.002
Reports hunger	71 (57–83)	83 (73–90)	80 (65–91)	87 (76–94)	NS
Reports being overfull	53 (38–67)	55 (45–66)	32 (18–48)	41 (29–54)	0.004
Food preference					
Prefers sweet foods or drinks more than before	67 (52–80)	91 (84–96)	90 (77–97)	97 (90–100)	<0.001
Drinks more tea/coffee	22 (12–37)	39 (29–50)	61 (45–76)	62 (49–73)	<0.001
Adds more seasoning to their food (e.g., adds more salt)	8 (2–20)	18 (11–28)	27 (14–43)	29 (19–42)	0.03
Hoards food	10 (3–22)	17 (10–27)	22 (11–38)	29 (19–42)	NS
Eating habits					
Wants to eat the same dishes or foods each days	31 (18–45)	30 (21–41)	34 (20–51)	35 (24–48)	NS
Buys exactly the same food each days	14 (6–27)	24 (16–34)	37 (22–53)	43 (31–55)	0.004
Wants to use the same sauce, the same seasoning or the same spice	6 (1–17)	13 (7–22)	17 (7–32)	46 (33–58)	<0.001
Eats with hands	61 (46–75)	37 (27–48)	14 (6–29)	19 (11–30)	<0.001
Takes a long time to eat	61 (46–75)	43 (33–54)	14 (6–29)	28 (18–40)	<0.001
Other oral behavior					
Tends to overfill mouth	59 (44–73)	49 (38–60)	37 (22–53)	49 (36–61)	NS
Chews or sucks on things (e.g., pens) without trying to eat them	18 (9–32)	28 (19–39)	22 (11–33)	15 (7–25)	NS
Eats non-edible foodstuffs or things not normally eaten	14 (6–27)	26 (17–36)	34 (20–51)	21 (12–32)	NS
Tends to snatch or grasp any food items within reach	43 (29–58)	26 (17–36)	15 (14–43)	19 (9–29)	0.003

The prevalence of each item related to abnormal eating behavior was analyzed. Because the domain of appetite included items for both increase of appetite and loss of appetite, we analyzed these items separately. The frequency of increased appetite was more than 50% in all age groups, whereas loss of appetite was less common (Ogura et al. 2008: 472, Elsevier)

NS not significant

in several neural networks, one of which is related to the integration of food-related sensory, visceral, and reinforcing information (Rolls 2005). Patients with damage to the OFC showed changes in eating habits and escalating desires for sweet food (Uher and Treasure 2005). Studies of patients with FTD have demonstrated that overeating and sweet-tooth were associated with atrophy involving the OFC region (Woolley et al. 2007). As noted earlier, recent neuroimaging studies have demonstrated that PWS subjects had a dysfunction of the satiety system in prefrontal areas, especially in the OFC (Shapira et al. 2005; Hinton et al. 2006; Holsen et al. 2006; Miller et al. 2007b). Visceral and other satiety-related signals reach the OFC and modulate the representation of food, resulting in an output that reflects the appetitive value of food. Food is a natural reinforcer, with reward value implicated in the risk for addiction (Volkow and Fowler 2000). Obesity in PWS, like drug addiction, seems to result from foraging for food and ingestion habits that are maintained and reinforced, despite the potentially serious health consequences. Furthermore, food intake in humans is not only regulated by

a

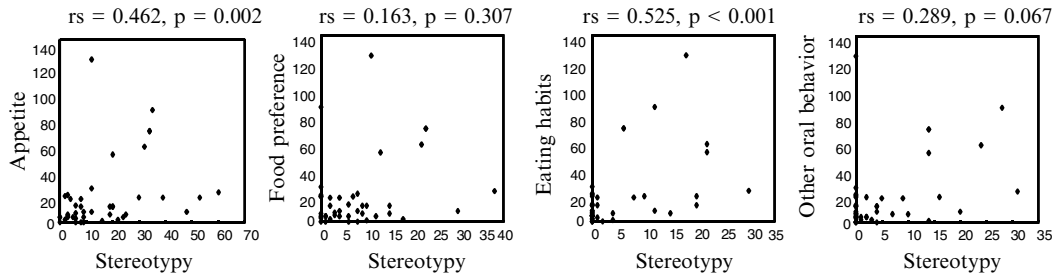
adolescence


adulthood
Fig. 93.4 (**a**) Correlations of stereotypy (severity score) with abnormal eating behaviors (severity score) for each age band and (**b**) correlations of collecting behavior (severity score) with abnormal eating behaviors (severity score) for each age band. Spearman's rs was used to test correlations between the domain scores included in abnormal eating behavior and the total score of the stereotypy or collecting behavior. The severity scores for all domains included in the abnormal eating behavior were significantly correlated with those for stereotyped behavior and collecting behavior (rs = 0.30–0.45, *p* < 0.001) when all the age bands were analyzed together. For each age band, although there were some exceptions, the severity scores for most of the abnormal eating behavior were significantly correlated with those for stereotypy and collecting behavior

b

early childhood

rs = 0.302, p = 0.035 | rs = 0.357, p = 0.012 | rs = 0.571, p < 0.001 | rs = 0.292, p = 0.042

late childhood

rs = 0.265, p = 0.011 | rs = 0.334, p = 0.001 | rs = 0.308, p = 0.003 | rs = 0.470, p < 0.001

adolescence

rs = 0.374, p = 0.016 | rs = −0.022, p = 0.890 | rs = 0.407, p = 0.008 | rs = 0.263, p = 0.096

adulthood

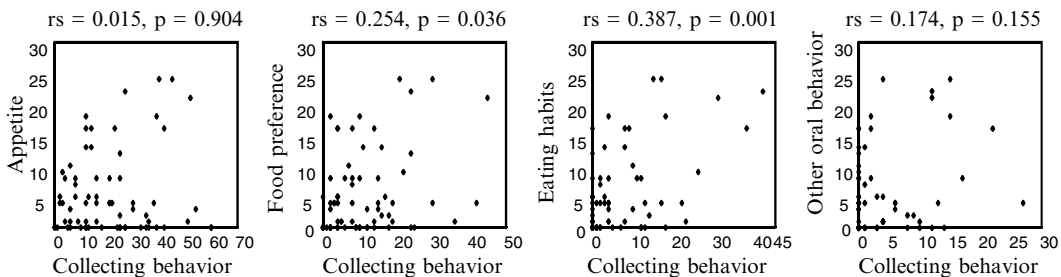
rs = 0.015, p = 0.904 | rs = 0.254, p = 0.036 | rs = 0.387, p = 0.001 | rs = 0.174, p = 0.155


Fig. 93.4 (continued)

homeostatic processes, but also relies on interactions between homeostatic regulation and hedonic experience (Pecina et al. 2003). Thus, dysfunctioning of the OFC could lead individuals with PWS to both overeating and a propensity for detrimental food preferences such as overindulgence on sweet foods (Caldwell and Taylor 1983; Ogura et al. 2008).

In addition, a dysfunction of the OFC is likely to be involved in both compulsions and collecting behavior. One study showed that a patient with an infarction restricted to the OFC showed obsessive-compulsive symptoms such as ritualistic repetitive behavior (Kim and Lee 2002). Another study showed that patients with damage to ventromedial frontal regions including the OFC showed pathological collecting behavior, i.e., excessive extent of collecting, collection of useless items, and interference with normal daily functioning (Anderson et al. 2005). Hahm et al. (2001) reported on a patient who developed pathologic collecting behavior after a left OFC and caudate injury. It has become evident that collecting symptoms in the broader population are part of a discrete clinical syndrome that involves symptoms reminiscent of those associated with prefrontal damage, including difficulties in decision-making and organization (Saxena et al. 2004). As an alternative view, Kringelbach and Rolls (2004) argued that the lateral OFC is associated with the monitoring of punishment value, which may lead to an adjustment of current behavior. It is likely that maladaptive behaviors in PWS result from an impairment in making use of feedback to guide an appropriate behavior, which require controlling their impulse and monitoring outcomes to guide future decisions.

93.4 Applications to Other Areas of Diet and Behavior

The OFC is thought to be a part of the serotonergic system in the brain (Fig. 93.5). Serotonin, an important neurochemical messenger, plays an important role in impulse control and influences eating. Abnormalities in this system have been reported in individuals with PWS (Dimitropoulos et al. 2000) and FTD (Huey et al. 2006). Furthermore, psychopharmacological agents that act on the serotonergic system have been shown to reduce repetitive behavior in both disorders (Benjamin and Buot-Smith 1993; Moretti et al. 2003). Therefore, both the anatomical and neurochemical abnormalities associated with PWS could contribute to these behavioral features. The elucidation of the pathophysiological basis of the behavioral phenotype including food-related and food-unrelated behaviors in PWS would provide a clue to the treatment of the behavioral symptoms, as well as throw light on the mechanisms underlying the similar abnormal behavior involved in pathological overeating and obesity. Neuroimaging studies would also clarify the neural basis for behavioral traits in persons with PWS, and might allow us to understand the link between the neuroanatomical abnormalities and the genetic mechanism involved.

Fig. 93.5 Serotonergic system. The serotonergic system projects widely in the brain and influences multiple functions. This system is important for the control of emotion and behavior, and it modulates pain sensation as well as motor and autonomic functions

Raphe nuclei
Summary Points

- PWS is generally regarded as a genetic model of obesity, and is characterized by a distinctive behavioral phenotype, including food-related and food-unrelated behaviors.
- The behavioral features in PWS are strikingly similar to behavioral symptoms of patients with frontal pathologies affecting the OFC.
- Our nation-wide survey along with those of some previous studies suggested that behavioral features in PWS are likely to be associated with the dysfunction of the OFC and its related areas.
- Recent neuroimaging studies showed that individuals with PWS had changes in regional activities in the OFC, although past studies focused on hypothalamic dysfunction.
- The elucidation of the pathophysiological basis of the behavioral symptoms of PWS would throw light on the mechanisms underlying the similar abnormal behaviors involved in pathological overeating and obesity.

Keywords and Their Explanations

Prader-Willi syndrome (PWS): Prader-Willi syndrome is a genetically determined neurodevelopmental disorder and is generally regarded as a genetic model of obesity. The syndrome is characterized by defects in cognitive and motor development, short stature, hypogonadism, hyperphagia with progressive obesity, and behavioral problems.

Hyperphagia: Hyperphagia is excessive eating behavior, also known as gluttony.

Compulsive behavior: This is abnormal comportment that a person does compulsively, not because she/he wants to behave that way, but irrespective of her/his will. The behavior shows a spectrum of complexity, with simple motor mannerisms and verbal repetitions at one end and complex behavioral routines and repetitive conversational themes at the other.

Abnormal collecting behavior: Abnormal collecting behavior is a symptom that involves acquiring things extensively, retaining objects even when they are of no immediate use, and resisting discarding the collected items. The behavior can appear as a manifestation of compulsive behavior.

Orbitofrontal cortex (OFC): The orbitofrontal cortex is a region of association cortex located within the frontal lobes, resting above the orbits of the eyes. The OFC is thought to have a role in adjusting behavior based on the social values of the outcomes of previous behavior.

Frontotemporal dementia (FTD): Frontotemporal dementia is a progressive neurodegenerative disorder affecting the frontal and anterior temporal lobes. Patients with FTD show a wide range of behavioral abnormalities, including mental rigidity, impulsivity, mood changes, and compulsive behaivior, and they share many behavioral and cognitive features with PWS individuals.

94.1 Introduction

With the shift from infectious disease to nutritional and chronic lifestyle disorders in countries whose economies and cultures are in transition (Nasser et al. 2001), it has yet to be established whether disordered eating is triggered by recent affluence and changing lifestyles bringing newly acquired attitudes towards food consumption, or whether it is an inherent part of globalization and the maladjustment that the process may create (Lee 1996; Fedoroff and McFarlane 1998; Jackson et al. 2003), or whether it has an exclusive cultural component in spite of globalization. Studies show that younger women in non-Western societies in transition toward modern affluence may be embracing the body image dissatisfaction of Euro-Americans (Ford et al. 1990; Soomoro et al. 1995). Although the cultural dimension has occasionally been considered in the available literature (Littlewood 1995), one salient gap in the literature is sociocultural studies exploring whether there are inherent cultural features that may contribute to the idiom of distress central to the presentation of disordered eating outside the realm of Euro-American populations.

The first wave of research on this topic explored the presence of disordered eating in various populations. These studies shed light on whether rates of disordered eating in non-Western cultures are similar to Western populations. Emerging epidemiological studies suggest that rates of disordered eating in non-Western societies fluctuate in a complex and multifaceted way (Nasser 2006), but that there is indication that the rates are rapidly outpacing those reported in Western Europe and

North America (Wassenaar et al. 2000; Bhugra et al. 2000). Makino et al. (2004) synthesized the available literature in order to compare the rates of eating disorders in non-Western countries with those in 11 Western countries. These authors report that gender is significant for both Western and non-Western countries, with women aged 15–24 years appearing to be at increased risk of developing eating disorders. The study concludes that the rate of eating disorder in non-Western countries, though generally lower compared to Euro-American populations, is however rising at a significantly faster rate. Prevalence rates in Euro-American populations ranged from 0.1% to 5.7%, whereas they range between 0.46% and 3.2% in non-Western countries (Makino et al. 2004). This data indicates the need to open another research dimension, that is, whether dieting and disordered eating are culture-bound or culture-reactive phenomena. Further, it is unclear whether the literature takes into account the impact on the younger generations of aggressive media campaign in the form of TV, glossy magazines, and the Internet, which transcend geographic boundaries and influence the younger generations with respect to societal perception and expectations of what constitutes beauty and which type of body image is appreciated. The influence of movie stars and thin models cannot be underestimated. Similarly, it is difficult to disentangle whether dieting is in fact the conscious choice of young females who want to achieve, at any cost, those specific body characteristics that they hope will earn them appreciation and translate into riches if they get into a glamor business such as modeling. The presence of a great number of slimming centers in these neo-affluent societies, along with over-the-counter herbal preparations for slimming, and the acceptance of smoking by females to maintain weight also needs to be investigated. This consideration of conscious choice should help to decipher whether dieting and disordered eating are really a culture-bound phenomenon in the context of the last decade or two.

The second wave of research attempts to highlight the factors that influence the emerging trend of eating disorders in non-Western populations. The data are obtained mainly from comparative studies of non-European migrants and their children living in the West (Table 94.1). They have led to the view that cultural exposure may cause immigrants from cultures where thinness is not highly valued to adopt Western positive valuations of thinness, resulting in pathological preoccupation with body image and weight-loss behavior (Ford et al. 1990; Gunewardene et al. 2001). In other words, exposure to the Western ideal of beauty, the phenomenon of medicalization, and the stigmatization of the overweight have denigrated traditional features of body preference. Many traditional conceptions of female beauty tilt toward a voluptuous female form.

In some parts of the world, prior to marriage, adolescents are force-fed to achieve a highly favored plumpish figure (Al-Adawi et al. 2006). While modernity may have partly denigrated traditional features of body preference, the picture is not entirely clear. This is clearly shown in the phenomenon of *gavage* for girls before marriage. G*avage* means force-feeding and is an ancient practice that has largely disappeared in some parts of Oman, or, if it still exists, remains a furtive activity. The practice involves a nubile who is coerced into consuming a large amount of food or liquid deemed essential to increase one's weight (Resnikoff 1980; Gerteiny 1967). A voluptuous figure or, in modern parlance, obesity is equated with beauty, health, and wealth in such a cultural setting. This practice is deemed to constitute abuse, but the phenomena challenges the Western perception of beauty and health being characterized with thinness. This suggests that how obesity is conceived is dependent upon the sociocultural context.

Some studies have concluded that susceptibility toward disordered eating is related more to a traditional rather than a Westernized cultural orientation, possibly due to the stress of cultural adjustment, rather than to the influence of Western cultural values of femininity and beauty (Mumford et al. 1991a; Koneru et al. 2007; Reddy and Crowther 2007). Although many studies have explored disordered eating in cross-cultural populations (Cummins et al. 2005), most have generally employed a Western cultural microscope to glean the phenomenology of disordered eating among people of

diverse ethnic backgrounds whose conception of beauty and health may not parallel those in the Western world (Nasser et al. 2001; Casper 1998). Kleinman (1986) cautions that a view of human nature developed for one cultural group should not be uncritically applied to members of another group, for whom its validity has not been established. For both theoretical and clinical relevance, studies are needed to examine the interplay of culture and disordered eating. By exploring specific eating disorder symptoms, it would then be possible to determine whether ethnic and cultural variations in disordered eating are related to currently available algorithms for quantifying the presence of eating disorders.

In the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) (American Psychiatric Association 1994) and International Classification of Disease (ICD) (World Health Organization 1993), disordered eating is characterized by significant weight loss, amenorrhea, distorted body image, and a relentless pursuit of thinness. Despite its centrality to the biomedical model, there are conflicting results on whether the relentless pursuit of thinness is a common occurrence among teenagers with a subclinical or clinical syndrome of disordered eating. In Western populations, manifestations of laparophobia have been shown to vary among various ethnic groups (Altabe 1998; Contento et al. 2003), with a notably low incidence among African-Americans in

some studies, but not in others (Duncan and Robinson 2004). In some of these studies, the rate varies from 15% to 20% in certain ethnic groups (Ramacciotti et al. 2002). Studies carried out in several Asian populations also reveal contradictory results. For example, a lack of laparophobia is shown to characterize the majority of patients with dieting disorders among a number of Chinese populations; however, this is not consistently confirmed in other Chinese populations (Ngai et al. 2000). In studies carried out among Arab populations, the trend indicates increasing presence of disordered eating, but without the presence of the explanatory construct pertinent to laparophobia (Kayano et al. 2008; Al-Adawi et al. 2004, 2002a). Such patterns are also observed in other cross-cultural populations (Khandelwal et al. 1995). It is possible that the concept of body image, as reported in Western populations, may not be applicable to some cross-cultural populations. Alternatively, there may be culture-specific manifestations of eating disorders that may not parallel those observed in Western adolescent populations. This issue has received scant treatment in the literature.

Despite the orthogonal manifestation to fat aversion found in Western teenagers, laparophobia is still not associated with a marked reduction in BMI and all the health consequences this may entail (Rieger et al. 2001). Within the context of conflicting findings on the prototypical conception of fear of fatness or laparophobia, more studies are needed. Comparative studies are needed to examine whether the lower incidence of a drive towards thinness, as one of the indices of nonlaparophobia in eating disorders, is not as common in non-Western populations, as has been alluded to in some studies (Ngai et al. 2000; Kayano et al. 2008). As distress is experienced in a sociocultural context, there is a strong rationale for undertaking such studies in order to shed light on pluralism within globalization. If cultural teaching does not encourage distress in the form of laparophobia, the question arises whether other idioms of distress are sanctioned. In various ethnic groups, numerous studies have suggested that some individuals tend to use somatopsychic idioms of distress rather than verbalize their distress in a psychological manner as is often reported in some populations in Western Europe and North America (Kleinman 1987). In some cross-cultural settings, women often come to health care settings for treatment of physical discomfort that has no apparent organic cause. There is empirical support, although not widely accepted, that in Western cultures there is a tendency to psychologize distress, which can be contrasted with the tendency in non-Western cultures to somatize it. Although the possibility remains that the somatizer may be suffering from, albeit hitherto unrecognized, unidentifiable physical illnesses, there are common denominators among somatizers to suggest that this may be a culturally specific idiom of distress. Al Lawati et al. (2000) report that somatizers tend to perceive themselves as sick despite repeated assurance to the contrary. As a clinical entity, somatization remains a chronic, disabling syndrome that, while presenting a physical facade, is associated with significant psychopathology that appears akin to affective and anxiety disorders. It is usually assumed that somatization occurs in response to psychological stresses on a background of predisposing personality factors, but by adopting the sick role, psychological equilibrium is achieved. Clinical and epidemiological surveys over the past decades suggest that acute forms of somatoform disorders are invariably present in all primary care settings (Ohaeri and Odejide 1994; Mumford et al. 1997). Naturalistic observations of somatization disorders reveal that the condition begins in adolescence. The disorder is inversely related to social position, occurs most often in communities with little urbanization and literacy, and affects more women than men. Ohaeri and Odejide (1994) and Mumford et al. (1997) find that the incidence of somatization ranges from 20% to 80% in various cultures among developing countries. Since the geography of somatization is in non-Western cultural groups, it has been speculated that physical symptoms are often seen as a more legitimate and morally acceptable manifestation of distress since the expression of negative feelings, and conflict of any kind, are generally seen as not acceptable (Eloul et al. 2009). Afflictive emotional states are not articulated due to cultural teaching that the expression of emotion is not only shameful

(Dwairy 2006) but also is perceived to be disruptive to group cohesion that is essential in group-oriented cultural setting. This has resulted in primarily somatic presenting complaints (Eloul et al. 2009). Such an idiom of distress has not received due attention in the literature on eating disorders. In order to fill this gap in the literature, studies are needed to examine whether there are ethnic variations in idiom of distress that may have relevance to eating disorders. Since the Western view of human nature is based on the concept of individualism, this begs the question: how could cross-cultural populations with a strong sense of collective identity develop disordered eating?

94.2 The Study in Oman

Due to their negative impact on health, the deliberate food restriction, and body image dissatisfaction, manifesting as anorexia nervosa, bulimia nervosa and their variant spectrum disorders, are now being recognized in many parts of the world (Nasser et al. 2001; Lee and Lee 2000), including Oman (Al-Adawi et al. 2002b). Oman is an Arab/Islamic country with distinct sub-cultural diversities. Its diverse society has experienced minimum acculturation until 2 decades ago. Oman is also characterized with a heterogenic mixture of various ethnicities because of the presence of a highly educated workforce and also a large number of contract laborers from many diverse foreign countries. Recent globalization and Westernization has endowed the country with economic development, technological, and educational advances and access to media similar to that seen in Western countries, and therefore this region provides fertile ground on which to examine the interplay between acculturation and social distress.

With emerging globalization, health care providers will encounter more clients with a wide range of cultural, social, regional, educational, and ethnic backgrounds. In this new medical environment, the viability of health care delivery will depend upon the medical community's ability to evolve and adjust to ethnic and cultural variations. Only through an awareness and appreciation of a patient's unique background can the modern health care provider delivering allopathic services decide on the best method to enhance health and the quality of life.

94.2.1 Culture to Culture: Deliberate Food Restriction

It has been suggested that, in the light of increasing Westernization/globalization, eating disorders in the non-Western world are taking on a Western pattern, in line with the suggestion that significant obsession with disordered eating such as in anorexia nervosa, bulimia nervosa and their variant spectra is a pathoplastic effect of globalization (Lai 2000; Barr and Garner 2001) due to the cult of thinness reinforced by the media (Abou-Saleh et al. 1998; Morant 2000) or obesogenic behaviors that is characterized by sedentary life but also complemented with a dietary habit that is rich in fat and calories (Mellor et al. 2009). Although acculturation may play a pivotal role in reinforcing the emerging trend of disordered eating in non-Western societies, sociocultural determinants must be identified to establish enlightened and culturally sensitive interventions. This issue is more complex than has been acknowledged in the available literature. For example, it is always taken for granted that thinness is the most desirable standard of beauty. However, there are some societies, including Oman, where the beauty preference would make mockery of the modern preoccupation with thinness. In traditional Omani society, beauty and wealth is equated with, in modern parlance, an obesity-like body silhouette. Society used to institute various methods to achieve a desirable weight as exemplified by the following vignettes.

Vignette 1

> *Buthaina is a 10 year old girl, growing up in an extended family in a semipastoral tribal region in the Southern region of Oman. She was brought to the primary health care in a comatose state. The accompanying family informed the attending medical team that she had spasms whenever she ingested any food or liquid. The clinical team noted that she was emaciated, dehydrated, cold intolerant, and had difficulty in maintaining core body temperature. Neither psychosocial nor medical history from the accompanying family revealed or suggested any clear trigger for her present predicament. She has normal developmental milestones. She attended school until a year ago, with insistence from her grandmother that she quit her education despite her performance being adequate. After inconclusive medical investigation, antiemetic and nutritional rehabilitation was instituted. She gradually became stable and was subsequently discharged. Three weeks later, she was brought back to the hospital in a similar state. It was noted by chance that Buthaina's distress coincided with the culturally sanctioned practice of forced overeating, akin to gavage. This furtive traditional practice aims to 'help' girls perceived as thin to transform themselves into much cherished voluptuous figures. Buthaina's family was counseled regarding the detrimental effect of such a practice. Initially, the grandmother resisted the suggestions and insisted that if Buthaina remains thin, she will be condemning herself to live the rest of her life as a spinster. Counter-arguments from other family members eventually moderated the view of the grandmother. Buthaina subsequently resumed her education and there was no relapse of the condition that brought her to the medical attention in the first instance.*

With the above-mentioned background, studies in Oman (Al-Adawi et al. 2002b, 2004; Kayano et al. 2008; Viernes et al. 2007) took advantage of the heterogeneous population to compare performance on indices of deliberate food restriction among teenage girls of diverse cultural and ethnic backgrounds living in Oman and the Philippines (for demographic characteristics, see Table 94.2).

The major themes emerging in the literature are, on the one hand, that the prevalence rates of deliberate food restriction in many non-Western populations sometimes exceed the trend previously reported among Westernized populations (Wassenaar et al. 2000). On the other hand, although it appears to be increasing, the overall rate of disordered eating in non-Western countries is lower than that of Western countries. Such a contradictory finding suggested the need for further study.

The comparison of Filipino, Indian, Omani, and Euro-American teenagers suggests that the four ethnic groups appear to have significant differences in their scores on dieting behavior and aberrant eating, derived from The *Eating Attitude Test (EAT-26)*. This is a 26-item, self-reporting questionnaire that measures symptoms implicated with deliberate food restriction and, at a pathological level, aberrant eating (Garner and Garfinkel 1979). Participants rate the frequency with which they experience each statement on dieting, bulimic behaviors, and self-control of eating behavior, using a six-point scale. Various authors report that EAT-26 is effective for assessing a wide range of attitudes and behavior characteristics of deliberate food restriction in both clinical and general populations (Nasser et al. 2001; Al-Subaie et al. 1996). While high scores on EAT-26 do not necessarily equate with clinical eating disorders, many of the characteristics represented constitute deliberate food restriction. EAT-26 is considered an appropriate screening device for eating disorders and has been widely translated. In the majority of studies in the Arab world and the Philippines, its cross-cultural application has been found to be acceptable (Nasser et al. 2001; Al-Subaie et al. 1996; Lorenzo et al. 2002).

On the whole, using EAT-26, Al-Adawi et al. (2006) have shown that non-Western teenagers have a greater tendency toward deliberate food restriction and dieting behavior than their Euro-American

Table 94.2 Criteria for diagnosis of deliberate food restriction, according to the Western psychiatric taxonomy (*Diagnostic and Statistical Manual of Mental Disorders* (DSM) and International Classification of Disease (ICD))

- Absence of a menstrual period in a woman of reproductive age.
- Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
- Idiom of distress that primarily involves intense fear of gaining weight or becoming fat, even if underweight.
- Failure to make expected weight gain during the period of growth, leading to body weight less than 85% of that expected.

expatriate counterparts. This finding is seemingly consonant with earlier observations that in non-Western societies, preoccupation with food restriction and dieting behavior appears to be as common as those reported in Western countries (Hoek and van Hoeken 2003; Tsai 2000). The authors noted that the rate among non-Western teenagers is beginning to outpace the rate observed among Euro-American teenagers.

However, caution is needed in extrapolating the present findings with the background that a view of human nature developed for one cultural group should not be uncritically applied to members of another group for whom its validity has not been established. The utility of EAT-26 is a case in point. Al-Adawi et al. (2002a) have shown that although the EAT-26 is the most used screening instrument in cross-cultural studies, it does not appear to be reliable in identifying possible cases of anorexia among Omani adolescents. A previous study from Oman (2002), in which the cases identified using the EAT-26 were scrutinized with a gold standard structured interview and diagnostic criteria based on the Composite International Diagnostic Interview (World Health Organization 1993), the percentage of genuine positives was reduced from 29% to 9.5%. The authors opine that some available quick screening tools may give spurious results and hence in cross-cultural studies, qualitative interviews are likely to be more fruitful.

94.2.2 Culture to Culture: Fatphobia

With the realization that there is variation in the manifestation of eating disorders that may not be parallel to that observed in the Western adolescent population, the next step is to decipher performance on a core feature of eating pathology, namely, fear of fatness. Studies are needed to determine whether there is a difference in body dissatisfaction between Western and non-Western teenagers, in order to shed light on differences in idiom of distress. The diagnostic importance of laparophobia is testified to by the fact that it constitutes the central criterion in the diagnosis of anorexia nervosa for both DSM-IV (American Psychiatric Association 1994) and ICD-10 (World Health Organization 1993) (Table 94.3).

In Western populations, the manifestation of laparophobia is shown to fluctuate widely among various ethnic groups (Johnson et al. 2004; Williamson 1998). Similar variations are also observed in studies from some Asian countries (Ngai et al. 2000).

Finding an instrument that is appropriate for international comparison is essential, if not paramount, in this regard. Al-Adawi et al. (2004) have examined the presence of laparophobia using the drive for thinness, a subscale derived from one of the most widely used assessment measures of eating disorders, the *Eating Disorder Inventory* (EDI) (Garner et al. 1983). The EDI is a self-reporting measure, validated on both clinical and non-clinical populations (Garner et al. 1983). It has valid and reliable psychometric properties that were established in various ethnic groups, including the populations under scrutiny in the present study (Al-Subaie et al. 1996; Yates et al. 2004). The subscale utilized contains seven items that elicit information on the drive for thinness. Higher scores indicate greater levels of laparophobia, with a score of 15 or more on the composite scale suggesting a preoccupation with weight and/or body shape, or demonstration of a morbid fear of weight gain, an excessive concern with dieting or a strong desire for thinness (Garner et al. 1984).

Using this scale, Al-Adawi et al. (2002b) have shown that perceptions of fatness differed by ethnicity. The Euro-American students score significantly higher (more than twice the average) scores compared to the Omani, Filipino, and Indian groups. There is no difference in this perception between the Filipino and Indian groups, while the Omani and Euro-American students differed significantly from every other group. The Euro-Americans have significantly higher median composite EDI scores compared to the other groups. This evidence, along with other findings (Gupta et al. 2001), underscores the view that

constructs of laparophobia, an essential diagnosis for disordered eating, may be expressed differently from culture to culture and that this merits further investigation. First, many problems previously thought of as universal because of their shared attributes with similar latent manifestations in different parts of the world, are sometimes expressed in forms that are unique to particular cultures. As a result, many interventions tend to have only modest success because sociocultural factors often downgrade supposedly universal phenotypic presentations. One direct consequence of this is that many conditions are proliferating, not only because of acculturation, but also because of a lack of understanding of the contribution of sociocultural factors to these conditions. Secondly, and directly relevant to eating

	DSM IV	ICD 10	Comments
1.	Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected)	There is weight loss or, in children, a lack of weight gain, leading to a body weight at least 15% below the normal or expected weight for age and height	Refusal component not addressed in ICD
2.	Intense fear of gaining weight or becoming fat, even though underweight	There is self-perception of being too fat, with an intrusive dread of fatness, which leads to a self-imposed low weight threshold.	Combining 2 and 4 of DSM column, denial of seriousness not addressed in ICD
3.		The weight loss is self-induced by avoidance of "fattening foods."	Avoidance of fatty foods not addressed in DSM
4.	Disturbance in the way in which one's body weight or shape is experienced; undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight		
5.	In post-menarchal females, amenor-rhea, i.e., the absence of at least three consecutive menstrual cycles. (A woman is considered to have amenorrhea if her periods occur only following hormone, e.g., estrogen, administration)	A widespread endocrine disorder involving the hypothalamic–pituitary–gonadal axis is manifest in women as amenorrhea and in men as a loss of sexual interest and potency. (An apparent exception is the persistence of vaginal bleeds in anorexic women who are on replacement hormonal therapy, most commonly taken as a contracep-tive pill)	Male component not addressed in DSM
6.		If onset is pre-pubertal, the sequence of pubertal events is delayed or even arrested (growth ceases; in girls the breasts do not develop and there is primary amenorrhea; in boys the genitals remain juvenile)	Pre-pubertal issue and male component not addressed in DSM

Table 94.3 (continued)

DSM IV	ICD 10	Comments
7. **Specify type**: **Restricting type**: During the current episode of anorexia nervosa, the person has not regularly engaged in binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas) **Binge eating/purging type**: During the current episode of anorexia nervosa, the person has regularly engaged in binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas)	The disorder does not meet criteria A and B for bulimia nervosa.Bulimia nervosa: A. Recurrent episodes of overeating (at least twice a week over a period of 3 months) in which large amounts of food arte consumed in short periods. B. Persistent preoccupation with eating and a strong desire or sense of compulsion to eat (craving). C. The patient attempts to counteract the "fattening" effects of food by one or more of the following: • Self-induced vomiting • Self-induced purging • Alternating periods of starvation • Use of drugs such as appetite suppressants, thyroid preparations or diuretics; when bulimia occurs in diabetic patients, they may choose to neglect their insulin treatment D. Self perception of being too fat, with an intrusive dread of fatness (usually leading to underweight)	• Specific subtypes not addressed explicitly in ICD 10. • Self-induced vomiting, self-induced purging, excessive exercise, use of appetite suppressants and/or diuretics SUPPORT diagnosis in DSM but not essential in ICD.
8.	ICD gives researchers ample scope to make their own decisions on the following: • Atypical anorexia nervosa • Atypical bulimia nervosa • Overeating associated with other psychological disturbances • Vomiting associated with other psychological disorders	Researchers have no scope for decisions in DSMIt is imperative from the ICD that culturally sensitive nomenclature ought to be established addressing the prevailing deficiency in coming to grip with the stated conditions

The above comparison between DSM and ICD suggest disordered eating is protean concept that differs from one nosological entity to another. The influences of sociocultural factors that critically play part in food and dietary habits including hospitality, generosity or simply altruism, often perceived as essential social modesty have received scant attention in the available nosology on disordered eating

disorders, unless nonlaparophobia progresses to advanced and irreversible pathology, such as overt emaciation, some sufferers of these debilitating disorders are likely to go unrecognized, since laparophobia is absent in the clinical presentation in some populations. According to Cummins et al. (2005), among psychiatric disorders, eating disorders are among the most fatal with mortality rates ranging from 0.3% to 20.0% and the situation is likely to be heightened among those who use different idioms of distress, and whose cultural practices place them outside the realm of diagnostic criteria based on Western norms. The following clinical vignette (Vignette 2) of an Omani teenager presenting with unacceptable low weight and amenorrhea highlights the dilemma of strictly relying on Western classification of distress.

Vignette 2

Nasra is a 14-year-old-girl who has grown up in rural Oman until her age of 12 years, attending an all girls secondary school in Muscat, urban metropolis of the country. Her father is a petroleum engineer working in the oil and gas sector while her mother is a homemaker with secondary school education. Nasra is the first born among 10 other siblings. Other than congenital mental disorder in one of her brothers, there is no history of adverse or delayed developmental milestones for Nasra or other siblings. Premorbidly, she was described by her mother as performing among the top percentile in her class. However, coinciding with the start of the new academic semester last year, Nasra was noted as being less enthusiastic during family dinner sessions, spending more time in front of the mirror to get ready and dress herself, besides spending more time seeing movies on TV. She performed poorly in academics. According to her accompanying mother, she also took a long time to finish her meals and unless prompted, she did not take any initiative on matters related to eating. Her mother praised all her other daughters as being beautiful and plumpish. She was worried that if Nasra remained skinny she might not attract a suitable husband.

Previous encounters assessment at hospital with health professionals did not result in any changes in Nasra's ever-increasing weight reduction. The family took her to a traditional healer to rule out if her current distress was due to evil eyes, a common idiom of distress in Oman. The traditional healer recommended some rituals but this did not increase her appetite. Opinion regarding mental health was sought as the last resort since the family did not perceive her to be 'crazy'. In the initial evaluation, she concurred to the mental health professional that her emaciation was due to nauseated feelings after consuming food, bloating and pain in the stomach. Despite unacceptably low weight and amenorrhea, she strongly rejected the idea that her distress was psychological in origin. Protracted examination using DSM-IV criteria for diagnosis of disordered eating was inconclusive.

Despite concerted psychotherapeutic and pharmacological intervention, her distress appeared to be impervious to psychiatric intervention. She insisted that she wanted to see a general physician, a view that was supported by her mother. Eventually her menses normalized and her weight returned to its premorbid level in the ensuing four to five months and this coincided with her completion of secondary school in which she performed outstandingly. The family attributed her 'cure' to selective serotonin reuptake inhibitors and tricyclic antidepressants dispensed from primary health doctors as well as unverified 'treatment' from the traditional healer.

94.2.3   Culture to Culture: Somatization

If the rate of disordered eating fluctuates differently from culture to culture and also if disordered eating may be expressed differently from culture to culture, the third dimension that would be necessary to contemplate is to shed light on whether idioms of distress, culturally specific experiences of expressing pain, suffering or social discontent, may partly contribute to variations in presentation and on what constitute core features of disordered eating. Although this does not amount to Rudyard Kipling's (Stedman 2005) conception of "East is East, and West is West, and never the twain shall meet", in general, Western societies are suggested to employ psychological language whereas other societies have a greater tendency to manifest the idiom of distress as somatization. This concept owes its origin to the view that some debilitating emotion is repressed, which, in turn, is converted into physical symptoms. In contrast to Vignette 2, which indicates a predominance of the somatic tendency, Vignette 3 suggests a Western idiom of distress that is compatible with Western diagnostic nosology.

Vignette 3

Sylvia, the only child in the family, is a 14-year-old girl who has been living in Oman for the last 4 years. Her father works in an international oil and gas company. Prior to the secondment to Oman, the father was working in the UK and USA. Sylvia attends an English-speaking school for the expatriate community in Muscat. According to the referral note from the school counselor, her school performance has been excellent. Sylvia has

keen interest and aptitude in sport. During her childhood, she participated in ballet school. More recently, she has also been keenly engaging in extra-school activities including swimming and volleyball. She has been a keen runner and she participates regularly in interschool competitions. She buys exercise videos that she uses in the family's private gym and swimming pools. In the last three years, Sylvia's mother has noted that her BMI appears to be 'too low'. Her mother concurred that she cuts her food into small pieces and takes longer to finish it. She also has been avoiding food items that are high in calories and she often reads about the content of the food eaten at the house. The relationship with her mother has been turbulent since she reached puberty, which the mother interpreted as 'typical adolescence turmoil' such as she once heard of in an Oprah Winfrey's talk show. Initial medical examination was not remarkable.

During the protracted psychiatric interview, Sylvia was cooperative. She concurred to the attending mental health specialist as having strong desire to be thin. She does want to look like her mother. A quick screening for the presence of eating pathology using EAT-26 suggests a presence of clinically significant pervasive and persistent anorexia nervosa. She appears to endorse all the clinical features including amenorrhea, distorted body image, intense fear of gaining weight and refusal to maintain minimal body weight. Due to the lack of multidisciplinary services for eating disorders in Oman, the family took her elsewhere for treatment.

Somatization in non-Western cultures have been explained in terms of the inability of some people to express emotional distress or simply not to have the words to describe certain emotions (Leff 1977). Although language may facilitate the expression of emotions, other psychosocial factors are suggested to have been involved. Somatization is reported even in those societies where psychological mindedness prevails (Mumford et al. 1991b); therefore, somatization may also serve as an adaptive social function rather than as a defense against anxiety. Various psychosocial factors are shown to play a part in increasing the tendency toward a somatic idiom of distress. Distress in a non-Western culture is not perceived to be precipitated by the trajectory of one's own behavior and one's own self. In a society where development of the self is not recognized, it is unlikely that a psychological façade would be endorsed. In reference to Chinese adolescents, Lee et al. (2001) remark that "Obligation to one's family is deeply ingrained in the Asian philosophy of life and is highly valued by all in the society. It is, therefore, not surprising that Asian-Americans reported extreme concerns about meeting high parental expectations… and achievement orientation and the consequent striving for perfection could possibly predispose these youngsters to the development of anorexia nervosa." (p. 229). In many non-Western societies, value systems have an affinity to the collective self. In these societies, from the time of birth, children are brought up in an environment that ushers them into a collective mindset, as the development of selfhood is generally discouraged. The development of the self, as conceived in Western psychology, is generally not lauded in a collective society (Al-Sinawi et al. 2008). According to Dwairy (2006), in the absence of a distinct domain for the self, somatic complaints are often the only channel to communicate any discomfort. It is worth noting that characteristics of somatopsychic culture are believed to have a lack of laparophobia (Kayano et al. 2008; Viernes et al. 2007; Al-Adawi et al. 2004). The lack of laparophobia, despite the presence of overt cachexia, is depicted as a tendency toward concealment or denial (Lee et al. 2001) or solely reflecting the traditional conception of beauty that often leans toward plumpness. Lee et al. (1993) suggest that laparophobia is predominantly characterized by subjective complaints involving abdominal pain, a bloated feeling, a lack of taste or diminished appetite, the presence of constipation, or being unable to consume adequate amounts of food. However, to date, no studies have examined whether the conception of somatization may partly contribute to the variation in pattern of disordered eating.

Viernes et al. (2007) have employed the *Bradford Somatic Inventory* (BSI) (Mumford et al. 1991b) to examine variation in the tendency for somatization. BSI is an inventory for psychosomatically expressed psychological distress which is relatively free of cultural bias (Al Lawati et al. 2000). The BSI enquires about a wide range of somatic symptoms during the prior month, and whether the subject has experienced a particular symptom on fewer or more than 15 days during that month (scoring 2 or 1, respectively). This study employs 12 items derived from the BSI. These items cover the parts of the body that are likely to be affected by eating and body image due to preoccupation with food.

The psychometric property of BSI is established for Arabic speaking populations (Zahid et al. 2001) as well as other cross-cultural populations (Havenaar et al. 1996; Al-Adawi et al. 2002a). A higher score suggests preoccupation with somatic attributes.

The study in Oman study suggests the preponderance of a somatopsychic idiom of distress and endorsement on indices of somatization among the cohorts from the Philippines, India and Oman. In these students, the tendency toward disturbed weight and dieting behavior increases along with the preoccupation with somatic attributes. The Euro-American counterparts however differ on the above counts. Here, the question arises whether the observed association between somatization and ethnicity implies that somatization is a predisposing factor, or simply a reaction to disturbed weight and dieting behavior. More studies that address this issue are imperative. On the other hand, the fact that the somatic metaphor is part of how particular cultural groups communicate distress gives rise to new ideas in the ongoing debate regarding core features of eating disorders. Despite the potential importance of this issue, no previous studies we reviewed have examined the idiom of distress in the context of disordered eating. It might be more constructive to explore different idioms of distress using assessment measures that have heuristic value for non-Western cultural groups.

94.3 Conclusion

Emerging global epidemiological trends suggest that the burden of noncommunicable disease has negative ramifications with direct bearing on the quality of life, in addition to a stifling of the contribution of much-needed human resources to sustainable development. In some non-Western societies, to complicate an already gloomy picture of poverty and rapid urbanization, diseases of affluence and a culture of affluence, with all the social and medical impacts they entail, are beginning to emerge (Al-Adawi 2006). These include eating disorders and body image disturbance, previously thought to be Euro-American culture-bound syndromes, diseases or a pet mental disturbance of modern affluent cultures (Swartz 1985; Halmi 1996).

Studies on diverse regional, cultural, and linguistic groups have yielded important insights into food and eating practices (Rozin et al. 1999; Lawton et al. 2008). As food is central to survival, disordered eating increases the risk of various medical, neurological, and psychiatric complications (Uher and Treasure 2005; Wong and Fielding 2008) and, when occurring during childhood and adolescence, it can affect physical and emotional development (Angold 2009). Golden and Meyer (2004) have summarized the factors associated with increased risk of disordered eating. The most notable is cachexia that manifests as loss of fat and muscle mass. Continued severe restrictive dietary habit could affect various organs that precipitate heart problems and, for that matter, sudden death. Emergency gastrointestinal problems, impaired reproductive health, osteoporosis, dermatological and dental problems are also common. Persistent and pervasive food restriction also affects cognitive, emotional, and behavioral functioning (see Fig. 94.1). This often makes it impossible to differentiate whether diminutions of higher function are causes or effects of disordered eating.

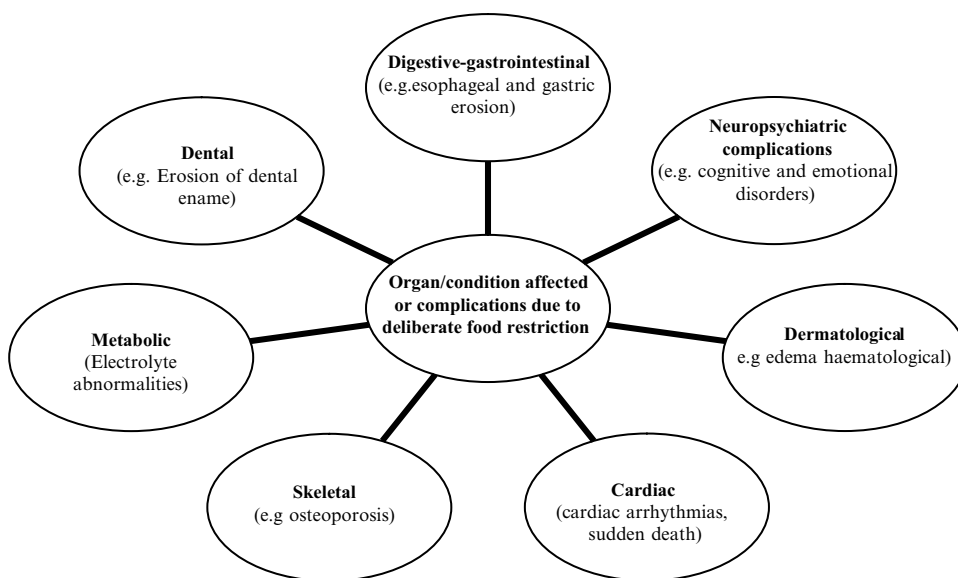
The present review has considered three interrelated themes among a cross-cultural population with reference to the unique situation in Oman. In this age of globalization and mass migration, health care services will require adjustment to ethnic and cultural variation to enhance health and the quality of life to be viable. Health-related behavior should be examined within its sociocultural context. With the ongoing globalization of the world community, the health care industry in many parts of the world will face an increasingly diverse and heterogeneous patient population, especially in urban areas. Health care providers will encounter more clients with a wide range of cultural, social,


Fig. 94.1 Eating and associated increased the risk of various medical, neurological, and psychiatric complications. Many organs compromised and while medical, neurological, and psychiatric conditions are exacerbated due to chronically mal-nourished in individuals with deliberate food restrictions which in turn may cause life-threatening complications

regional, educational, and ethnic backgrounds. In this new medical environment, the viability of health care delivery will depend on the medical community's ability to evolve and adjust to ethnic and cultural variation. Only through an awareness and appreciation of each patient's unique background can a health care provider decide on the best method to enhance health and quality of life. Firstly, in comparing Western and non-Western teenagers, non-Western teenagers have a greater tendency toward deliberate food restriction and dieting behavior than their Euro-American counterparts do. The rate among non-Western countries appears to outpace the rate observed among Euro-American teenagers. Secondly, the studies in Oman have examined whether reliance on Western norms, on which diagnostic criteria are heavily based, are appropriate in cross-cultural populations. In one of the most employed diagnostic nomenclature such DSM and ICD-10, the core feature of disordered eating include amenorrhea, distorted body image, intense fear of gaining weight, and refusal to maintain minimal body weight. As would be expected, differences in culture tend to relate to differences in idiom of distress, and studies in Oman suggest that one example of a core feature of disordered eating, laparophobia, does not feature in non-Western population (see >Table 94.4).

Third, the quest of the present review was to ascertain whether somatopsychic idioms of distress would be common in the non-Western population. Previous studies have indicated that "psychological mindedness" is a sociocultural concept. The data points to the Western population tending to endorse cognitive metaphor in distress, while evidence suggests that non-Westerners tend to physical metaphor for their distress. Tables 94.4 and 94.5 the performances of indices of deliberate food restriction, laparophobia and somatization among Western and non-Western teenagers (Table 94.5).

Understanding cultural forces may help in devising preventive measures and, at a theoretical level, shed light on which are universal and which are culture-specific behaviors. The highly variable incidence of eating disorders found across ethnically diverse populations and geographies leads us to believe that sociocultural or ecological factors play a substantial role in the etiology of eating disorders.

Table 94.4 Performance of indices of deliberate food restriction, laparophobia and tendency toward utilizing psychosomatically expressed psychological distress in Western and non-Western population (*N* = 596) (Al-Adawi et al., in preparation)

Study cohort	Assessment measures	Kruskal's gamma	*p*-Value
Euro-American vs. Non-Western	Indices of deliberate food restriction and somatization	0.659	<0.001
	Indices of deliberate food restriction and laparophobia	−0.231	<0.001
	Indices somatization and laparophobia	−0.132	0.019

Non-Western teenagers having increased propensity toward deliberate food restriction and psychosomatically expressed psychological distress while Western teenagers show a greater tendency toward laparophobia. This suggests ethnicity and culture difference in food ingestion patterns and eating practices

Table 94.5 Performance of indices of deliberate food restriction, laparophobia and tendency toward utilizing psychosomatically expressed psychological distress in different ethnic groups (*N* = 596) (Al-Adawi et al., in preparation)

Study cohort	Assessment measures	Kruskal's gamma	*p*-Value
Indian	Indices of deliberate food restriction and somatization	0.556	<0.001
	Indices of deliberate food restriction and laparophobia	0.093	0.513
	Somatization and laparophobia	−0.615	<0.001
Omani	Indices of deliberate food restriction and somatization	0.648	<0.001
	Indices of deliberate food restriction and laparophobia	−0.187	0.083
	Somatization and laparophobia	0.412	<0.001
Euro-American	Indices of deliberate food restriction and somatization	0.804	0.160
	Indices of deliberate food restriction and laparophobia	−0.162	0.231
	Somatization and laparophobia	−0.651	0.167
Filipino	Indices of deliberate food restriction and somatization	0.679	<0.001
	Indices of deliberate food restriction and laparophobia	0.239	0.043
	Somatization and laparophobia	0.229	0.042

Non-Western teenagers were more likely to have propensity toward deliberate food restriction and somatization. In contrast, present defined Western teenagers show a greater tendency toward idiom of distress that primarily involves intense fear of gaining weight or becoming fat, even if underweight

94.4 Applications to Other Areas of Health and Disease

- Although eating disorders were initially perceived to be triggered by acculturation and modernization, their emergence in non-Western cultural groups may not necessarily hinge on pathoplastic globalization, since their expression stems from cultural patterning. This has implications for teasing out what is universal versus what is cultural in food ingestion patterns and eating practices.
- There are culturally specific patterns of expressing pain, suffering or social discontent that must be considered in cross-cultural studies, because illness and distress are experienced within sociocultural domains.
- Reliance on Western norms, on which diagnostic criteria are heavily based, may not always be appropriate in cross-cultural populations since there is no universal idiom of distress.
- In this age of globalization and mass migration, the viability of health care services will require adjustment to ethnic and cultural variation to enhance health and the quality of life.

Summary Points

- This study endeavors to determine whether well-known, culturally specific modes of expressing pain, suffering, or social discontent could also manifest as disordered eating.
- The study employs screening tools that bear directly on various aspects of idiom of distress, including a tendency to "psychologize" for Western populations and to "somatize" among non-Western populations, as well as a tendency toward deliberate food restriction.
- The rate of deliberate food restriction is higher among non-Western teenagers than their Western counterparts – a finding that is seemingly consonant with previous observations suggesting that eating disorders in non-Western societies are rapidly increasing or, to some extent, outpacing the trend in Western populations.
- Performance on indices of psychological distress and fat-phobia is higher among Western teenagers in this study. This supports the contention that Westerners tend to vocalize their distress in a language framed with psychological metaphor.
- Performance on indices of somatization is higher among non-Western groups, consonant with the view that, among these groups the expression of idiom of distress is commonly framed with somatic metaphor.
- These findings, as well as other reports amassed in the literature, have implications for further research as to what is universal vis-à-vis what is cultural, and the pathoplastic versus pathogenic viewpoints in disordered eating along with its consequences.

Definitions and Explanations

Idiom of distress: Culturally specific experiences of expressing pain, suffering or social discontent

Culture-bound: Pain, suffering, or social discontent that occurs only within a specific society or culture

Culture in transition: Traditional society that is acculturating and globalizing

Culture-reactive phenomena: Pain, suffering, or social discontent that is a pathoplastic effect of globalization

Fat-phobia: Idiom of distress that primarily involves intense fear of gaining weight or becoming fat, even if underweight. Fat-phobia has been predominantly reported in Western populations; also see laparophobia

Gavage: Practice involving a nubile who is coerced into consuming a large amount of food or liquid deemed essential to increase one's weight

Laparophobia: Idiom of distress that primarily involves intense fear of gaining weight or becoming fat, even if underweight. Laparophobia has been predominantly reported in Western populations; also see fat-phobia

Somatization: Idiom of distress that primarily involves presentation of somatic complaints as all forms of expressing pain, suffering, or social discontent

Psychologization: Idiom of distress that primarily involves presentation of psychological complaints as all forms of expressing pain, suffering, or social discontent

---

Key Facts

1. Diagnostic criteria and assessment measures are based on Western norms.
2. Based on the above, the cultural patterns noted to be prevalent are as follows:

Western population:	**Non-Western population:**
(a) Tendency to psychologize distress	Tendency to somatize distress
(b) Rate of food restriction is lower	Rate of food restriction comparatively higher and rapidly increasing
(c) Fat phobia higher	Fat phobia lower

3. Key confounders that must be addressed with respect to dietary habits: Global impact of media (TV, glossy magazines, Internet), movies (movie stars as role models), fashion and modeling industry, service industry (slimming centers), over-the-counter drugs (herbal slimming medicines), societal perception, and expectations of what constitutes beauty and which body image type is appreciated, and whether dieting is in fact the "preferred choice" of young females.

Chapter 95
Examining the Relationship Between Binge Eating and Coping Strategies in Adolescents

DSM-IV-TR	*Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision
SD	Standard deviation

95.1 Introduction

Binge eating, the consumption of large quantities of food accompanied by a sense of loss of control, is an essential symptom of two eating disorders – included in the fourth edition, text revision, of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR) (American Psychiatric Association [APA] 2000) – Bulimia Nervosa (BN) and Binge Eating Disorder (BED), which is a provisional category included in the Appendix in need of further study. In addition, binge eating is also present in individuals with Anorexia Nervosa and subclinical eating disorders. Moreover, this behavior is not restricted to individuals with eating disorders, but it has also been reported in community samples (Williamson 1990; Beglin and Fairburn 1992; Spitzer et al. 1993; Vanderlinden et al. 2001; Croll et al. 2002; Ackard et al. 2003), being more frequent in obese populations, especially in those who are in weight-reduction programs (Amigo 2003; Didie and Fitzgibbon 2005).

According to the DSM-IV-TR (APA 2000), in order for an eating episode to be considered a binge, both a large amount of food in a discrete period of time and loss of control must be present. This is something important to keep in mind as binge eating is a concept widely used by both laypersons and professionals, yet the meaning attached to it may not be the same, thereby hindering proper communication between clinicians and patients in some cases (Beglin and Fairburn 1992). Consequently, it is important to further explore the variables which make up a binge eating episode to reach a more adequate definition of binge eating and therefore improve its assessment methods for both research purposes and clinical diagnosis. The key features of the definition of binge eating can be seen in Table 95.1.

Table 95.1 Key features of the definition of binge eating

- The diagnostic manuals describe binge eating as the consumption of large quantities of food (compared to what most people would eat) in a discrete period of time (for example 2 h), while experiencing a sense of loss of control.
- Therefore, three variables are taken into account in the definition: the amount eaten, the time it takes to eat the food, and loss of control.
- The presence of loss of control is important to distinguish overeating episodes form episodes of binge eating. Loss of control markers are for example eating much more rapidly than usual, eating when not hungry, eating until uncomfortably full, and feeling disgusted with oneself after the episode.

This table shows the key aspects of the definition binge eating described in the diagnostic manuals

Table 95.2 Problems associated to binge eating

- In the long run, binge eating is associated to weight gain and obesity.
- Binge eating is accompanied in some individuals by unhealthy compensatory methods to avoid weight gain which can be very physically and psychologically harmful, such as self-induced vomiting, misuse of laxatives, diet pills, over exercising, etc.
- Increased risk of developing a subthreshold or a full-blown eating disorder.
- Depression, anxiety, low self-esteem, body image disturbance.
- Higher risk of suicide.
- Social isolation and impaired social relationships.

This table summarizes the main psychological, physical, and social problems associated to regular binge eating

Binge eating is an unhealthy behavior present in a wide range of individuals associated with great distress as well as psychological, physical, and social problems (see Table 95.2). It is especially important to identify the factors associated with the development of this unhealthy eating behavior in young adolescents who have not yet developed an eating disorder in order to find ways of preventing this behavior from appearing.

95.2 Binge Eating in Adolescents

There is no question that adolescence is a particularly interesting period for the study of maladaptive eating behaviors which can be viewed as risk factors for the future development of eating pathology (Williams and McGillicuddy-De Lisi 2000). This is due to the diversity of physical, social, affective, and cognitive changes that take place during this developmental stage and its temporal proximity to the onset of the major eating disorders (Williams and McGillicuddy-De Lisi 2000; Liu et al. 2004). The literature has consistently shown that binge eating is a relatively frequent behavior in adolescents (e.g., Aljadir and Liprie 1999; Vanderlinden et al. 2001). Research studies have reported frequencies of binge eating which vary depending on the assessment method used, but, in general terms, it appears to be quite significant (Aljadir and Liprie 1999; Vanderlinden et al. 2001; Ackard et al. 2003; Sierra-Baigrie and Lemos-Giráldez 2008). For example, Ackard et al. (2003) examined the presence of binge eating in a sample of adolescents from public middle and high schools in Minnesota and found that this behavior was reported by 7.9% of the girls and 2.4% of the boys in their sample. Vanderlinden et al. (2001) found in their study that 41% of the women aged 14–25 who participated reported binge eating at least once with 15% of these women indicating that they had daily binges. Especially interesting was the high rate of binge eating in a nonclinical sample. Similarly, in another study (Aljadir and Liprie 1999), 51% of adolescents aged 10–15 who participated reported at least one episode of binge eating in the previous week. The authors were surprised by the high percentage of males (46%) who indicated binge eating, considering that most eating disorders are more frequent in females. Therefore, these

results highlight the importance of including males in the samples when studying binge eating in order to reach a better and more complete understanding of the phenomenon. They also found that binge eating was negatively correlated with age, with the highest rates in the 10-year-old group. Thus, this finding suggests that the onset of binge eating may be at an earlier age than was previously believed.

95.2.1   Binge Eating in Spanish Adolescents

With respect to binge eating in Spanish adolescents, research focused solely on this problem (and not only as a symptom of bulimia) is very scarce and, therefore, data are limited on the prevalence of binge eating in Spanish adolescent populations. One study by Rodriguez et al. (2001) examined the presence of eating disorders and altered eating behaviors in normal-weight Spanish adolescents. The sample consisted of 491 adolescents aged 14–18 from Cadiz, a city located in Southern Spain. The authors found that 42% of the adolescents reported "recurrent episodes of binge eating" with a sense of loss of control. More recently, we found in another study of 259 Spanish adolescents that 33.2% of these reported binge eating at least once in the last 6 months (Sierra-Baigrie and Lemos-Giráldez 2008). More epidemiological studies on binge eating in Spanish adolescents are needed in order to determine the prevalence of this behavior in this population and make comparisons with other cultures.

95.3   Factors Associated with Binge Eating and Theoretical Models

A great number of studies have attempted to determine the factors associated to binge eating (e.g., Stickney et al. 1999; McLaren et al. 2001; Vanderlinden et al. 2001; Ghaderi 2003; Fischer et al. 2004; Benjamin and Wulfert 2005). Among some of the factors identified, we find interpersonal stress, anxiety, body-weight concern, weight cycling, body dissatisfaction, boredom, depressive mood, avoidance coping, and restrictive dieting (Mayhew and Edelmann 1989; Stickney et al. 1999; Vanderlinden et al. 2001). Other studies have shown that stress is an antecedent to eating pathology in general (e.g., Bennett and Cooper 1999; Quiles Marcos and Terol Cantero 2008) and that individuals with eating disorders tend to view stressful situations as more stressful than those with no eating disorders (Hansel and Wittrock 1997; Bittinger and Smith 2003; Quiles Marcos and Terol Cantero 2008). However, most people are confronted with many stressful situations throughout their lives and do not develop an eating disorder. Hence, stress may be a possible antecedent to eating-disordered behavior mediated by other contributing factors in the development of disordered eating.

Over the years, researchers have proposed some interesting theories attempting to explain the mechanisms behind binge eating: for example, the restraint hypothesis, the binge–purge hypothesis, the set-point hypothesis, and theories that consider binge eating an affective disorder or an addiction (Beebe 1994; Fairburn 1995). Heatherton and Baumeister (1991) proposed an interesting explanation for binge eating with the escape model. These authors posit that binge eating acts as an escape from negative self-awareness. According to the authors, individuals who binge eat are very sensitive to not meeting their high standards, feeling an aversive negative state from which they wish to escape. For these individuals, binge eating is a way of focusing all the attention on immediate sensations, thus, turning attention away from themselves and the negative feelings they are experiencing. This model offers an interesting explanation for binge eating although perhaps it does not offer an explanation for this behavior in all individuals. In addition, more research is needed regarding many aspects of the underlying theory.

95.4 The relationship Between Coping and Binge Eating

Numerous studies have examined the relationship between the different coping strategies used and eating pathology (e.g. Mayhew and Edelmann 1989; Yager et al. 1995; Hansel and Wittrock 1997; Wolff et al. 2000; Ball and Lee 2002; Schwarze et al. 2003; García-Grau et al. 2004; Jáuregui Lobera et al. 2009). In one of these studies, Yager et al. (1995) compared the coping strategies used by recovered and nonrecovered women diagnosed with BN. The nonrecovered women with BN had a tendency to use less productive and fewer coping strategies than the recovered women (Yager et al. 1995). Moreover, another study (Garcia-Grau et al. 2004) found that Self-blame, which is a scale of the Intropunitive avoidance dimension in the ACS, was the strategy with the strongest link to the predisposition to eating disorders. Similarly, Mayhew and Edelmann (1989) also found that higher scores on the Eating Disorders Inventory (EDI) were associated to lower self-esteem, more irrational thinking, decreased use of cognitive and behavioral coping strategies, and increased use of avoidance coping. More recently, Quiles Marcos and Terol Cantero (2008) conducted a literature review regarding the role of coping in the eating disorders. They found that eating-disorder patients use avoidance and emotion-oriented coping more often and problem-oriented coping strategies less often than individuals with no eating disorders.

Regarding the relationship between coping and binge eating in particular, based on Heatherton and Baumeister's theory (1991), it may be considered that adolescents who do not have the appropriate skills to confront and deal with their daily problems in a constructive manner may try to escape from the negative feelings and thoughts surrounding the unresolved problems through an escape mechanism, such as binge eating. Therefore, we consider that adolescents with a greater tendency to use avoidance coping strategies would be more prone to binge eating. The individual´s coping style could be viewed as the mediating factor between the stressful situation and binge eating.

Research examining the link between coping strategies and binge eating has shown inconsistent results. Freeman and Gil (2004) found that distraction coping (which is part of avoidance coping) was related to the later risk of future binge eating. Similarly, Wolff et al. (2000) found in their study that the women who binge ate did not differ from the ones who did not binge eat in the number of coping strategies used, but did differ in that they used avoidance coping more frequently. Furthermore, in another study by Hansel and Wittrock (1997), the women who reported binge eating used positive and negative coping strategies more often than the nonbinge eating women. In another study we conducted to explore this relationship in Spanish adolescents, binge eating was found to be associated with avoidance coping (Sierra-Baigrie and Lemos-Giráldez 2008). The adolescents who had problems with binge eating used significantly more frequently avoidance coping and introversion in comparison to those adolescents with no binge eating problems.

On the other hand, several studies have failed to find an association between avoidance coping and binge eating (e.g., Paxton and Diggens 1997; Schwarze et al. 2003). Schwarze et al. (2003) found that the female undergraduate students in their study who reported problems with binge eating were more prone to using avoidance coping strategies than the women who did not binge eat. However, when depression was statistically controlled they did not find a significant difference between the two groups. In addition, Paxton and Diggens (1997) did not find a clear link between avoidance coping and binge eating in a sample of 149 undergraduate students. They also found a confounding effect of depression, that is, the relationship between binge eating and coping depended on the level of depression. Consequently, there is a need to clarify the role of coping strategies in the development and maintenance of binge eating in nonclinical adolescents, given that adolescence is a period of especial interest for the study of these types of subclinical symptoms.

95.5 Coping and Binge Eating in Spanish Adolescents

Recently our research team has conducted a study to further explore the relationship between coping and binge eating in Spanish adolescents. The main objective was to examine the relationship between the coping strategies used by adolescents and the presence of binge eating. Following Heatherton and Baumeister (1991), it was expected that the adolescents who used avoidance coping more often would be more likely to binge eat. Another objective was to examine the adolescents' definition of binge eating and compare it with the actual DSM-IV-TR (APA 2000) definition used by clinicians and researchers.

One thousand nine hundred and thirty-six adolescents from the Principality of Asturias, a northern region in Spain, participated in the study. The age of the participants ranged from 12 to 21 ($M = 14.72$; $SD = 1.73$), 50.3% males and 49.7% females. The participants completed the *Bulimic Investigatory Test, Edinburgh (BITE)* (Henderson and Freeman 1987), the *Adolescent Coping Scale* (ACS) (Frydenberg and Lewis 1993) and *three additional open-ended questions* to obtain more information about the binge eating episodes. The BITE (Henderson and Freeman 1987) is a self-report questionnaire used to evaluate the presence and severity of bulimic symptomatology. It is composed of 33 items divided into two different subscales: a 30-item symptom subscale and a three-item severity subscale. The minimum score on the symptom subscale is 0 and the maximum possible score is 30. The adolescents' coping strategies were measured using the ACS (Frydenberg and Lewis 1993), which is a self-report inventory for the assessment of general coping strategies in 12–18 year-old adolescents. It consists of a total of 80 items (one open-ended question) that reflect different ways of coping and that are rated on a 5-point Likert scale based on the frequency with which the adolescent feels that he/she uses that strategy (1 "It never happens to me or I never do it"; 5 "It happens very frequently or I very frequently do it"). The Spanish adaptation was employed for this study. According to the manual, these 18 coping strategies can be grouped into four different major coping dimensions: positive and effortful action (for example: "I ask a competent person for their advice"), hedonist-positive action (for example: "I do sports"), intropunitive avoidance (for example "I feel guilty") and introversion ("I avoid being with others"). Table 95.3 describes these coping dimensions in more detail.

Finally, to examine the adolescents' binge eating episodes, the participants completed three additional open-ended questions; one of these allowed them to define binge eating in their own words.

Table 95.3 Key Features of the dimensions of coping measured by the ACS

- The ACS is a useful instrument that can be used as a research tool for assessing adolescent coping strategies or as a practical tool for teaching adolescents constructive ways of coping.
- The ACS consists of 18 scales which refer to 18 different ways of coping. According to Frydenberg and Lewis (1993), these scales can be grouped into three different coping dimensions, namely: Solving problem, Reference to others, and Nonproductive coping.
- In the Spanish version of the ACS, the authors found four major coping dimensions which were used in this study. The *Positive* coping dimension refers to the effortful action of attempting to solve the problem, working hard, and achieving. The *Positive-hedonist* dimension refers to looking for healthy ways of distraction from the problem, wishful thinking, investing in close friends, and engaging in physical distraction. *Intropunitive avoidance* refers to not dealing with the problem, looking for ways of reducing the tension, and blaming oneself. Lastly, the *Introversion* dimension makes reference to keeping problems to oneself, not approaching others for help, avoiding professional help or social support.
- These dimensions are useful for comparing styles of coping in adolescents and for examining their relationship with different psychopathological variables.

This table describes the dimensions of coping measured by the ACS

ACS Adolescent Coping Scale

95.5.1 Rate of Binge Eating and Binge Eating Problems in Our Spanish Sample

To question 24 of the BITE *Have you ever binged on food?* 35.9% (688) of the adolescents answered yes (31.5% of the girls and 40.4% of the boys). In Table 95.4 the percentages of the participants who reported binge eating at least once are shown.

Regarding the presence of binge eating problems, the mean score on the BITE for the total sample was 5.22 (SD = 4.34) raging from 0 to 26 points. The mean score was 4.63 (SD = 3.75) for boys and 5.82 (SD = 4.79) for girls. The mean BITE score increased with age (χ^2 = 106.271, p < 0.001) and there were statistically significant differences between the genders (χ^2 = 16.430, p < 0.001) with females obtaining higher mean scores than males.

Consistent with findings from previous research (Aljadir and Liprie 1999; Rodriguez et al. 2001; Vanderlinden et al. 2001; Ackard et al. 2003), the results show that binge eating is a fairly common behavior in nonclinical adolescents. The rate of binge eating obtained in our sample of Spanish non-clinical adolescents (35.6%) is intermediate compared to rates reported in previous studies (e.g., 51% of adolescents in Aljadir and Liprie 1999; 41% in Vanderlinden et al. 2001; 5.15% in Ackard et al. 2003). One interesting finding of the present study was that the rate of binge eating was higher in males than in females, which is contrary to what has been found in other investigations (e.g., Aljadir and Liprie 1999; Ackard et al. 2003). Moreover, many studies do not include males in their samples when exploring eating pathology, such as binge eating. The high rate found in males in the present study, as well as in the study by Aljadir and Liprie (46%), suggest that it is important to include both males and females when studying binge eating in order to explore this behavior using representative samples.

95.5.2 Findings and Implications Regarding the Link Between Coping and Binge Eating

With respect to the link between coping strategies and binge eating, the results showed statistically significant differences in the mean scores on the four dimensions of coping between the adolescents who reported binge eating and those who reported no binge eating (Wilks' λ = 0.949, p < 0.001) (see Table 95.5).

The adolescents who reported at least one episode of binge eating obtained higher mean scores on the dimensions of Intropunitive avoidance (e.g., tension reduction, ignore problem) and Introversion (e.g., keep to oneself, avoid contact with others) and lower mean scores on the Positive dimension of coping (e.g., focus on the positive, concentrate on solving the problem) compared to the adolescents who

Table 95.4 Percentage of reported binge eating by age and gender

Age	Boys	Girls	Total
12–13 (n = 572)	67 (23.42%)	61 (21.32%)	128 (22.37%)
14–15 (n = 694)	139 (37.46%)	100 (30.12%)	239 (34.43%)
≥16 (n = 670)	180 (54.54%)	140 (41.17%)	259 (47.76%)

This table shows the percentages of the adolescents who answered affirmatively to question 24 on the BITE (have you ever binged on food?). As we can observe, this percentage increases with age (χ^2 = 106.271, p < 0.001). In addition, there are also statistically significant differences between males and females (χ^2 = 16.430, p < 0.001), with more males reporting binge eating

Table 95.5 ANOVA results comparing the mean scores (and standard deviations (SDs)) on the dimensions of coping

Coping dimension	Binges ($n = 677$)	No binges ($n = 1203$)	F	p	η^2
Positive	257.68 (40.02)	265.91 (44.97)	15.67	0.000	0.000
Avoidance	141.41 (38.18)	125.16 (35.52)	85.96	0.000	0.043
Positive-hedonist	447.83 (67.19)	442.45 (72.10)	2.53	n.s	0.000
Introversion	201.68 (41.80)	196.86 (42.97)	5.55	0.019	0.000

This table displays the ANOVA results comparing the adolescents who reported binge eating (i.e., those who answered affirmatively to question 24) and those who reported no binge eating (i.e., those who answered negatively) in the four dimensions of coping measured by the Adolescent Coping Scale (ACS)

n.s. non significant, *ANOVA* Analysis of Variance

Table 95.6 ANOVA results comparing the mean scores (and standard deviations (SDs)) on the four dimensions of coping between participants with high and low BITE scores

Coping dimension	High BITE score ($n = 252$)	Low BITE score ($n = 544$)	F	p	η^2
Positive	258.31 (41.10)	269.38 (48.11)	9.982	0.002	0.012
Intropunitive avoidance	163.65 (35.93)	114.29 (32.36)	373.34	0.000	0.320
Positive-hedonist	450.44 (63.95)	436.39 (74.24)	6.712	0.010	0.000
Introversion	205.85 (45.11)	195.97 (41.47)	9.229	0.002	0.011

This table shows the ANOVA results comparing the participants with a high BITE score (i.e., BITE ≥ 10) (indicating binge eating problems) and those with a low BITE score (BITE < 2) in the four dimensions of coping measured by the Adolescent Coping Scale (ACS)

BITE Bulimic Investigatory Test, Edinburgh, *ANOVA* Analysis of Variance

reported no binge eating. However, on the Positive-hedonist dimension the adolescents who reported binge eating obtained higher mean scores than the adolescents without binges, although this difference was not statistically significant. In order to control for the possible confounding effect of age, given that binge eating increased with age, the same analysis was conducted introducing age as a covariate. The analysis showed that age did not alter the results and, therefore, did not affect this relationship.

When this relationship was further explored by comparing the coping strategies used by the adolescents who have binge eating problems (BITE ≥ 10) and those who do not (BITE < 2), the results showed significant differences in all four dimensions of coping (Wilks' $\lambda = 0.673$, $p < 0.001$) (see Table 95.6).

As can be seen in Table 95.6, the group with binge eating problems obtained significantly higher mean scores in the Intropunitive avoidance and Introversion coping dimensions than the group with no binge eating problems. Therefore, the adolescents with binge eating problems use nonproductive coping strategies more frequently, such as not coping with the problem, keeping it to oneself, self-blame or seeking ways of reducing tension, in comparison to those with no binge eating problems. On the other hand, the adolescents with binge eating problems use positive strategies such as working hard and achieving and focusing on the positive less frequently.

The results are consistent with past research regarding the link between avoidance coping and binge eating and eating pathology in general (Hansel and Wittrock 1997; Wolff et al. 2000; Ball and Lee 2002; García-Grau et al. 2004; Sierra-Baigrie and Lemos-Giráldez 2008); however, other studies have found inconsistent results (Paxton and Diggens 1997; Schwarze et al. 2003). With respect to the Positive coping dimension, previous studies have found that the adolescents who report binge eating use positive strategies less frequently (Quiles Marcos and Terol Cantero 2008) whereas other studies have failed to support this association (e.g., Hansel and Wittrock 1997; Wolff et al. 2000). The adolescents in our sample who reported binge eating use positive-coping strategies, such as trying to solve the problem, focusing on the positive, or asking for help, less frequently than the adolescents who

reported not having binges. On the other hand, they reported using avoidance coping more frequently, perhaps due to the fact that they lacked the positive coping strategies needed to appropriately deal with stressful situations. These findings suggest that those adolescents who have a tendency to engage in binge eating may lack the proper skills to deal with daily problems or stressful situations, therefore, making use of less constructive ways of coping, such as avoidance coping. It would be interesting to determine which situations are associated with the use of avoidance-coping strategies in adolescents who binge eat and compare them to the strategies used by those who do not.

95.5.3 The Adolescents' Definition of Binge Eating: Analysis and Implications

With respect to the adolescents' definition of binge eating, there was a clear tendency to describe eating binges solely in terms of the large amount of food eaten. In our study, 76.23% of the participants' who answered ($n = 1662$) described binge eating solely in terms of amount eaten, 13.23% also mentioned time in their definition and only 9.40% described binge eating using the three variables included in the DSM-IV-TR (APA 2000) definition of binge eating (amount, time and loss of control). There were no significant differences in the variables mentioned by the adolescents who have problems with this behavior (BITE ≥ 10) and those who do not (BITE < 2) ($\chi^2 = 4.435$, $p = 0.218$). However, significant gender differences were found in the variables mentioned ($\chi^2 = 55.649$, $p < 0.001$) with a higher percentage of girls taking the three variables into account. On the other hand, there were no significant differences in the variables mentioned in the definitions by the different age groups ($\chi^2 = 9.006$, $p = 0.173$). Regarding the adequacy of the DSM-IV's definition of binge eating (APA 1994), a study was conducted at the University of Manitoba (Sierra-Baigrie 1997), which examined the effect of these three variables (amount eaten, time, and loss of control) in the identification of eating episodes as binges. There was a significant effect of amount eaten on the ratings with no effect found for time. Furthermore, loss of control interacted with both time and amount eaten. The results underscore the importance of loss of control in the identification of eating episodes as binges. However, in the present study there were very few adolescents who mentioned loss of control in their definition of binge eating. There are some possible explanations for this finding. On the one hand, the adolescents may have difficulties in verbalizing different behaviors or feelings thus focusing on the objective factors (such as amount) as opposed to the more subjective variables (such as loss of control). Perhaps when defining what a binge is, people take into account more objective variables with the more subjective variables being more important when rating one's own behavior.

95.6 Future Lines of Research

Some questions still remain regarding the relationship between coping and binge eating, such as why some studies have found that individuals who binge eat use more positive and negative coping strategies than those who do not engage in this behavior, that is, that binge eaters seem to use a greater number of strategies. More research is needed to clarify this relationship to further explore the types of avoidance-coping strategies used by the adolescents who binge eat before binge eating becomes a significant problem in order to gain understanding of the development of this eating problem. Longitudinal studies are needed to determine if those adolescents who have a tendency to use avoidance coping when confronted with stressful situations have a higher future risk of binge eating problems. Furthermore,

studies should also explore the circumstances under which binge eaters use avoidance coping more frequently as well as the factors associated with the use of avoidance coping in children and adolescents. Strategies for the prevention of binge eating problems could focus on these unproductive-coping strategies by helping children and adolescents find positive ways of dealing with stressors and, therefore, avoiding the development of unhealthy habits such as drug abuse or binge eating.

Regarding the adolescents' definition of binge eating, the findings of the study have important implications as well. The results suggest that the definition used by the adolescents and that used by clinicians and researchers may differ, which brings doubts about whether studies that measure binge eating without explicitly mentioning the three variables considered by the DSM-IV-TR (APA 2000) obtain a true measure of this behavior. Adolescents may be referring to overeating episodes as binge eating episodes which may falsely identify adolescents as binge eaters who in reality are not. It may be necessary to either explain what binge eating is according to the diagnostic manuals or formulate questions which explicitly consider the three variables mentioned in the definition. Another possibility is to use a two-stage procedure for the detection of individuals who binge eat, which has been shown to provide more accurate ratings as the interviewer in the second stage can explain more clearly what the questions mean, which significantly reduces the misunderstanding of questions (Peláez-Fernández et al. 2008). Future research could attempt to examine the variables which are taken into account by adolescents when rating their own eating episodes as binges.

In short, the review of the literature shows that binge eating is a fairly frequent behavior among adolescents and that it is associated to the use of avoidance coping strategies. These findings have important implications with respect to the prevention of binge eating and, consequently, of eating disorders and obesity, as well as contribute to the advancement in the understanding of this phenomenon in nonclinical adolescents. One possible means for the prevention of binge eating could be to focus on the adolescents' coping skills, helping them develop healthy and productive ways of coping with their problems. Moreover, it may be useful to identify when adolescents use avoidance coping strategies more often and show them ways of dealing with the feelings or the situations that trigger an escape mechanism.

95.7 Applications to Other Areas of Health and Disease

Regular binge eating has important consequences for the person's physical and psychological health. Binge eating has been found to be associated to a higher body mass index (BMI), lower self-esteem, depressive symptoms, decreased satisfaction with body image, and a higher risk of suicide attempts (Ackard et al. 2003). Individuals who engage in frequent binge eating episodes have a greater probability of developing a full-blown eating disorder in the future, such as BN or BED (Didie and Fitzgibbon 2005). On the other hand, binge eating is often associated to other pathological eating-related behaviors (such as fasting or extreme or unbalanced diets) and compensatory methods to prevent weight gain (such as vomiting, laxative misuse, etc.) which can also be very harmful. Moreover, frequent binge eating not accompanied by compensatory methods can lead to weight gain and obesity which also have important physical, psychological, and social consequences for the person. For example, it is well documented that obesity increases the risk for cardiovascular disease, sleep disorders, and Type II diabetes, among others (de la Serna 1998). Furthermore, obesity can be associated to a decrease in social relationships, difficulties in finding a partner, low self-esteem, depression, anxiety, and so on (de la Serna 1998). All these risks and consequences associated to binge eating clearly show the importance of its study, prevention, and treatment. Thus, the study of binge eating is important to prevent the onset of this behavior in young individuals who have not yet developed an eating-related disorder, and therefore, prevent the development of all the aforementioned associated risks.

With regards to coping strategies, numerous studies have shown that the use of avoidance coping is associated to a higher risk of developing other psychological problems, for example, depressive symptomatology, anxiety, or substance abuse (e.g., Liu et al. 2004; Figueroa et al. 2005; Ireland et al. 2005). Thus, showing children and adolescents healthy and constructive ways of coping with daily stressors can also prevent other mental problems in the future.

Summary Points

- The literature shows that binge eating is a fairly frequent behavior in adolescents.
- Binge eating is associated to considerable psychological, physical, and social impairment in some individuals and it is a symptom of two major eating disorders.
- It is important to study the variables associated to this maladaptive eating behavior in nonclinical samples to establish the mechanisms involved and find ways of preventing this behavior and, therefore, future eating problems.
- Numerous studies have found an association that avoidance coping is associated to binge eating; however, some studies have failed to find this association. Therefore, more research is needed to clarify this relationship.
- In our study of nonclinical Spanish adolescents, those who reported binge eating used avoidance coping and introversion strategies more frequently than those who reported no binge eating. On the other hand, they used positive coping strategies less frequently.
- Most of the Spanish adolescents in our study defined binge eating solely based on the amount eaten with very few adolescents mentioning loss of control. Therefore, there could be an overestimation of this behavior when using selfreport measures.
- Thus, the clinical definition of binge eating seems to differ from the nonprofessional understanding of the term, which could hinder proper communication between clinicians and patients.

Definitions and Explanations of Key Terms

Binge eating: This refers to eating a large amount of food in a relatively short period of time with a feeling of not being able to control how much one eats. The individual usually feels very distressed, uncomfortably full, and extremely upset with him/herself after the episode.
Coping strategies: This makes reference to the ways in which a person deals with daily stressors or stressful events. These can be behavioral, emotional, or cognitive approaches to deal with the problem.
Avoidance coping: It refers to unproductive or nonconstructive ways of coping with problems or problematic situations. Examples of avoidance coping are: not dealing with the problem, blaming oneself, or engaging in behaviors to reduce the associated tension, such as binge eating or alcohol consumption.
Compensatory methods: These refer to those behaviors eating-disordered individuals use to avoid gaining weight after overeating, such as vomiting, abusing laxatives, and excessive exercise. The most common compensatory method used by bulimics is self-induced vomiting.
Subthreshold or subclinical eating disorder: These are eating problems of clinical significance which do not meet the criteria for the diagnosis of a recognized eating disorder but that, nevertheless, are very distressing for the person.

Chapter 96
Nutritional Influences on Antisocial Behavior

David Benton

Abbreviations

ADHD	Attention deficit hyperactivity disorder
DHA	Docosahexaenoic acid
EPA	Eicosapentaenoic acid
GI	Glycemic index
LCPUFA	Long chain poly-unsaturated fatty acids

96.1 Introduction

There have been a series of suggestions that what we eat may either increase or decrease irritability or the likelihood of displaying antisocial behaviour, even violence or criminality. Various possible mechanisms have been explored. It has been proposed that some individuals are sensitive to particular foods, so that their consumption leads to antisocial behaviour; in particular, sugar and food additives have attracted attention. Diets low in vitamin, minerals, and essential fatty acids have also been related to displays of violence. Finally the influence of the consumption of meals that result in low levels of blood glucose has received attention. This is an area where there has been relatively less research although there are a growing number of well-designed double-blind placebo-controlled trials. There is a need for studies that use this approach as it is clear that changing some aspects of the diet often produces a large placebo effect, a reflection of suggestion and expectation (Table 96.1).

96.2 Food Intolerance

Food intolerance or food hypersensitivity reflects an adverse physiological response to a food item by means other than that of the immune system. Although in the past, on occasions, an allergic reaction to food has been included as a form of food intolerance, more recently, the correct medical term has become nonallergic food hypersensitivity. Food allergy by definition reflects an immunological

Table 96.1 Key ways that diet influences antisocial behavior

Ways that diet may influence antisocial behavior:
- Food intolerance
- A lack of essential fatty acids
- Developing low blood glucose levels
- A diet low in minerals and vitamins

Diet had been suggested to influence behavior in various ways. The four most commonly proposed are listed

reaction that can be monitored by measuring the release of Immunoglobulin E. In contrast, food intolerance may reflect a pharmacological reaction, for example, to histamine, or alternatively a response to a toxin. Finally, a problem in the metabolism may also occur such as that associated with an enzyme deficiency; for example, lactase deficiency prevents the normal breakdown of the milk sugar lactose. As well as reacting adversely to food items, it is possible to respond to food additives; for example, a preservative, coloring, or artificial flavor. In particular it has been suggested that ADHD can be induced or at least exacerbated by diet.

As placebo effects can be substantial in this area, it is particularly important to consider double-blind trials. Children eat a "few-foods" diet, one that contains a limited number of items with a small chance of inducing an adverse reaction. Additional foods are then reintroduced that remain as part of the diet if there is no adverse reaction. Finally those foods to which there was an adverse reaction are tested using a double-blind procedure in which two similar meals are cooked that either do or do not contain the suspect food item. Benton (2007) subjected five such studies to meta-analysis and found an effect size of 0.8 of a standard deviation, i.e., a large response. The nature of the effect can be illustrated by the study of Egger et al. (1985). They found 48 foods to which at least one child responded adversely. Although, 79% of the children responded to the yellow artificial colour tartrazine and the preservative sodium benzoate, there was no child who did not in addition react to other food items. However, as there are many thousands of food additives and flavorings this cannot be generalized to other substances as each needs to be considered individually. The 8 most common problem foods are listed in Table 96.2. It is clear that an adverse response was not particularly associated with processed foods. There is an impression that many if not most foods can be a problem for at least a minority. Apparently "natural" and "healthy" items such as fruit were a problem for some. Sugar, that has attracted a great deal of negative attention, was less of a problem than 13 other foods. In fact the term "natural" has been frequently misused. Some of the most poisonous substances come from nature and similarly the chemist is capable of creating health-promoting molecules. In both instances we need to test the item to establish its safety in general and in particular whether there is a behavioral response. In this area it is not possible to offer general advice as each child has an individual pattern of response. No particular additive or food has been found to be a universal cause of problems.

Although these studies produce strong evidence that the behavioral problems of some children reflect a response to their diet, it should be remembered that this was a self-selected group whose parents believed prior to the study that they responded to what they ate. As such we cannot assume that a response to diet occurs in all children with a diagnosis of ADHD. In addition as the etiology of ADHD is known to be multifactorial, at the most, diet is one potential problem among many others.

At least among self-help groups, the ideas of Feingold (1975) continue to be advocated. Although his views were based on clinical observations rather than well-designed studies, he suggested that hyperactive behavior was stimulated by a diet containing salicylates (chemicals in food that have a similar structure to aspirin). Although it was not the purpose of the studies that used elimination diets

Table 96.2   Foods to which hyperactive children react

Cows milk	64%
Wheat	49%
Cows cheese	40%
Hens egg	39%
Beef	16%
Pork	13%
Chicken	11%
Potatoes	11%

The data are from the study of Egger et al. (1985) that studied children with ADHD whose parents prior to the study suspected that they responded adversely to their diet. They initially ate a "few foods" diet and then additional items were added one by one. If there was no adverse reaction the food item remained as part of the diet. Finally under double-blind conditions genuine adverse responses to diet were established. In total there were nearly 50 foods to which at least one child responded; the 20 most problematic foods and the percentage of children who responded are reported

Table 96.3   The number of children reacting to the Feingold diet

Tartrazine/sodium benzoate	79%	Fish	23%
Cows milk	64%	Oats	23%
Chocolate	59%	Pineapple	19%
Grapes	49%	Beef	16%
Wheat	49%	Sugar	16%
Oranges	45%	Malt	15%
Cows cheese	40%	Beans	15%
Hens egg	39%	Peas	15%
Peanuts	32%	Apples	13%
Maize	29%	Pork	13%

The Feingold diet proposes that a diet containing food items low in salicyclic acid will decrease hyperactive behavior and recommends the consumption of the above foods. These data taken from Egger et al. (1985) show the proportion of hyperactive children who responded adversely to the foods in the Feingold diet. The data do not support this approach

they are a powerful test of the Feingold hypothesis. It is clear in these double-blind trials that many children responded adversely to the foods low in salicyclates, which form the core of the Feingold diet (Table 96.3). Thus, although diet can be a problem for some children, the evidence from well-designed studies suggests that a diet low in natural salicylates is not helpful (Benton 2007).

There are isolated yet similarly convincing data from adults. For example Mackarness (1976) described a patient with a history of violence both toward her children and herself, who was being recommended for brain surgery to control her behavior. Similar to the study of children mentioned earlier, the test of a "few-foods" diet established the items to which she responded adversely. In this case they were then tested under double-blind conditions by introducing them via a tube directly into the stomach. When a new diet was developed the antisocial behavior ceased. Although it is unlikely that this is a unique case there is no way of knowing how frequently such a reaction occurs.

96.2.1 Additives

Repeated attention has been drawn to the suggestion that children may react adversely to food additives by displaying hyperactive-related behavior. Although the study of food intolerance produced evidence that some children react adversely to some additives, among other aspects of diet (Egger et al. 1985; Benton 2007), it is important to establish the extent of the problem. Schab and Trinh (2004) statistically integrated the findings of 15 well-designed studies that had examined the effect of artificial food colorings on those who displayed hyperactivity. They concluded that some additives adversely influenced behavior, however, to a greater extent in children whose parents, prior to the study, suspected that they did react to their diet. The influence of such food additives on the general population has been considered less than in those with ADHD. It has been suggested that younger children maybe more susceptible, in particular those with a general tendency to display an allergic reaction to many substances, for example, grass pollen.

Although data from samples of the general population are limited, an interesting study of 4-year-olds compared the reaction to a cocktail of food additives in those who either had or did not have a history of hyperactivity, and did or did not react to a series of allergens in a skin prick test. Based on parental ratings of activity, a reaction was found irrespective of whether there was a history of hyperactive behavior or an allergic tendency (Bateman et al. 2004). Similar findings were produced in a subsequent study of 3-year-old and 8/9-year-old children drawn from the general population (McCann et al. 2007). The use of a cocktail of five additives makes it unclear which substance was influential or whether combinations of additives rather than a single substance may be critical. It would be premature to draw conclusions from such limited data but the use of a community-based sample raised the possibility of a more general response to additives than had been suspected. However, when the European Food Standards Agency reviewed these studies they found the findings in this area to be inconclusive.

96.3 Fatty Acids

Two families of fatty acids, n-3 (omega-3) and n-6 (omega-6), have attracted an increasing amount of interest as it has been suggested that they are associated with a predisposition to depression, schizophrenia, anxiety, aggression, antisocial behavior, and ADHD. A review, however, concluded that "the evidence available is currently limited and highly inconsistent" (Appleton et al. 2008).

These two families of fatty acids are said to be "essential" as they form part of the diet as they cannot be manufactured by the body. Oily fish and some white fish are good sources of essential fatty acids although they are also found in flax; hemp; sunflower, pumpkin, and rape seeds; walnuts; and leafy vegetables.

As well as an effect on the brain these essential fatty acids have been suggested to help many dozens of physical ailments, in fact virtually all common diseases. Although we await confirmation of their influence, if these molecules affect so many seemingly unrelated biological phenomena then they must be acting at a fundamental level. These fatty acids play many important roles including the formation of eicosanoids that are signaling molecules involved in the control of inflammation and immunity as well as acting as messengers in the brain; they become cannabinoids (the endogenous molecules that act at the same neural sites as the active ingredients of cannabis); they influence protein activity directly and by influencing transcription. They have both a structural and a functional role in the brain and, in particular, attention has been directed to their influence as part of neuronal membranes. Cell membranes are a double layer of phospholipids, each of which contains two fatty acids

as part of their structure. Within the resulting phospholipid matrix are receptors and ion channels, so that the nature of the fatty acids will influence the structure of membrane-bound receptors and therefore the passage of information in and out of the cell (Stillwell and Wassall 2003).

Table 96.4 illustrates the sequence of n-3 and n-6 fatty acid metabolism. The essential fatty acids are α-linolenic acid, the beginning of the n-3 sequence; and linoleic acid, the starting point of n-6 metabolism. It is not, however, these genuinely essential substances that are important but rather some of their metabolites. From these two starting points the two metabolic pathways are illustrated with DHA being the finishing point in the case of n-3 metabolism, with the corresponding end point for n-6 being Docosapentaenoic acid. When considering the brain, attention should be paid to

Table 96.4   The synthesis of omega-3 and omega-6 fatty acids

Omega-3 FATTY ACIDS		Omega-6 FATTY ACIDS
Alpha-linolenic acid		Linoleic acid
↓	*Delta 6-desaturase*	↓
Octadecatetranoic acid		Gamma-linolenic acid
↓	*Elongase*	↓
Eicosatetraenoic acid		Dihommogamma linolenic acid
↓	*Delta 5-desaturase*	↓
Eicosapentaenoic acid (EPA)		**Arachidonic acid**
↓	*Elongase*	↓
Docosapentaenoic acid		Adrenic acid
↓	*Elongase*	↓
Tetracosapentaenoic acid		Tetracosatetraenoic acid
↓	*Delta 4-desaturase*	↓
Tetrahexaenoic acid		Tetacosapentaenoic acid
↓	*Beta-oxidation*	↓
Docosahexaenoic acid (DHA)		Docosapentaenoic acid

Omega-3 and omega-6 fatty acids are described as "essential" as they have to form part of the diet as they cannot be manufactured by the body. They are of particular interest as they are found in particularly high amounts in the brain and a relationship with many aspects of behavior, including depression, violence and intellectual development has been proposed. The metabolic pathways of these essential fatty acids are shown. Those in bold have attracted particular interest

Arachidonic acid and DHA as they play major structural roles, making up about 20% of the dry mass of the brain. High amounts of DHA are found in both synapses and photoreceptors. In addition, EPA has attracted attention as it has often been used in addition to DHA as a supplement.

Diets in industrialized countries are generally low in n-3 fatty acids and the DHA status of both the newborn and infants who are breast-fed, depends greatly on the diet of the mother. Human breast milk contains n-3 and n-6 fatty acids and during neonatal life these rapidly become part of the quickly growing brain. However, although there are many reports that the cognitive development of breast-fed infants is better than those who were bottle-fed, it is difficult to disassociate confounding factors such as the background and education of the mother. Fleith and Clandinin (2005), however, concluded that the "literature suggests that LCPUFA is important to the growth and development of infants".

96.3.1 Attention Deficit Hyperactivity Disorder

Although ADHD is known to be multifactorial in origin, Richardson and Puri (2000) reviewed the evidence that it is associated with a deficiency of essential fatty acids. For example Stevens et al. (1995) reported that those with ADHD had lower levels of fatty acids in plasma and red blood cells. In addition they were less likely to have been breast-fed and were more likely to suffer with allergies that are known to be associated with a deficiency of fatty acids. Other signs of deficiency were also found such as dry skin, dry hair, and drinking a lot. Interestingly, the dietary intake of poly-unsaturated fatty acids was greater in those with ADHD and did not differ in those with symptoms of deficiency, suggesting the possibility of a metabolic rather than dietary problem. Four out of five studies found low levels of n-3 fatty acids in those with ADHD and that there was a high n-6 to n-3 PUFA ratio (Appleton et al. 2008).

However, in three out of four intervention trials of children with a diagnosis of ADHD the consumption of n-3 fatty acid supplements failed to improve symptoms. In contrast, in four out of five studies of children with problems such as a lack or coordination, autism or self-harming, supplementation improved symptoms such as hyperactivity or impulsivity (Appleton et al. 2008). The area is, however, characterized by unsystematic results, where in a particular study one measure of hyperactivity-related behavior was influenced but others were not, or that significant findings were obtained from parental but not teachers ratings.

96.3.2 Aggression/Hostility

In a sample of nearly 5,000 American children, those with a total cholesterol concentration in the lowest quartile were almost threefold more likely to have been suspended or expelled from school (Zhang et al. 2005): it maybe that a low total cholesterol level is a risk factor for aggression. Although it has not been demonstrated that a diet-induced increase in serum cholesterol reduces antisocial behaviour in humans, monkeys fed a low fat diet have been found to be more aggressive (Kaplan et al. 1991). More specifically PUFA status has been considered. When examining risk factors for heart disease, young men who consumed fish rich in omega-3 fatty acids were found to be less likely to report feeling hostile (Iribarren et al. 2004). More specifically, in a sample of habitually violent and impulsive prisoners the level of dihomogammalinolenic acid and some subsequent n-6 acids were elevated (Virkkunen et al. 1987), perhaps indicating the importance of the n-3/n-6 ratio. However, although there is increasing epidemiological data that relates aspects of fat metabolism to aggressive and impulsive behavior, more easily interpreted data come from intervention studies.

Benton ([2007]) used meta-analysis to consider eight well-designed intervention studies that had given PUFA supplements and monitored the response using standard questionnaires to assess violence, hostility or aggression. He found that the incidence of aggression was significantly less in those taking PUFA supplements rather than a placebo. Six out of the eight studies had given a large dose of DHA combined with a smaller dose of EPA. The findings were obtained in a range of populations that varied in terms of age and pre-existing behavioral tendency, a consistency that suggested a fairly general influence on aggressiveness, although replications in specific populations will be necessary before making a recommendation.

In summary, fatty acids are essential dietary components that are found in high concentrations in the brain. Repeatedly, an association has been reported between PUFA levels found in biological samples and aggressive/impulsive behavior. Intervention studies have tended to find that n-3 fatty acid supplements decrease aggression although we need to further consider the composition of the supplements and the interaction with both individual differences in the ability to metabolize fatty acids and the pre-existing diet.

96.4 Hypoglycemia

In the general public there is a common assumption that a fall in blood glucose levels is associated with feelings of irritability, or even a predisposition to aggression. In turn, a fall in blood glucose has been popularly assumed to reflect the consumption of refined carbohydrate; in particular, sugar. Blood glucose levels rise progressively during the first half hour after eating a meal, as the carbohydrate in the meal is digested and released into the bloodstream. The rise in blood glucose stimulates the release of insulin that helps blood glucose levels to return to the optimal range for the body by causing glucose to be taken up by the liver and other cells. Figure 96.1 illustrates the phenomenon. On occasions, in susceptible individuals, the release of insulin is sufficient to cause blood glucose to
Fig. 96.1 Changes in blood glucose after consuming glucose. In a Glucose Tolerance Test blood glucose levels are monitored following the consumption of a glucose drink. In one individual after 2½ h the values are below the baseline. A tendency to develop low levels of blood glucose has been associated with a tendency to be aggressive. The data are mmol/L

fall to levels low enough to disrupt brain functioning. This marked fall in blood glucose was originally called spontaneous hypoglycemia but is also termed food-stimulated, reactive, functional, or postprandial hypoglycemia.

The brain is the most metabolically active organ in the body and unlike other organs, except under extreme conditions such as starvation, relies on a supply of glucose as its source of energy. As the stores of glucose in the brain are enough for only about 10 min, the supply of this basic fuel has to be continuous (Benton 2005). When glucose values fall to low levels the functioning of the brain is impaired causing confusion, blurred vision, and even violent outbursts. Under such circumstances counter-regulatory mechanisms increase blood glucose levels; these include the release of adrenaline (epinephrine) and glucagon that both cause the liver to release glucose into the blood. In turn other effects of adrenaline, such as stimulating heart rate, can be mistaken for anxiety.

Such has been the concern about this possible adverse reaction to our diet that various nutrition-related professional bodies issued a statement (Ad hoc committee 1973): "Valid evidence is lacking to support the hypothesis that reactive hypoglycemia is a common cause of violent behavior…." However, more recently there has been some evidence that a response to diet may play a role in antisocial behaviour, although it may occur with levels of blood glucose that are not sufficiently low to attract a diagnosis of clinical hypoglycemia.

Benton (2007) reviewed the evidence that individual differences in the ability to control the level of blood glucose may be important. In three very different samples a tendency to develop low levels of blood glucose was associated with hostility and violence: in Peruvian Indians, violent criminals, and undergraduates. Two intervention-studies were described in which consuming a glucose-containing drink, rather than a placebo, decreased the likelihood of behaving in an irritated manner. Donohoe and Benton (1999) gave a drink containing 50 g of glucose after fasting overnight and monitored changes in blood glucose. The lower that the levels of blood glucose fell after the initial rise the more likely it was that the subjects described themselves as aggressive. There was a cutoff, below a nadir of 60 mg/dL (3.3 mmol/L) in the Glucose Tolerance Test, where an aggressive tendency was more likely to be reported.

Throughout the day the level of blood glucose is usually maintained in the range 70–150 mg/dL (3.9–7.8 mmol/L). There is no commonly agreed value below which hypoglycemia is said to occur, although the lower limit of the normal range is variously said to be 60 or 70 mg/dL (3.3 or 3.9 mmol/L). The level of blood glucose below which the normal functioning of the brain is compromised will vary from individual to individual but is likely to be about 40 mg/dL (2.2 mmol/L) (Benton 2005). It is likely that few, if any, of the subjects reviewed by Benton (2007) had blood glucose levels low enough to attract a clinical diagnosis of hypoglycemia. Thus, it appears that an aggressive tendency occurs when blood glucose are low, yet higher than the levels needed to diagnose clinical hypoglycemia.

The question arises as to the frequency with which low blood glucose influences aggressiveness. The Glucose Tolerance Test monitors blood glucose levels for several hours after a glucose drink. Lev-Ran and Anderson (1981) found that the blood glucose levels of only 1 in 40 individuals fell to 40 mg/dl (2.2 mmol/L), the value at which hypoglycemic symptoms would begin to appear. However, the consumption of pure glucose by itself, after fasting overnight, is not typical of a normal diet. Benton (2007) after reviewing the topic concluded that when eating a normal diet throughout the day there is surprisingly little evidence of marked changes in blood glucose; rather there is a picture of blood glucose stability. The presence of both protein and fat alters the rate at which glucose is released into the blood stream, such that typical meals rarely stimulate reactive hypoglycemia.

It remains possible that there maybe an interaction between the composition of the diet and basic physiology; such that those with a tendency to release larger amounts of insulin might benefit from a low glycemic diet. The findings of an American study are consistent with this view. In a Florida institution,

those who did and did not report symptoms of hypoglycemia were distinguished (Fishbein 1982). Half ate their usual diet and half consumed meals designed to reduce the release of glucose into the blood. The scores on a questionnaire dealing with maladaptive behavior declined only in a quarter of those monitored; those with a history of hypoglycemic symptoms who had eaten the low glycemic diet.

96.4.1 Sugar Consumption

Sugar has had a particularly bad press as it has been suggested that it causes behavioral problems in children. As only double-blind intervention trials can offer evidence of a causal relationship, the meta-analysis of such data is critical. Based on 23 samples of children Wolraich et al. (1995) found that irrespective of the measure recorded, or the behavior monitored, sugar did not have an adverse influence. Benton (2008) considered a variety of suggestions made to account for these negative findings; for example, it may be only children with ADHD who react, or a reaction may be more likely to occur in younger children. Again, well-designed studies did not support such suggestions.

It has also been proposed that the incidence of violent behavior in prison can be decreased by reducing the level of sugar in the diet (Schoenthaler 1982). In the USA, a series of early studies claimed to have reduced the instance of antisocial behavior in prisoners when sugar in the diet was reduced. However, these were open trials and a wide range of changes in the diet inevitably altered several aspects of nutrition in addition to sugar intake. Benton (2008) discussed the three major mechanisms by which the level of sugar intake has been suggested to influence antisocial behavior; food intolerance, hypoglycemia or nutrient deficiency. Table 96.3 shows that sugar is by no means the most common cause of food intolerance. The influence of sugar consumption on micronutrient status is discussed below leaving the possible induction of hypoglycemia to be considered.

96.4.2 Glycemic Load

Although its use is controversial it is possible to classify foods by the calculation of the Glycemic Index (GI). The area under the curve created by plotting the changes in blood glucose for the 2 h following the consumption of a 50 g glucose drink is arbitrarily given a score of 100. On another day, sufficient of a test food is consumed to give 50 g of carbohydrate and the effect on blood glucose is expressed as a percentage of that obtained with glucose (Foster-Powell et al. 2002). Foods with a high-GI are rapidly digested and absorbed resulting in a rapid and marked increase in blood glucose levels. A low-GI food is slowly digested and causes more gradual changes in blood sugar. Table 96.5 gives a representative selection of foods that illustrates the phenomenon. It is apparent that many common assumptions about the influence of food items on blood glucose levels are mistaken.

Sucrose has only a moderate influence on blood glucose, not surprising as it is formed from the combination of a molecule of fructose and a molecule of glucose and the former does not influence blood glucose levels. Other foods such a bread and breakfast cereals have a greater impact. In addition, complex carbohydrates do not necessarily slowly release energy as much depends on food preparation. A baked potato has a GI of 85 that compares with a GI of 50 when they are boiled. Similarly the GI of rice varies greatly depending on the nature of starch. Chocolate illustrates one problem associated with the GI concept. There is an interaction between nutrients so chocolate has a low GI because the presence of fat and protein slows the release of glucose into the blood stream. It is clear that sucrose does not play a major role in inducing rapid swings in the level of blood glucose.

Table 96.5 The glycemic index (GI) of some common food items

High		Glucose	100
	>70	Low amylose white rice	88
		Baked potato	85
		Cornflakes	81
		White bread	70
Medium		Table sugar	65
	55–69	Honey	58
Low		Boiled potato	50
		Chocolate	49
	<55	High amylose rice	38
		Apple	38

The extent to which a food item causes the level of blood glucose to rise has been summarized by calculated the glycemic index. The change in blood glucose following the consumption of a 50 g glucose drink is arbitrarily given a score of 100. Then the change in blood glucose following the consumption of 50 g of carbohydrate from another food item is expressed as a percentage of that obtained with a glucose drink and is termed the glycemic index. A representative selection of foods are presented using data from Foster-Powell et al. (2002)

96.5 Micronutrient Status

One mechanism by which it has been proposed that a change in diet may affect the instance of antisocial behaviour is by influencing the levels of micronutrients consumed. Specifically it has been suggested that a diet high in refined carbohydrate, in particular sugar, may provide a marginal intake of micronutrients. There are two issues– whether a subclinical intake of micronutrients influences antisocial behaviour and if it does, whether it is associated with a particular dietary style.

Benton (2007) reviewed three well-designed published studies in which a multivitamin/ mineral supplement was administered and the incidence of antisocial behavior was found to decrease. As an example the disciplinary record of young offenders, over the age of 18 years, improved following supplementation. The taking of the supplements decreased violent incidents by 26% with a greater reduction in more serious offences (Gesch et al. 2002). An independent statistical reviewer, appointed by the UK Home Office, commented that it was "designed properly and with a good analysis" and there emerged "convincing scientific proof that poor nutrition plays a role in triggering aggressive behavior." The Dutch government responded to these findings by carrying out their own study. In prisoners who received a similar supplement to the British study, reports of violence decreased by 34% compared with a 13% increase in violence in those who received the placebo. The Dutch study was the fourth to report a beneficial response to micronutrient supplementation.

As the supplement in the British study offered 13 vitamins, 12 minerals, and fatty acids (Gesch et al. 2002) it is unclear which nutrients were influential. Were all the nutrients in the supplement important or alternatively did the response reflect the influence of a single or only a few nutrients? Were there synergistic interactions between nutrients? What is the optimal dose? These are questions that we have not begun to ask, never mind answer. As there are reports that supplementation with omega-3 fatty acids decreases violence (Benton 2007) they may have played a part. However, the report that a multivitamin/ mineral without fatty acids also reduced violence suggests that other nutrients are also important (Schoenthaler et al. 1997). We await the clarification that will be offered by future studies.

96.5.1 Micronutrient Status and Sugar Consumption

It has been proposed that particular dietary styles may predispose to a decreased intake of micronutrients. For example, according to the "empty calorie" hypothesis, sugar and other refined foods are said to provide energy stripped of micronutrients. However, those studies that have related sugar intake to micronutrient status have tended to conclude that there are no grounds for concern (Benton 2008). In fact one of the most extensive reviews concluded that a low rather than high intake of sugar tended to be associated with poor micronutrient status (Gibney et al. 1995). As micronutrient status is better predicted by total energy intake, rather than the level of sugar, it is likely that a low sugar intake was simply a predictor of a low energy intake. The key dimension in this area is the overall energy intake as in those who consume sufficient calories the level of micronutrient intake tends to achieve the recommended levels, irrespective of the sugar consumed.

96.6 Applications in Other Areas of Health and Disease

Given the serious consequences of antisocial behavior, any conclusive demonstration that diet was beneficial will have obvious public health implications. Both in specific situations, such as schools or prisons, but more generally in society, we would wish to decrease any predisposition to violence. However, although a number of well-designed trials have found that manipulating the diet can reduce antisocial behavior and violence, the available evidence is limited. We are, however, reaching the point where it is reasonable to suggest that the adequacy of diet should be added to the list of factors that predispose to the display of antisocial behavior. However, the body of knowledge is such that we are at present unable to readily distinguish those individuals who are nutritionally at risk. In addition we have only a sketchy idea of the nutrients that are important and therefore have not begun to establish the optimal intake.

   It is likely that the topic will raise questions for genetics and physiology. Rather than studying the diet in isolation it is probable that we will need to look at the interaction between the diet and individual differences in basic biology. It is a minority who display extreme food intolerance; we differ in our bodily need for micronutrients; glucose tolerance varies between individuals. One likely approach is the rapidly developing area of nutriomics, where the interaction between genetic differences and diet will be explored. In the future we may be able to screen for those who are likely to respond adversely to aspects of their diet. If this prediction is upheld then we will need to treat people as individuals such that general nutritional advice may be inappropriate.

   Yet even if causal mechanisms are satisfactorily demonstrated their significance will need to be kept in context. We should not too readily assume that diet is a major cause of antisocial behavior or that its modification is a simple means of solving difficult problems. Although there are examples of individuals where food intolerance has a dramatic impact (Mackarness 1976) a subtle response is more probable with many food-related approaches. By its nature our diet can only influence our basic biological functioning; that is it can only modify potential. Whether the potential to act in a peaceful or violent fashion is realized will depend on the interaction with the environment. The individual will need to be provoked and will or will not react depending on socialization, subcultural norms, and the current situation. Diet may change the basic biological predisposition but whether that predisposition is expressed will reflect the social situation and past history. At best, changes in diet are likely to be only one of several interventions that are required, although they may be influential in an appropriate psychological and social context.

Summary Points

- Although there is no suggestion that diet is the most common reason for children displaying ADHD, in well-controlled studies some children with the disorder have been shown to suffer with food intolerance. The pattern is individual to the child with a response being found to a wide range of foods.
- There is no support from well controlled studies for the suggestion of Feingold that hyperactive behavior was stimulated by a diet containing salicylates; chemicals in food that have a similar structure to aspirin.
- In double-blind trials supplementation with essential poly-unsaturated fatty acids has been found to decreased violence.
- Similarly there are reports that supplementation with multivitamins and minerals decrease aggressive behavior.
- There is an association between a tendency to develop low blood glucose and acting aggressively. The levels at which this occurs is higher than the levels required to produce a diagnosis of clinical hypoglycemia.
- The evidence is mainly of idiosyncratic responses to diet that prevent the offering of general rather than individual advice.
- The influence of diet must be kept in context as a biological predisposition will only be realized in an appropriate social and psychological environment.

Key Terms

Attention deficit hyperactivity disorder: This affects between 3% and 5% of children. It starts before the age of 7 and occurs more commonly in boys than girls. It is characterized by an inability to sustain attention, impulsive behavior, and hyperactivity.

Docosahexaenoic acid: It is found in high levels in the brain and the retina. It is the end point of the metabolic pathway that starts with the essential n-3 fatty acid alpha-linolenic acid.

Eicosapentaenoic acid: This is an n-3 fatty acid produced by the pathway that converts alpha-linolenic acid to docosahexaenoic acid.

Essential fatty acids: These cannot be created by the human body and therefore need to be part of the diet. In humans there are two families of essential long chain poly-unsaturated fatty acids, n-3 (omega-3) and n-6 (omega-6).

Food intolerance or food hypersensitivity: This is an adverse physiological response to a food item by a means other than the immune system. In contrast, food allergy by definition reflects an immunological reaction.

Glycemic index: The area under the curve created by plotting the changes in blood glucose following the consumption of a 50 g glucose drink is arbitrarily given a score of 100. The glucose response to consuming a test food that offers 50 g of carbohydrate is expressed as a percentage of that obtained with glucose. Foods with a high-GI result in a rapid increase in blood glucose while a low-GI food causes more gradual changes.

Hypoglycemia: This literally means a low level of glucose in the blood. When the levels of blood glucose fall to very low levels, the functioning of the brain can be compromised; resulting in slurred speech, blurred vision, and irritability. In some people the nature of the diet can induce a marked fall in blood glucose, a response called spontaneous, food-stimulated, reactive, or postprandial hypoglycemia.

97.1 Introduction

Attempts at food restriction and dieting have become a way of life for many in search of the "ideal" body type. In the United States, the high prevalence of eating disorders among women suggests a preoccupation with thinness, yet obesity rates in the USA are among the highest across the globe. How are we to understand the contradiction between an increasingly overweight nation that is fixated upon the ideal of being thin? With a high demand for weight loss and thinness comes a surplus of messages and advertisements focused on dieting, body shape, weight, and attractiveness. Yet not everyone is adversely affected by these messages, and it may be that only certain individuals are predisposed to develop disordered eating when placed in a "weight-focused" environment. In this chapter, we approach this paradox from the perspective of "mental workload", or the ability to mentally process information pertaining to making food choices. Initially, we examine eating disordered eating and mental workload, and further explore factors that can impact this relationship, such as craving. We then discuss the demand that disordered eating places on cognitive processing

capabilities, and then present empirical evidence to date that has examined this issue. Finally, we relay this information to the practitioner in an effort to continually advance the care given to individuals with eating disorders.

97.1.1 Eating Disorders

Disordered eating occurs in epidemic proportions in Western society; it is estimated that five to ten million women in the United States suffer from eating disorders (Crowther and Mizes 1992). Evidence indicates that women with a predisposition for disordered eating are at an increased risk when the environment promotes unhealthy thoughts or habits regarding food and weight (Bulik et al. 2004). Mainstream society sets high and often incompatible standards for women, and cultural pressure for women to be thin and have an ideal body is much greater than that for men (Mitchell and Eckert 1987). Women should have big breasts but small waists; they should be able to build-up stamina in an athletic manner, but not sweat; they should exercise daily, but not get too muscular (Brownell and Rodin 1994). Cultural pressure and the power of the media are implicated in the high prevalence for women to have an eating disorder.

The resultant morbidity associated with these disorders is considerable, and over the past 20 years societal attention, research, and clinical resources have increased alongside the prevalence of eating disorders (Fairburn and Brownell 2002). These disorders are marked by extremes, whether it is a severe disturbance in eating behavior (e.g., Bulimia Nervosa (BN)), such as reduction of food intake or overeating or significant feelings of distress about the shape of one's body.

Among women, the lifetime prevalence of BN is between approximately 1% and 3%; the rate of occurrence of this disorder in males is approximately one-tenth of that in females per the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV TR) (American Psychiatric Association (APA) 2000). Approximately 19% of female college students report symptoms of BN (Hoek 1993), an eating disorder characterized by recurrent episodes of binge eating, a sense of lack of control over food, and engagement in drastic compensatory measures, such as purging via vomiting, laxatives, or over-exercising (APA 2000). BN appears to have a chronic and sometimes episodic course in which periods of remission alternate with recurrences of binge/purge cycles. Eating disorders appear to be more common in college women, as a funtion of peer "enmeshment" and are confronted with adjustment difficulties and the challenges of newfound independence (Rand and Kuldau 1992).

Binge eating disorder (BED), currently categorized in DSM-IV-TR as an Eating Disorder Not Otherwise Specified (EDNOS), may be the most common of eating disorders, affecting approximately 3% of all adults in the United States, most of whom are women (NIH 2008). Although most obese people do not have BED, individuals with this problem are typically overweight or obese. BED is characterized by eating very rapidly until uncomfortably full, eating large amounts of food in the absence of hunger, eating alone because of embarrassment over the amount of food being consumed, and feeling disgust, guilt, or depressed after overeating. Binge episodes must occur, on average, at least two days a week for a period of at least six months to be clinically diagnosed as BED.

Despite the debate surrounding the assessment of "true" binge eating, considerable evidence supports the characterization of binge eating, whether in the context of BN or BED, as an impulse control disorder (McElroy and Kotwal 2006). The core feature of which is the failure to control a behavioral drive that may be detrimental to an individual (APA 2000). Some researchers suggest that binge eating is facilitated by a cognitive shift, wherein which the individual stops keeping track of

their food intake (Heatherton and Baumeister 1991). However, little is known about this cognitive shift or the mental effort expended to make food and weight decisions. If individuals are preoccupied with eating, they must constantly ignore food cues and suppress urges, requiring continual mental effort to control their behavior. Thus, a heightened "mental workload" may result when making food choices, especially in individuals with a predisposition toward disordered eating.

97.1.2 Mental Workload

Mental workload is the information processing load or resource demand imposed on a person by a specific task (Eggemeier 1988). Researchers, attempting to describe perceived mental workload, developed several theories describing characterizing the demand for processing capacity as "resources" (Wickens 1986). These theories suggest that when individuals are asked to perform several different tasks simultaneously, performances deteriorate as competition for mental resources or mental energy increase (Hirst and Kalmar 1987). That is, the more information a person is presented with, the more energy and mental resources they have to dedicate to processing that information, and the less energy and faculties they have in reserve. When individuals' attention is divided among two or more activities and they are not given the opportunity to rest, they will not fully replenish their "reserve" of mental energy. This view suggests that cognitive reserves are finite. Not only are a person's resources utilized for task performance and information processing, but they also regulate thoughts, emotions, and impulses (Baumeister et al. 2000). A further explanation of mental workload is presented in Table 97.1.

In the context of disordered eating, mental workload refers to the demand and the resulting ability of an individual to perform a particular task when presented with food cues. Because individuals with eating disorders may experience a "preoccupation" with certain foods, as well as difficulties with mood and personality characteristics that elicit distress (Strober 2000), they may have great difficulty managing all of the mental demands put on them. Thus, a young woman who has symptoms of disordered eating must resist temptation for a food substance and exert strong self-control to prevent her from carrying out an impulse she is attempting to suppress. If this same individual is presented with the sight or smell of a particular food, her performance on tasks requiring cognitive control will be impaired. This would result in the depletion of available resources due to the mental energy required to suppress thoughts and emotions pertaining to the food substances.

Table 97.1   Key points of mental workload

Mental workload is defined as the demand on the brain's resources as a function of the amount of task information being presented at a given moment.

Mental workload can be understood in terms of an economic model of supply and demand: The brain has a limited *supply* of mental resources while input can be thought of as the *demand* to which the brain must attend.

As more input occurs, greater attention is needed to attend to these stimuli. As more of the brain's resources are used, there are less in reserve and mental and physical performance can suffer

Mental workload is multidimensional and comprised of:

Mental Demand: The amount of mental or perceptual activity required (i.e., thinking, deciding, calculating, etc.)

Physical Demand: The amount of physical activity required (i.e., level of pushing, pulling, turning, etc.)

Temporal Demand: The amount of time pressure involved with the task (i.e., the pace of the task)

Performance: Success in accomplishing goals (i.e., how well one completed the objective)

Effort: How hard one had to work for the task (i.e., both mental and physical exertion)

Frustration: Level of discouragement at completing the task (i.e., level of stress, irritation, and contentedness)

This table provides a definition of mental workload along with its multiple components

97.1.3 Craving

Craving is an intense desire for a particular food or drug, also defined as a distinct state of especially urgent desire for a substance (Gendall et al. 1997). In typical cue reactivity paradigms, disordered eating individuals are presented with food-related cues without the opportunity to consume the substances. The sight and smell of a preferred substance with no opportunity for consumption have been shown to increase self-reported desire and autonomic arousal, such as increased heart rate (Cooney et al. 1997). Cravings can also be thought of as expectations for the pleasurable sensations that accompany consumption of a desired substance. Sights and smells are two food cues which tend to create a desire for a particular food or foods (Cornell et al. 1989). Thus, olfactory and visual exposure to food stimuli increase self-reported cravings. The combination of craving and disordered eating may amplify mental activity and increase sensation-seeking toward the food substance (Kambouropoulos and Staiger 2004). Conversely, if levels of craving are low in persons with symptoms of disordered eating, a lower desire for the food cues may occur (Perkins et al. 2003). As desire and craving appear to move in tandem, so also should the amount of mental energy necessary to process desirable food cues. This suggests that craving may moderate eating behavior, and is an important component of understanding the mental energy required of a person in the context of making food choices.

97.2 Mental Workload

Despite the prevalence of eating disorders in women, little is known about the effort expended to make food and weight decisions. If individuals are preoccupied with food choices, they must constantly ignore cues and suppress urges, requiring continual mental processing to control their behavior. Resource theories suggest that the more a person's mental energies are dedicated to decision making, the less energy they will have for other mental tasks. This infers that mental workload is associated with food choices, and this demand may be greater in those with eating disorders. Only one novel study has examined whether individuals with disordered eating feel more "mentally overwhelmed" by cues to eat.

This research exposed a sample of college women to food cues and then asked them to perform a challenging mental task related to food, on which they then rated the amount of "mental effort" expended by the task. The hypotheses for this study were that women with more disordered eating symptoms would rate the cognitive tasks as more mentally taxing compared with those with fewer symptoms of disordered eating. It was also thought that craving would operate as a moderating variable. Among women who endorsed high cravings, those high in disordered eating would rate the cognitive tasks as mentally more difficult than those low in disordered eating. Finally, it was hypothesized that women with high levels of Neuroticism and disordered eating would rate the cognitive tasks as more mentally taxing than those low in disordered eating. (A similar relation between disordered eating and mental workload was not predicted for individuals low in Neuroticism.)

97.2.1 Cue Reactivity and Craving in Women with Disordered Eating

Due to the high prevalence of eating disorders and symptoms in college women, undergraduate females are an ideal cohort. The study by Rofey et al. (2007) examined undergraduate women at a large Midwestern university (n = 175, ages 17–34 [mean age = 19.7 ± 1.9]). Most of the participants

were single (98.8%), Caucasian American (93.2%), and of freshman or sophomore status (89.2%). Racial/ethnic minority representation included African American (2.5%), Asian American (1.5%), Hispanic American (<1%), and others (1%). Participants completed several measures, including:

The Eating Disorder Inventory-2. The Eating Disorder Inventory-2 (EDI-2) is a self-report measure that assesses eating-disorder symptomatology (Garner 1991). Drive for Thinness, BN, and Body Dissatisfaction are the three subscales assessing attitudes and behaviors concerning eating. The Drive for Thinness scale measures the pursuit of thinness and the clinical manifestation of an intense fear of fatness, including excessive concern with dieting, preoccupation with weight, and fear of weight gain – all cardinal features of BN and anorexia nervosa (AN). Scores on the Drive for Thinness scale have been found to predict bulimic symptoms over a 10-year period (Joiner et al. 1997). The BN subscale measures the tendency to think about and engage in bouts of uncontrollable eating (binging), and has shown high convergent validity with other instruments assessing BN (Garner 1991). The Body Dissatisfaction subscale measures unhappiness with the shape and size of the regions of the body that are of greatest concern to those with eating disorders. Although every region of the body may be an area of concern, legs, buttocks, and stomach typically top the list.

Food Craving Questionnaire-State. The Food Cravings Questionnaire-State (FCQ-S) is designed to measure physiological and psychological motivation states that promote substance-seeking and ingestive behaviors (Cepeda-Benito et al. 2000). The FCQ-S is useful for measuring multiple dimensions of cravings such as anticipating positive feelings that may result from eating, relief from negative states as a result of eating, or an obsessive preoccupation with food or lack of control.

The Disorder Salient Stroop Task. The Stroop (1935) task has been used extensively by experimental psychologists to study attentional processes. In this task, participants are presented with words written in different colors of ink and are instructed to ignore the word and its meaning and instead indicate the color of the ink in which the word is printed. Stroop (1935) found that participants take longer to choose the color of the word when the word's meaning and ink color do not match (e.g., there is a longer color-naming latency when the word "blue" is written in red ink, verses when the word "blue" is written in blue ink). Researchers in the 1970s then began utilizing the Stroop test to examine cognitive processing and emotional disturbance. Instead of using color words, emotionally sensitive words were used. They found that emotionally sensitive words led to greater latency in color naming than did neutral words. This revised Stroop task, termed the disorder-salient Stroop, reveals that emotional sensitive words are selectively attended to by individuals with a particular disorder (Rofey et al. 2004). A recent meta-analysis of 27 studies using the disorder-salient Stroop task (with food and body-related words instead of color words) indicated that individuals with an eating disorder diagnosis exhibited greater delays in color naming compare to controls (Johansson et al. 2005). This infers that, for individuals with an eating disorder, there is an emotional connection to food-related words that may result in a delay in reaction times.

This emotion-connection view has extended to studying mood and affect as it pertains to disordered eating. Thus, research has examined how affect moderates the relationship between an eating disorder and reaction time. As Fig. 97.1 shows, individuals with higher bulimic scores who report low mood demonstrate slower response times to food cues than do bulimic women reporting more positive mood (Rofey et al. 2004).

The Labeled Magnitude Scale. The Labeled Magnitude Scale (LMS) is a scale of perceptual intensity used to rate pleasurable aspects of olfactory stimuli (Green et al. 1996). Pilot data show that the more pleasurable and more easily identifiable the olfactory cue, the higher the likelihood for craving (Rofey et al. 2004). Studies of eating-disordered women show that olfactory cues heighten eating-related cognitions (Staiger et al. 2000). Women suffering from BN like the smell and taste of high caloric foods as long as the possibility of ingestion is excluded (Drewnowski et al. 1987). Under a classical conditioning model, stimuli repeatedly associated with the consumption of a substance
Fig. 97.1 Reaction time and Bulimia scores for high and low mood individuals. This figure shows a comparison of reaction times on a cognitive task using emotionally sensitive words, and Bulimia scores for individuals with high and low affect. As shown, women with low moods react faster when they have low levels of Bulimia, but as they score higher for Bulimic symptoms, they react slower to the cognitive task. Conversely, positive or high moods react faster as they have greater levels of bulimic symptoms. This shows that mood moderates the relationship between reaction time and Bulimia scores (Adapted from Rofey et al. 2004. With permission from Elsevier Ltd.)

(such as the sight and smell of food) are thought to elicit an increased desire to consume the food. Thus, presenting olfactory cues to persons predisposed to disordered eating may lead to heightened mental workload similar to that of visual cues on the disorder-salient Stroop task (Rofey et al. 2004). Therefore, if individuals with disordered eating are presented with olfactory cues related to pathological thoughts (i.e., the smell of peanut butter, graham crackers, chocolate, oatmeal, vanilla cookies, etc.), their ability to respond to a task without cognitive delay may be impaired.

NASA Task Load Index. The NASA Task Load Index (NASA-TLX) is a multidimensional rating procedure that provides a workload score based on a weighted average of six subscales: Mental Demand, Physical Demand, Temporal Demand, Performance, Effort, and Frustration. An overall workload score (0–100) and a paired comparison score (indicating which scale was rated the hardest) is obtained for each rated task by multiplying the weight by the individual dimension scale score, summing across scales and dividing by 15. The validation and sensitivity of the NASA-TLX has been demonstrated on a variety of multitask contexts (Hart and Staveland 1988).

Eysenck Personality Inventory – Revised. An issue neglected by existing workload research is the relationship between subjective performance and personality characteristics (Rose et al. 2002). The Eysenck Personality Questionnaire – Revised (EPQ-R) measures personality tendencies of Psychoticism (P), Extraversion (E), Neuroticism (N), and Lying. Studies that have been carried out with the EPQ-R and eating disorders suggest that BN is associated with high levels of Neuroticism and Psychoticism (Feldman and Eysenck 1986). This would infer that personality may affect the workload ratings of persons who experience disordered eating.

97.2.2 Review of Procedures

Methodological review shows that in the study by Rofey et al. (2007) participants completed questionnaires on troubled eating patterns and craving levels. Approximately two days after completing a self-report battery, participants were assessed for color blindness and given olfactory food cues, which they rated on a scale of "most pleasant" to "not pleasant." An intervening task occurred

between each cue to reduce carryover effects. Immediately following the sensory experience, the participants completed the LMS to assure that she was able to smell the substance.

After completing the LMS, the participant proceeded to the other side of a partition separating the laboratory and completed the disorder salient stroop task. A five minute computer program presented three groups of words: (1) color words (blue, green, red, and yellow); (2) neutral words: phone, bowl, shoe, watch, mouse, floor, violin, window, deer, elephant, falcon, coyote, crocodile, geese, raccoon, and mules, each matched to an appetitive or alcohol word; and (3) appetitive words: chips, caramel, pastry, chocolate, cake, spaghetti, pizza, and cookie (Stroop 1935; Israeli and Stewart 2001). After the Stroop task, the participants answered questions about levels of workload difficulty and craving.

97.2.3 An Analysis of Eating Disorders and Mental Workload

As shown in the Table 97.2, college women tended to score the highest on the Neuroticism and Drive for Thinness scales and lowest for Psychoticism and Bulimia. The greatest variability existed for Drive for Thinness and Bulimia, indicating that more women reported levels at opposite ends of the continuum.

Women rated each component of mental workload (first described in Table 97.1) immediately following the Stroop task. As shown, Mental Demand was the greatest contributing factor to workload while Physical Demand was the least influential component. This is not surprising since the Stroop task is designed as a measure of cognitive processing, and requires practically no physical movement except pushing a button. The Effort and Performance Scales were also important factors as the college women clearly indicated that they had to work hard and desired to perform well on the task. The time pressure or Temporal Demand along with Frustration did not appear to be as important as the demand placed on achievement and cognition in the food task. Interestingly, the Effort Scale was inversely associated with many of the other indices such that as the Mental Demand increased Effort subsided. This suggests that in certain individuals, as the task becomes more demanding and difficult there is a decrease in mental energy expenditure and a decline in desire to succeed.

This results show that individuals rate cognitive demands as the most difficult portion of mental workload. An important question is then if individuals with more disordered eating also have greater difficulty on factors such as Mental Demand and Performance scales when performing a food task.

Table 97.2 Shows means and standard deviations (SD) for disordered eating variables (Adapted from Rofey et al. 2007. With permission from Taylor & Francis Ltd.)

Variable	Mean	SD	Range
1. EDI-2 – Drive for Thinness	5.30	6.34	0–22
2. EDI-2 – Bulimia	2.33	5.81	0–32
3. EPQ-R – Psychoticism	2.49	1.83	0–8
4. EPQ-R – Neuroticism	5.64	3.30	0–12

This table shows descriptive data of college women for eating disorders and personality assessment. Of the eating disorders, women had a higher Drive for Thinness than for Bulimia. Of the personality characteristics, a greater level of Neuroticism was shown in these females.

EDI Eating Disorder Inventory, *EPQ-R* Eysenck Personality Scale-Revised; *SD* Standard Deviation

A multiple regression analysis showed that individuals with higher levels of disordered eating also had a more challenging time completing the food task. Interestingly, level of craving did not appear to impact this relationship (Rofey et al. 2007).

Additional factors that may be associated with mental workload include personality factors, such as Neuroticism, shown in Table 97.2. Broad personality traits such as Neuroticism and Psychoticism have been linked with performance goals, and have been associated with BN (Feldman and Eysenck 1986). For this reason, personality may impact mental workload, especially the performance component. As recently shown, a multiple regression analysis revealed that Neuroticism alters the strength of the relationship between Performance Workload and Drive for Thinness (Rofey 2005) (Table 97.3).

Individuals with higher levels of Neuroticism were more likely to be at greater risk of showing performance difficulties when they also had a higher Drive for Thinness. As shown in Fig. 97.2, workload scores differed between women with and without a strong Drive for Thinness, moderated by high and low levels of Neuroticism.

Among women who reported high levels of Neuroticism, those with a high Drive for Thinness reported the olfactory and Stroop tasks to be significantly more demanding on the Performance sub-scale than women who reported low Drive for Thinness and Neuroticism. High Neuroticism women with either high or low Drive for Thinness did not differ significantly on their rating of the tasks difficulty (Rofey et al. 2007).

Table 97.3 Key features of disordered eating and mental workload

1. Eating disorders affect 5–10 million women in the USA.
2. Mental workload is the demand placed on the brain's resources as a function of the amount of task information being presented at a given moment.
3. Individuals with eating disorders appear to be influenced by food cues (i.e., they have more difficulty processing food-relevant information).
4. As mental workload reaches capacity, less effort and energy appear to be expended.
5. Personality (e.g., Neuroticism) appears to influence mental workload as well as performance.

This table lists the key facts of disordered eating and mental workload as they pertain to the reviewed research in this chapter
Fig. 97.2 Relation between Performance Workload and Drive for Thinness score for low and high levels of Neuroticism. This figure shows a comparison of slopes for Performance difficulty and Drive for Thinness. The slope is greater for women who are highly neurotic compared to those with low levels of Neuroticism. This shows that Neuroticism moderates the relationship between Performance difficulty and Drive for Thinness (Adapted with permission from Rofey 2005)

97.2.4 Summary of Analyses

To our knowledge, this is the first study to utilize the concept of mental workload to examine cognitive factors relevant to disordered eating. These analyses indicate that disordered eating symptoms appeared to directly influence participants' difficulty ratings on the olfactory and disordered salient Stroop tasks. For subscales on the NASA-TLX, disordered eating accounted for a significant portion of the variance in mental workload. While measures of food craving did not prove to be a significant moderator of the relationship between disordered eating, levels of bulimic symptoms were related to participants' difficulty ratings of olfactory and visual cues on measures of mental workload. For women who reported high Neuroticism, those with high disordered eating symptoms reported more difficulty in responding to salient cues than those with low disordered eating symptoms. Among women who reported low Neuroticism, women with high and low Drive for Thinness did not differ significantly on their ratings of task demand.

97.2.5 Interpretation of Hypotheses

Relationship between disordered eating and mental workload. Results revealed that disordered eating contributed to participants' rating the olfactory and Stroop tasks as being difficult. During these cognitive tasks, participants were asked to make continuous discriminations without rest, the nature of which prevented full replenishment of resources. Women who reported more symptoms of disordered eating found it more difficult to make appropriate responses on this demanding mental task. It is evident that Mental Demand and Performance subscales contributed most to overall workload ratings for women high in disordered eating on the disorder salient Stroop task and olfactory cues. Multiple, pertinent cues are being responded to simultaneously; consequently, women rate olfactory and Stroop tasks as more demanding. In other words, participants' limited mental resources are being expended to do many things at once; regulate thoughts, control emotions, and inhibit impulses (Baumeister et al. 2000). Theoretically, extension of these controlled laboratory findings into a "real-life" context suggests that an individual high in disordered eating must consistently resist dietary temptation and exert strong self-control to prevent the carrying out of a "forbidden" impulse, which may ultimately result in a depletion of resources necessary for suppression of substance food-related thoughts and emotions. At a certain point, these mental reserves may become depleted to the point where this individual no longer feels capable of self-restraint, and they may experience a "cognitive shift" toward more impulsive behavior (e.g., binge eating).

Craving as a moderator of the relationship between disordered eating and mental workload. Interestingly, craving did not appear to affect ratings of mental workload. Since 1955, there have been many articles debating the use of craving in science (Gendall et al. 1997; Kozlowski et al. 1989). The DSM-IV-TR (APA 2000) does not contain any discussion of the term, and cravings have generally been viewed as a motivational and individualistic state within the person. The existing literature on food has several limitations that may help explain the insignificant findings. First, the operational definition is still uncertain and the majority of studies rely on the participant's subjective understanding of the term (Kozlowski et al. 1989). For example, Marlatt and Gordon (1985) proposed that cravings be distinguished from urges by referring to the former as a subjective motivational state and the latter as an intention to engage in the behavior.

Second, studies examining the nature of food cravings are biased to certain groups within the population. Craving may have different implications for people on the low end of the disordered eating continuum within this normal population. For example, people who are experiencing hunger pains may rate craving as being present (e.g., I want a sandwich) whereas people high in disordered eating symptomatology may rate craving as present if it predisposes a binge (e.g., I need to go through the fast-food window and order four hamburgers).

There is also the issue of a subjective threshold. At which point does a desire for a food qualify as a craving? While psychophysiological indices (e.g., heart rate, salivation, skin conductance) have been proposed as objective measurements of craving, an individual's self-report may not follow with the physiology (Nirenberg and Miller 1982). Thus, utilizing varied measures of craving may be a more effective method to ascertain whether this threshold has been met.

Relationships between workload and Drive for Thinness and Neuroticism. Study findings indicated that among women who reported high Neuroticism, those with a high Drive for Thinness reported the olfactory and Stroop tasks to be significantly more demanding than those with low Drive for Thinness. Among women who reported low Neuroticism, women with high and low Drive for Thinness did not differ significantly on their mental workload ratings of the tasks. Ballard (1996) identifies personality as the most significant individual difference in human factors research. Studies have reported that individual differences in human factors experiments can be explained by personality traits such as field dependence (Moore and Gross 1973), Type A personality (Perry and Laurie 1992), and locus of control (Sanders et al. 1976). Neuroticism has also been found to be strongly associated with eating disorder symptom level (Diaz-Marsa et al. 2000), and has been predictive of subsequent bulimic symptomatology including future binge episodes and compensatory behavior (Leon et al. 1997).

An overarching finding of this study was that, in comparison with women low in disordered eating symptoms, participants with higher levels of disordered eating exerted less effort on the Stroop task as rated on the NASA-TLX Effort subscale. From a resource model of attention perspective, participants may have been affected by the emotionally sensitive food words because these cues are connected to things that are meaningful, and resources are being used to process these extraneous thoughts. As a coping mechanism, the women may have exerted less effort as the cognitive task becomes mentally taxing. Muraven et al. (1998) argue that similar to a limited supply of strength or energy, people have a limited capacity for self-regulation. Repeat exertion will diminish capacity to perform mental tasks. Thus, when individuals engage in repeated self-regulation of the visual and olfactory cues, they may show subsequent decrements of effort due to energy depletion (Muraven et al. 1998).

Overall, this chapter reviews research demonstrating that persons with eating disorders are expending more mental resources to suppress food urges and impulses. Personality characteristics can worsen task performance, and a person's available mental energy is depleted during and possibly after food cue exposure. Although understanding eating disorders can be a challenge for both researchers and clinicians, broad cognitive behavioral interventions targeting thought processes, possibly alongside personality characteristics, may be conducive in reducing mental demand and heightening ability to choose healthy behaviors.

Future areas of research would benefit from studying other human factors. Human factors researchers have spent decades studying vigilance and fatigue, two cognitively oriented facets that may lend themselves to achieving a better understanding of the underlying symptoms of eating disorders. While this is a new paradigm within clinical psychology, it may be advantageous to compare the NASA-TLX profiles with other human factors profiles (e.g., vigilance, memory, tracking, time estimation).

97.2.6 Applications

Media messages often convey unrealistic standards of appearance, perhaps leading to unhealthy attempts at food restriction (Harrison and Cantor 1997). When coupled with feelings of shame, low self-esteem, or other negative mood symptoms, these dieting behaviors may "backfire" and ultimately contribute to an eating disorder. The rise in prevalence of eating disorders over the past 20 years has been accompanied by heightened levels of attention from the clinical and research communities, along with society at large. Researchers and clinicians continue to search for ways to intervene upon existing patterns of disordered eating, and perhaps reduce individuals' overall susceptibility to eating disorders.

Cognitive-behavioral therapy is considered to be the treatment of choice for BN, particularly when used in combination with medications (Whittal et al. 1999), and the strategies for treatment of binge-eating disorder are similar to those for Bulimia (Wilfley et al. 1993). In addition to focusing on behaviors such as binge eating, purging, and ritualistic exercise, Cognitive Behavioral Therapy for Bulimia Nervosa (CBT-BN; Fairburn et al. 1993) involves a systematic series of interventions aimed at addressing the cognitive aspects of BN, such as the preoccupation with food, as well as one's body shape and weight. Initially, the goal of CBT-BN is to restore **control** over dietary intake, and avoid environments that "set up" opportunities to binge. To accomplish this, patients are asked to record their caloric intake while also noting environments or situations that may trigger bouts of disordered eating. Patients are then instructed in methods for coping with these challenging situations, which may include assertiveness training, ways to increase self-esteem, identifying mood states, and healthier alternatives for emotional expression.

The study presented here reveals an intriguing focus area for improving the treatment of disordered eating. If, in fact, individuals high in disordered eating symptoms become "overwhelmed" more easily in situations in which mental demands are high, they may be more at risk of shifting into a binge eating pattern in certain environments. This can be especially true when the environment promotes unhealthy thoughts or habits regarding food and weight. Evidence indicates that environmental factors can exacerbate a predisposition for disordered eating and can contribute to the onset and maintenance of an eating disorder (Bulik et al. 2004).

Although additional research in this area is needed, clinicians may advise patients being treated for an eating disorder to avoid certain "overstimulating" environments, particularly when patients are still in the vulnerable first stages of treatment. Of particular concern are "trigger foods" that enter the household from other members of the family. The patient must then the patient must then constantly attend to suppressing the urge to consume the food, and may dedicate large reserves of their mental energy to avoiding the substance. If their reserves are depleted to a low enough point, they may engage in a binge episode or sneak eating. Removal of these "trigger foods" from the environment may free the mental work associated with them, and will decrease the likelihood of unhealthy food behaviors.

Avoiding food-related stimuli may even extend to television, movies, or electronic media, especially in the context of eating a meal. One area for further study involves the possible link between mental workload and television viewing. If individuals are distracted when they are eating, they may consequently overeat due to the depletion of mental reserves necessary to suppress the urges to overeat. Further, food advertisements may spur additional urges to eat. Options may include replacing television viewing with a physical activity, or choosing chewing gum instead of high calorie snacks.

Although cognitive-behavioral therapy is the first-line treatment of choice for BN, its effectiveness is limited. Approximately 50% of patients who receive CBT-BN stop binge eating and purging, while some patients show partial improvement, and a small number do not benefit at all

(McGilley and Pryor 1998). A comorbid personality disorder is associated with a poorer response to cognitive-behavioral therapy. In reference to the study reviewed in this chapter, if attentional resources are finite, then individuals who exhibit higher trait Neuroticism and who also experience problematic eating may expend a great deal of available resources by attending to food stimuli. This could drain available resources and lower the ability to focus and suppress impulses, which could lead to a binge or overeating episode.

In clinical and research settings, routine screening for eating disorders in young women is another important implication of this research. It is possible that disordered eating symptoms often go undetected due to the sub-threshold clinical nature of many of these symptoms. When intervention is warranted, the results of the current study support a cognitive-behavioral treatment approach. Cognitive -behavioral therapies for eating disorders may be enhanced by targeting automatic food-related thoughts that underlie complex schemas related to coping with these pathological thoughts (Garner and Garfinkel 1997). The results reported here, as they pertain to emotionally sensitive olfactory and visual cues, also support the use of muscle relaxation with visual imagery or direct exposure to a series of situations that involve food cues. In using this technique, therapy would assist in lessening the emotional sensitivity of pertinent food cues. In addition, assisting individuals to identify and cope with food triggers may be critical in helping reduce the likelihood of disordered eating (Kozlowski et al. 1989).

Summary Points

- Having an eating disorder, such as BN, results in slower response times to tasks that include relevant food cues.
- This infers that there is an emotional connection to food-related words in individuals with an eating disorder.
- There are finite mental resources available, and when an individual has an eating disorder their thoughts may be consumed with eating-related stimuli.
- The brain of a person with an eating disorder processes food-related information differently than those without an eating disorder.
- Higher levels of craving do not appear to be associated with mental workload.
- This may be due to the inexact science of measuring craving, and a lack of understanding as to how craving differs along a continuum of eating disorders.
- Neuroticism, coupled with a Drive for Thinness, appears to be associated with greater Mental Demand and Performance difficulties.
- Personality characteristics appear to be linked with mental workload in the context of eating disorders.
- Individuals with higher levels of disordered eating report exerting less effort.
- As the task becomes more mentally taxing, less effort is exerted as a coping mechanism to resource depletion.

Definitions and Explanations

Cognition: This refers to the process of thought, the act of knowing, and applying knowledge. It is also related to abstract concepts such as reasoning, perception, and learning.

Craving: An intense, urgent, or abnormal desire or longing.

Disordered eating: An irregular behavior of food consumption often classified as either bulimia nervosa (BN), anorexia nervosa (AN), or eating disorder not otherwise specified (EDNOS).

Extraversion: A personality trait where gratification is obtained from outside the self. Extraverts tend to enjoy human interactions and are enthusiastic, talkative, and gregarious.

Mental workload: The information processing load or resource demands imposed by a task on an individual's mind.

Neuroticism: A personality trait where there is an enduring tendency to experience negative emotional states, such as anxiety, anger, guilt, and clinical depression.

Psychoticism: To display or have the propensity to display qualities commonly found among psychotics, such as recklessness, disregard for common sense, immaturity and inappropriate emotional expression. Higher Psychoticism scores have been reported among psychopaths and criminals.

Chapter 98
Psychiatric Comorbidity in Eating Disorders

Tahany M. Gadalla

98.1 Introduction

Associations between eating disorders and other psychiatric disorders have been observed in samples drawn from treatment-seeking patients, high school/college students and the general populations. To date, the majority of these studies have been based on samples of women. Few studies included men and most of these did not report findings separately by gender. In addition, very few studies examined eating disorders and/or their psychiatric comorbidity in older women.

Researchers have proposed a few possible explanations for the observed high comorbidity rates in individuals with eating disorders. Although the exact mechanisms are yet to be determined, the importance of comorbidity studies cannot be over-emphasized. Examination of comorbid psychiatric disorders in individuals with eating disorders is important because studies have shown that those with multiple disorders tend to have a worse prognosis, longer episodes and are less responsive to treatment. Further, they tend to be at increased risk for engaging in parasuicidal behaviors and suicide attempts (Wildman et al. 2004).

Population-based studies are especially important in assessing the extent and nature of comorbidity (Dansky et al. 2000). Clinical-based studies are vulnerable to several sources of sampling bias especially when studying patients with multiple health problems since these patients may seek treatment for either problem and thus, are more likely than patients with one health problem to be found in clinical settings (Berkson 1946). Thus, comorbidity rates obtained in clinical studies may over estimate the actual comorbidity in the population. In addition, only in population-based samples can the whole range of symptom severity of psychiatric disorders be represented. Yet, few studies examined the comorbidity between disordered eating patterns and other psychiatric disorders in community-based samples.

98.2 Findings of Research Using Clinical Samples

Comorbidity studies conducted in clinical populations have suggested strong associations between eating disorders and other psychiatric disorders. For example, significantly high prevalence of major depression was found in samples of disordered eating adult patients (e.g. Blinder et al. 2006) and

e-mail: tahany.gadalla@utoronto.ca

disordered eating adolescent patients (Geist et al. 1998). Additionally, in a sample of 135 male patients with eating disorders, 54% had lifetime diagnosis of major depression (Carlat et al. 1997). In a review of the literature on the comorbidity of mood disorders with eating disorders, Godart and colleagues (2007) found lifetime prevalence of major depression to range between 9.5% and 64.7% in restrictive anorexia nervosa patients and between 50% and 71.3% in anorexia nervosa with bulimic subtype patients.

Elevated prevalence of anxiety disorders were also found in women seeking treatment for eating disorders (Blinder et al. 2006; Carlat et al. 1997; Hinrichsen et al. 2004; Iwasaki et al. 2000; Milos et al. 2004) and vice versa (Roderiguez et al. 2004). For example, 43% of a sample of Japanese patients with eating disorders had a lifetime comorbidity of at least one anxiety disorder (Iwasaki et al. 2000), 54% of a sample of Swiss patients with eating disorders had lifetime anxiety disorders (Milos et al. 2004), and 56% of US female inpatients with eating disorders had anxiety disorders (Blinder et al. 2006). In general, reported lifetime prevalence of at least one anxiety disorder ranged from 25% to 75% in individuals with bulimia nervosa and from 23% to 54% in those with anorexia nervosa (Godart et al. 2002).

Although as a group, the reported prevalence of anxiety disorders does not differ across types of disordered eating, the reported prevalence of specific anxiety disorders varies widely across types of disordered eating (Blinder et al. 2006; Brewerton et al. 1995; Bulik 2003; Fornari et al. 1992; Jordan et al. 2008; Kaye et al. 2004). For instance, while social phobia has been indicated as the most common comorbid anxiety disorder in individuals with anorexia nervosa (Fornari et al. 1992; Jordan et al. 2008), high prevalence of obsessive-compulsive disorder has also been observed in people with anorexia nervosa (Bulik 2003; Kaye et al. 2004). In individuals with bulimia nervosa, however, the prevalence of specific anxiety disorders varied significantly across studies with some studies reporting high rates of prevalence of social phobia, simple phobia, and obsessive-compulsive disorder (e.g. Fornari et al. 1992), while others did not (Brewerton et al. 1995).

High rates of substance use have been found in clinical samples of women with eating disorders (e.g. Milos et al. 2004) and high rate of disordered eating patterns have been found in women with substance use diagnoses (e.g. Schuckit et al. 1996). The elevation in substance use has been found in women diagnosed with bulimia nervosa and bingeing and purging anorexia but not in restricting anorexia (Stock et al. 2002). In a sample of male patients treated for eating disorders, 37% were found to fulfill DSM-IV criteria for substance abuse (Carlat et al. 1997). More recently, measures of illicit drug abuse and dependence were significantly associated with disordered eating patterns in female inpatients with eating disorders (Blinder et al. 2006). Moreover, in a study of substance abuse patients, men and women reported similar levels of engagement in binge eating and compensatory behaviors, however, the women had higher disturbed attitudes toward body weight and shape (Jackson and Grilo 2002).

98.3 Findings of Research Using Community Samples

Elevated levels of mood and anxiety disorders in individuals with eating disorders have been found in community-based samples. In a national sample of US women, 36% of those meeting the criteria for BN, also met the criteria for a lifetime diagnosis of major depression (Dansky et al. 1998). Similar results were reported by Telch and Stice (1998), who found significantly higher rates for major depression in a community sample of women with binge eating disorder relative to control participants, and by Lewinsohn and colleagues (2000) who reported a high prevalence of psychiatric comorbidity in a sample of high school female students with eating disorders. Significant association

between eating disorders and mood disorders has been found for both men and women in other community samples (John et al. 2006; Schuckit et al. 1996). Reviewing the literature on the association of mood disorders and eating disorders, Godart and colleagues (2007) concluded that in community samples, the lifetime prevalence of mood disorders was 2.6–4 times higher in individuals with anorexia nervosa than those found in controls.

Kaye and colleagues (2004) found obsessive-compulsive disorder and social phobia to be the most common anxiety disorders among women with eating disorders. These authors found that anxiety disorders in general and obsessive-compulsive disorder in particular to be more prevalent in women with anorexia nervosa and bulimia nervosa compared with control women from the community. Significant associations between eating disorders and major depression, social phobia, agoraphobia, and panic disorder have been observed in men with eating disorders (Woodside et al. 2001). In another community-based sample of men and women, those who screened positive for binge eating disorder had significantly higher odds of depression, panic attacks, and generalized anxiety disorder (GAD) compared with controls (Grucza et al. 2007). Hudson and colleagues (2007) examined the association between threshold- and subthreshold-level eating disorders and a range of lifetime psychiatric comorbidities in a large, nationally representative sample of US men and women. The authors found high prevalence of lifetime comorbid psychiatric disorders in individuals with all eating disorders except subthreshold binge eating disorder. Specifically, the authors found individuals with bulimia nervosa or binge eating disorder to have elevated odds of having lifetime diagnosis of major depression, dysthymia, bipolar disorder, panic disorder, agoraphobia without panic, specific phobia, social phobia, post-traumatic stress disorder, obsessive-compulsive disorder, and separation anxiety.

Significant associations between disordered eating patterns and substance dependence were observed in community samples, regardless of the type of diagnostic assessment used (Bulik 2003; John et al. 2006; Woodside et al. 2001; Piran and Gadalla 2006). Measures of alcohol consumption, dependence, and interference were significantly associated with disordered eating attitudes and behaviors in a nationally representative sample of Canadian women (Piran and Gadalla 2006) and with bulimia nervosa in a nationally representative sample of US women (Dansky et al. 2000). Similar associations have been found in adolescents (e.g. Benjamin and Wulfert 2005) and in university students (e.g. Krahn et al. 2005). A few studies, however, did not find such association (Dunn et al. 2002).

Additionally, lifetime and 12-month measures of illicit drug abuse and dependence were significantly associated with disordered eating behaviors in a national sample of women (Piran and Gadalla 2006) and with disordered eating patterns in other community samples (e.g. von Ranson et al. 2002). Specifically, amphetamine use was found to be associated with the risk for eating disorders in both men and women while illicit drug use, dependence, and interference were associated with risk for eating disorders in women but not in men (Gadalla and Piran 2007). Associations between the use of illicit substances and disordered eating patterns have also been found in other community samples (e.g. von Ranson et al. 2002).

Gadalla (2008a) examined the associations between disordered eating symptomatology, defined as a score of 20 or more on EAT-26 (Garner et al. 1982), and measures of selected mood, anxiety, and substance use disorders as well as psychological distress in a nationally representative sample of Canadian men and women. Assessment of 12-month and lifetime prevalence of mood, anxiety, and substance use disorders were based on the short form of the Composite International Diagnostic Interview (CIDI-SF). Level of psychological distress during the 30 days previous to the interview was determined using the scale known as K10 (Kessler et al. 2002). As shown in Table 98.1, findings of this study indicated that while 12-month prevalence of major depression, manic disorder, panic disorder, agoraphobia, social phobia, and substance dependence were significantly associated with disordered eating symptomatology in women, only major depression, panic disorder, and social phobia were significantly associated with disordered eating syptomatology in men. A woman with

Disorder	Score on Eat-26	Odds ratio (95% CI)	
		Women	Men
Major depression	Score < 20	–	–
	Score $\geq$ 20	5.03 (4.08, 6.17)[***]	4.52 (2.48, 8.26)[***]
Manic episodes	Score < 20	–	–
	Score $\geq$ 20	4.76 (3.06, 7.41)[***]	1.69 (0.31, 9.09)
Panic disorder	Score < 20	–	
	Score $\geq$ 20	4.39 (3.14, 6.10)[***]	5.29 (2.02, 13.89)[**]
Agoraphobia	Score < 20	–	–
	Score $\geq$ 20	3.85 (2.44, 6.02)[***]	4.08 (0.69, 24.39)
Social phobia	Score < 20	–	–
	Score $\geq$ 20	4.20 (3.24, 5.49)[***]	3.80 (1.80, 8.06)[***]
Substance dependence	Score < 20	–	–
	Score $\geq$ 20	3.03 (2.02, 4.55)[***]	1.96 (0.90, 4.27)
Major depression/manic episodes	Score < 20	–	–
	Score $\geq$ 20	5.13 (4.18, 6.29)[***]	4.31 (2.40, 7.69)[***]
Any anxiety disorder	Score < 20	–	–
	Score $\geq$ 20	4.20 (3.37, 5.24)[***]	4.57 (2.47, 8.40)[***]
Any mood, anxiety or substance dependence	Score < 20	–	–
	Score $\geq$ 20	4.76 (3.98, 5.68)[***]	2.78 (1.66, 4.65)[***]

Data presented in this table indicate that both men and women with disordered eating symptomatology had significantly elevated odds for major depression, panic disorder, social phobia, and psychological distress. The 1-year prevalence of manic episodes, agoraphobia, and substance dependence were associated with disordered eating symptomatology for women but not for men

Assessment of 12-month prevalence of mood, anxiety, and substance use disorders were based on the short form of the Composite International Diagnostic Interview. Level of psychological distress was determined using the scale known as K10 (Kessler et al. 2002)

$*p < 0.05$, $**p < 0.005$, $***p < 0.0005$

disordered eating symptomatology was five times more likely to have at least one major depressive episode while a man with disordered eating symptomatology was more than four times more likely to have at least one such episode within the same year. As shown in Table 98.2, in women, disordered eating symptomatology was strongly associated with lifetime prevalence of manic episodes, panic disorder, agoraphobia, and social phobia. In men, it was strongly associated with lifetime prevalence of panic disorder and social phobia and moderately associated with agoraphobia. Disordered eating symptomatology was associated with a fivefold increase in women's odds of having panic disorder and fourfold increase in men's odds of having panic disorder. Data presented in Table 98.3 reveal a highly significant association between disordered eating symptomatology and concurrent psychological distress in both genders.

98.4 The Effect of Participants' Age on Comorbidity Rates

Research has shown that prevalence rates and illness duration of eating disorders and other psychiatric disorders are age dependent (Hudson et al. 2007; Kessler et al. 1994; Piran and Gadalla 2006). For example, Kessler and colleagues (1994) found lifetime and 12-month prevalence of DSM-III-R

Table 98.2 Association between Disordered Eating (EAT-26 score ≥20) and Lifetime Measures of Selected Mood, Anxiety and Substance Use Disorders in Canadian Men and Women (Published with permission, from Gadalla 2008a)

Disorder	Score on Eat-26	Odds ratio (95% CI)	
		Women	Men
Major depression	Score < 20	–	–
	Score ≥ 20	2.94 (2.45, 3.53)***	3.70 (2.31, 5.95)***
Manic episodes	Score < 20	–	–
	Score ≥ 20	3.98 (2.90, 5.46)***	2.22 (0.83, 5.71)
Panic disorder	Score < 20	–	–
	Score ≥ 20	4.15 (3.27, 5.29)***	4.98 (2.60, 9.52)***

***$p < 0.0005$

psychiatric disorders to be age dependent with the highest lifetime prevalence in the 25–34 year age group and the highest 12-month prevalence in the 15–24 year age group.

The above findings highlight the importance of taking participants' age into consideration when examining the comorbidity of psychiatric disorders. One such study was carried out by Gadalla and Piran (2008) in which the authors examined the associations of disordered eating behaviors with selected mood, anxiety, and substance use disorders in a national sample of Canadian women in three different age groups, 25–24, 25–44 and 45 years or above. The authors found significant associations between disordered eating behaviors and major depression, substance dependence, and psychological distress for women in all three age ranges. Prevalence of specific classes of anxiety

disorders in women who reported disordered eating behaviors differed according to their age. Having disordered eating behaviors was significantly associated with both 12-month and lifetime prevalence of social phobia for women above 25 years of age. Lifetime prevalence of agoraphobia was associated with disordered eating behaviors in women 15–44 years old, and the 12-month prevalence was associated with disordered eating behaviors only in women 15–24 years of age. Disordered eating behaviors was significantly associated with lifetime prevalence of panic disorder in women in all three age ranges and with 12-month prevalence of panic disorder in women in two age ranges, 15–24 and 45 and above.

98.5 Psychological Comorbidity in Elderly Women with Eating Disorders

Eating disorders and their associated psychopathology in elderly individuals, especially those living in the community, have received limited attention. To date, research on eating disorders in the elderly have focused on under-nutrition and eating difficulty in institutionalized women (e.g. Chapman 2006). However, reports on body image have provided evidence that drive for thinness and body dissatisfaction in women do not decline with advancing age (Cosford and Arnold 1992; Gadalla 2008b; Mangweth-Matzek et al. 2006; Webster and Tiggemann 2003). For example, Webster and Tiggemann (2003) reported that there were no differences between groups of young, middle aged, or older women in body dissatisfaction and importance of body shape. These authors also found that body dissatisfaction was negatively related to self-concept and self-esteem of women of all ages. More recently, in a community sample of 60–70 year-old women, 80% practiced some form of weight control and 60.0% stated dissatisfaction with their bodies (Mangweth-Matzek et al. 2006). Furthermore, in a national sample of women, 15.9% of 50–60 year-old and 7.4% of those 65 years or older were strongly concerned about their weight or body shape (Gadalla 2008b). This author also reported that 2.6% of women 50–64 years old and 1.8% of women 65 years or older, exhibited disordered eating behaviors, such as elevated frequency of dieting behaviors and preoccupation with food intake and body shape. There as a significant negative association between disordered eating behaviors and women's physical health and a significant positive association with stress level.

Research reports provide evidence that eating disorders may also occur at any age throughout the lifespan. For example, Mangweth-Matzek and colleagues (2006) found that 3.8% of elderly women living in the community met the criteria for eating disorders. Eating disorders in older women could be new episodes occurring for the first time, relapsing or persistent episodes of earlier disorders that had occurred earlier in their lives (Cosford and Arnold 1992). Additionally, as the population ages and the idealized images presented by the media become progressively thinner, the prevalence of eating disorders in the elderly is expected to increase and hence, there is pressing concern for a careful consideration of disordered eating patterns and their associated psychiatric comorbidity in this population.

Gadalla (2008b) examined psychiatric comorbidity in women 50–64 years old and 65 years or older who exhibited disordered eating behavior using a large sample of women in the general population. Findings of this study indicated highly significant associations between disordered eating attitudes and behaviors and mood and anxiety disorders for women in both age groups. Women 50–64 years old who scored over 20 on EAT-26 (Garner et al. 1982) were 6.9 times more likely to have at least one mood disorder, 2.6 times more likely to have at least one anxiety disorder and 6.0 times more likely to be alcohol dependent compared to women who scored 20 or less. Women 65 years and older who scored above 20 on EAT-26 were 3.2 more likely to have at least one mood disorder and 5.6 more likely to have at least one anxiety disorders.

98.6 Discussion and Recommendations

Findings of previous research on prevalence of mood and anxiety disorders in individuals with eating disorders varied a great deal (Godart et al. 2002, 2007). Possible reasons for these variations include the use of different types of participants and sample selection and the use of different criteria for assessing both eating disorder patterns and psychiatric disorders. In addition, the reference time used for the diagnosis of disorders ranges from point-prevalence or concurrence rates to lifetime occurrence. Further, when authors report prevalence rates that had been collapsed over a number of anxiety or mood disorders, these rates will vary according to the number of specific disorders included in the collapsed rate (Wittchen 1996). These methodological differences make it difficult to compare findings across studies. Researchers are thus, encouraged to use standardized and validated instruments for the assessment of eating disorders and other psychiatric disorders and report prevalence rates separately for each disorder and each gender.

A central issue in comorbidity studies is the temporal sequence of the disorders. Knowledge of the temporal sequence of eating disorders and other psychiatric disorders is essential when examining possible explanations for their relationship. Very few studies examined the temporal sequence of eating disorders and other psychopathologies. One such study was carried out by Measelle and colleagues (2006) who found that initial depression predicted increases in eating disorders and substance abuse symptoms, while initial eating disorders' symptoms predicted an increase in substance abuse problems in a community sample of adolescent women. In addition, in a sample of women with anorexia nervosa or bulimia nervosa, the onset of obsessive-compulsive disorder, social phobia and generalized anxiety disorder preceded the development of eating disorders in the majority of them (Kaye et al. 2004). The chronology of eating disorders and other psychiatric disorders can only be examined in longitudinal studies.

Generational differences, with younger generations at higher risk of experiencing psychiatric comorbidity, have also been suggested (Gadalla and Piran, 2008). Hudson and colleagues (2007) found the risk of bulimia nervosa and binge eating disorders to increase with successive birth cohorts. Studies with longitudinal design can be used to separate the effects of age on women's susceptibility to psychiatric disorders from generational differences. It has also been suggested that developmental trajectories of these disorders might be gender-specific (Beato-Fernandez et al. 2007). Consequently, such studies should be carried out for men and women separately.

The age of onset and the duration of each disorder should be taken into account when studying comorbidity of multiple disorders. For instance, according to the Diagnostic and Statistical Manual of Mental Disorders (APA 1994), the average age onset of anorexia nervosa is 17 years and of bulimia nervosa is18 years while depression is usually observed later. Thus, if eating disorders are usually observed at younger age than depression, the chronology of these two disorders may be a result of their natural courses rather than a causal link between them (Godart et al. 2007).

A few conceptual explanations for the high comorbidity rates between eating disorders and other psychiatric disorders have been proposed. One possible explanation is that the comorbid disorders share common risk factors. A second possible explanation is that the presence of one disorder increases the risk for the development of the other. A further possible explanation is that comorbidity reflects a developmental process where one disorder is the early stage of the other disorder. Future gender-specific studies examining alternative conceptual models with regards to the multivariate comorbidity of eating disorders and other psychiatric disorders are needed.

There is also a need for better description of treatment strategies that would best help individuals suffering from them. Research findings suggest that women with disordered eating patterns should be screened for symptoms of depression, manic episodes, agoraphobia, social phobia, panic disorders,

substance dependence, and psychological distress, while men with disordered eating patterns should be screened for symptoms of depression, panic disorder, social phobia, and psychological distress. Men and women presenting with the above mentioned disorders should be screened for eating disorders. The high prevalence of depression in eating disordered men and women calls for special attention, especially in the light of data suggesting that disordered eating patients whose depression begins before their eating problem more often engage in parasuicidal behaviors (Wildman et al. 2004). The development of short screening instruments for assessing depressive symptoms as well as symptoms of specific classes of anxiety disorders could be proven useful. These screening instruments should be gender-specific, focusing on mood and anxiety disorders found to be more prevalent for each gender. It is also of importance to continue developing treatment and prevention programs, which take into consideration the psychological comorbidity specific to men and women with eating disorders.

98.7 Applications to Other Areas of Health and Disease

Comorbidity studies have an important role to play in the clinical management of disease as well as the understating of the etiology of different physical and psychological conditions. One other area in which comorbidity studies can prove extremely useful is the interplay of physical and mental health.

A burgeoning body of research has shown that mental disorders, such as mood and anxiety disorders are more prevalent in individuals with chronic physical illness compared to individuals with no such illness. A diagnosis of a disabling physical illness and the associated decline in physical health may cause enough distress to trigger a depressive episode or invoke anxiety in vulnerable persons. On the other hand, individuals with mental illness can develop physical symptoms and illnesses, such as weight loss and biological disturbances associated with eating disorders.

High prevalence of mental disorders among individuals with chronic physical conditions represents a significant burden to individuals and society. At the individual level, mental illness can affect individuals' response to the treatment of their physical illness and adversely affect the course of physical illnesses**. In addition, mental illness may interact with physical illness to amplify the disability associated with it, thus, leading to occupational impairment, disruption in interpersonal and family relationships, poor health, and suicide. At the national level, comorbid anxiety disorders can adversely affect the economy through reduced productivity and higher health care costs.

Summary Points

- Empirical research provides evidence of high prevalence of psychiatric disorders, such as mood, anxiety, and substance use disorders in disordered eating individuals. This comorbidity was observed for both genders and is highest between eating disorders and major depression.
- In contrast with the consistent pattern regarding the association of eating disorders and alcohol use disorders in women and men, research findings regarding illicit drug use are markedly different between genders.
- More research is needed to determine the temporal sequence of the occurrence of eating disorders and other psychiatric disorders and to explain their comorbidity.
- Emerging research indicates that disordered eating occur in men and older adults. However, few studies examined eating disorders and their psychiatric comorbidity in these populations.
- Future research is encouraged to use longitudinal data collected from population-based samples.

- The importance of taking into account the age of onset and the duration of each disorder when studying comorbidity of multiple disorders is highlighted.
- Generational differences in the prevalence of eating and other psychiatric disorders should also be considered when studying comorbidity of multiple disorders.

Definitions and Explanations of Key Terms

- **Anorexia nervosa:** Anorexia nervosa is a psychiatric diagnosis that describes an eating disorder characterized by low body weight and body image distortion with an obsessive fear of gaining weight.
- **Bulimia nervosa:** Bulimia nervosa is an eating disorder characterized by recurrent binge eating, followed by compensatory behaviors, such as self-induced vomiting and the use of laxatives, enemas, and diuretics.
- **Purging:** Purging refers to the act of using self-induced vomiting and the use of laxatives, enemas, or diuretics to get rid of ingested food.
- **Binge eating disorder:** Binge eating consists of episodes of uncontrollable overeating during which, a person rapidly consumes a large amount of food.
- **EAT-26:** Eating Troubles module was developed by Garner et al. (1982). A score of 20 or more indicates disordered eating attitude and behavior, suggesting that the person is at risk of having eating disorder.
- **Mood disorders:** Mood disorders include depressive disorders, of which the best known and most researched is major depressive disorder commonly called major depression, and bipolar disorder, formerly known as "manic depression" and described by intermittent periods of manic and depressed episodes.
- **Anxiety disorders:** Anxiety disorders include several conditions of pathological fears or anxieties, such as generalized anxiety disorder, panic disorder, agoraphobia, social anxiety disorder, obsessive-compulsive disorder, post-traumatic stress disorder, and separation anxiety.

Key Points

- Empirical research provides evidence of high comorbidity between disordered eating patterns and other psychiatric disorders, especially mood, anxiety and substance use disorders. This comorbidity is highest with depression.
- Several hypotheses have been proposed to explain the high prevalence of mood and anxiety disorders in individuals with eating disorders. These hypotheses have not been empirically tested. In addition, the temporal sequence of the occurrence of eating disorders and comorbid psychiatric disorders is not yet determined.
- Although there is evidence to suggest that disordered eating patterns occur in men and in older adults, few studies examined eating disorders and their comorbid psychopathologies in these populations.
- Comorbidity studies have important implications for understanding the etiology of mental disorders as well as the clinical management of patients.

Chapter 99
Cognitive Performance Deficits of Dieters

Michael W. Green

Deliberate restriction of food intake to control weight is one of the most common food choice-related behavior in the developed world. Indeed, over one third of the general US population is classed as obese (National Center for Health Statistics 2006), with an associated impact on health treatment resources (Bray 1996) (see Fig. 99.1).

Within the context of these rising obesity rates (Department of Health (DOH) 2008), an understanding of the psychological impact of undernutrition and weight loss assumes an increasing importance. Food deprivation is a situation which, to varying degrees, affects a large proportion of the world's human population. In economically developed countries, however, it is a comparatively rare phenomenon except during times of war. Indeed, most of the occurrences of food deprivation observed in such countries are the result of a self-initiated choice, such as that found with eating disordered psychopathology, weight loss dieting, or fasting for religious reasons (such as the Muslim festival of Ramadan). Aside from the obvious physiological consequences of prolonged periods of food deprivation, there is an increasing body of literature indicating that this activity is associated with a range of psychological effects. These range from effects on cognitive functioning to the range of dysphoric affective states associated with eating disordered psychopathology and dieting behavior. The current chapter will describe this literature, both in terms of the effects of dieting-related food deprivation on cognitive function and affective state, and to consider a number of mechanisms which may underlie these effects. In turn, the chapter will consider the effects of laboratory-based food deprivation on psychological function, the effects of naturalistic attempts at dieting on psychological function, the practical and conceptual differences between dieting and dietary restraint and possible mechanisms to account for these phenomena.

The difference between laboratory-based studies of imposed caloric restriction and studies of naturalistic dieting is an important distinction on a number of levels. First, there are obvious motivational differences separating those who volunteer to take part in laboratory-based studies of food deprivation and those individuals who are already dieting to lose weight at the time of testing in naturalistic studies of the psychological effects of dieting. Second, for ethical reasons, laboratory-based studies of the psychological effects of caloric restriction tend to examine participants who are already in the upper end of the body mass index distribution (e.g. Kretsch et al. 1997), whereas naturalistic studies have found dieting-related psychological effects in individuals within the normal or low body mass index range (Green and Rogers 1995a).

99.1 Studies of Laboratory-Induced Food Deprivation

The main features of the studies which have examined the effects of laboratory-induced food deprivation are outlined below in Table 99.1.

The first systematic study of the effects of food deprivation was the famous Minnesota Study of Semi-Starvation (Keys et al. 1950). With a view to understanding the effects of starvation in order to determine refeeding strategies for malnourished refugees and prisoners of war following World War Two. In this study, participants were fed a diet comprising 50% of normal caloric intake for a period of 6 months, followed by a period of refeeding. Medical and psychological variables were measured at several time points over the course of the study. Over the course of the study, it was found that semistarvation resulted in increase in preoccupation with food and self-reported depression, in addition to self-reported problems with memory, concentration, alertness, and judgment. However, these effects were not borne out by objective performance measures. As there was no nonstarved control group for comparison, this lack of an effect of food deprivation on objective test performance could be interpreted in terms of a confounding practice effect. A more recent study has, however, partially replicated these findings (Sutker et al. 1992). It was found that, compared to nonstarved individuals, former prisoners of war with a history or malnutrition and body wasting (exceeding 35% of their precaptivity body weight) during captivity displayed poorer performance on a range of standardized tests of memory and learning. This study is important in two respects. First, it contained a nonstarved control group and so demonstrates that the results of the Minnesota Study may not be an experimental artefact. Second, effects on psychological function were observed several years after the period of food deprivation. It has to be remembered, however, that these studies examined the effects of relatively severe food deprivation, with roughly 25% of body mass being lost amongst participants in the Minnesota Study. Subsequent laboratory-based studies have not induced comparable degrees of food deprivation.

There are a number of studies which have examined the effects of laboratory-induced food deprivation of varying degrees on psychological function in a more controlled manner. In general, the results of these studies demonstrate that laboratory-induced food deprivation does not lead to significant impairments in psychological function (e.g. Shukitt-Hale et al. 1997; Corby et al. 2007), although there are methodological and procedural issues which need to be borne in mind when interpreting these data.

Table 99.1 Summary of studies investigating effects laboratory-induced food deprivation on cognition

Study	Participants	Deprivation	Findings
Corby et al. (2007)	Healthy adults (total N = 48)	4 conditions, ranging from normal feeding to 15% weight loss	No deprivation-related effects on cognition
Deijen et al. (1989)	Experimentally controlled dieting vs. nondieting controls (N = 10) per group	3 week weight loss diet	Dieting improved motor speed but impaired memory, but only when tested during morning
Green et al. (1995)	Healthy adults (N = 21)	Missing 1 meal to 24 h deprivation	No deprivation-related effects on cognition
Keys et al. (1950)	Healthy males (N = 36) No control group	24 weeks semi caloric intake	Impaired mood, attention, and memory (self reported)
Kretsch et al. (1997)	Obese women (N = 14) on diet, (N = 11) non- dieting controls	15 weeks of 50% caloric restriction	impaired reaction times No effect on other cognitive functions
Shukitt-Hale et al. (1997)	Healthy males (N = 17 per group)	30 days undernutrition vs. 30 days normal diet	No deprivation-related effects on cognition
Sutker et al. (1992)	Former POWs with history of malnutrition	Weight loss exceeding 35% of precaptivity weight	Range of impairments on various memory tasks
Wing et al. (1995)	Obese women (N = 21) No nondieting controls	Ketogeic vs. non- ketogenic diet	Ketogenic diet showed poorer spatial ability. Baseline differences make Clear interpretation difficult

The effects of prolonged experimentally-induced weight loss have been studied in a population of noneating-disordered obese individuals (Kretsch et al. 1997). During 15 weeks of 50% caloric restriction, obese subjects were regularly assessed on measures of sustained attention, immediate verbal free recall, distractibility, simple reaction time, and motor speed (2-finger tapping performance). Relative to nondieting control subjects, simple reaction times significantly slowed over the course of caloric restriction. However, there were no significant food deprivation-related deficits in the more complex measures of cognitive function. In fact, verbal recall was actually found to improve in the obese subjects, over the course of caloric restriction.

Other studies have examined the effects of experimentally-induced low energy diets on cognitive function. Wing, Vazquez and Ryan (1995) reported that the administration of a low carbohydrate diet (549 kcal/day) over 28 days amongst obese subjects was associated with impaired performance on a trail making task, relative to a group administered a low fat diet (590 kcal/day). There are, however, a number of problems with this study. Foremost of these is that, although beta-hydroxybutyrate levels (a metabolic indicator of starvation) rose significantly over the whole 28 days of the diet, trail making task performance was only significantly impaired at 7 days of dieting, compared to baseline. Subsequent measurements showed that trail making performance was actually better than baseline, with performance after 28 days of low carbohydrate dieting actually being better than at baseline. This was further confounded by marginally significant baseline differences between trail making performance (p = 0.06). Further support for the hypothesis that experimentally-induced weight loss per se does not significantly affect cognitive processing efficiency was provided by Deijen, Heemstra and Orlebeke (1989). This particular study found that, after a 3 week long, experimentally-induced weight loss diet, non-dieting subjects performed better than non-dieting subjects on a measure of motor speed (2-finger tapping). Although the dieting subjects performed more poorly than non-dieters on the Sternberg Memory Scanning Task, this difference was only apparent during morning test sessions, and not during the afternoon. There were no significant diet-related differences in

performance on a continuous performance task, pattern comparison task or the Symbol-Digit substitution sub-test of the Weschler Adult Intelligence Scale (WAIS). It has also been found that experimentally-induced food deprivation of up to 24 h in duration produced no significant performance decrements (Green et al. 1995).

The results of these studies raise the question of possible differences between food deprivation imposed as part of an experimental regime and weight loss spontaneously undertaken by the subject. Although such laboratory-based studies of food deprivation have the advantage of being able to study weight loss in tightly controlled conditions, they lack ecological validity of studies carried out on dieting "in the real world". This is because such spontaneously initiated dieting is often associated with swings in affective state (Tiggemann 1994), depression (Smoller et al. 1987), and self-reported stress (Beiner and Heaton 1995). It is also the case that such dieting frequently occurs within the context of a history of repeated failed attempts at weight regulation (French et al. 1995).

99.2 Spontaneous Dieting

In comparison to laboratory-induced food deprivation, there is consistent evidence that spontaneous dieting, undertaken as a response to dissatisfaction with current body shape or weight, is associated with impairments in cognitive function and mood. This is related to, but not necessarily the same as, the concept of dietary restraint. This can be defined as being "the self initiated tendency to control eating behavior in order to lose weight or maintain weight at a low, but stable level" (Tuschl 1990). Therefore, whilst high levels of dietary restraint are a prerequisite of dieting, it is possible to be a restrained eater without actually being a dieter. These studies are summarized in Table 99.2.

A series of studies has shown that individuals who report themselves as being currently dieting to lose weight at the time of testing display poorer performance on a range of performance measures, compared to nondieting restrained and nonrestrained eaters. For instance, Rogers and Green (1993) found that current dieters ($N = 13$) performed more poorly than nondieters on a 6 min long vigilance task. Replicating and extending this finding, it was found that current dieters also displayed poorer performance on measures of immediate verbal recall and simple reaction time (Green et al. 1994). Significantly, 2-finger tapping performance was not impaired in dieters, indicating that these findings cannot be explained in terms of a general impairment in motor performance or lowered motivation to complete the task battery amongst dieters. Both of these studies also found that nondieting, highly restrained eaters performed at a level intermediate to that of dieters and nondieting unrestrained eaters. This suggests that the phenomenon is fundamentally psychological, rather than physiological in nature, since nondieting, restrained eaters are not normally in a state of food deprivation. This hypothesis is supported by the finding that, whereas dieters reported a significantly lower caloric intake than unrestrained nondieters, there was no difference between the caloric intakes of restrained and unrestrained non-dieters (Green et al. 1994).

The hypothesis that this phenomenon represents an effect of dieting per se, rather than an epiphenomenon relating to pre-existing individual differences between subjects who happen to be dieting or not, at the time of testing has also been supported. It has been found that, within the same subjects, performance on the same cognitive task battery used in the first two studies in the series, was poorer when dieting than when not dieting (Green and Rogers 1995a). Three groups of current dieters were tested twice, 3 weeks apart. It was found that the two groups who were dieting on one session, but not the other displayed poorer performance on a vigilance task, slower simple reaction times and poorer immediate recall during the session on which they reported themselves as being "on a diet". It was also found that the dieting associated decrement in performance tended to be worse amongst the group who were dieting on the first

Table 99.2 Summary of studies investigating effects of spontaneous dieting on cognition

Study	Participants	Findings
Green et al. (1994)	Dieters ($N = 15$), nondieters ($N = 42$)	Dieters showed impaired ability to sustain attention, poorer immediate verbal memory, and slower reaction times
Green et al. (2005)	Unsupported dieters ($N = 25$), supported dieters ($N = 14$), non dieting controls ($N = 16$)	Unsupported dieters showed impaired ability to sustain attention, immediate verbal memory, and central executive function after 1 week of dieting. Results related to cortisol secretion
Green et al. (1997)	Dieters ($N = 21$), nondieters ($N = 48$)	Dieters poorer on measure of overall working memory capacity than nondieters, but no Differences in attentional focus. Task performance related to food-related preoccupations
Green et al. (2003)	Dieters ($N = 19$), nondieters ($N = 34$)	Dieting-related central executive Deficit. Related to preoccupying Cognitions, but not urinary 5-HIAA output
Green and Rogers (1995)	Dieters ($N = 19$ on first but not second session), ($N = 14$ on second session but not first), ($N = 28$ dieting on both)	Vigilance performance, verbal immediate memory, and reaction speed poorer in crossover groups on session in which they were dieting. Unrelated to weight loss
Green and Rogers (1998)	Dieters ($N = 19$), nondieters ($N = 52$)	Dieters poorer at tasks loading onto central executive and phonological loop components of working memory. Performance related to body shape-related preoccupations
Jones and Rogers (2003)	Dieters ($N = 20$)	memory performance poorer after consumption of sugary snack than before. Related to food preoccupations
Kemps and Tiggemann (2005)	Dieters ($N = 33$), nondieters ($N = 33$)	Dieting-related central executive impairment, mediated by preoccupying cognitions
Kemps et al. (2005)	Dieters (32), nondieters (N 32)	Dieters performed more poorly central executive tasks than other aspects of working memory. Mediated by food and body shape Preoccupations
Rogers and Green (1993)	Dieters ($N = 13$), nondieters ($N = 42$)	Dieters showed impaired ability to sustain attention
Shaw and Tiggemann (2004)	Dieters ($N = 19$), past dieters ($N = 29$), never dieters ($N = 44$)	Clear evidence of phological loop impairment in dieting. Less clear evidence of central executive impairment. Results mediated by preoccupying cognitions
Vreugdenburg et al. (2003)	Dieters ($N = 20$), nondieters ($N = 20$)	Dieters poorer at tasks loading onto central executive and phonological loop components of working memory. Performance related to food and body shape-related preoccupations

session (but not the second) than in the group who were dieting on the second session (but not the first). This is illustrated by their performance on the Bakan vigilance task (see Fig. 99.2), I addition to performance on tasks measuring immediate verbal memory and reaction speed.

It was concluded, therefore, that the decrement in performance was related to the stress of a change to habitual or preferred food intake, since this group had been dieting for a far shorter period of time.

Having demonstrated that this negative effect of dieting on cognitive function is a replicable effect, the next question relates to the precise nature of the cognitive deficit. Is it the case that dieting independently affects a number of cognitive domains or is there an overarching cognitive system affected by dieting which give the appearance of a relatively global deficit? There are a number of
Fig. 99.2 Results of Green and Rogers (1995), showing Bakan task performance in three groups of dieters over the course of a 3 week attempt at weight loss (mean correct hits per minute; ± SE included). This shows performance on the Bakan vigilance task for three groups of dieters when either dieting (Y) or not dieting (N) on a first test session (1) and a second (2), 3 weeks later. In the two crossover groups, performance is poorer when dieting than when not dieting. The improvement in the Y1 Y2 group over time is attributed to practice

possible structures for this dieting-related cognitive impairment. Aside from the global deficit hypothesis, it is also possible that dieting is associated with a breakdown in the ability to attend to the task stimuli; the third possibility being a dieting-related reduction in cognitive processing (working memory) capacity (Baddeley 1986). The global deficit hypothesis is unlikely, since several studies show that performance is not affected on all cognitive tasks in a given performance battery (e.g. Green et al. 1994). Evidence regarding the second and third possible structures can be found in the results of the study of Green, Elliman and Rogers (1997). Dieting and nondieting subjects completed a measure of spatial and semantic distractibility and a measure of overall verbal working memory capacity, in addition to a number of self-report measures of somatic sensation and affective state. There were no dieting status-related differences on the flankers task. It was found, however, that current dieters exhibited smaller reading spans than nondieters and that this significantly covaried with self-reported "desire to eat". The data, therefore, supported the hypothesis that the deficit in cognitive processing associated with dieting is essentially one of a limitation in working memory capacity, rather than a failure in attentional focus. The data further indicated that this limitation is related to preoccupying cognitions concerning food.

Having established that spontaneously undertaken dieting is associated with impairment in working memory capacity, the next study in the series (Green and Rogers 1998) attempted to elucidate which of the sub-components of working memory are compromised in dieting. Processing Efficiency Theory (Eysenck and Calvo 1992) hypothesizes that preoccupying cognitions affect working memory capacity by means of subvocal worry, preferentially consuming the capacity of the Phonological Loop and Central Executive components of the system, these being the subsystems which deal with verbal information. The hypothesis that the working memory deficit associated with dieting bears similarity to deficits in the same system associated with the preoccupying cognitions accompanying anxiety and depression was the focus of an investigation by Green and Rogers (1998). Current dieters and nondieters completed computer-based measures of Central Executive capacity (Tower of London Task), Phonological Loop capacity (letter recall of visually presented material with/ without

articulatory suppression and with/ without phonological confusability) and Visuo-Spatial Sketchpad capacity (mental rotation). Consistent with the hypothesis that impaired cognitive processing in dieters is related to preoccupying cognitions, dieters displayed slower planning times on the Tower of London Task (four and five minimum move problems) and poorer performance on the letter recall task than nondieters. There were no dieting-related differences in performance on the mental rotation task. Further support for this hypothesis was found in the significant correlations between a self-report measure of body shape esteem and the two processing measures upon which dieters performed more poorly than nondieters.

The negative impact of current dieting status on working memory capacity is a finding which has been replicated several times. Vreugdenburg, Bryan and Kemps (2003) also found dieting-related impairments in central executive and phonological loop (but not visuo-spatial sketchpad) function which were related to a specific measure of food and body shape cognition. Other studies have broadly, but not consistently, also supported this conclusion. For instance, Shaw and Tiggemann (2004) investigated the precise nature of the phonological loop deficit associated with dieting and found that there was no dieting-related impairment in an auditory version of the phonological loop task used by Green et al. (1998), this measuring the storage capacity of the phonological loop. However, a dieting-related impairment in the articulatory control component of the phonological loop (the component resembling subvocal rehearsal), as measured by immediate recall for long and short words, presented via audio recording. This effect was significantly related to self-reported food-related preoccupations. Although the authors do not attempt to explain the discrepancy between their findings and those of Green and Rogers (1998), a possible explanation may lie in the differences between visual and auditory presentation of stimulus materials.

Other studies have found that the fundamental nature of the cognitive impairment associated with dieting is fundamentally related to central executive function, this being the overall attentional control and resource allocation component of working memory (Baddeley 1986). Kemps and Tiggemann (2005) found that spontaneous dieters performed more poorly on a measure of central executive capacity (combined verbal and spatial memory) than on measures of phonological loop or visuo-spatial, sketchpad capacity and that this is related to food-related preoccupying cognitions. The authors claim that the lack of effect on the phonological loop task was due to a comparative lack of cognitive loading, compared with the version of the task used by Green and Rogers (1998). However, the significant dieting-related impairment on what the authors claim is a central executive task could actually be due to a reduction in phonological loop capacity since a common way of increasing the cognitive load of a verbal recall task is to introduce distraction by means of concurrent motor activity. Stronger supporting evidence of a central executive impairment associated with spontaneous dieting has been found by Kemps, Tiggemann and Marshall (2005). This study employed a number of tasks previously validated as primarily loading onto central executive function (e.g. random number generation, task switching), in addition to phonological loop and visuo-spatial sketchpad function. It was found that current dieters displayed poorer performance on a number of central executive and phonological loop tasks, but not the visuo-spatial sketchpad task (Corsi block task). Further, these data support those of Green and Rogers (1998), by finding that these selective working memory impairments were partially mediated by food and body shape preoccupying cognitions.

It would appear then, that spontaneously undertaken dieting behavior, but not experimentally-induced food deprivation, is associated with selective impairments in cognitive function. Further, rather than being a global deficit or a breakdown in attentional focus, these deficits appear to be primarily due to a reduction in processing capacity of working memory. Specifically, it appears that the central executive and phonological loop components of the working memory system are affected by the attempt to lose weight, irrespective of whether the attempted weight loss is successful or not. Further evidence for the role of preoccupying cognitions in the dieting-related cognitive impairment

can be seen in the results of Jones and Rogers (2003). This study found that the dieting-related impairment in task performance was greater in dieters who had consumed a confectionary bar prior to the test session than in those who had not. This mitigates against a simple food/ glucose deprivation explanation. Although evidence suggests that this reduction in working memory capacity is the result of preoccupying cognitions relating to food, hunger, and body shape, there are still a number of other candidate biological mechanisms which could explain the dieting-related cognitive deficit.

99.3 Biological Mechanisms

As stated, there are a number of possible biological mechanisms which could account for the observed dieting-related impairment in cognitive function. These include food deprivation-induced impairments in neurotransmitter function, reduced iron metabolism, and the actions of cortico-steroid hormones. Each of these will be discussed.

99.3.1 Dieting-Related Alterations in Serotonergic Function

Although the studies relating to the effects of spontaneously undertaken dieting indicate that cognitive processing efficiency can be compromised even in the absence of any substantial weight loss (Green and Rogers 1995a), there is a body of research indicating that experimentally-induced weight loss can affect neurotransmitter function. Specifically, a number of studies have found that experimentally-induced weight loss compromises serotonergic function by lowering the relative availability of the serotonin (5-HT) precursor tryptophan and, therefore, levels of 5-HT (reviewed by Cowen et al. 1992). For instance, it has been found that a 3-week-long weight loss diet (1,000 kcal/day) lowered levels of plasma tryptophan in female subjects ($N = 12$) (Cowen et al. 1995).

A study which indicates that such tryptophan depletion may be responsible for the deficits in cognitive processing efficiency which accompany weight loss is that of Park, Coull, McShane, Young, Sahakian, Robbins and Cowen (1994). It was found that ingestion of an amino acid laden drink without tryptophan (vs. a control drink in which tryptophan was present) decreased the relative amounts of tryptophan available for 5-HT synthesis. Further, it was found that subjects in the tryptophan-deficient condition performed more poorly on a number of measures of cognitive processing efficiency. In particular, planning times on the Tower of London Task were longer in this group than in control subjects. However, there are research findings which indicate that it is unlikely that this mechanism mediates the working memory impairments associated with spontaneously undertaken dieting. Foremost of these is the finding that such impairment are present even in the absence of any substantial weight loss; although this does not preclude the nutritional composition of these diets may be deficient in certain micronutrients or indeed that they might lower 5-HT neurotransmission. Another method whereby tryptophan uptake to the brain may be affected is by alterations in the dietary carbohydrate (Wurtman and Wurtman 1989). It is hypothesized that the ingestion of carbohydrate causes the manufacture of insulin in the pancreas and, therefore, has the effect of increasing the relative concentration of tryptophan in the bloodstream, leading to increased uptake into the brain and increased 5-HT synthesis. The psychological impairments characteristic of dieting may, therefore, be due to a lack of sufficient dietary carbohydrate. Recent evidence (D'Anci et al. 2009), suggests that this relationship is not a simple one. It was found that, whilst low carbohydrate dieting over a period of weeks led to impairments in memory function (compared to a balanced, low-calorie diet), this regime actually led to an improvement in attentional function. The authors interpret their mixed finding in terms of the relative availability of glycogen

stores and the increased availability of protein during low carbohydrate dieting. These results are not congruent, however, with the results of studies which have found impairments in both of these cognitive domains in nutritionally balanced, low calorie dieters (e.g. Green et al. 1994) and may be explained in terms of a lack of statistical power (total sample size = 19).

It is possible, however, that neuro-endocrine imbalances are, at least in part, responsible for the deficits in brain function found in more severe states of starvation. There appears to be a complex relationship between neuro-endocrine function, depression, and severe starvation. In essence, this relationship is that clinical depression is frequently associated with both decreased levels of plasma tryptophan (Cowen et al. 1989) and loss of appetite (Cowen et al. 1992). In addition, weight loss (Green et al. 1997) and depression (Channon et al. 1993) and tryptophan depletion (Park et al. 1994) are associated with impairments in working memory capacity. The evidence for the role of tryptophan as a mediating variable in this relationship is further strengthened by the evidence indicating a comorbidity of depression with anorexic psychopathology (e.g. Laessle et al. 1987) and dieting behavior (Warren and Cooper 1988).

It is also possible that this relationship between tryptophan, affective state, and cognition may have some power as a means of explaining the information processing effects noted in less severe forms of food deprivation such as dieting. There is reliable evidence to indicate that the administration of diets specifically designed to alter the relative availability of tryptophan are associated with changes in affective state. For instance, tryptophan depletion has variously been associated with increased aggression (e.g. Cleare and Bond 1995) and depression (e.g. Benkelfat et al. 1994; Miller et al. 1992).

There are, however, a number of problems with this postulated relationship. First, impaired cognitive processing has been observed amongst dieters who do not display higher levels of self-rated depression than nondieting control subjects (Green et al. 1997). Second, it has been noted that the loss of appetite leading to weight loss in clinical depression is rarely severe (Casper and Beaton 1992). The causal direction of this hypothesized relationship must, therefore, be the subject of future research in this area. It has been found, however, that the effects of tryptophan depletion on affective state are related to the susceptibility of the subjects to depression (Benkelfat et al. 1994). In addition, there are a number of published studies which describe no effect of tryptophan depletion on affective state (Oldman et al. 1995, 1994).

Perhaps the strongest piece of experimental evidence against a serotonergic explanation for the impairment in cognitive function during dieting comes can be found in the study of Green et al. (2003). Using substantially the same methodology as Green and Rogers (1998), this study partially replicated these findings, with the demonstration of a significant dieting-related central executive impairment and a marginally significant phonological loop impairment in current dieters. In addition, 24 h urine collection over the course of the test day revealed no significant dieting-related differences in levels of the main serotonin metabolite, 5-HIAA. Whilst it could be argued that peripheral measures such as metabolite levels do not accurately reflect central serotonergic function, this study found a significant correlation between urinary 5-HIAA levels and self reported depression, indicating a relationship between central and peripheral measures of serotonin turnover. This study is a strong indicator that the impairments in working memory found during spontaneous dieting behavior are not related to compromised serotonin function/ metabolism.

99.3.2 Alterations in Iron Metabolism

Another possible nutritional factor which may mediate the effects of dieting on cognitive processing is that of iron status. Certainly, there is a body of research indicating that iron deficiency is associated with impairments in processing efficiency. For instance, a number of studies have found associations

between iron deficiency anemia amongst children and poor cognitive abilities (e.g. Pollitt and Leibel 1976; Pollitt and Kim 1988). Further, it has also been found that performance on the Bayley Scales of Infant Development (Bayley 1969) was poorer amongst iron deficient anemic children was poorer than that of iron-sufficient children both on baseline testing and after a 3 month intervention designed to normalize iron status (Lozoff et al. 1987). This finding is not unequivocally supported, however, since iron supplementation has also been found to improve the performance of non-anemic, iron-deficient children on the Bayley Scales of Infant Development (Oski et al. 1983).

Amongst adults, relationships have been found between serum ferritin levels and EEG readings, consistent with activation of the left cerebral hemisphere (Tucker et al. 1984). In addition, a significant negative correlation was found between ferritin levels and performance on a tonal memory backward span task and a significant positive correlation between ferritin levels and performance on a verbal fluency task. It was concluded that body iron stores are an important mediator of attentional function. Although statistically significant, the observed correlation coefficients were small ($r = 0.30$, $p < 0.05$ in both cases) and the conclusions drawn may, therefore, be subject to Type I error. In addition, no explanation is offered for the observed negative correlation between ferritin levels and performance on the memory span task. This interpretation of Tucker et al.'s data is supported by further evidence indicating the lack of a relationship between ferritin levels and cognitive processing efficiency (Fordy and Benton 1994). Low iron status in adults has, however, also been found to be significantly related to impairments in the function of the central executive in working memory and motor speed (Kretsch et al. 2006). The relationship between iron status and cognitive function, therefore, does not appear to be simple.

There is a small body of evidence suggesting that weight loss compromises iron status. It has been found that a 12 week long liquid formula very-low-energy diet (420 kcal/day) produced declines in transferrin saturation and increases in plasma ferritin concentration amongst obese subjects (Beard et al. 1997). Further, it has been found that decreasing hemoglobin concentrations resulting from an experimental weight loss program were significantly correlated with performance on a vigilance task (Kretsch et al. 1998).

A body of evidence exists, therefore, which suggests that impaired iron status is associated with impaired cognitive processing efficiency and, further, that iron status is compromised during weight loss. The obvious mechanism whereby iron status and cognition interact is that of cerebrovascular function, whereby low plasma iron levels may lead to inefficient oxygenation of the brain. Whether this can explain dieting-related cognitive impairments in the absence of any significant weight loss (e.g. Green and Rogers 1995a) is, however, a matter for debate.

99.3.3 Stress Hormones

While the evidence strongly suggests that spontaneous dieting is associated with working memory impairments, and that these are likely to be due to preoccupying cognitions concerning food, hunger, and body shape-related self esteem, these preoccupations may result in a concurrent effect on stress hormones. As stated earlier, self-initiated dieting is not without negative psychological consequences. For instance, dieting has been associated with increased depression and low self-esteem (e.g. Warren and Cooper 1988; French et al. 1995; Roncolato and Huon 1998). There is also evidence to show that dieting for short periods of time (6 days) is associated with an increased stress response (Johnstone et al. 2004). While the majority of published experimental evidence supports this relationship, dieting and depressed psychosocial status are not universally linked. Some studies have found that dieting leads to improved psychosocial status, although this appears to depend on the eventual success

of attempted weight loss and weight loss strategy adopted (Miller-Kovach et al. 1999) or whether an approach specifically designed to enhance self-esteem is adopted (e.g. Kenardy et al. 2001). Conversely, there are also a number of studies which show that successful weight loss is associated with a positive affective outcome (see Foster and Wadden 2002 for a review of this literature). The disparity between the findings of these studies can be attributed to a number of factors, such as the age and starting weight of the participants in each study. However, an important difference is that those studies which have found a positive effect of dieting concentrate on the eventual successful outcome of attempted weight loss whereas those which have found negative effects examine the active process of attempting weight loss.

Studies which have demonstrated a negative impact of dieting on psychological function have examined this phenomenon amongst individuals spontaneously dieting in an unsupported setting. As mentioned above, dieting-related cognitive impairments have even been found in the absence of any significant weight loss (e.g. Green and Rogers 1995a). There is evidence which suggests that supervised, supported weight loss promotes successful weight loss, results in a relatively better mood state, and avoids some of the potential negative health consequences of unsupported dieting (Blackburn 1993; Lowe et al. 1999) and a greater expectation of weight loss (Bagozzi and Edwards 1998). Unsupported dieting, however, is associated with a greater degree of eating disordered psychopathology and body dissatisfaction (Juda et al. 2004). The cognitive impairments associated with unsupported dieting may, therefore, be related to an elevated stress response during the early stages of attempted weight loss. There are a number of strands of evidence which support this hypothesis. The first is that acute cortico-steroid administration selectively impairs performance on working memory tasks and not on tasks which assess declarative memory or on vigilance tasks with a low working memory load (Lupien et al. 1999). Second, both urinary and salivary cortisol secretions are found to be higher in those with a high degree of dietary restraint than unrestrained eaters (restraint being the habitual tendency to restrict caloric intake to control weight) (McLean et al. 2001; Anderson et al. 2002). Green, Elliman and Kretsch (2005) provide further evidence to support this hypothesis. It was found that unsupported dieting was associated with working memory and vigilance impairments in the early stages of weight loss (within the first week) and that this was associated with elevated cortisol secretion. It was also found that dieting in a supported, group setting led to comparable weight loss, but no cognitive impairments or alterations in cortisol secretion or self-reported stress/arousal. These results, in terms of cortisol secretion and performance on a sustained attention task with a high working memory load (expressed in terms of mean correct hits per minute) are shown below in Fig. 99.3.

These impairments were structurally similar to those found with experimentally-induced mild stress (e.g. Lupien et al. 1999). From these and other data, it can be concluded that spontaneous, unsupported, dieting is associated with impairments in working memory resulting from preoccupying stressful cognitions relating to both body shape and thoughts of food/hunger.

99.4   Applications to Other Areas of Health

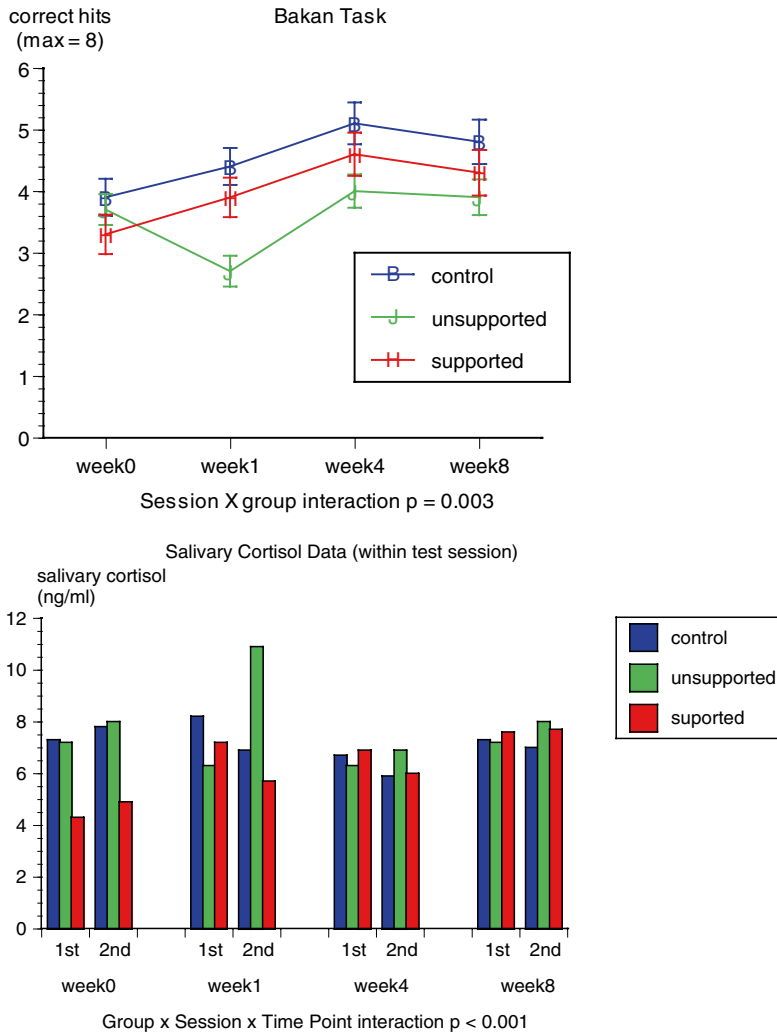
The impairment in psychological function found during unsupported spontaneous dieting is a function of preoccupying cognitions preferentially consuming working memory capacity. These impairments are structurally similar to those found in anxiety (Darke 1988) and depression (Channon et al. 1989) and, therefore, can be conceptualized as reflecting the effects of any preoccupation upon cognitive processing efficiency. In the case of dieting, however, the nature of this preoccupation is specific to body shape, food, and hunger. While dieting is primarily related to overweight, there are a


Fig. 99.3 Results of Green et al. (2005), showing salivary cortisol secretion and sustained attention task performance over the course of 8 weeks in supported dieters, unsupported dieters and nondieting control participants. Cortisol secretion rises over the course of the test session after 1 week of attempted weight loss in unsupported dieters only. Performance on Bakan task (mean hits per minute, ± SE included) is poorer in unsupported dieters after 1 week of dieting. There is a significant correlation between task performance and cortisol change during this session ($p < 0.001$)

number of other obesity-related health conditions in which dietary modification is recommended, including Type II Diabetes, atherosclerosis, hypercholesterolemia, and coronary heart disease. It is possible that dietary changes made in response to diagnosis with any of these conditions will be accompanied by the same psychological problems as is the case with dieting. Certainly, it has been found that cholesterol reduction (by means of statin drugs or dietary treatment) has been found to result in impaired performance on tasks sensitive to the effects of weight loss dieting (e.g. Wardle et al. 2000), shown in Fig. 99.4.

The studies reviewed here indicate that such dietary changes would be best attempted in a supported, group setting in order to minimize their possible negative psychological impact.
Fig. 99.4 Results of Wardle et al. (2000) showing Bakan task performance (mean correct hits per minute; ± SE included) in low fat diet, low saturated fat diet and non-intervention control groups over the course of a 12 week dietary intervention designed to lower cholesterol. Bakan task in nonintervention controls improves as a function of practice over 12 weeks improves in the nonintervention control groups. In the two cholesterol lowering diet groups, performance does not improve over 12 weeks, with performance significantly poorer than control group at the end of the intervention ($p < 0.05$). This significantly correlated with change in cholesterol levels

99.5 Conclusions

There are a number of clear conclusions that can be made concerning the work summarized in the current chapter. The first of which is that, under certain given circumstances, states of food deprivation outside of the severity of a fully diagnosed eating disorder are associated with impairments in psychological functioning. While a number of studies of severe, noneating disorder-related, starvation (e.g. Keys et al. 1950; Sutker et al. 1992) have shown that extreme induced food deprivation is associated with negative impacts on mood and the function of various cognitive domains. The evidence relating to mild, experimentally-induced food deprivation is, however, equivocal. A number of studies show that experimentally-induced mild food deprivation impairs psychological function, a number show that it has no effect and a number are subject to methodological difficulties which make clear interpretation of their data problematic. In addition, there seem to be study to study task-based inconsistencies in the cognitive domains affected which make clear interpretation of the results difficult.

Spontaneously undertaken dieting, however, is reliably associated with impaired cognitive function and that the nature of this deficit appears to be primarily due to a reduction in available working memory capacity. Given that working memory is the primary cognitive system which serves to allocate processing resources to ongoing cognitive operations and remember the moment to moment rules of action, this working memory impairment can give the appearance of a more global cognitive processing impairment. It can be further concluded that this phenomenon is the result of preoccupying concerns with body shape and food/hunger in the early stages of spontaneous dieting, acting in a manner similar to the role of preoccupying conditions typical of clinical depression and anxiety. There are, however, a number of other possible biochemical routes whereby dieting may affect cognition, but these are of varying plausibility.

Summary Points

- Chronic, severe caloric restriction, aside from anorexic psychopathology is associated with impaired mood and cognitive function.
- Experimentally-induced mild caloric restriction is less reliably associated with impaired psychological function and results are dependent on the methodology and psychological assessment tools employed.
- Spontaneous dieting is reliably associated with impaired psychological function, which is not necessarily related to weight lost or the success of the diet.
- Effects of spontaneous dieting on psychological function are most marked in the early stages of attempted weight loss and appear to be specific to unsupported dieting and not dieting within the context of an organized weight loss group.
- The effect of attempted weight loss on psychological function appears to be primarily a reduction in working memory capacity arising from preoccupying cognitions related to body shape, food, and hunger.
- There are a number of possible biological mechanisms underlying the effect, such as compromised iron or serotonin metabolism. The most likely biological correlate of these effects is a dieting-related increase in cortico-steroid levels resulting from the stress of attempted weight loss.

Key Facts

Bakan task: A highly sensitive cognitive performance task measuring the ability to sustain attentional focus for periods of time. Participants have to detect a number of series of three odd or three even numbers appearing on a display before responding. This task contains a high working memory and is sensitive to both nutritional and pharmacological manipulations.

Beta-hydroxybutyrate: A ketone body produced as the result of the metabolism of protein such as muscle tissue.

Body mass index: A measure of weight, adjusted for height. Calculated as mass (kg)/height $(m)^2$.

Cortico-steroid levels: Corticosteroids such as cortisol and DHA are steroid-based hormones which are involved in the regulation of arousal levels and the stress response. They have also been found to be associated with cognitive function and their metabolism is linked to body fat levels.

Ferritin: A compound which is involved in iron storage in the body.

Glycogen: A carbohydrate. The form in which glucose is stored in the body.

5-HIAA: The major metabolite of the neurotransmitter serotonin. Can be detected in blood or urine and is a reliable marker of serotonin turnover.

Sternberg memory scanning task: A memory task in which participants are presented with a list of numbers and then presented with a single number. They then have to decide whether this number was part of the original set or not, with response time being the dependent measure.

Tower of London task: A task involving mental movement of a series of objects which measures the capacity of the Central Executive component of working memory and the functioning of the brain's frontal cortex.

Transferrin: A compound found in plasma which is involved in the transport of iron to bodily tissues from the gut.

Tryptophan: The amino acid from which the neurotransmitter serotonin, or 5-HT is synthesized. This only comes from dietary sources and cannot be manufactured within the body.

Working memory: This can be regarded as *the* fundamental cognitive processing system, which serves to remember the moment-to-moment rules of action and allocate processing capacity to other, ongoing cognitive activities. It comprises three subsystems; these being the Central Executive (an overall attentional control and allocation system), the Phonological Loop (which serves to deal primarily with oral and written information), and the Visuo-Spatial Sketchpad (which primarily deals with spatial information).

100.1 Introduction

Neurobiological and epidemiological studies provide evidence indicating that disturbed growth in early life may lead to the later development of physical problems as well as psychiatric disorders. Alterations in development at early stages of life (i.e., from the fetal stage through childhood) are known to determine the risk of development of various conditions later in life (e.g., obesity; type II diabetes; cardiovascular diseases; cognitive impairment; and psychiatric disorders such as autism spectrum disorders (ASDs), mood disorders, schizophrenia, and Alzheimer's disease) (Schlotz et al. 2009). The transitional phase from intra- to extra-uterine development is critically important in preparing for adjustments in adult life. During this adaptive period, fetuses and infants are particularly susceptible to environmental as well as genetic factors (i.e., epigenetic influences). Environmental factors include placental dysfunction, maternal malnutrition during pregnancy, psychological distress in pregnant mothers, and infections during both gestation and the postnatal period. Furthermore, the effects of these environmental factors have been associated with alterations in gene expression regulated by epigenetic factors such as DNA methylation and histone methylation/acetylation processes (Ross et al. 2008). Such alterations have been proposed to trigger permanent changes in the programming of physiological systems and predispose individuals to various abnormal conditions in adult life (Table 100.1); this conceptualization of the origin of certain conditions conforms to the notion suggested by the "Developmental Origins of Health and Disease" (DOHaD) model (Barker 2003). This transitional phase of development is pivotal for the development of the central nervous system (CNS), which includes neural cell programs such as cell proliferation and migration, neuronal extension and growth of dendrites, maintenance of the plasticity of synaptic connections, oligodendrocyte maturation, and myelination, all of which are vulnerable to the influences of exogenous modulating factors such as nutritional state, stress, endocrine disruption, exposure to chemical agents and drugs, maternal infections, and premature birth. Thus, along with genetic factors, environmental factors that exert a detrimental effect on CNS development during the pre-, peri-, and post-natal period are thought to be linked to neurodevelopmental disorders (Connors et al. 2008). In this chapter, we describe the mechanisms by which some early environments predispose individuals to adverse sequelae in adult life. Here, we will focus on the origins of health and disease, and in particular on nutritional factors or adverse events during early life that signal the emergence of neurocognitive impairments and psychiatric disorders later in life (Fig. 100.1).

Table 100.1 Key features of fetal programming

1. The transitional phase from intra- to extrauterine development is critically important in preparing for adjustments in adult life. For instance, during this transition, the brain is most vulnerable to nutritional deficiency or exposure to harmful environments.
2. During this phase, fetuses and infants undergo physical, metabolic, and hormonal adaptations for postnatal life.
3. Environmental factors (e.g., placental dysfunction, maternal malnutrition during pregnancy, psychological distress of pregnant mothers, and infections during both the gestational and postnatal period) have been associated with alterations in gene expression regulated by epigenetic factors.
4. Altered gene expression in response to the intra- and extrauterine environment has been proposed to trigger permanent changes in the programming of physiological systems and to predispose individuals to various adverse neuropathological conditions in adult life.

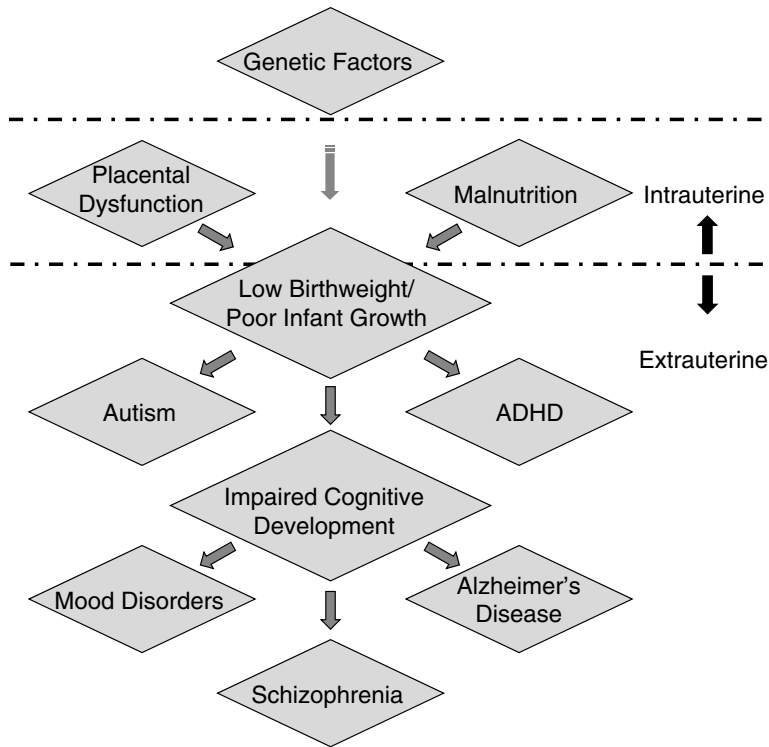
This table presents the concept of fetal programming and lists key features of this process


Fig. 100.1 Schema for the relationship between altered growth in early life and subsequent development of various neuropsychiatric disorders. Intrauterine environmental factors (e.g. placental dysfunction and malnutrition) and genetic factors predispose individuals to various psychiatric disorders in adult life. *Arrows* represent the relationship between risk factors and outcomes (disorders)

100.2 Spatially and Temporally Diverse Patterns of Development of the Central Nervous System (CNS)

In humans, CNS development is accomplished in a predetermined order, as exemplified by neurogenesis, cell migration (i.e., final "inside-out" positioning of cells in the cortex), molecular specification, synaptogenesis, and myelination. By the second trimester, most of the neurons in the human cerebral cortex have already been produced and have migrated to appropriate regions. However, delayed neuronal generation appears in some cortical areas such as the primary sensory area and the visual and/or auditory cortices, which form in very well-developed layers. In a similar manner, neurotransmitter systems (e.g., monoamines that originate in the brainstem) exhibit unique spatial and temporal patterns of development (Connors et al. 2008). At the beginning of the third trimester, synaptogenesis starts to accelerate, and a dramatic increase in synaptic formation continues until the individual reaches about 2 years of age (Connors et al. 2008). Myelination of the brain, which takes place in early infancy, is similarly a regional and temporally specific maturation process. The speed and timing of myelination vary in different areas of the CNS; that is, many parts of the cerebral hemispheres experience rapid, extensive myelination in individuals between ages 1 and 9 months old, whereas the frontal and temporal lobes continue myelinating even through the fifth decade of life (Bartzokis et al. 2001). Such diversity in CNS development may play a role in the emergence of

Fig. 100.2 Time frame for developmental processes in the human central nervous system (CNS). The time frame of developmental processes in the human CNS is outlined in this figure. The intrauterine period is scaled in trimesters, and the extrauterine period is shown in years

Table 100.2 Key points of neurocognitive development

1. Neurocognitive development incorporates multiple processes such as neurogenesis, neural cell migration, neuronal extension and growth of dendrites, synaptogenesis, oligodendrocyte maturation, and myelination.
2. Neurogenesis and neural cell migration are most prominent during the second trimester.
3. Synaptogenesis begins to accelerate at the beginning of the third trimester, and this dramatic increase in synaptic formation continues until the individual reaches about 2 years of age.
4. Myelination is most extensive between the ages of 1 month and 9 months.
5. The brain is vulnerable to nutritional deficiency and exposure to harmful environments while the individual is undergoing neurocognitive development.

This table presents the basic concepts of neurocognitive development in early life

various complicated characteristics of abnormalities and dysfunctions (e.g., the manifestation of particular neuropsychiatric disorders) that arise from abnormal neural development in specific brain regions and/or disturbed timing of developmental events (Fig. 100.2, Table 100.2).

100.2.1 Low Birthweight (LBW), Small-for-Gestational-Age (SGA), and Sequelae

Birthweight is a simple index of development, and yet it provides valuable information about disturbances in the in utero growth of the fetus, including CNS development. Low birthweight (LBW; <2,500 g) can arise as a result of preterm delivery or intrauterine growth restriction (IUGR), and can also be associated with being small-for-gestational-age (SGA; <10% percentile). Although the underlying pathobiology of IUGR is heterogeneous, it is primarily caused by maternal malnutrition or placental dysfunction (Table 100.3); the latter is characterized by a disturbance in placental-fetal circulation that maintains the supply of important nutrients such as oxygen, glucose, and amino acids (Cottrell et al. 2008). Moreover, IUGR has been shown to be associated with the development of adult diseases; this phenomenon is referred to as "fetal programming" (Ross et al. 2008). In response to poor nutritional states, the fetus undergoes metabolic and hormonal adaptations as a "thrifty phenotype" to maximize the chance of postnatal survival under conditions of deprivation. This "fetal programming" is partially beneficial in the prevention of adult diseases, provided that such poor conditions persist (Desai et al. 2007). However, when the postnatal environment provides plentiful nutrition, the "thrifty phenotype" will be turned into a risk factor for developing chronic diseases such as obesity, type II diabetes, and cardiovascular disease as a result of this early programming conflict (Cottrell et al. 2008).

Animal studies have demonstrated that IUGR induced by placental hypoperfusion results in structural and functional abnormalities in the CNS, including low total brain weight, reduced hippocampal formation with a decreased number of CA1 pyramidal neurons, and a reduction in the number of

Purkinje neurons in the cerebellum (Mallard et al. 2000). Thus, IUGR and subsequent SGA have been considered to be associated with perinatal mortality and long-term morbidity, in addition to being risk factors for physiological, neurological, and behavioral deficits (Tolsa et al. 2004). In effect, epidemiological studies have shown significant associations between the presence of IUGR/SGA and impairments of subsequent neurocognitive development (O'Keeffe et al. 2003). For instance, a prospective study (Breslau et al. 1994) demonstrated that the mean IQ of LBW children at 6 years of age was 4.9 points lower than that of normal birthweight children, when adjustments were made for maternal IQ. Furthermore, a gradient relationship was observed between birthweight and IQ, with the largest IQ deficit in those born weighing ≤1,500 g, an intermediate deficit in those born weighing from >1,500 g to 2,000 g, and the least pronounced deficit in those born weighing >2,000 g, indicating that children born weighing 2,000 g or less bear the major burden of cognitive deficits (Breslau et al. 1994).

More recent studies have revealed that SGA children born at either term or preterm are associated with long-term developmental consequences. O'Keeffe et al. (2003) examined the relationships between full-term SGA and subsequent cognitive impairment, learning problems, and attentional deficits in adolescents. The authors found that adolescents who were born SGA at full-term exhibited the tendency to experience learning difficulties and attentional problems, with a higher prevalence of these problems in those with lower birthweight.

On the other hand, Tolsa et al. (2004) used volumetric magnetic resonance imaging (MRI) to study the brain tissue volume of 14 infants, aged only 2 weeks, who were born at preterm and SGA (mean and SD birthweight, 1,246 ± 299 g), and that of 14 infants matched for gestational age with appropriate-for-gestational-age (AGA) birthweight (1,843 ± 246 g). Premature infants with SGA were found to have both significantly reduced intracranial volume and cerebral cortical gray matter volume, compared with that of preterm AGA infants. The behavioral assessment revealed that compared with the scores of preterm AGA infants, those of preterm SGA infants indicated that the latter were significantly less mature in terms of attention-interaction availability; the reduced score of preterm SGA infants corresponded to a reduction in their cerebral cortical gray matter volume. Furthermore, a different research group (Feldman et al. 2006) found that preterm SGA infants exhibit a less organized state and have less mature neurobehavioral profiles in terms of their orientation and motor domains, and they also exhibit difficulties with the mother–infant relationship during infancy; these findings suggest that SGA infants are at higher risk for developmental and cognitive delays. In particular, SGA infants born weighing <1,000 g showed the poorest neonatal neurobehavioral maturation, social, and cognitive development, and these individuals were found to be at a twofold increased risk of cognitive deficits, compared with SGA infants born weighing >1,000 g.

The association between birthweight and subsequent cognitive development has been further highlighted by studies examining a population of very low birthweight infants (VLBW; ≤1,500 g). Although birthweight-related cognitive deficits are most prominent during infancy, they disappear

with age. However, cognitive impairments in VLBW infants have been found to persist later in life. For example, Kulseng et al. (2006) noted that adolescents with VLBW exhibit deficits in attention, executive function, working memory, and IQ, and over 70% of these individuals perform poorly (<2 SD) on tests of at least one of these measures of cognitive function. A recent MRI study using a diffusion tensor imaging (DTI) technique demonstrated a reduced fractional anisotropy (FA) value in the periventricular area (including the internal and external capsule; the corpus callosum; and the superior, middle superior, and inferior fasciculus) of adolescents born prematurely with VLBW; in general, low FA values are indicative of white matter damage (Skranes et al. 2007). That study also revealed an association between lower FA values and various clinical manifestations such as low IQ, a relatively high rate of ADHD-like symptoms, and mild social deficits. The results of the study by Skranes et al. (2007) suggest that infants born with VLBW are at high risk of perinatal white-matter injury in the periventricular areas, which has been associated not only with long-lasting perceptual, cognitive, and motor impairments, but also with mental health disturbances (Table 100.4).

In addition, most SGA infants with restricted growth during fetal life subsequently grow rapidly, exhibiting so-called "catch-up" growth within the first 2 years of life (Cottrell et al. 2008). One twin study addressed the effects of such catch-up growth, revealing that a larger gain in weight during the first 2 years of life is associated with lower IQ (Estourgie-van Burk et al. 2009), which implicated that catch-up growth is not a good sign in terms of development, or rather that such growth is a risk factor for impaired development.

100.2.2 Malnutrition in Early Life and Subsequent Development

Prenatal and postnatal nutritional deficiencies are major causes of disturbed growth in early life and have been postulated to play an important role in the etiology of neurodevelopmental disorders. Even as early as the 1950s, a relationship between prenatal malnutrition and the later risk of schizophrenia, one of the most devastating psychiatric disorders widely considered to be neurodevelopmental in origin, was postulated (Weinberger 1987; Murray et al. 1987); this nutritional hypothesis has until recently remained unchallenged due to the difficulty of conducting properly designed prospective studies. However, the Dutch famine was a "natural experiment" based on an unusual historical event known as the Dutch "Hunger Winter" of 1944–1945. During World War II, the Netherlands was invaded by the German army, and all food was rationed to a daily range of 1,500–2,000 kcal per person. However, at the end of 1944, a severe and pervasive food shortage occurred when the German army imposed an embargo on food transport. The famine reached its peak during the 4 weeks before

Table 100.4 Birthweight and cognitive deficits

Weight at gestational age		Birthweight	
AGA at term	-	LBW (>2,000 g)	±
SGA at term	±	LBW (<2,000 g)	+
AGA at preterm	±	VLBW (>1,000 g)	+
SGA at preterm	+	VLBW (<1,000 g)	++

The association between birthweight and later risk of cognitive deficits is summarized in this table

AGA appropriate-for-gestational-age, *SGA* small-for-gestational-age, <10% percentile, *LBW* low birthweight, <2,500 g, *VLBW* very low birthweight, <1,500 g, – no evidence, ± inconsistencies across studies, + significant evidence, ++ strong evidence

Table 100.5   Essential nutrients for CNS development in early life

Nutrient	Functional role in CNS development
Iron	Myelination, monoamine synthesis
Zinc	Neurotransmitter release, DNA and RNA synthesis
Copper	Neurotransmitter synthesis
LC-PUFAs	Synaptogenesis, myelination
Choline	Myelination, neurotransmitter synthesis, DNA methylation
Iodine	Cell energy metabolism
Folate	DNA and RNA synthesis, DNA methylation
Vitamin A	Signal transduction
Vitamin B6	Amino acid neurotransmitter synthesis
Vitamin B12	Myelination, DNA synthesis

This table lists the essential nutrients for CNS development and their respective functions

LC-PUFAs long-chain polyunsaturated fatty acids

the Liberation of early May 1945, and the daily ration yielded less than 1,000 kcal per person, per day. During the height of the famine, malnutrition was the leading cause of death (>22,000 deaths total). Unlike other famines, the Dutch "Hunger Winter" struck at a precisely circumscribed time and place, and is well-documented in terms of the timing and severity of nutritional deprivation and its effects on fertility and health. Utilizing the data from this unusual event, researchers have investigated the health sequelae of nutritional deficiencies, finding that prenatal exposure to severe malnutrition (especially in the first trimester of gestation, in which the most active neurogenesis takes place) was related to congenital anomalies of the CNS as well to a future risk for the development of schizophrenia and schizophrenia-spectrum personality disorders (Hoek et al. 1996; Susser et al. 1996). However, more recent studies (Georgieff 2007) have suggested that in the last third trimester of gestation and in the subsequent early postnatal stage, when rapid neuronal synaptogenesis and myelination are in full progress, the brain is most vulnerable to an inadequate diet. For example, an early-life deficiency of various micronutrients (e.g., iron; zinc; copper; long-chain polyunsaturated fatty acids [LC-PUFAs]; choline; iodine; folate; and vitamins A, B6, and B12) has been found to exert harmful and long-lasting effects on cognitive development (Georgieff 2007; Benton 2008) (Table 100.5).

100.2.3 Specific Clinical Syndromes as a Manifestation of Disturbed Growth in Early Life

Thus far, we have provided a general overview of the relationship between disturbed growth in early life and subsequently impaired development. We will now focus our attention on specific cognitive and/or behavioral consequences that are known to be linked to early-life disturbances such as nutritional deficiency and environmental exposure to toxins.

100.3 Autism Spectrum Disorders (ASDs)

Autism is a pervasive developmental disorder characterized by the behavioral traits of impaired social cognition and communication, as well as repetitive/obsessive behavior and interests. More broadly, ASDs include autism, Asperger's disorder, Rett's disorder, childhood disintegrative disorder, and not

otherwise-specified pervasive developmental disorder (American Psychiatric Association 2000). Earlier studies demonstrated that autism was associated with exposure to the preservative thimerosal, which contains ethylmercury, during early childhood (Bernard et al. 2002). However, recent epidemiological studies have failed to demonstrate any such association between exposure to ethylmercury in early life and the prevalence of autism (Schechter et al. 2008). Family studies, and especially twin studies, have generated primarily theories of ASDs that lean towards considering genetic factors causative (Bailey et al. 1995); however, recent research has provided evidence in support of the involvement of obstetric complications and adverse events in early life as risk-increasing factors. Kolevzon et al. (2007) systematically reviewed studies that examined the relationship between prenatal and perinatal events and the risk of autism. In their review, all seven epidemiological studies provided evidence that a history of obstetric events, including LBW and intrapartum hypoxia, is generally associated with an increased risk of ASDs, although the risk was not specific to the narrow condition of autism alone. On the other hand, Limperopoulos and colleagues (2008) carried out screening for early autistic features in children with a history of VLBW. They found that 26% of VLBW infants had at least one autistic feature. However, screening was conducted in children with a mean age of 21 months, an age at which instruments for identifying ASD features can be imprecise. Nonetheless, the authors also found that an elevated autistic-features score in their VLBW cohort was related to a history of chorioamnionitis and acute intrapartum hemorrhage. Such a history contributes greatly to the Score of Neonatal Acute Physiology II (SNAP-II; representing illness acuity) and is closely associated with abnormal findings on brain MRI (e.g., diffuse periventricular leukomalacia, periventricular hemorrhagic infarction, cerebellar hemorrhage, and ventriculomegaly).

Adverse conditions such as chorioamnionitis and placental hemorrhage are known to stimulate the ß2 adrenergic receptors; this mechanism is thought to be involved in the risk for autism. In fact, it has been shown that use of the ß2 adrenergic receptor stimulant with tocolytic action for preterm labor increases the risk for autism (Connors et al. 2008). A recent study (Field 2008) revealed that a potential risk factor for autism is a deficient supply of members of the omega-3 family of long-chain polyunsaturated fatty acids (n-3 FAs) (e.g., docosahexanoic acid [DHA], and eicosapentaenoic acid [EPA]), which are known to play an important role in CNS development (Georgieff 2007). An α-linolenic acid (ALA) can be converted to DHA in females, but not in males; this gender difference in the metabolism of fatty acids may contribute to the preponderance of autism among males.

However, obstetric complications and nutritional deficiencies may not necessarily be independent risk factors for autism. These variables need to be separately examined in large, population-based cohorts that provide sufficient statistical power for investigating each potential risk factor while at the same time allowing for various confounding factors.

100.4 Attention Deficit/Hyperactive Disorder

Attention-deficit/hyperactivity disorder (ADHD) is a disorder that affects children under 7 years of age and is characterized by a persistent pattern of inattention and/or hyperactivity-impulsivity (American Psychiatric Association 2000). Several case-control studies have reported that children born with SGA are at high risk of having attentional deficits (O'Keeffe et al. 2003; Tolsa et al. 2004). However, a population-based cohort study has shown that the presumed risk factors, including a history of pregnancy and delivery complications, LBW, and delivery of a twin birth, are not associated with ADHD (St. Sauver et al. 2004). Thus, the relationship between early events occurring around the time of birth and the development of ADHD remains controversial, and has yet to be determined.

Indredavik and colleagues (2005) explored the association between the presence of ADHD symptoms and cerebral MRI abnormalities in adolescents who had a history of LBW or VLBW, or had been

born SGA. Their results showed that when compared with control adolescents born at term, the VLBW group had an increased prevalence of ADHD symptoms, which was associated with white matter volume reductions, thinning of the corpus callosum, and white matter gliosis. Such an association between ADHD symptoms and brain abnormalities was not found in either the LBW or SGA group. Based on these findings, the researchers contend that a specific form of ADHD in VLBW children could be ascribed to perinatal events that impair white matter connectivity and brain development.

Furthermore, recent evidence points to the gene-environment interaction in the pathophysiology of ADHD. Catechol-O-methyl transferase (COMT) is an enzyme that catalyzes the degradation of dopamine in the prefrontal cortex, and it has been proposed to play a key role in prefrontal cortical function (Winterer et al. 2003). Val158Met (rs4680), a functional single nucleotide polymorphism (SNP) of the gene, has been shown to produce an amino acid substitution of methionine (Met) to valine (Val) at position 158 of the amino acid sequence, resulting in a significant change in enzyme activity. In fact, the Val allele is associated with approximately 40% higher enzyme activity than the Met allele (Chen et al. 2004). This SNP has been demonstrated to be related to prefrontal cognitive performance (e.g., working memory, executive function); the *met/met* genotype is associated with the best performance, whereas the *val/val* genotype is associated with the poorest performance (Malhotra et al. 2002). A family-based genetic study of children with ADHD has revealed that early-onset antisocial behavior, which has been shown to be linked to prefrontal cortical damage, in children with ADHD is associated with the *val/val* genotype (Thapar et al. 2005). Moreover, individuals with perinatal complications, as indexed by LBW, and with the *val/val* genotype have been shown to be more susceptible to ADHD.

100.5 Mood Disorders

Mood disorders are among the most common mental health problems in the general population. Whereas mood disorders cut across a wide range of age populations, predominantly women are affected. There are two major types of mood disorders: major depressive disorder and bipolar disorders. The etiology of mood disorders is considered to be heterogeneous, and the pathphysiological mechanisms underlying these disorders are still unknown. While earlier studies suggested an association between early life events (e.g., poor parent-child relationship) and a vulnerability to mood disorders (Brown 1966), there is increasing evidence that exposure to other hazardous environments in early life may play an important role in predisposing certain individuals to developing a mood disorder. The abovementioned Dutch Famine study provided the initial evidence indicating that exposure to malnutrition during the second trimester of gestation was associated with an increased risk of mood disorders later in life (Brown et al. 1995).

In Swedish large-scale cohort studies, Mittendorfer-Rutz et al. (2004) found an inverse relationship of birthweight to suicide, which predominantly occurs in patients with mood disorders. Intrigued by this report, other researchers further explored the postulated relationship. A gender-mediating effect was suggested in a study by Gale et al. (2004), who found an association of LBW with depression in females, but not in males; women in whom birthweight was less than 3,000 g were at higher risk of depression than those who weighed more than 3,500 g at birth. On the other hand, a retrospective study conducted in Helsinki demonstrated that being born at a weight appropriate for gestational age was not associated with depression. In contrast, VLBW participants born SGA were 2.5 times more likely to receive a diagnosis of depression than were controls born at standard birthweight (Raikkonen et al. 2008). Although further studies are needed to confirm the association, a tentative conclusion can be drawn based on these results, namely, that IUGR/SGA rather than birthweight per se may pose a risk of depression.

100.6 Schizophrenia

Schizophrenia is a complex neurodevelopmental disorder characterized by abnormalities in the perception of reality (i.e., delusions and hallucinations). Although the pathogenesis of schizophrenia is still poorly understood, accumulating evidence suggests that genetic, (early) environmental, and socio-psychological factors contribute to the etiology of the disorder. An involvement of gene(s) in the predisposition to schizophrenia is indisputable, as based on the results of family studies and, in particular, twin studies). Moreover, recent molecular biology studies have reported particular loci as responsible for the disorder, although the findings across studies have remained inconsistent. Nonetheless, there is a large body of evidence supporting an association between exposure to adverse environmental factors during the perinatal period and the subsequent development of schizophrenia. For instance, a meta-analysis of prospective population-based studies has shown that a history of obstetric complications is associated with schizophrenia later in life (Cannon et al. 2002). In analyses of individual complications of pregnancy, all of the following have been indicated to increase the risk of schizophrenia: bleeding, diabetes, rhesus incompatibility, pre-eclampsia, disturbed fetal growth (e.g., LBW), congenital malformations, reduced head circumference, and complications of delivery such as uterine atony, asphyxia, and emergency Cesarean section.

As noted above, studies of individuals who experienced the Dutch Famine have demonstrated that prenatal exposure to severe malnutrition, especially during the first trimester of gestation, is related to future risk for the development of schizophrenia (Susser et al. 1996). In a large population-based cohort study, Wahlbeck et al. (2001) examined whether nutritional factors in early life would have a risk-increasing effect. They found that a low late-pregnancy maternal body mass index (BMI), low placental weight, and LBW – each of which is postulated to be associated with intrauterine undernutrition – were related to an increased risk of schizophrenia. However, other studies have shown an inverted U-shaped association between birthweight and schizophrenia. For instance, Gunnell et al. (2003) demonstrated a sevenfold increased risk amongst individuals with LBW and a threefold increased risk for those with high birthweight (>4.0 kg). A similar pattern of the association has also been found for maternal BMI in our study (Kawai et al. 2004), showing that schizophrenia is linked to lower maternal BMI during late pregnancy, as well as to higher BMI during both early and late pregnancy.

More recently, a specific nutrient has attracted attention as a putative predisposing factor for schizophrenia. Iron is essential for the generation of hemoglobin, as well as for brain development and functioning. Emerging evidence has suggested that an iron deficiency in early life can lead to long-lasting neurocognitive deficits in infants and children (Georgieff 2007; Benton 2008). A population-based cohort study also revealed that a mean maternal hemoglobin concentration of 10.0 g/dL or less during the entire pregnancy was associated with a nearly fourfold increased rate of schizophrenia and schizophrenia-spectrum disorders in the offspring, when compared with a mean maternal hemoglobin concentration of 12.0 g/dL or higher (Insel et al. 2008). In addition, the findings of that study indicated a 27% decrease in the rate of the disorder for every 1 g/dL increase in the mean maternal hemoglobin concentration.

100.7 Personality Disorders

Personality disorder is defined as an enduring pattern of inner experience and external behavior that deviates markedly from the expectations of an individual's culture (American Psychiatric Association 2000). Little research has been done on possible associations between adverse events early in life and the risk of personality disorders, with the exception of one group who investigated the effects of

the Dutch Famine in 1944–1945 Hoek et al. (1996) investigated the association of prenatal malnutrition with the risk for personality disorders in a cohort affected by the famine, and found that prenatal nutritional deficiency was associated with a greater risk of schizoid personality disorder. The same group subsequently examined the relationship of severe prenatal nutritional deficiency to the risk for antisocial personality disorder, and found an increased risk only in men who had been prenatally exposed to the famine during the first and second trimester of pregnancy (Neugebauer et al. 1999).

100.8 Alzheimer's Disease

Alzheimer's Disease (AD) is the most common form of dementia among the elderly. The symptoms of AD include severe and progressive loss of memory and cognitive function (Hebert et al. 2003). A community-based case-control study examined the association between environment in early life and later risk for AD, and showed that the area of residence prior to reaching 18 years of age and the number of siblings were associated with the subsequent development of AD, indicating a possible involvement of early-life environment in the risk for AD (Moceri et al. 2000).

On the other hand, recent studies have shown a significant association between body size and risk for AD. Body size may reflect a difference in genetic background and varying environments to which individuals were exposed early in life. A study by Huang et al. (2008) has shown that greater knee height and a longer total arm span are associated with lower risk of AD among women. It was also found that women in the lowest quartile in terms of arm span were approximately at 1.5 times greater risk of AD than were other women studied. Among men, only longer arm span has been shown to be associated with lower risk of AD. Although no specific hypothesis has thus far been able to account for the possible involvement of early-life environment in the determination of future risk of AD, Sarter et al. (2004) speculated that ontogenetic abnormalities in the cortical cholinergic system, which is disturbed in subjects with AD, could mediate early-life cognitive limitations that later escalate to mild cognitive impairment and AD through the process of aging. Early-life cognitive limitations are presumed to begin with a disruption of the neurotrophic support of the cholinergic system, which is accompanied by subsequent dysregulation of cortical cholinergic function. The accelerating decline of the cholinergic system with age may be responsible for the clinical manifestation of AD.

100.9 Summary

In this chapter, we have expounded on the link between early-life growth disturbances, especially those associated with nutritional deficiencies, and subsequently impaired neurocognitive development. In general, it is well acknowledged that exposure to an adverse environment during a susceptible period, such as that in utero, is associated with physical illnesses in adulthood such as type II diabetes and cardiovascular disease. As noted above, early adverse events and associated altered growth early in life also contribute to the subsequent development of various neuropsychiatric disorders. Given that the time frame of susceptible (i.e., pre-, peri-, and postnatal) periods is also critical in terms of CNS development, it is not unreasonable to assume that early events with the potential to impair CNS development may in turn lead to subsequent disturbances in neurocognitive function, which can manifest as neuropsychiatric disorders.

Indeed, the accumulating evidence suggests that altered growth caused by malnutrition, placental dysfunction, or exposure to harmful environmental factors during early development is associated with clinical manifestations later in life such as pervasive developmental disorders (i.e., ASDs), major psychiatric disorders (i.e., mood disorders, schizophrenia), and Alzheimer's disease (AD).

The brain itself is a very complex organ; notably, its early development includes complicated processes of cell proliferation and migration, neuronal growth, synaptogenesis, and myelination. Furthermore, such processes are not uniform across brain regions. Any alteration or dysfunction in the brain that occurs at a particularly critical point in time in a specific location (or in a specific neurotransmitter system) may yield a wide range of pathological features as a consequence.

Although it will remain important to explore any associations between deviations from normal early developmental processes and subsequent disease-related consequences in adulthood, the need to elucidate the mechanisms underlying such associations should be emphasized, as such an emphasis is likely to enhance our understanding of the pathophysiology of a number of neuropsychiatric disorders.

100.10 Application to Other Health- and Disease-Related Issues

As overviewed above, several lines of evidence have suggested that disturbed growth in early life, in particular that caused by nutritional deficiency, is associated with the development of physical and psychiatric disorders later in life. In developing countries, food shortages remain a serious social issue, not least because they lead to malnutrition of pregnant women as well as their newborns. When the magnitude and persistence of nutritional deficiency in underdeveloped countries is taken into account, it is unfortunately not difficult to imagine that the consequences will be devastating. Infants exposed to severe malnutrition throughout gestation and early life will be predisposed to ill health, perhaps to a greater extent than even that described in this chapter. It should also be noted that young women of childbearing age in developed countries are likely to perceive slenderness as attractive, as they are often misguided by images in the media (e.g., fashion shows), which encourage them to lose weight. In some cases, even pregnant women may continue to smoke to achieve appetite reduction and to remain slim, in spite of abundant data demonstrating that tobacco smoking increases risk of premature birth. This is of great concern, since adequate nutrition in early life – in particular, a sufficient intrauterine nutritional supply that depends on maternal nutrition and health – is critically important for the healthy development of fetuses and infants. Therefore, providing nutritional assistance for individuals living in developing countries is an urgent issue, as is educating young women worldwide about body size and nutrition as they relate to both healthy pregnancy and the well-being of children.

Summary Points

- Disturbed growth in early life is known to determine the risk of physical and psychiatric disorders in adulthood.
- Environmental factors linked to altered development include placental dysfunction, maternal malnutrition during pregnancy, psychological distress in pregnant mothers, and infections during both the gestational and postnatal period.
- The effects of harmful environmental factors are thought to trigger permanent changes in the programming of physiological systems and to predispose individuals to various neuropathological conditions in adult life.
- The developing brain at early stages of life is quite vulnerable to nutritional deficiency and exposure to harmful environments.
- Altered CNS development caused by environmental factors is associated with cognitive impairments and various psychiatric disorders, including autism-spectrum disorders, ADHD, mood disorders, schizophrenia, and Alzheimer's disease.

Key Terms

Intrauterine growth restriction (IUGR): IUGR is attributed primarily to maternal malnutrition and placental dysfunction.

Small-for-gestational-age (SGA): SGA refers to a birthweight lower than the 10th percentile of newborns at a particular gestational age.

Low birthweight (LBW), very low birthweight (VLBW): Babies born weighing less than 2,500 g or 1,500 g are considered LBW or VLBW, respectively.

Fetal programming: Environmental factors in early life have been associated with alterations in gene expression, which are postulated to trigger permanent changes in the programming of physiological systems.

Thrifty phenotype: Under poor nutritional conditions, fetuses undergo metabolic and hormonal adaptations by which they survive, despite the lack of nourishment.

Chapter 101
Coronary Heart Disease, Diet and Neurocognitive Functioning

Colin R. Martin, Mick P. Fleming, and David R. Thompson

Abbreviation

CHD   Coronary heart disease

101.1 Introduction

Coronary heart disease (CHD) refers to disorders of circulation, which lead to a restricted supply of blood, oxygen and nutrients to the cardiac muscle. In most cases, this interruption is temporary but in some cases where the interruption is more prolonged this can lead to myocardial infarction and serious damage to the cardiac muscle. Atherosclerosis or the furring of the artery by fatty deposits causes blockages in the artery supplying blood to the heart. The main sign of CHD is chest pain caused by the restricted blood supply. Three different syndromes are categorised under the heading of CHD: unstable angina, myocardial infarction and heart/cardiac failure. Heart failure is seen as the end stage of hypertensive and valvular cardiovascular disease and has a mortality rate —four to eight times that of the general population (Kannel 2000). Nonspecific effects of CHD can include reduced activity, cognitive deficits, reduced quality of life, anxiety and depression (Lewin et al. 2002). Risk of cerebral vascular accident is much higher in people who have CHD, just over 55,000 people a year will die from stroke (BHF 2008). From an economic point of view, CHD costs the NHS in the UK £3.2 billion (BHF 2008).

101.2 Mortality/Morbidity

Measurements of how a disease is distributed across a population is usually categorised as incidence, which is a measure of new cases over a specific period of time, usually 1 year, and prevalence, the total number of cases when new cases are added to existing cases in a population over a specific time period, usually 1 year (Tandon et al. 2008).

Ayr KA8 0SR, UK
e-mail: colin.martin@uws.ac.uk

Mortality rates refer to the total number of deaths across a population over a given time period, usually 1 year. CHD is the most common cause of death in the UK, causing around 94,000 deaths in the UK each year, one in five men and one in seven women will die from CHD in the UK each year (BHF 2008). Around 19% of men and 10% of women will die prematurely as a result of CHD. Thirty-one thousand premature deaths were attributed to CHD in the UK in 2006 (BHF 2008).

Morbidity rates refer to the rate of illness within a population over a given time period, usually 1 year. There are gender differences with higher rates of CHD in men than women and the total number of myocardial infarctions range between 113,000–146,000 depending on the formula used to calculate the incidence. Four percent of men and 0.5% of women have had a heart attack. The incidence of CHD rises steeply with age, over 60% of all cardiovascular deaths in men and 80% in women occur after the age of 75 (Stanner 2009). The incidence rates for both angina and heart failure show gender differences with 52,000 new cases of angina per year in men and 43,000 in women and 38,000 new cases of heart failure in men versus 30,000 in women (BHF 2008). Again, there are variations in the prevalence of both angina and heart failure increasing with age (see Table 101.1).

The estimate is that 726,000 men and 393,000 women in the UK between the ages of 35–75 have had angina (BHF 2008).

An analysis of two studies found a prevalence of 393,000 men and 314,000 women have heart failure in the UK. Age differences show that the prevalence of heart failure rises sharply with age (see Table 101.1; BHF 2008).

Over the last 3 decades, trends have shown that deaths from CHD have been falling but morbidity statistics have not shown the same downward trend (BHF 2008; Jefferson 2008; Stanner 2009).
Fig. 101.1 Comparison of the total number of deaths in the UK in 2006 with the total number of deaths from cardiovascular disease in the UK in 2006. This figure compares the total number of those that died in the UK in 2006 with the total number of those that died from cardiovascular disease in the UK in 2006

Table 101.1 Measure of the prevalence of heart failure in the UK population by age range (BHF 2008)

Age range	Prevalence of heart failure in UK population (%)
65	1
75–84	6–7
85+	12–22

This table provides summary details in percentages of the prevalence of reported heart failure in the UK population across three significant age ranges (BHF 2008)

Total deaths from stroke in the UK
55, 098

Total deaths from CHD in the UK
94, 381

Total deaths from other forms of circulatory disease in the UK
48, 288
101.3   Modifiable Risk Factors

Several risk factors have been consistently recognised as contributing significantly to increasing the risk for CHD (Table 101.2). The consensus is that CHD is a hereditary condition, where people are predisposed to CHD through an inherited genetic vulnerability. Environmental risk factors further can precipitate the onset and contribute to the severity of CHD.

Smoking causes mortality from CHD, death rate from CHD was around 60–80% higher in smokers than in nonsmokers (BHF 2008). Exposure to second-hand smoke increases the risk of CHD by 25% (Law et al. 1997). Other studies have found that smoking cessation in people with CHD reduces the risk of death by 36% (BHF 2008).

Diet contributes significantly to CHD particularly where diet consists of high saturated fats raising cholesterol levels, high saturated fats and high sugar leading to weight gain and obesity, high sodium intake, which contributes to high blood pressure, and generally low intake of healthier food such as fresh fruit and vegetables. There is a strong correlation between higher systolic and diastolic blood pressure levels and CHD. Over 50% of CHD being linked to systolic blood pressure levels in

Table 101.2 Key facts of coronary heart disease (CHD)

1. The cause of CHD is a restricted flow of blood, which carries oxygen and nutrients to the heart muscle.
2. An interruption of blood flow to the heart is often caused by atherosclerosis, which is the blocking of the main arteries that lead to the heart by fatty deposits.
3. A prolonged interruption of blood flow can lead to myocardial infarction commonly known as a heart attack.
4. The term CHD refers to three different and distinct syndromes which are unstable angina, myocardial infarction and heart/cardiac failure.
5. The main signs of CHD are chest pain and tightness in the chest, tightness in the jaw, breathlessness, pain in the back of the legs, palpitations, and irregular heartbeat. The main signs of a myocardial infarction include tightness and severe pain in the chest, sweating, light headiness, breathlessness and nausea.
6. The death rate for CHD in the UK has been falling since the 1970s around 94,381 people died from CHD in the UK in 2006 (BHF 2008)

This table list's the key facts of CHD including the physiology, cause, the main signs and death rate

excess of 115 mmHg and 22% of heart attacks in Western Europe being attributed to a history of high blood pressure (BHF 2008). A link between increased systolic blood pressure of 10 mmHg and a 15% increase in risk for CHD has been noted by Turner et al. (1998).

Around 30% of CHD was due to deficiencies of fresh fruit and vegetables intake under 600 g/day or 7.5 portions (BHF 2008). As well as fruit and vegetables whole grains, soluble fibres, omega 3 fatty acids, plant sterols and stanols, folic acid and probiotics are considered to be important in improving cardiac functioning (Jefferson 2008). There is robust evidence that n-3 fatty acids have a beneficial effect on the cardiovascular system (Leaf 2008). A diet high in saturated fat and high sugar combined with a lack of physical activity will lead to increased weight gain and further increase the risk of CHD. Physical inactivity and a lack of exercise also contribute directly to CHD. The World Health Organization has calculated that taking less than 2.5 h of moderate intensity exercise/1 h of vigorous activity per week contributed to 20% of CHD (BHF 2008). Being overweight not only contributes to CHD directly but can lead to high blood pressure, raised cholesterol and diabetes. In their review, the BHF found evidence from the World Health Organization that being overweight accounted for 60% of high blood pressure in developed countries. They provide further evidence that suggests abdominal obesity (waist-to-hip ratio/waist circumference) contributed to 63% of heart attacks in Western Europe and that abdominal obesity was a more significant risk factor for heart attack than other types of obesity (BHF 2008). Type 2 diabetes has also been linked to the development of CHD. People with type 2 diabetes have a twofold increase in the risk for atheroma compared to the general population and for those aged between 40–50 years there is a twofold risk of death as a consequence of atheroma (Turner et al. 1998). It would be expected that the health issues relating to type 2 diabetes would be considered as causal risk factors for CHD, obesity, abdominal obesity, physical inactivity and raised insulin concentration but Turner et al. (1998) found in their sample that once type 2 diabetes had developed these risk factors for CHD became less predictive and that hypertension, increased concentrations of high-density lipoprotein cholesterol and hyperglycaemia become more significant as risk factors. High cholesterol level has been considered as a major risk factor for CHD and is influenced by the type of diet. Each 1% reduction in cholesterol leads to a 2% reduction in CHD risk (Jefferson 2008). Fatty foods increase the amount of lipid fat (cholesterol) produced by the liver and can cause hyperlipidemia. The transportation of these lipid fats is through the circulatory system via molecules known as lipoprotiens. Where there is a high level of cholesterol, this can cause a narrowing of the arteries (atherosclerosis) through the fatty deposits (plaques) left in the arteries, which reduce the amount of blood flow that carries oxygen and vitamins through the circulatory system and so is a precursor to CHD. The type and action of low-density lipoproteins in

carrying cholesterol from the liver to the cells for storage can be further influenced by the total amount of cholesterol. The density of low-density lipoproteins has been identified as a major risk factor for CHD (Turner et al. 1998). Where there is too much cholesterol or too much low-density lipoprotein for the cells to store and use then this leads to a harmful build up of cholesterol in the circulatory system. Over 60% of CHD in developed countries is linked to cholesterol levels above 3.8 mmol/L (WHO 2002). Blood cholesterol levels can vary and increase with age in both sexes. Men aged 45–64 are three times more likely to have a cholesterol level above 5.0 mmol/L than when they were aged between 16 and 24. Women aged 55–64 are more than twice as likely to have a cholesterol level above 5.0 mmol/L than when they were aged between 16 and 24 (BHF 2008) see Fig. 101.3. In order to reduce the risk for CHD the UK Government aim for a target of less than 5.0 mmol/L (DoH 2000).

The evidence linking alcohol intake and CHD is mixed. In his review, Marmot (2001) found evidence from heavy drinkers and an increased risk of CHD and this correlation was confirmed in data from 22 towns across the UK. Whereas the findings from international studies showed an inverse relationship between alcohol consumption and CHD. Comparative studies also found moderate drinkers to have a lower risk of CHD in comparison to abstainers (Marmot 2001). A positive relationship was found between women and their alcohol consumption and CHD. Alcohol consumption reduced the risk of CHD (BHF 2008).

In a systematic review, Hemingway et al. (2003) noted that four psychosocial factors, type A personality/hostility, depression and anxiety, psychosocial work characteristics, and social support, played an aetiological role in CHD. The same study found that psychosocial work characteristics, depression and anxiety and social support can also affect outcome and prognosis. Anxiety and minor and major depression has also been reported in people who have suffered a myocardial infarction (Rodgers et al. 2005) and people who have angina (Lewin et al. 2002).
Fig. 101.3 Comparison of percentage age and gender differences in the prevalence of angina in the UK in 2006 (BHF 2008). This figure compares the number of people who have presented with angina in the UK in 2006 divided into two age ranges from both genders

101.4 Evidence for the Cardioprotective Properties of Dietary Interventions

101.4.1 Polyunsaturated Fatty Acids

N-3 fatty acids have been shown to have a beneficial effect in lowering the risk of CHD (Erkkila et al. 2008). Findings from a year cohort study comparing the CHD outcomes and the dietary intake of Green land Inuits with a sample from the USA and Denmark showed that the Greenland Inuits had only 10% mortality from CHD compared to the other two groups. The main difference in the diet of the Greenland Inuits compared to the other groups was that it is high in n-3 fatty acids primarily from fish fats (Bang et al. 1976). N-3 fatty acids are part of the long chain polyunsaturated fatty acids made up of eicosapentaenoic and docosahexaenoic acids. In his historical review of n-3 fatty acids and their effect on CHD Leaf (2008) found robust clinical evidence of the beneficial effects of n-3 acids. Benefits included a 29% reduction in fatal arrhythmias, reduction in cardiovascular mortality by 17–30%. The subjects in these studies had recently suffered myocardial infarction and were considered high risk. The cardioprotective action of n-3 fatty acids is unclear. The action influences arrhythmia, lipid concentrations, blood pressure, platelet aggregation, vascular relaxation, inflammation and arterial cholesterol delivery (Jung et al. 2008; Johnston 2009). Hypotheses about the nature of this action include the modulation of eicosanoid and other immune pathways that mediate inflammatory processes, modulation of enzymes associated with pathways that determine cell functioning and direct influence on gene expression (Jung et al. 2008). Evidence supporting these hypotheses suggests that chronic stimulation of inflammatory responses leads to lasting vascular reactivity, insulin resistance and hyperlipidemia. The suggestion is that fatty fish high in the n-3 acids eicosapentaenoic and docosahexaenoic acid interfere with the metabolic process that stimulate inflammation and protect against both the effects of chronic stimulation of inflammatory responses and arterial inflammation (Johnston 2009). In other words, the cardioprotective action of n-3 acids maybe anti-inflammatory.
Fig. 101.4 Percentage age and gender differences in the numbers of people with cholesterol level above 5.0 mmol/L (BHF 2008). This figure compares the number of people who have recorded cholesterol level above 5.0 mmol/L in the UK in 2006 divided into two age ranges from both genders (BHF 2008)

Clinical trial evidence suggests that only a modest amount of n-3 fatty acid is required for effective protection. One to two servings of oily fish per week or an equivalent 250 mg/day of eicosapentaenoic and docosahexaenoic acids significantly reducing the risk of CHD and a 36% reduction in mortality (Mozaffarian 2008). Intake of lean fish four times per week was associated with reductions in both systolic and diastolic blood pressure in a small group of 12 participants (Erkkila et al. 2008).

101.5 Mediterranean Diet

Diets low in saturated fats, dairy products, and red meat but high in antioxidants such as plant foods, polyunsaturated fats, vegetables, fruit, nuts, beans and olive oil and that reflects the dietary patterns of the countries around the Mediterranean basin have been called the Mediterranean diet. This type of diet has been associated with a reduction of risk factors for CHD. 74,886 women between the ages of 38–63 years with no history of CHD were followed up over a 20-year period and those that adhered more strictly to a Mediterranean diet as determined by higher scores on the Mediterranean diet score were at lower risk for both CHD and stroke. Cardiovascular disease mortality was also significantly lower for those women who adhered more strictly to a Mediterranean diet (Fung et al. 2009). The evidence of the cardioprotective effects of the Mediterranean diet in terms is offered by Johnston (2009). She reviews evidence regarding its action on the markers of inflammation in high risk groups and its effects in reducing both cardiac mortality and overall mortality at 27 months (Johnston 2009). The study sample was made up of people who had survived myocardial infarction within the last 6 months rather than those with established CHD the effects cannot be generalised to this group of people.

101.6 Fibre

Water-soluble fibre found in fruits, vegetables, oats, barley, and dried peas/beans has a hypothesised action of decreasing the absorption of cholesterol from the gut, increasing the production of bile acids from cholesterol by increasing the amount of bile acids excreted in the faeces and inhibiting cholesterol synthesis in the liver (Coats 1998). There is robust evidence to link oat fibre and barley to reductions in plasma and low-density lipoprotiens and total cholesterol. In his review of 38 studies from 1963–1994 measuring the effects of oat fibre, oat meal and oat gum concentrate Truswell (2002) found total cholesterol was reduced by between 3–23% and low-density lipoprotien was reduced by between 3–9%. Two of the 38 studies showed no change in cholesterol levels and only one of the studies showed an increase in total cholesterol of 2%. In the majority of the 38 studies reviewed oat bran and oat fibre was given in the form of cereals which can have other potential cardioprotective ingredients such as nutrients and antioxidants and these may also help secondary prevention of CHD. A decrease of up to 15% in total cholesterol levels in a review of five studies using dietary fibre as the main intervention between 1988 and 1992 (Coats 1998).

101.7 Sodium

There is a strong correlation between the amount of sodium intake and hypertension and therefore CHD. Consequently, reductions in salt intake have been associated with lowering blood pressure in both people with hypertension and those who have blood pressure within normal limits. Based on the

findings of three studies including a meta-analysis He and MacGregor (2003) predict a reduction in dietary salt of 3 g a day would lead to a fall in blood pressure of 3.6–5.6 mmHg systolic and 1.9–3.2 mmHg diastolic. They also predict that doubling and then tripling the reduction would double and triple the effect on blood pressure and would reduce strokes by 13%, 26% and 39% and Ischaemic heart disease by 10%, 20% and 30%. Which they predict would reduce mortality from strokes by 20,500 and mortality from ischaemic heart disease by 31,400 in the UK. Sodium intake varies around the world but remains well above that required for physiological need in all areas of the world (Brown et al. 2009).

101.8 Fruits and Vegetables

Antioxidant nutrients such as vitamin C, which is found in fruits and vegetables, have been found to offer significant protection against cardiovascular and circulatory problems. The action is to protect cells of the body against the damage caused by free radicals through the process of oxidation and to prevent low-density lipoproteins from blocking arteries. Higher intake of fruit and vegetables was found to be cardioprotective in a sample of 832 men aged between 45–65 years in a 20 year longitudinal study (Gillman et al. 1995). Meta-analysis of nine cohort studies which included total sample sizes of 91,379 men and 129,701 women found that there was a 4% reduction in risk for CHD for every extra portion of fruit and vegetable or for each 7% increase of fruit alone (Dauchet et al. 2006). This reduction was particularly strong for the risk of cardiovascular mortality. The authors of the meta-analysis conclude that there was a publication bias which may mean the relative risks reported in the studies reviewed was overstated. There was no clue in the analysis as to the causal action of the fruit and vegetable on cardioprotection. One extra portion of fruit and vegetables was found to increase the forearm blood flow by 6.2% in a randomised trial of a fruit and vegetable intervention indicating an effect on endothelial functioning (McCall et al. 2009).

Dietary management is an essential part of secondary prevention of CHD.

101.9 Modifying the Risk Factors

Each of the risk factors for CHD mentioned above is based on a changeable lifestyle behaviour. Mediating factors such as illness beliefs, anxiety, depression and culture also influence the lifestyle behaviours that underpin these risk factors. Adapting these lifestyle behaviours would have significant impact on the severity, course and outcomes of CHD. Lifestyle behaviour changes such as dietary changes, smoking cessation and weight control have been recommended for the secondary prevention following myocardial infarction (NICE 2007).

101.10 Service Models/Delivery of Intervention to Modify Risk-Maintaining Lifestyle Behaviours

National health policy drivers within the UK have acknowledged the importance of interventions designed to modify lifestyle behaviours and other mediating factors that maintain the risk factors for CHD. Within UK health policy CHD is seen as a holistic concept; with a physical, psychological and behavioural component for both the patient and their family (DoH 2000). The National Service Framework for CHD recommends cardiac rehabilitation as a phase-specific intervention across the

four phases of treatment. Phase 1 – before discharge from hospital, Phase 2 – the early discharge period, Phase 3 – the formal rehabilitation programme, Phase 4 – long-term maintenance of the best possible health (DoH 2000).

There are various definitions of cardiac rehabilitation, and UK policy drivers base their recommendations for service models on the World Health Organization holistic definition: "¼the sum of activities required to influence favourably the underlying cause of the disease, as well as the best possible physical, mental and social conditions, so that they may, by their own efforts preserve or resume when lost as normal a place as possible in the community. Rehabilitation cannot be regarded as an isolated form or stage of therapy but must be integrated within secondary prevention services of which it forms only one facet" (DoH 2000, Chapter 7, p. 3).

Cardiac rehabilitation interventions should be tailored to individual need and aim to help the person understand their illness, provide psychological and emotional support, facilitate effective change in lifestyle behaviours and assisting with the transition back as normal life as possible (Thompson et al. 1996).

Specific interventions within cardiac rehabilitation include engagement strategies, health education and specific information about cardiac rehabilitation programmes and following these programmes in the home environment. Lifestyle advice is given about improving diet, controlling alcohol consumption, increasing activity levels with guidelines, smoking cessation and weight control.

Cardiac rehabilitation services should be integrated with other health services so specific help for increasing activity and smoking cessation is available. Stress-management interventions and other psychological support is also part of cardiac rehabilitation interventions (NICE 2007). This is understandable as anxiety and depression are consequences of CHD particularly after myocardial infarction. Although not recommended elements of more complex psychological interventions such as motivational enhancement, family management and cognitive behavioural therapy interventions are likely to be helpful.

In a combined systematic review and meta-analysis of 18 randomised controlled trials of home- versus centre-based cardiac rehabilitation interventions were found to be superior to routine care in terms of a 4 mmHg (95% CI 6.5, 1.5) greater reduction in systolic blood pressure, reduced relative risk of being a smoker (RR 0.71, 95% CI 0.51, 1.00), increased exercise capacity, decrease in total cholesterol and reductions in anxiety and depression (Jolly et al. 2006). The authors of the review recommend exercising caution when interpreting these results as the trials reviewed were clinically heterogeneous, small samples (less than 750 in total) and the quality was poorly reported.

Though effective, efficient and safe, cardiac rehabilitation service provision is suboptimal because of problems with referral, access and uptake and completion. Improving access to and equity of services is vital to improving cardiovascular health (Thompson and Clark 2009).

The EUROACTION model of cardiovascular disease prevention and rehabilitation (Wood et al. 2008) was effective in, for example, reducing saturated fat consumption and increasing fruit and vegetable and oily fish consumption in patients. A practice manual based on these principles (Jenning et al. 2009) is likely to be a useful aid to health-care professionals.

101.11   Application to Other Areas of Health and Disease

There is a commonality between the risk factors for type 2 (non-insulin-dependent) diabetes and CHD. Obesity, lack of exercise, high alcohol consumption and diet high in sugar and saturated fat are all modifiable risk factors for both diseases. Studies have found that people with type 2 diabetes have a two and threefold increased risk of death from CHD (Juutilainen et al. 2005) and myocardial infarction (Haffner et al. 1998).

Dietary interventions based on cardioprotective ingredients such as lean fish antioxidants, fresh fruit, plant foods, polyunsaturated fats, vegetables, nuts, beans and pulses. Are likely to reduce the incidence of both CHD and type 2 diabetes. Early dietary intervention and supporting education aimed people of high risk of developing type 2 diabetes may be preventative. Once the disease has been diagnosed delivery of cardioprotective dietary interventions may influence the course of the disease and may well protect against future CHD in people who may be candidates for this.

People who have serious mental health problems are at high risk of CHD compared to the general population (McCreadie 2003). This is partly as a consequence of poor diet as well as treatment. Some cardioprotective diets such as those diets high in N-3 polyunsaturated fatty acids and low in sugar, saturated fat and dairy products have also found to have a beneficial effect on the outcomes for people with serious mental health problems (Peet 2004). Dietary interventions may well have a twofold benefit in terms of psychotic symptoms and cardiac functioning. Perhaps a threefold benefit in terms of weight loss and reductions in the risk of type 2 diabetes in this vulnerable group.

Summary Points

- Blockages in the arteries caused by fatty deposits can restrict or interrupt the blood supply to the heart which can lead to myocardial infarction and serious damage to the cardiac muscle. This damage can reduce the efficient functioning of the heart and result in angina, myocardial infarction and heart failure. These three syndromes are all part of CHD.
- CHD is the most common cause of death in the UK, causing around 94,000 deaths in the UK each year in 2006, around 20% of men and 15% of women will die from CHD in the UK each year (BHF 2008).
- Between 113, 000–146, 000 people will suffer from a myocardial infarction. Around 4% of men and 0.5% of women will have a myocardial infarction each year. Angina and heart failure are more prevalent in men than women and the incidence both syndromes increases with age (BHF 2008).
- Environmental risk factors further can precipitate the onset and contribute to the severity of CHD. Smoking, obesity and being overweight, excessive alcohol, diet high in saturated fat, salt and sugar and a lack of exercise increase the likelihood of developing CHD. Other associated risk factors are high blood cholesterol level; high blood pressure and having type 2 (non-insulin-dependent) diabetes also significantly increase the risk for CHD.
- Certain types of foodstuffs such as fruit, beans, polyunsaturated fatty acids, lean fish, plant vegetables and diets low in saturated fats, red meat and salt have been found to protect cardiac functioning.
- Clinical trials of dietary interventions based on the introduction of cardioprotective foods and measuring the effects on cardiac functioning over time has confirmed the benefit of these dietary interventions on cardiac functioning.
- Cardiac rehabilitation programme based on tailoring programmes to individual need are recommended by national policy documents and clinical guidelines. These programmes include weight control and dietary interventions as well as interventions for changing lifestyle behaviours. In trials of cardiac rehabilitation programmes that include dietary and weight-control interventions, these have been found to have a beneficial effect on reduction in systolic blood pressure, reduced relative risk of being a smoker, increased exercise capacity, decrease in total cholesterol and reductions in anxiety and depression when compared to routine treatment (Jolly et al. 2006).

Definitions of Key Terms

Cardiac rehabilitation: This is the term used to describe treatment programmes that aim to improve recovery from cardiac events, help the person to manage their condition effectively prevent cardiac complications.

Cardioprotective: Anything that protects the heart and its functioning can include exercise, diet and medications.

Coronary Heart Disease (CHD): Diseases that are caused by disorders of the circulatory system, which lead to a reduction of blood supply to the heart. Three different syndromes are categorised under the heading of CHD, these are unstable angina, myocardial infarction and heart/cardiac failure.

Lifestyle: Patterns of social relationships, culture and consumption of material goods.

Mortality: The measured death rate from a syndrome over a specified time period, usually given as a unit of population, for example, 3 per 10,000.

Morbidity: The number of people or cases of a syndrome or illness over specified time period, usually given as a unit of population for example 3 per 10,000.

Polyunsaturated fatty acids: A group of unsaturated fatty acids where the carbon chain has two or more double or triple valence bond per molecule. These include omega 3 and omega 6 and occur as linolenic acid and arichidonic acid. These acids are found in vegetable, fish and seed oils.

Risk factors: Factors that mediate or influence the development of a disorder; in this case smoking may increase the risk of CHD. Modifiable risk factors are those mediating factors that are under the control of the person and can be altered through changes in behaviour.

Saturated fatty acids: A group of fatty acids that do not have the double or triple valence bond. Derived from animal fats or by the hydrogenation of unsaturated fatty acids.

PAL   Physical activity level
RMR   Resting metabolic rate

102.1 Introduction

The continuing obesity epidemic of the past 3 decades is a result of economic and environmental changes that have affected both components of the energy balance equation (Table 102.1). Cheaper and more readily available foods, increased dietary energy density, and larger portion sizes are among the changes that have increased the possibility, and the probability, of ingesting more energy than required; at least for most people in developed and developing societies.

Although less well studied, and less easily quantified because of a lack of earlier good quality measurements, daily energy expenditure appears to have declined over the same period that has seen the rapid increase in obesity, and patterns of physical activity have changed. It is popularly believed, and often stated, that activity levels are currently lower than 30, or more, years ago, with increased television viewing (Prentice and Jebb 1995), mechanization of work (Tremblay and Doucet 1999), and increased reliance on mechanized transport (Haines et al. 2000) being cited to support this in the absence of good empirical data. The little evidence that is available suggests that, for many people, physical activity energy expenditure is about as low as it can be, and there is little scope to reduce it further.

Humans evolved under conditions where higher-than-current levels of activity were necessary to hunt and gather sufficient food. The PAL of preagricultural humans has been estimated at about 1.8, and for contemporary foragers with lifestyles similar to those assumed for our more recent ancestors, at 1.7–2.2 for males, and slightly less for females (Cordain et al. 1998). Furthermore, a re-evaluation of the methods used suggests that these may be underestimates (Leonard et al. 1997). An average PAL for modern, predominantly sedentary populations has been measured at 1.6 (Black et al. 1996). Moreover, only 15% of the 574 individuals in the meta-analysis conducted by Black et al. had PALs towards the

Table 102.1 Key features of the energy balance equation

- The energy balance equation is often given as:
  Energy Intake = Energy Expenditure ± Energy Stores
- Energy balance can be thought of as a set of scales with intake on one side and expenditure on the other. The energy from food and drink needs to be balanced by the energy we expend in bodily functioning and physical activity
- When energy intake is greater than expenditure the excess if stored, mainly as fat, and body weight increases
- When energy intake is less than expenditure the deficit is supplied from fat stores, resulting in weight-loss
- When intake matches expenditure, body weight is stable
- People are rarely in energy balance in the short-term (over days). What is important (for body weight) is energy balance over the medium and longer-terms (weeks and months)
- One can be in energy balance at a low level of energy turnover (being sedentary but eating less), or a very high level of energy turnover (such as elite athletes), or anywhere between

This table gives the key features of the energy balance equation, and its implications for body weight maintenance

upper end of the normal range, above 2.0, and these were mainly individuals who regularly participated in active sports or active transport (Black et al. 1996). Obtaining our normal (from an evolutionary point of view) levels of activity has become a matter of choice rather than necessity, and one made by the atypical few.

It would be reasonable to suppose that energy expenditure is coupled to energy intake, such that increases or decreases in activity level would bring about compensatory changes in food intake through appetite and hunger mechanisms to realize energy balance. However, the sedentary are more likely to be overweight than the active (Martinez-Gonzalez et al. 1999), and adding an exercise program to an energy-restricted diet improves weight loss, and reduces weight regain (Miller et al. 1997), which would suggest otherwise. Conversely, individuals who frequently exercise, or participate in sports regularly, must be in long-term energy balance, as a prolonged energy deficit and continuing weight loss could not be maintained for long. It is likely that coupling between energy expenditure and intake will depend on whether the individual is in a transition of energy balance (i.e. dynamic) or in a steady state (i.e. static). Physically active individuals with high energy intakes, which match high expenditures, have been through a series of transitional periods to reach this steady state. Therefore, a new equilibrium at a higher level must be established eventually, although it appears to take several weeks at least for any adjustment to become detectable (Whybrow et al. 2008). The apparent contradiction in the interaction between energy expenditure and intake will be covered in this chapter by considering firstly whether exercise-induced increases in energy expenditure drive energy intake upwards undermining dietary approaches to weight management, and secondly whether sedentariness alters levels of energy intake or subsequent energy expenditure. Thirdly, if elevated levels of energy intake alter physical activity or exercise, and fourthly whether reduced energy intake (dieting and starvation) results in decreased energy expenditure. Finally, the implications of the links between energy expenditure and intake for achieving and maintaining weight loss, and preventing weight gain, will be considered.

102.2 Does Exercise/Increased Physical Activity Raise Energy Intake?

102.2.1 Exercise-Induced Energy Expenditure and Energy Balance

From a homeostatic perspective it is logical to assume that an exercise-induced increase in energy expenditure leading to an energy deficit is automatically followed by an equivalent increase in caloric intake. This assumption probably originates from empirical evidence that dietary-induced energy

deficits through food restriction induce marked increases in hunger and food intake (e.g. Hubert et al. 1998) and the theoretical approach that any perturbations in energy balance will be compensated for by compensatory adjustments (Mayer et al. 1956). Therefore, it is intuitive to expect food intake to increase in response to an exercise-induced energy deficit. Collectively, this leads to the belief that physical activity is a futile strategy for successful weight loss because the increase in energy expenditure will automatically drive up hunger and food intake. However, it should not be assumed that exercise will automatically exert the same effect as dieting or that the biological system is sensitive enough to detect acute increases in energy expenditure. The empirical evidence provides a positive view for the role of exercise in weight management.

102.2.2 What Does the Evidence Say?

Despite a minority of studies showing a compensatory increase in energy intake (e.g. Verger et al. 1992), most of the evidence shows that acute exercise-induced increases in energy expenditure generate little or no immediate effect on levels of hunger or daily energy intake. Therefore, the evidence points to a weak coupling between energy intake and acute activity-induced increases in energy expenditure (see Blundell et al. 2003).

It can be argued that the lack of compensatory increase in energy intake in response to acute and small increases in energy expenditure is not surprising. Accordingly, a series of seminal studies by Stubbs and colleagues provided evidence for the effect of increasing energy expenditure through exercise and extending the observation period of acute interventions to 7–14 days (Stubbs et al. 2002a, b). The results of these studies demonstrated that, despite a slight compensatory increase in energy intake in women, although not in men, energy intake did not fully compensate for relatively large increases in energy expenditure with an exercise intervention lasting 7 days. Extending the intervention to 14 days (Whybrow et al. 2008) and from a similar study of 52 days (Woo and Pi-Sunyer 1985) provided further evidence of partial compensation – approximately 30%. Therefore, although acute manipulations show no automatic compensatory increase in energy intake, after several days of imposed exercise-induced energy deficits intake does start to increase – but not sufficiently to fully compensate for the additional expenditure. From an energy balance perspective, the weak coupling between activity energy expenditure and intake generates an optimistic view of the role of exercise in weight management. It is worth noting that an increase in intake is not the only compensatory response that could potentially undermine the beneficial effect of exercise on weight control – other metabolic and behavioral compensatory barriers could occur (for a review, see King et al. 2007).

When considering the various ways in which energy intake could potentially increase (see Table 102.2) through changes in eating patterns, it is not surprising that there is some resistance to increasing food intake. It is important to remember that eating behaviors (food choice, meal frequency, etc.) have developed over many years and are heavily influenced by physiological limits (e.g. preabsorptive factors), psychological, and social factors (Blundell and King 1996).

Table 102.2 Changes in eating behavior changes that can increase in energy intake

1. Increased meal size (i.e. individual eating episodes)
2. Increased frequency of eating episodes (increased snacking)
3. Increased selection of energy dense (kcal/g) foods
4. Increased intake of energy-rich fluids

In addition to simply eating more food, energy intake can be increased through several behavioral changes, either independently or collectively

Some medium term exercise intervention studies also provide evidence for an orexigenic effect, which is exhibited as increases in fasting hunger (e.g. Doucet et al. 2000). However, it is important to note that this change is accompanied by significant reductions in body weight. It is not known whether the increase in the drive to eat is due to chronic exercise-induced physiological changes or in response to a significant reduction in body weight. Therefore, one of the problems when interpreting the appetite responses to chronic exercise interventions is whether any observed changes in appetite are independent of body weight or body composition changes.

102.2.3 Does Exercise Improve the Sensitivity of Appetite Control?

It is possible that exercise has the capacity to improve the sensitivity of appetite control, and to contribute to a better regulation of energy balance. Based on evidence that physically active individuals are leaner and have a lower BMI than sedentary individuals (Martinez-Gonzalez et al. 1999), and an isolated example of a strong coupling between energy expenditure and energy intake in Tour de France cyclists, albeit at very high levels of energy turnover (Saris et al. 1989) exercise could potentially promote better regulation. Data from two cross-sectional studies demonstrates that physical activity status influences the accuracy to compensate for covert manipulations in the energy content of meals or preloads. The evidence shows that physically active individuals have a better capacity to detect differences in energy in preloads compared to their sedentary counterparts (Long et al. 2002), and to adjust energy intake accordingly. There is some indication that the sensitivity of appetite regulation can be improved in sedentary individuals by raising energy expenditure (Martins et al. 2007). Data from a 12-week exercise intervention study revealed that exercise exerts two different processes on appetite sensitivity expressed as a function of fasting (pre-eating) and meal-induced states – which was partly dependent on the magnitude of weight loss (Caudwell et al. 2008). In individuals who did not experience substantial weight loss (nonresponders), exercise caused an increase in the drive to eat (see Fig. 102.1) compared with responders, who lost the amount of weight, or more, predicted from the planned energy deficit. In contrast, a fixed energy preload improved satiation and satiety (Fig. 102.2) after 12 weeks of exercise in both responders and nonresponders – hence the improvement in satiety was independent of weight loss. In essence, this latter effect suggests that 12 weeks of exercise raised the sensitivity of the physiological signaling system allowing a fixed amount of food to realize a greater suppression of hunger.

These novel data indicate the potential of exercise to exert effects on appetite regulation, which involves at least two processes: an increase in the orexigenic drive to eat and a concomitant increase in the satiating efficiency of a fixed meal. These data also provide evidence for interindividual variability in response to exercise (King et al. 2008) – such that these processes do not operate with the same intensity in all individuals who experience a chronic exercise-induced increase in energy expenditure.

102.3 Does Sedentariness Lower Energy Intake?

The previous section described a weak coupling between exercise-induced energy expenditure and energy intake. While this has positive implications for the role of increased physical activity in weight management, it provides a less optimistic scenario if the same phenomenon exists when exercise is reduced or stopped, and when people become more sedentary. Exercise is important in helping to achieve weight loss, and for maintaining the new lower body weight; of importance for limiting the development of obesity is how sedentariness, and changing from a high to a lower level of activity, affects energy
Fig. 102.1 Average daily hunger ratings before and after 12 weeks of supervised exercise in responders and nonresponders. Average daily hunger ratings expressed as the area under the curve (AUC) before (week 0) and after (week 12) the supervised exercise program. Individuals who lost less weight than predicted (nonresponders) showed an increased motivation to eat compared to responders who did lose weight
Fig. 102.2 Satiety responses to a fixed breakfast meal over a 12-week exercise program. Satiety responses, measured by the Satiety Quotient (SQ), to a fixed breakfast meal at weeks 0, 4, 8, and 12 in both responders and nonresponders (data pooled). After 12 weeks, satiation and satiety responses to a standardized breakfast were improved in both responders (who lost weight during the intervention) and nonresponders (who did not lose weight), suggesting that the improvement in satiety was independent of weight loss. SQ is calculated by dividing the difference between ratings of motivation to eat before and after the eating episode by the energy content of the test meal

intake to re-establish energy balance at a lower level of energy turnover. There is very little *direct* evidence to link sedentariness to the development of a positive energy balance. Instead a number of intuitively obvious arguments and proxies of physical activity have been used in (largely) cross-sectional comparisons, to suggest that a lowering of physical activity levels (PALs) in the population is predisposing us further to weight gain (Prentice and Jebb 1995). Despite the attractiveness of these arguments, it is remarkable that few studies have attempted to assess the impact on energy balance of imposing sedentary routines, within the normal range of activity, on healthy humans feeding ad libitum.

102.3.1 Evidence from Laboratory Studies

Murgatroyd et al. (1999) conducted 2-day experiments where subjects underwent active versus sedentary routines and consumed a high-fat or a low-fat diet, ad libitum, in a 2 × 2 design. Energy intake was the same on a given diet regardless of the level of energy expenditure. Similarly, decreased activity while resident in a whole body calorimeter for a day generated a positive energy balance in both lean and obese subjects (Shepard et al. 2001). However, the periods of enforced inactivity in both of these studies were very short and may not have provided sufficient opportunity to allow compensatory changes in intake to begin. In general, studies of this duration fail to produce a change in feeding behavior under a variety of conditions (King et al. 1997). The impact of a sedentary routine on energy balance has been assessed over a period that is long enough to allow compensatory changes in energy intake to be seen. Total daily energy expenditure was clamped at approximately 1.4 and 1.8 RMR in six male subjects who were continually resident in a whole body indirect calorimeter for seven consecutive days. The impact of this on subjective ratings of hunger and appetite, and energy intake was examined. Energy expenditure amounted to 9.7 and 12.8 MJ/day on the sedentary and active treatments respectively, while the corresponding energy intakes were not significantly different at 13.5 and 14.4 MJ/day. By day 7, cumulative energy balances for the sedentary and active treatments were 11.1 and 26.3 MJ respectively, with most of the excess energy being stored as fat (Fig. 102.3, Stubbs et al. 2004). Importantly, there were no time trends in either energy intake or expenditure over the 7 days this study, indicating no tendency to compensate for an acute decrease in physical activity energy expenditure over this time period.
Fig. 102.3 Effects of imposed physical activity level on cumulative changes in energy balance in six men. Cumulative energy balance for six men during active (◊) and sedentary (□) regimes between days 1 and 7. Values are means (±SEM). Energy balance was calculated as energy intake minus energy expenditure. Energy balance became more positive from day 1 to day 7 on both treatments. Cumulative energy balance was 11.1 and 26.3 MJ by the end of day 7 on active and sedentary regimens, respectively. This was significantly different from zero on the sedentary treatment only ($P < 0.001$) (Stubbs et al. 2004)

It is possible to detect decreases in energy intake as a response to a sustained decrease in energy expenditure. For instance, in the experimental model of six-degree head-down tilt-bed rest, designed to simulate the energy expenditure during space flight, Ritz et al. (1999) have shown that energy intake does drop significantly as a consequence of long periods of extreme sedentariness; 6 weeks in this experiment. Energy intake fell by 17%, which was sufficient to place the eight male subjects in a negative energy balance, such that body weight fell by 3%. Subjects started to lose weight in the first week and continued to do so during the remainder of the period of sedentariness. Thus, the change in energy intake showed a fast response that was absent during the later calorimetry chamber experiment (Stubbs et al. 2004), where energy expenditure during the sedentary protocol (1.4 RMR) was similar to that during the head-down-tilt protocol (1.46 RMR) (Blanc et al. 1998). However, as the authors noted, the findings could have been an artefact of the experimental conditions associated with either the presentation of the food or some other aspect of the experiment.

102.3.2 Evidence from Studies in Free-Living People

Data from the NHANES series of studies suggest that, for most people, body weight tends to drift upwards at around 0.3–1.7 kg/year (Kant et al. 1995). A more recent study showed a similar increase in body weight in a sample of 6,406 individuals over an average follow-up period of 7.4 years (Williams and Thompson 2006). At baseline, body weight, BMI, and other indices of adiposity were inversely related to usual exercise levels (running distance). Furthermore, there was a dose-dependent effect of change in running distance on change in body weight, BMI, and other measures of adiposity over the observation period. Individuals who quit running between the baseline and followup assessments gained weight; the amount being proportional to the change in running distance, and up to 8 kg for those who reported running >48 km/week at baseline but who subsequently quit. Weight gain was considerably less at around 3 and 0.5 kg in those who took up running and who reported running <23 and >24 km/week respectively. Weight and BMI changes in people who were initially sedentary, and who remained sedentary, were in between the other two groups.

The difference in energy balance between those who quit, and those who started, running may well be greater than the changes in body weight alone suggest, as changes in weight are poor indicators of energy balance in the presence of changes in body composition. There is some evidence for body composition changes in the reported waist circumference measurements (Williams and Thompson 2006), which are consistent with increases and decreases in exercise levels and suggest proportionally greater losses and gains of lean tissue (muscle) respectively for those who quit and started running. However, the weight gain of the runners who quit was still considerably less than had there been no compensatory changes in energy intake or some other aspect of energy expenditure. Decreasing weekly running distance from 48 to 0 km would produce an initial positive energy balance of around 6 MJ a week, which could result in a weight gain in the order of 12 kg in the first year. Therefore, some compensatory adjustments, albeit incomplete, must have occurred.

The little evidence available suggests that abrupt decreases in activity energy expenditure, through training cessation or injury, leads to marked gain in body weight. Several life events, such as marriage (Jeffery and Rick 2002) and starting at university, that produce abrupt changes in lifestyle are associated with weight gain (Ogden et al. 2009), and it is possible that it is the change in habitual PAL per se and the time period needed to re-establish energy balance that are the risk factors for weight gain. Although it should be possible to achieve energy balance while maintaining a sedentary life style, a number of cross sectional studies provide evidence that this is unlikely in practice, as sedentariness is highly correlated with increased adiposity. For example, Martinez-Gonzalez et al. (1999) estimated the

association of leisure-time sedentary and nonsedentary, self-reported activities on BMI and the prevalence of obesity in 15,239 subjects across the European Union. They found that… "obesity and a higher body weight are strongly associated with a sedentary lifestyle and a lack of physical activity in the adult population of the European Union" (Martinez-Gonzalez et al. 1999). The more time people spent sitting the more likely they were to be obese; and the less active people were in their leisure time, the more likely they were to be obese. Furthermore, the two effects were additive.

102.3.3 Sedentary Lifestyle and Overeating

In addition to lowering daily energy expenditure, a number of studies suggest that the lifestyle correlates of a sedentary routine promote a positive energy balance through affording greater opportunities to overeat (Temple et al. 2007); for example time spent watching television is positively related to the consumption of energy-dense snack foods (Gore et al. 2003). There is however little evidence that a sedentary routine promotes greater levels of energy intake per se. Rather, people appear to continue to eat as they did when they were active, at least initially, and intake overshoots expenditure leading to weight gain.

These lines of evidence suggest that reduced activity energy expenditure is very weakly linked, through physiological signals, to energy intake and has little effect in reducing intake. Under these conditions it is likely that the rate of weight gain slows with time if energy requirements remain lowered. Whether the extent to which this occurs is due to changes in the components of expenditure, or to active cross-talk between reduced activity and intake is unclear at present. The evidence thus suggests an absence of any strong cross-talk between reduced activity energy expenditure and energy intake, resulting in a positive energy balance and a tendency to gain weight when activity is reduced and food is available ad libitum. Alternatively, a positive energy balance can be achieved by increasing energy intake, rather than decreasing expenditure, and this is probably of greater relevance to most Western consumers given that generally, PALs are already low, and where it is rare for food not to be available ad libitum. A series of studies has suggested that some people actively respond to overfeeding by elevating energy expenditure by increasing their ambulatory and positional movements; this has been termed the Non-Exercise Activity Thermogenesis (NEAT) phenomenon (Levine et al. 2000).

102.4 Does Overconsumption Raise Energy Expenditure?

102.4.1 Overconsumption and Energy Balance

It is well established that prolonged, and severe energy intake restriction (or underconsumption) leads to a decrease in energy expenditure, which is an attempt to prevent a continuing reduction in body weight (see following section). Therefore, overconsumption, in theory, should promote an increase in energy expenditure. However, energy balance is not necessarily symmetrical – the body will strongly defend attempts to lose weight, but weakly defend a positive energy balance. Indeed, it can be argued that this latter phenomenon exists naturally in today's environment in which overconsumption is easily promoted; especially through the passive overconsumption of high-fat and energy dense foods. Similar to the adaptations in RMR to underfeeding, any increases in total energy expenditure in response to overfeeding will be mainly due to changes in fat and fat-free mass associated with the energy demand of a greater body weight. Periodically through this chapter we have discussed several examples of

compensatory adjustments or adaptations to challenges to energy balance. The evidence indicates that, overall, adjustments to perturbations in energy balance will eventually "kick-in", although the intensity and time course of these adjustments tends to vary among individuals. This will depend on the direction (negative or positive) of interventions in energy expenditure or intake, and the magnitude or intensity of the perturbation. Furthermore, there is a large interindividual variability in the capacity to adjust or regulate the various components of energy balance. There is strong evidence to indicate that individuals vary in their resistance to lose or gain weight in response to increases or decreases in energy expenditure respectively. What about increases in energy intake? Do the same phenomena of resistance and variability to gain weight exist in response to overconsumption?

102.4.2 Overconsumption and Energy Expenditure

In effect, an overfeeding study is already taking place naturally in the habitual free-living environment. Whilst this provides a proxy indicator that overconsumption leads to weight gain, it does not quantify the contribution of increased energy intake to weight gain and obesity; neither does it provide information about the corresponding compensatory adjustments in energy expenditure that may attempt to counteract the food-induced positive energy balance. Carefully controlled studies that have attempted to measure the various components of energy expenditure provide some evidence of how imposed increased energy intake could be potentially offset by adaptations in energy expenditure. Problems with this type of study are associated with methodological constraints including practical implications of enforced overfeeding and monitoring, and the ability of measurement techniques to detect potentially small adjustments in energy expenditure. Furthermore, some of the conclusions are based on calculations of increases in body weight relative to the increment in energy intake, which estimate the proportion of weight gain relative to the amount of overfeeding.

To compound the problem further, there are very few available data that address the effects of imposed overconsumption on energy expenditure. Despite a majority of studies indicating that there is some evidence of proportional increases in energy expenditure in response to overconsumption, overall the evidence is equivocal. The most marked and least equivocal effect is the increase in RMR due to overfeeding. Harris et al. overfed subjects by 1,000 kcal/day (4.2 MJ/day) for 8 weeks and showed that there was a marked increase in RMR during the first 2 weeks that tended to plateau after approximately 5 weeks (Harris et al. 2006).

Given that DIT is related to the amount of digested and absorbed food, it is an ideal candidate for one component of energy expenditure that would automatically increase in response to overfeeding. Whilst some studies purported an increase in DIT (Levine et al. 1999) using more indirect measures, a majority of studies demonstrated no significant increases in DIT (e.g. Tremblay et al. 1992). There appears to be little evidence of adaptive thermogenesis, whereby weight gain is limited by upregulation of heat production to dispose of excess energy intake, during human overfeeding studies. The third component of energy expenditure, activity-induced energy expenditure, is unlike RMR and DIT in that it can be increased by volitional changes in behavior.

102.4.3 Non-exercise Activity Thermogenesis

It has been suggested that some people actively respond to overfeeding by increasing their ambulatory and positional movements, or NEAT (Levine et al. 1999). When 16 nonobese subjects were overfed by 4.2 MJ/day for 8 weeks fat gain was inversely related to change (increase) in NEAT,

which ranged from 0 to 3 MJ/day, and around 66% of the increase in daily energy expenditure was due to increased NEAT. This suggested that activation of NEAT dissipates excess energy to preserve leanness during overfeeding – at least in some people (Levine et al. 1999). However, a potential problem is that changes in energy balance were estimated assuming that all of the additional food was consumed. Any noncompliance with the aggressive overfeeding regimen in these lean subjects would be registered as NEAT, since NEAT was estimated by difference. The average energy cost of weight gain in this study was around 50% higher than expected from theoretical (Stubbs et al. 1998) and empirical (Forbes et al. 1986) sources. The possibility that subjects did not entirely comply with the overfeeding regime cannot be excluded.

Two key features of overfeeding experiments are the interindividual variability in weight gain and the proportion of energy intake that remains unaccounted for. One could infer from this that adaptations in energy expenditure are possible, and occur to differing degrees in different people, but current measurement methods lack the ability to detect them sufficiently well, and the phenomenon has yet to be clearly demonstrated.

102.5 Does Dieting Lower Energy Expenditure?

The effect of energy intake restriction on reducing activity has been less widely studied in humans than it has in animals but there is some evidence that it occurs.

Johnstone (2002) and Gibney (2001) examined the effect of three common regimens on the physical activity patterns of obese men (BMI 30–40) in a program of three studies (i) total fast (to lose a nominal 5% weight over 6 days); (ii) very-low-calorie diet (VLCD, 2.5 MJ/day to lose 10% weight over 3 weeks); (iii) low-calorie diet (LCD, 5.2 MJ/day to lose 10% weight over 6 weeks). Clearly, the energy deficit and rate of weight loss occurred in the order total fast > VLCD > LCD. Subjects rated their subjective feelings of fatigue every hour throughout the study. On both the total fast and the VLCD, fatigue ratings increased steadily throughout the weight-loss period. The increase in fatigue followed the same pattern as the dietary restriction, being greatest for subjects on the total fast, and unchanged compared to the prestudy period for those following the LCD (Johnstone 2007). At 5% weight loss PALs were significantly different at 1.38, 1.71 and 1.84 RMR for subjects on the fast, VLCD and LCD respectively (Stubbs et al. 2003). These data suggest that in obese subjects the more extreme the energy intake restriction, the greater the reduction in physical activity. These values amounted to daily energy expenditures of around 11.5, 13.5 and 13.9 MJ/day. The difference in physical activity between the total fast and LCD amounted to 2.4 MJ/day, while intake differed by 5.0 MJ/day. The decrease in physical activity therefore compensated for almost half of the difference in energy intake. Thus, there is evidence that an increased rate of weight loss through dietary restriction will produce a "compensatory" decrease in physical activity. This response may take a while to happen, at least in lean individuals, as subjective ratings of fatigue and tiredness were not affected by an acute fast of 36 h (Johnstone et al. 2002).

In Keys et al.'s classic 24-week semistarvation study, daily energy expenditure was 8.0 MJ/day lower at the end of the restricted energy intake period than at the beginning. The largest change in energy expenditure was a fall in physical activity (4.6 MJ/day), 64% of which was due to a decrease in volitional physical activity (Elia et al. 2003). Thus the greatest single response to prolonged semistarvation was a change in activity behavior. The remaining 36% was from several obligatory reductions in energy expenditure, resulting from changes in body weight and composition.

Dietary Induced Thermogenesis is proportional to the amount (and to a lesser extent composition) of ingested food, and will clearly be lower during food restriction. The energetic cost of movement will decrease as body weight decreases, as will the cost of maintenance, which results in a lower RMR.

Energy intake restriction, at least when it is more severe and for longer than is recommended for normal dieting and weight loss, does appear to lower energy expenditure, and therefore energy requirements. Some components are obligatory and are a direct consequence of the amount and composition of the weight lost, or through the decreased food intake per se. But there appears also to be a reduction in voluntary activity. During short-term total fasting, or when the energy intake restriction is around the maximum recommended for long-term weight-loss, there is little evidence of decreases in physical activity that would counter the diet-induced negative energy balance. Severe energy intake restriction, or "crash dieting", is not recommended as a solution for long-term weight loss for this reason, among others.

102.6 Pathology and Implications for Weight Control

A sedentary lifestyle is a risk factor for many chronic diseases, even after adjustment for the effects of obesity in their development. Regular moderately intense physical activity reduces the risk of developing a wide range of diseases, including type-2 diabetes, cardiovascular disease and some types of cancer (Warburton et al. 2006). A reduction in risk is seen with as little as 30 min moderately intense activity each day (Bassuk and Manson 2005). However, this level of activity may be insufficient to impact on energy balance, with much more activity being needed to prevent weight gain and to achieve weight loss.

102.6.1 How Much Exercise Is Needed to Prevent Weight Gain?

Hill et al. (2003) estimated the energy intake decrease, or energy expenditure increase, that would counter the 0.8–0.9kg average annual weight increase seen in two large epidemiological studies, NHANES and CARDIA. They concluded that 418 kJ/day of additional activity (approximately the cost of leisurely walking for 20-min) could prevent the gradual weight gain seen in 90% of the two cohorts. This is much less than the recommended 627–836 kJ/day (or 30 min moderately intense activity) to confer health benefits. However, the consensus from an IASO conference was that "… moderate intensity activity of approximately 45–60 min/day, or 1.7 PAL is required to prevent the transition to overweight or obesity" (Saris et al. 2003). This equates to almost 1,500 kJ/day additional activity depending on the person's body weight. Recently the American College of Sports Medicine updated its guidelines for physical activity, recommending that between 150 and 250 min/week (20–35 min/day) moderately intense activity to be effective at preventing weight gain (Donnelly et al. 2009).

Much of the data comes from retrospective studies that have looked at those who are more, or less, successful at maintaining a lower body weight rather than the more powerful prospective, and randomized, trials. The amount and intensity of exercise is often self-reported in epidemiological studies, and can be subject to an overreporting bias.

102.6.2 How Much Exercise Is Needed to Prevent Weight Regain?

It is generally agreed that exercise, or increased physical activity, is an important component in any weight maintenance program. Weight maintenance post weight-loss is more difficult to achieve than the initial weight loss, but maintenance programs that include exercise are more effective than those that rely on changing diet alone.

More exercise is recommended to prevent weight regain than to prevent the initial weight gain. This is partly because the composition of tissue increase during weight regain and weight gain is different. Weight regain is predominantly through the "re-filling" of depleted, existing adipose tissue with fat, whereas weight gain requires the accumulation of more lean tissue. As fat has a higher energy content than lean tissue, *per unit weight* a greater surplus of energy needs to be ingested to increase weight through (predominantly) fat accumulation than if the tissue deposition includes lean tissue. Furthermore, both dietary behaviors and patterns of activity and exercise tend to drift back towards those practiced preweight loss. Approximately 80-min/day physical activity, additional to a sedentary lifestyle, is estimated to be necessary for the prevention of weight regain (Saris et al. 2003). This is supported by evidence from members of the National Weight Control Registry; those who are successful at maintaining their weight-loss report undertaking about 60 min/day of moderate-intensity activity (Wing and Phelan 2005).

In a recent 2-year long diet and exercise intervention to achieve and maintain weight loss in 191 overweight and obese women, around a quarter achieved and maintained at least 10% reduction of their initial body weight, and did so by increasing their physical activity by 1,500 kcal/week (6,270 kJ/week) compared to that preweight loss, in addition to reducing their energy intakes. This corresponded to an additional 39 min exercise a day at the prescribed level (Jakicic et al. 2008). Figure 102.4 shows the dose effect of reported amount of physical activity on weight loss and maintenance.
Fig. 102.4 Influence of physical activity on post-weight-loss weight-maintenance. Percentage weight loss by physical activity categories (kilocalories per week) in 170 overweight and obese women who increased physical activity energy expenditure, and reduced energy intake, for 24-months (Taken from Jakicic et al. 2008, with permission. 102.6.3 How Much Exercise Is Needed to Achieve Weight-Loss?

A reduction in energy intake, rather than increasing physical activity alone, is the first choice for achieving weight-loss. The recommended rate of weight-loss is 0.5–1.0 kg a week, which equates to an energy deficit of 13–26 MJ a week (Stubbs et al. 1998). To achieve this through increasing energy expenditure alone would require exercising at a moderately intense level (expending around 1.5 MJ/h in addition to RMR) for 1¼–2½ h every day. Exercising to expend 2 MJ/day (over two, 40-min sessions) for 2-weeks is achievable for lean men and women who are not dieting (Whybrow et al. 2008); but the barriers for overweight and obese people in achieving this for short periods, and for maintaining it for the weeks needed to realize meaningful weight-loss, are considerable (Table 102.3).

It is important to note that overweight sedentary people have higher absolute levels of energy expenditure than lean, but physically active, people. A larger body mass requires a larger amount of metabolically active lean tissue; the obese therefore have higher absolute resting metabolic rates then the lean. The energy cost of movement, especially for weight-bearing activities, also increases with body size. However, the PAL of lean active people and overweight sedentary people tends to be similar (Jebb and Prentice 1995). Many overweight individuals already have energy expenditures towards the upper end of their ability to exercise, and there is limited scope to increase it further.

Overcoming the barriers to increasing physical activity and habituating people to activity is a considerable challenge. Regular brisk walking is an ideal form of exercise for the unfit. The level of energy expenditure can be increased steadily by increasing intensity and duration, or both, and by fitting it into people's daily routines can obviate the time-constraint barrier. Self-monitoring equipment, pedometers (or step counters) are inexpensive and readily available. For people who are very inactive, even 30 min extra activity each week has important health benefits, and as people become more active they become habituated to physical activity more.

Generally, intervention studies show that total daily energy expenditure increases by about the same amount as the exercise prescription (Stubbs et al. 2002a, b; Whybrow et al. 2008). Nonexercise activity does not appear to decrease substantially as a compensatory response to increased exercise (Racette et al. 1995; Whybrow et al. 2008), except in the elderly (Westerterp 1998), or when accompanied by severe energy intake restriction (Kempen et al. 1995).

Dietary-induced weight-loss, difficult to achieve though it is, is far more effective at producing prolonged negative energy balances than exercise alone. From a meta-analysis of published studies, weight-loss using diet, exercise, or diet plus exercise was 10.7, 2.9, and 11.0 kg respectively (Miller et al. 1997). Adding a component of moderate exercise to a weight-reducing diet is generally the most effective way of achieving weight-loss (Wu et al. 2009), and especially at limiting the weight regain (Miller et al. 1997).

Table 102.3 Barriers to exercising and becoming physically active

- The obese already have physical activity levels that are similar to those of the lean
- For some obese individuals, walking costs 50% of their maximum exercise ability
- Physical exertion can be uncomfortable for people who are unfit
- People often underestimate their energy expenditure in activity and overcompensate energy intake
- The average consumer does not know how much energy they expend – they cannot measure it
- Society does not encourage increased activity in our everyday lives. Exercise is largely a segregated activity
- Exercising is seen as time-consuming and difficult to incorporate into the daily routine.

Behavioral and physiological barriers make it difficult for individuals to start to become habitually physically active

102.7 Conclusions

This chapter has considered the relationship between energy intake and expenditure.

One belief is that physical activity increases food intake by increasing hunger, thereby rendering it futile as a method of weight control. There is, however, no evidence for such an immediate or automatic effect. Indeed it is apparent that, in the short-term, only a weak coupling between the two exists and that, on average, acute changes in one do not lead to compensatory changes in the other. In the longer-term physiological changes and behavioral adaptations re-establish energy balance at a new level of energy turnover. Individual variability produces a range in the degree of response to increases or decreases in energy intake or expenditure. Pooling data and reporting the mean conceals these individual responses, which in turn undermines the examination of the processes involved in the development of weight gain and obesity. There is emerging evidence that some individuals are more resistant, and others more susceptible, to a positive energy balance and weight gain in the free-living environment. Similarly, individuals vary in their resistance (and susceptibility) to interventions intended to promote weight loss. If we are to achieve a more successful reduction in obesity, more attention should be directed at targeting individuals and identifying individual responses to energy balance interventions.

Being physically active is important in reducing the risk of developing many chronic illnesses, and is a valuable component in helping to prevent weight gain, and in maintaining weight loss.

Summary Points

- We are far less physically active than our ancestors, with the majority being so sedentary that it has pathological consequences. Sedentariness increases the risk of weight gain and obesity, and independently, the risk of developing a range of chronic illnesses such as diabetes, coronary heart disease, and some types of cancer.
- Physically active individuals are leaner and have a lower BMI than sedentary individuals. Taking up regular exercise results in weight loss or maintenance, stopping results in weight gain.
- There is a lack of physiological coupling between acute changes in energy expenditure and energy intake. We are far more tolerant of positive energy balances (overeating and being sedentary) than of negative energy balances (dieting and unaccustomed exercise). This appears to promote weight gain and resist weight loss.
- In the long-term, both increases and decreases in activity bring about physiological and behavioral changes that re-establish energy balance. Weight loss reduces the energy cost of all activity, and changes in feeding behavior increase energy intake. Sedentariness results in weight gain and consequently higher energy expenditure.
- Behavioral changes in activity resulting from decreases in energy intake are too weak, and take too long to activate, to seriously threaten dietary approaches to weight management.
- More exercise is needed to prevent weight regain after dieting than is needed to prevent weight gain in the first place. Even more is needed to achieve weight loss through exercise alone.
- Individuals vary in their ability to adjust or regulate the various components of energy balance, and therefore in their resistance to lose or gain weight in response to increases or decreases in energy expenditure respectively.

Definitions and Explanations

Energy expenditure: In healthy adults in a normal environment, total energy expenditure is the sum of:

- RMR, which is the largest component, by far, for sedentary people.
- Diet Induced Thermogenesis (DIT), which is about 10% of an ingested meal's energy and is expended in digesting and processing the food.
- Exercise or volitional physical activity usually performed for recreation, health or fitness, such as sports. This is the most variable contribution to total energy expenditure component, both between and among individuals.
- NEAT the activities of everyday living and working, and including fidgeting (Levine et al. 2000).

Exercise intensity: Moderate intensity activities use between 14.5 and 29 kJ/min and includes activities such as brisk walking and leisurely cycling. Vigorous intensity activities use >29 kJ/min, and includes jogging, swimming, and cycling uphill.

Physical activity level: To account for differences in body size and composition it is often more informative to express energy expenditure relative to minimum energy requirements. An animal at complete rest, but awake, and under standardized conditions, would have a PAL of 1.0. PAL = Total Energy Expenditure/RMR.

Resting metabolic rate: The energy needed for basic physiological functioning (maintaining ion gradients across cell membranes, breathing, pumping blood, etc.).

Chapter 103
Head Injury: Metabolic, Nutritional, and Energy Considerations

Christine Charrueau, Béatrice Morio, and Christophe Moinard

Abbreviations

ATP	Adenosine triphosphate
DNA	Deoxyribonucleic acid
GCS	Glasgow coma scale
HI	Head injury
IED	Immune-enhancing diet
IGF-1	Insulin-like growth factor-1
IL1	Interleukin-1
IL6	Interleukin-6
IL8	Interleukin-8
IL10	Interleukin-10
RMR	Resting metabolic rate
RNA	Ribonucleic acid
ROS	Reactive oxygen species
Sir2α	Mammalian silent information regulator
TNF$_\alpha$	Tumor necrosis factor-α
3-MH	3-methylhistidine

103.1 Introduction

Head injury (see Table 103.1) is recognized as an important public health problem. The incidence of head injury is highly variable from one country to another but it is estimated between 100 and 200 per 100,000 populations in Western Countries. In Europe, head injury is the leading cause of death between the ages of 15 and 44 years (Menon 2009). Worldwide, about 1.5 million people die from head injury per year (more than 90% in developing countries).

Table 103.1 Key features of head injury

1. Head injury is the leading cause of mortality and morbidity in young adults.
2. Head injury can result from either a physical impact (motor vehicle accident, falls, bullet impact…) or sudden acceleration (shaken baby syndrome…).
3. Clinical severity of head injury is classically assessed by the Glasgow Coma Scale which ranges from 15 (fully conscious) to 3 (near death).
4. Head injury is caused by both primary and secondary injury mechanisms.
5. Primary injury results from mechanical lesions, which can kill neurons directly (rupture of membranes), or indirectly (ischemia following brain swelling and elevated intracranial pressure).
6. Secondary injury initiated by the primary insult is the sequence of cellular, neurochemical, and metabolic alterations that continue to develop over time.
7. Head injury leads not only to cerebral lesions but also to a systemic response of hypermetabolism and hypercatabolism.

This table lists the key features of head injury

Different approaches to head injury classification have been proposed and traditionally, it has been classified using either one of the following three systems: (1) causative physical mechanism (including impact loading, inertial loading and blast), (2) clinical indexes of severity (the Glasgow Coma Scale (GCS) being the most commonly used neurologic injury severity scale), (3) assessment of structural damages by neuroimaging. More recently an alternative approach has been to classify patients by prognostic risk (Maas et al. 2008).

The primary injury of head trauma typically occurs due to direct damage to the brain (diffuse axonal injury, intracranial hematoma, intracerebral hemorrhage…). The secondary injury occurs after the principal insult and exhibits hemodynamic instability, hypercapnia, and intracerebral hypertension. This phase is rapid and interventions aim to treat cranial hypertension and surgical evacuation of hematoma and hemorrhages (Cook et al. 2008). These cerebral lesions are accompanied by a systemic metabolic response, which is due to the proinflammatory cascade subsequent to brain damage: head injury stimulates the secretion of many cytokines (TNF$_\alpha$, IL1, IL6…) and hormones (glucagon, cortisol,…) that induce profound alterations of the intermediary metabolism, promote muscle wasting, and lead to energy depletion at tissue level (Loan 1999).

Hypermetabolism and massive protein wasting compromise clinical outcome and thereby increase morbidity and mortality. Hence, it has been suggested that protein depletion contributes to the impairment of the immune system often observed in catabolic states. This dysimmunity results in an increase of septic episodes (50–75% of patients sustaining severe head injury develop infectious complications after initial hospitalization) (Quattrocchi et al. 1990). These infections are due to catheter related blood stream infection, or linked to ventilatory support and bacteremia related to gut translocation. Finally, in this population, septic episodes are responsible for 10–25% of the observed mortality. In this context, nutritional therapy can play a major role in attenuating the catabolic response and limiting the deleterious effects of prolonged hypermetabolism in head injury patients.

Animal models of head injury are essential to address pathology and/or treatment providing that the injury is controlled, reproducible, quantifiable, and clinically relevant (Cernak 2005). These models can be broadly classified as impact acceleration models, inertial acceleration models, and direct brain deformation models. The latter include fluid percussion models, mainly in rodents, which produce well-controlled levels of localized injury rather than diffuse damage (Finnie and Blumbergs 2002). Fluid percussion models are highly valuable to optimize the nutritional intervention that follows head injury since they have been demonstrated to reproduce the profound alterations of the nutritional status (Moinard et al. 2005).

103.2 Metabolic Consequences of Head Injury (Fig. 103.1)

In clinical practice, head injury patients undergo rapid weight loss, with negative nitrogen balance and enhanced whole-body protein breakdown that rapidly leads to wasting syndrome and may compromise the patients' outcome. These metabolic disturbances are related to inflammatory response and the degree of disturbances is proportional to the severity of stress.

As observed in other catabolic states, head injury exhibits hormonal changes with a large increase of counterregulatory hormones (i.e., cortisol, glucagon, and catecholamines), hyperinsulinemia (associated to insulinoresistance), and a modification of growth hormone, prolactin, and vasopressin concentrations (Cook et al. 2008). Moreover, cytokine-mediated inflammatory responses are known to play a central role after head injury. Hence, TNF_α is detectable in the first hours after trauma, and IL1 and IL6 responses have been reported to peak between 4 and 48 h. In a second phase, anti-inflammatory mediators (like IL10) are detectable several days after head injury and are maintained up to several weeks (Maegele et al. 2007). The consequence of this huge inflammation is an increase of basal metabolism and of cellular energy requirement, which may promote energy failure.

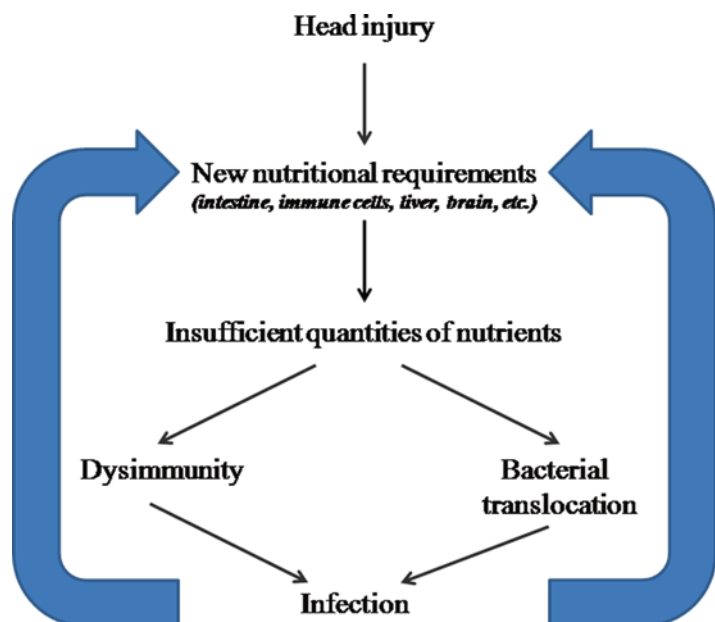
All these alterations have functional consequences at tissue level as illustrated by gastrointestinal dysfunctions. Hence, head injury patients display intolerance to enteral feedings (correlated with the severity of head injury), increase of intestinal bleeding, prolonged gastric emptying, and proximal intestinal obstruction. Moreover, head injury reduces the intestinal barrier function, most likely mediated by open tight junctions (Feighery et al. 2008). This intestinal permeability then favors bacterial translocation and dissemination, which are responsible for sepsis, the leading cause of mortality after head injury. This phenomenon is also amplified by the dysimmunity associated to head injury. Hence, in rodents, head injury induces thymus atrophy and impairment in the lymphocyte CD25 receptor density responsiveness to stimulation (CD25 antigen is the IL2 receptor) (Belabed et al. 2006). In humans, severe head injury is also associated to a suppression in early helper T-cell activation and an alteration in CD25 receptor expression on lymphocyte membranes (Quattrocchi et al. 1990). These data may explain that despite improved diagnosis and


Fig. 103.1 Pathophysiology of the metabolic response following head injury. This figure represents the cascade of metabolic events, which are classically observed after traumatic brain injury: head injury is associated to denutrition, which favors dysimmunity and promotes infection

management, infection remains the most common complication in the head injury patients who survive the initial injury.

103.3 Nutritional Impairment Consecutive to Head Injury

103.3.1 Glucose Metabolism

After head injury, hyperglycemia is frequent, due to increased glucose production by the liver and overall increase in glucose flow through the extracellular compartment. As part of the acute-phase response, the elevation of counterregulatory hormones (catecholamines, glucagon, cortisol), stimulates hepatic glucose production (mainly by gluconeogenesis from amino acids), while insulin production and utilization are impaired (Loan 1999). In addition, insulin resistance is enhanced in the peripheral tissues (Fitzsimmons and Hadley 1991). Hyperglycemia is related to the severity of head injury and has detrimental effects on the neural cells through lactate accumulation and acidosis (Marie and Bralet 2009). However, insulin therapy to tightly control systemic glycemia has been associated with reduced cerebral glucose availability, increased brain energy crisis and enhanced mortality (Oddo et al. 2008).

103.3.2 Lipid Metabolism

Alterations of lipid metabolism in critically ill patients result from changes in the status of hormones and other mediators (for review see Carpentier and Scruel 2002). Fat metabolism is well known in injury and stress: since carbohydrate reserves are limited, endogenous fat progressively becomes the predominant energy source and elevated plasma concentrations of free fatty acids and glycerol following trauma illustrate the increased lipolysis (Nordenstrom et al. 1983). At brain level, deregulated lipid metabolism is of major importance in head injury, as this organ has the highest lipid concentration next to adipose tissue. Specific consequences of head injury on the lipid metabolism are little documented but a significant decrease of the whole-body lipolysis has been reported in multiple-trauma patients with severe head injury compared to multiple-trauma patients without severe head injury (Petersen et al. 1993). An aspect of lipid metabolism, i.e. apolipoprotein E and cholesterol metabolism, has held attention in head injury: indeed, apolipoprotein E is an important mediator of cholesterol and lipid transport in the brain and a novel therapeutic derived from apolipoprotein E has been shown to reduce brain inflammation and to improve outcome after closed head trauma (Adibhatla and Hatcher 2008).

103.3.3 Protein Metabolism

In clinical practice, head injury patients undergo rapid weight loss, an increase of whole-body protein synthesis and an enhanced whole-body protein breakdown. Usually, the patients exhibit a highly negative nitrogen balance due to an inappropriate activation of muscular proteolysis (as shown by enhanced urinary 3-methylhistidine (3-MH) excretion, which is an index of myofibrillar proteolysis). Mansoor et al. (1996) have determined the effect of head injury on the intracellular proteolytic

systems in the mammalian skeletal muscle (the lysosomal pathway, responsible for the soluble and extracellular protein degradation; the Ca^{2+}-dependent proteinases (calpains) responsible for the catabolism of cytoskeletal proteins and the ATP-ubiquitin-dependent pathway, which catalyzes the selective breakdown of the myofibrillar proteins). According to the literature, skeletal muscle myofibrillar protein breakdown has been confirmed to increase in head injury patients. Using muscular biopsies, authors have demonstrated that these metabolic adaptations correlate with enhanced expression of critical components of the lysosomal, Ca^{2+}-dependent, and ATP ubiquitin-dependent proteolytic pathways. Moreover, the mRNA levels for several proteinases or cofactors involved in protein breakdown are also increased (Table 103.2). This massive muscle proteolysis during the initial phase of injury allows the release of muscular amino acids used for inflammatory protein synthesis in the liver, for gluconeogenesis and as energy substrates (i.e., immune cells, enterocytes). In some patients, muscle weakness is so great that ventilation is inadequate to overcome the respiratory insufficiency associated with trauma. The consequence of this protein wasting is an increase in morbidity and mortality (Table 103.3).

Concerning the modification of protein synthesis in head injury patients, whole-body protein metabolism was assessed 48 h after head injury, and was found to have increased (Mansoor et al. 1997). However, this result is different according to the tissue considered: it was largely decreased in muscles whereas hepatic synthesis of fibrinogen (a positive acute-phase protein) was largely increased (Mansoor et al. 1997). In conclusion, these metabolic adaptations of protein metabolism can be considered as necessary for the liver to be supplied with large amounts of amino acids for sustaining the acute-phase hepatic response and gluconeogenesis; the amino acids are derived from increased protein breakdown and decreased protein synthesis in muscle.

Table 103.2 Protein turnover and muscle proteolytic pathways in control and head injury patients (Adapted and reprinted from Mansoor et al. 1996. Copyright 2009 by Proc Natl Acad Sci USA. With permission)

	Control	Head Trauma	p
Whole-body protein turnover (μmol/kg/min)	2.36 ± 0.15	3.52 ± 0.10	<0.01
Whole-body protein breakdown (μmol/kg/min)	1.38 ± 0.15	2.51 ± 0.09	<0.01
3-MH urinary excretion (μmol/kg/day)	3.40 ± 0.58	6.98 ± 0.08	<0.01
Muscle proteasome subunits mRNA (expressed as % of the control value)			
Ubiquitin	100%	225%	<0.05
14-kDa E2	100%	205%	<0.05
HC2 subunit	100%	271%	<0.05
HC8 subunit	100%	213%	<0.05

Whole-body protein kinetics and 3-methylhistidine (3-MH, myofibrillar protein breakdown marker) were determined in head injury patients (day 8 after trauma) and in control subjects

mRNA of ubiquitin, 14-kDa E2, and the proteasome HC2 and HC8 subunits were determined in *vastus lateralis* muscle biopsies from head trauma patients and control subjects. Mean ± SEM

Table 103.3 Consequences of protein deficiency at tissue level in head injury patients

Tissues	Complications
Skin	Delay of wound healing
Muscles	Wasting syndrome
Respiratory muscles	Respiratory insufficiency
Immune cells	Dysimmunity

Protein deficiency in head injury patients results in specific complications

103.3.4 Other Nutrients

Trauma patients have abnormal vitamin and trace element losses linked to their pathology. The metabolic consequences of head injury are characterized by an increase in specific micronutrient requirements. A zinc deficiency is observed in the blood following head injury while the excretion of zinc is increased in the urine (McClain et al. 1986). At brain level, the translocation of zinc from the presynaptic boutons to postsynaptic somata is a contributing factor that controls the death or survival of neurons after head injury. This is why zinc chelators are considered for neuroprotection after traumatic brain injury (Suh et al. 2000). Magnesium concentrations are altered following head injury and patients with low serum magnesium level (<1.3 mEq/L) and high cerebrospinal fluid magnesium level are most likely to have poor outcome after severe head injury (Stippler et al. 2007). Plasma selenium and vitamin E, recognized as antioxidant agents, are also depleted in the early period following experimental head injury (Kiymaz et al. 2007). In humans with moderate-to-severe head injury, plasma vitamin E levels are severely depressed on hospital admission and the second day after trauma (Braughler and Hall 1992).

103.4 Energy Metabolism Following Head Injury

103.4.1 Total Energy Expenditure

It is well known that traumatic injury causes hypermetabolism and hypercatabolism. Hypermetabolism is characterized by increased oxygen consumption, i.e. enhanced energy expenditure as measured by increased resting metabolic rate (RMR) (Table 103.4). The occurrence of hypermetabolism after trauma and injury has been investigated for almost a century and is well documented (for review see Frankenfield 2006). The degree of hypermetabolism is inversely correlated, although not in a linear fashion, with the score on the GCS that ranges from 15 (fully conscious) to 3 (near death) (Frankenfield 2006). RMR of head injury patients increases by 40–200% compared to healthy subjects (for review see Frankenfield 2006), the highest level being observed in patients with decerebrate/decorticate activity (Frankenfield 2006). The degree of elevation of energy expenditure after head injury has been shown to correlate with intracranial pressure (Bucci et al. 1988), muscle tone, and contraction (Robertson et al. 1984). It is also related to body temperature depending on GCS score. At score 4–5, RMR increased by 45% for each degree centigrade rise in body temperature but increased only 15% when GCS score was 6–7. No relationship was found between body temperature and RMR for GCS score higher than 8 (Robertson et al. 1984). Energy expenditure is reduced by sedative treatment; especially in barbiturate coma, it can be depressed

Table 103.4 Modification of energy expenditure according to the catabolic state considered

Pathology	Energy expenditure
Postoperative	+ 0–10%
Long bone fracture	+15–30%
Severe head trauma	**+25–55%**
Sepsis	+50–70%
Burn (20% of body surface)	+50%
Burn (70% of body surface)	+110%

Depending on the pathology considered, the level of hypercatabolism leads to increased energy expenditure

to a level lower than the RMR of healthy subjects (Dempsey et al. 1985). Several other medications can also reduce RMR. The most common ones are central nervous system agents (sedatives, analgesics, narcotics, hypnotics), autonomic agents (neuromuscular blocking agent), and cardiovascular agents (beta-adrenergic receptor antagonists) (for review see Dickerson and Roth-Yousey 2005).

103.4.2 Brain (Fig. 103.2)

The brain is the organ with the greatest oxygen consumption, contributing to 20% of the whole-body energy expenditure. Most of the energy is used by the neurons. Although glial cells account for almost half of the brain volume, they have a much lower metabolic rate and account for less than 10% of brain energy expenditure (Siesjo 1984). Fifty percent of the energy produced by the brain is required for synaptic activity; 25% is used for maintaining ionic gradients across cell membranes; the remaining energy is used for other processes necessary for cell functioning, such as macromolecule synthesis.

Brain cells must be continuously supplied with oxygen and glucose to produce the required energy. ATP is produced through aerobic metabolism, which involves the oxidative phosphorylation carried out by the mitochondria. Continuous cerebral blood flow, cerebral oxygen tension and delivery, and normal mitochondrial function are therefore of vital importance for the maintenance of brain function and tissue viability (for review see Verweij et al. 2007). If one or several parameters are altered, neuronal events and functional deficits occur.

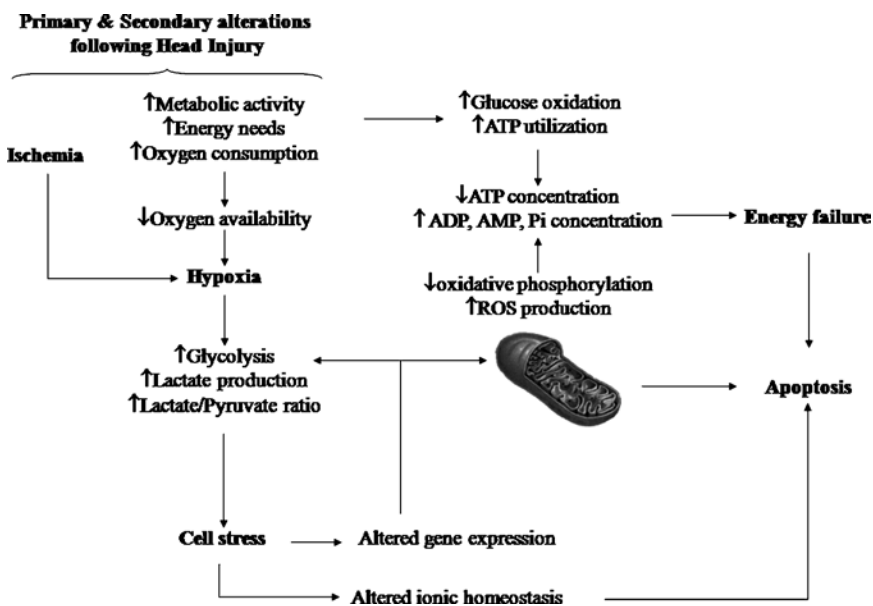
Brain ischemia and hypoxia have been shown to be the most significant predictors of poor outcome in head injury (Verweij et al. 2007). As a main energy supplier, mitochondria are very sensitive


Fig. 103.2 Effect of head injury on cerebral energy homeostasis. Primary and secondary alterations following head injury induce energy consumption at the cerebral level, impairment of mitochondrial function, and finally induce neuronal apoptosis

to ischemia and hypoxia. Studies showed that mitochondria first positively adapt to head injury by enhancing ATP production in order to meet enhanced energy requirement (Vink et al. 1994). However, rapid detrimental effects of head injury on these organelles have been extensively documented (Dai et al. 2009). Mitochondrial alterations, which are characteristic of cerebral ischemia, result in reduced mitochondrial oxygen consumption (Levasseur et al. 2000) and depressed intracellular ATP level (Vagnozzi et al. 2005). Altered mitochondrial gene expression (Matzilevich et al. 2002) and reduced metabolic enzyme activity (Harris et al. 2001) have been reported a few hours after head injury. However, anaerobic glycolysis may compensate for oxidative phosphorylation deficiency (Matzilevich et al. 2002) and this is evidenced by increased production of lactate and increased lactate/pyruvate ratio (Hartley et al. 2008). This is also associated with decreased glucose availability (Stahl et al. 2001).

As it is intrinsically associated to alterations in energy metabolism, head injury promotes brain cell death through the induction of apoptotic pathways. Indeed, head injury is associated with intense intracellular ionic shifts (Hayes et al. 1992), compromised mitochondrial membrane potential (Ahmed et al. 2000), and enhanced production of reactive oxygen species (ROS) (Sullivan et al. 1999). Increased ROS production has been demonstrated directly and indirectly by lipid peroxidation and nucleic acid oxidation. Excess ROS production can oxidize macromolecules such as proteins, lipids, and DNA, the result being altered cell functioning. It may promote mitochondrial permeability transition pore opening and the release of proapoptotic proteins (Soustiel et al. 2008), thus inducing cell death. Finally, cell apoptosis may also be promoted by damage to the endoplasmic reticulum, which alters intracellular calcium buffering (Paschen and Doutheil 1999), enhancing glutamate concentration that activates *N*-methyl-d-aspartate receptors. This contributes to sustained pathological accumulation of calcium in brain-injured regions (Osteen et al. 2004).

103.4.3 Liver

Substantial alterations in liver energy metabolism have been observed as a consequence of secondary brain injury. Depletion of ATP and glycogen hepatic content has been reported, which demonstrates the development of distant organ failure (Moinard et al. 2008). These alterations are the result of a stress-induced impairment in liver energy metabolism. Depletion of ATP and glycogen content in the liver is an effect that may be related to head injury-induced anorexia or to head injury *per se*, or even both. Moinard et al. (2008) showed in rats that enteral nutrition was not able to restore hepatic ATP and glycogen content in head injury, thus demonstrating that anorexia is not the cause of energy depletion. Moreover, these authors underlined that head injury induced localized liver inflammation as assessed by histological examination (i.e., immune cell infiltration, edema, fibrosis, and necrosis). One may hypothesize that abnormal oxygen use, organ failure, or increased inflammatory response in the critically ill may impact on the mitochondrial function. Although energy requirements are strongly elevated in hypercatabolic situations, the measurement of mitochondrial and glycolytic enzyme activities showed that the oxidative capacity of the liver was not modified in head injury and enterally fed head injury rats. Therefore, if mitochondrial oxidative activity is not impaired after head injury, it cannot be excluded that the liver is not able to enhance mitochondrial energy production in order to respond to huge energy requirements and that an impairment of energy synthesis is occurring. Mitochondrial oxidative phosphorylation uncoupling may also occur. A decline in the mitochondrial membrane potential could also explain a reduction in ATP production and a decrease in intracellular ATP availability.

103.5 Nutritional Intervention

As research on potential treatments of head injury patients has progressed, more emphasis has been placed on determining the most appropriate nutritional intervention (Table 103.5). Nutritional management of head injury patients is challenging because of the extensive alterations in metabolic responses, immunity and the gastrointestinal function. The nutritional intervention following head injury has three aims: first, to prevent the loss of fat-free mass; second, to modulate the immune response; third, to promote gastrointestinal structure and function. In addition, the nutritional support may also improve neurological outcome to some extent.

The latest Cochrane review on nutritional support for head injury patients indicates that early feeding may be associated with fewer infections and a trend toward a better outcome in terms of survival and disability. However, the randomized–controlled trials included to determine the best

Table 103.5 Examples of beneficial effects of nutritional intervention in head injury

Diet/Nutrient	Route	Subject	Benefit	References

Omega-3 PUFAs	*Per os*	HI rats	Neuroprotection	Wu et al. (2007)
Zinc	Parenteral/ *Per os*	Severely HI adults	↗ GCS score	Young et al. (1996)

Experimental and clinical studies show that nutrition by itself and supplementation with specific nutrients can favorably influence outcome after head injury (HI)

i.p. intraperitoneal, *s.c.* subcutaneous, *i.v.* intravenous, *ICU* intensive care unit, *GCS* Glasgow coma scale, *PUFAs* polyunsaturated fatty acids

also been tested in clinical settings. The enrichment of an enteral diet with a combination of glutamine (to improve the nutrition of both the gut mucosa and immune cells) and probiotic bacteria (to favorably alter the intraluminal environment and compete with pathogenic bacteria) decreased the infection rate and shortened the stay in intensive care unit of head injury patients (Falcao de Arruda and Aguilar-Nascimento 2004). In children with severe head injury, immunonutrition significantly lowered IL8 levels and gastric colonization, but had no additional advantages over a standard enteral nutrition in terms of nosocomial infections, length of stay, length of mechanical ventilation, and survival (Briassoulis et al. 2006). It is still difficult to conclude on the efficacy of immunonutrition since the qualitative and quantitative composition of the commercialized IEDs is highly variable. Despite promising effects, IEDs are still not recognized as standard care and the best composition of an IED adapted to head injury patients remains to be determined.

103.5.3 Promotion of the Gastrointestinal Function

An increase in gut permeability, which is correlated with the severity of injury, is observed in head injury patients (Faries et al. 1998). It is generally recognized that the presence of enteral nutrients promotes mucosal health, maintains the intestinal absorption capacity, and preserves the gastrointestinal barrier function, better than the parenteral nutrition does (Suchner et al. 1996). Experimental data in head injury rats support the fact that immunonutrition significantly lowers intestinal apoptosis, mucosal atrophy, and bacterial translocation especially when it is implemented early following head injury (Aydin et al. 2005).

103.5.4 Improvement of Neurological Outcome

Nutrition by itself can favorably influence neurological recovery and better neurologic outcomes have generally been seen in the head injury patients who received the earliest and largest amounts of nutrients (Wilson et al. 2001).

In addition, the supplementation of head injury patients with specific nutrients may further improve neurological outcome. Hence, supplementation of patients suffering severe closed head injury with zinc during the immediate postinjury period led to significant improvement in GCS score (Young et al. 1996). The creatine kinase/phosphocreatine system exerts a central role in cellular bioenergetics, especially in neurons that are characterized by high and fluctuating energy requirements (Andres et al. 2008). In a prospective randomized study in children and adolescents suffering from head injury, administration of creatine (or *N*-aminoiminomethyl-*N*-methylglycine) significantly improved the clinical outcome in cognitive, personality/behavior, self-care, and communication aspects (Sakellaris et al. 2006).

Experimentally, magnesium appears to protect against neurological deficits after head injury by its effects on glycolysis, oxidative phosphorylation, and synthesis of DNA, RNA, and proteins (McIntosh et al. 1989). Magnesium administration has been shown to decrease brain edema and early neurologic severity score (Feldman et al. 1996) as well as delayed post-traumatic neurologic impairments in head injury rats (Bareyre et al. 1999). However, the issue of magnesium neuroprotection in humans with head injury has not been resolved yet and needs further investigations. Consistent with some negative preclinical studies, a recent clinical trial has shown that magnesium treatment did not improve outcome and may be harmful in some cases (Temkin et al. 2007). The decrease in

cerebral blood flow usually observed after head injury could be prevented by the enteral administration of L-arginine (Dewitt et al. 1997). IGF-1 has been shown to improve both neurologic motor and cognitive outcomes following experimental head injury in the rat (Saatman et al. 1997). Preclinical studies have demonstrated the strong neuroprotective abilities of nicotinamide or vitamin B3 in the injured brain and suggest that this nutrient may have therapeutic potential for head injury treatment (Holland et al. 2008). Head injury reduces mammalian silent information regulator (Sir2α) expression in the hippocampus, a cerebral region implicated in synaptic plasticity, learning and memory, in proportion to increased levels of protein oxidation. This reduction may increase the susceptibility of neurons to secondary damages. Dietary supplementation of omega-3 polyunsaturated fatty acids is effective to normalize levels of Sir2α, which are essential to maintain the cellular homeostasis required for neural plasticity following head injury (Wu et al. 2007). Finally, the secondary damages that occur in the brain following head injury can be attributed to three mechanisms that lead to neuronal death, i.e. glutamate excitotoxicity, Ca^{2+} overload, and oxidative stress. Some authors have suggested that decreasing oxidative stress would minimize the amount of secondary damage due to trauma. For that purpose, aggressive nutritional support may contribute to maximizing antioxidant defenses. Cysteine precursors such as *N*-acetylcysteine could be used to maintain the level of reduced glutathione, which plays a central role in scavenging peroxides (Chen et al. 2008). Flavonoids such as quercetin could be employed for their radical quenching, iron chelating, and anti-inflammatory properties (Juurlink and Paterson 1998).

103.6 Conclusion

For several decades, research in the management of head injury patients has focused on therapies aiming to preserve cerebral functions. A large number of randomized trials on neuroprotective intervention have been carried out. However, a significant part of delayed mortality does not result from initial cerebral lesions. It is caused by extensive adaptation at the systemic level such as inflammatory cascade, hypermetabolism, debilitation leading to dysimmunity. The latter ultimately triggers infections and compromises patients' outcome. In this context, nutritional management is clearly of major importance. Nonetheless, due to the lack of robust randomized–controlled trials aiming to demonstrate the clinical benefits of nutrition in head injury, consensual recommendations have not yet been stated.

Summary Points

- Head injury induces a protein wasting that contributes to the impairment of the immune system. This dysimmunity results in an increase of septic episodes, which compromise clinical outcome and thereby increase morbidity and mortality.
- Head injury is recognized to induce major gastrointestinal dysfunction including intolerance to enteral feeding, prolonged gastric emptying, increase of intestinal bleeding, and proximal intestinal obstruction.
- Head injury profoundly affects the liver function, in particular energy homeostasis (i.e., depletion of ATP and glycogen contents) and induces cellular inflammation (i.e., immune cell infiltration, edema, fibrosis, and necrosis).
- Head injury rapidly and deeply alters brain energy metabolism around the injured tissue. This is characterized by hypermetabolism, which can lead to cell death due to energy failure. Secondary

brain damages can also be caused by compensatory mechanisms that lead to increased intracranial pressure and hyperoxia in noninjured brain regions.

- The rationale for nutritional intervention following head injury is: (1) to prevent the wasting syndrome, (2) to restore the immune response, (3) to preserve the gastrointestinal function, and (4) to improve the neurological outcome.
- Nutrition by itself can favorably influence neurological recovery and better neurologic outcomes have generally been seen in the head injury patients who received the earliest and largest amounts of nutrients.
- Despite interesting experimental and clinical data, there are no sufficient clinical trials at present to make some nutritional recommendations in head injury patients (except that enteral nutrition is considered as the preferred way of feeding critically ill patients).

Definitions of Key Terms

Artificial nutrition: A therapy that prevents the deleterious effects of starvation in patients not fulfilling their nutritional requirements. It includes enteral nutrition administered in the digestive tract and parenteral nutrition, which is provided by the intravenous route.

Immune-enhancing diets: Specific enteral mixtures containing nutrients (i.e. arginine, glutamine, taurine, ω3 polyunsaturated fatty acids, messenger RNA, and certain vitamins and trace elements) able to modulate the immune response to stress.

Resistance to renutrition: The fact that malnutrition persists despite a nutrition covering the basal nutritional requirements.

Bacterial translocation and dissemination: Bacterial translocation corresponds to the passage of bacteria from the gastrointestinal tract to mesenteric lymph nodes. Subsequent dissemination may occur in other internal organs (i.e. lung, liver, spleen, etc.).

Wasting syndrome: This syndrome is characterized by rapid weight loss, negative nitrogen balance, and loss of lean body mass. In some patients, muscle weakness is so great that ventilation is inadequate to overcome the respiratory insufficiency associated with trauma. The consequence is an increase in morbidity and mortality.

Chapter 104
Behavioral Consequences of Force-feeding

Malgorzata Starzomska and Marek Smulczyk

Motto
The Good Samaritan deserves sympathetic support, officious intermeddling must be
discouraged

(Anon. 1974).

Abbreviation

             Revision

104.1 Introduction

Food refusal may occur for a variety of reasons. For example, it may be used as a method of exercising control over others (either at family or society level), as a method of self-harm, or even as a way of committing suicide. It is sometimes a symptom of mental illness. Thus, management of self-starvation depends on the motivation behind it, and consequently, on specification of the extent to which incompetence influences the decision to refuse food. Forcible feeding is the most frequent behavioral intervention in the case of severely emaciated individuals but is it the only way in which they can be helped? Clearly, each case is very specific but it is important to try to analyze the unique character of food refusal and the difficulties involved in forcible feeding of emaciated individuals, at least on several examples. The author has chosen hunger strikes and anorexia nervosa to illustrate, among other things, the consequences of forcible feeding and the practical implications for therapy.

104.2 Forcible Feeding Under Existing Regulations of the Mental Health Act

Force-feeding can take the form of either oral refeeding, by which it is understood that the patient is effectively pressurized into feeding himself or herself, or tube feeding (Draper 2000). Some clinicians also apply nocturnal nasogastric refeeding (inserting a plastic tube through the nostril to the stomach to feed anorexics with a fluid diet) (Robb et al. 2002). Each forced treatment is a difficult situation for the patient, the patient's family, and the hospital staff; however, it is sometimes essential if a patient's life is to be saved (Melamed et al. 2003). Such intervention is usually undertaken within compulsory treatment. It must be underlined that any patient assessed for compulsory, and in the case of food refusal, forcible feeding, must be diagnosed not only with a mental disorder per se but also with a mental disorder with symptoms that support involuntary intervention (Brockman 1999). The key question in this case is testifying to the patient's competence (capacity), namely his or her ability to make informed decisions. Capacity (which is the equivalent of competence) (Tan et al. 2003a) is a very important issue with respect to treatment consent and refusal; it derives from the premise that the ability to decide about one's medical condition, irrespective of how imperfect or inaccurate that judgment might be, constitutes a fundamental human and legal right. Similarly, administering treatment against a patient's conscious and direct will is ethically dubious, even if not legally (Tan et al. 2003b). Nowadays, the capacity-centered approach is common in legal systems (Tan et al. 2003b). Therefore, a patient who is competent to make decisions may not be treated – and this includes artificial feeding – against his or her will (Dyer 2000).[1] It is important to remember that presence of a mental disorder does not always imply incompetence. The criteria for compulsory treatment are defined in the Review of the Mental Health Act (1999) and are shown in Table 104.1.

Table 104.1 The criteria for compulsory treatment

According to Review of the Mental Health Act 1983

"5.95. Before confirming a compulsory order the tribunal would have to be satisfied as to the following:

i. the presence of mental disorder which is of such seriousness that the patient requires care and treatment under the supervision of specialist mental health services;

and

ii. that the care and treatment proposed for, and consequent upon, the mental disorder is the least restrictive and invasive alternative available consistent with safe and effective care;

and

iii. that the proposed care and treatment is in the patient's best interests;

and, either

iv. that, in the case of a patient who lacks capacity to consent to care and treatment for mental disorder, it is necessary for the health or safety of the patient or for the protection of others from serious harm or for the protection of the patient from serious exploitation that s/he be subject to such care and treatment, and that such care and treatment cannot be implemented unless s/he is compelled under this section;

or

v. that, in the case of a patient who has capacity to consent to the proposed care and treatment for her/his mental disorder, there is a substantial risk of serious harm to the health or safety of the patient or to the safety of other persons if s/he remains untreated, and there are positive clinical measures included within the proposed care and treatment, which are likely to prevent deterioration or to secure an improvement in the patient's mental condition" (p. 70–71).

---

[1]With the exception of patients covered by the 1983 Mental Health Act who may be treated against their will even if they are competent, but only if the treatment is for their mental disorder (Dyer 2000).

104.3 Hunger Strikes

104.3.1 Definition of hunger strikes

The Declaration on Hunger Strikers (Declaration of Malta) (1991, http://www.wma.net/e/policy/h31.htm) defines a hunger striker as a mentally sound person who has voluntarily initiated a hunger strike and does not accept food and/or fluids over a considerable time. Oguz and Miles (2005) define a hunger strike as an action based on nourishment refusal, performed by an individual (possibly imprisoned) whose decision-making capacity is not impaired, with the aim of obtaining fulfilment of a specific demand. Most hunger strikes include the ingestion of some water and other liquids, salt, sugar, and vitamin B1 for a certain time without asserting intent to fast to death (Oguz and Miles 2005). Hunger strikes have a rich political history (Oguz and Miles 2005), starting with the suffragettes through the IRA in Britain or the Doukhobors in Canada (Lewey 1977) and ending with the famous case of Guantanamo Bay hunger strikers (e.g., Nicholl et al. 2006; Wilks 2006).

104.3.2 Causes of Hunger Strikes Among Prisoners

According to Brockman (1999), hunger strikes among prisoners may be motivated by a variety of factors. For example, sentenced young prisoners (particularly in the case of a first lengthy sentence) use self-starvation (which may be treated as a variant of self-harm) as a method of reducing tension or an attempt to precipitate change. Only a few prisoners choose to commit suicide (which may be chosen as a method of escaping punishment, a means of exercising autonomy or a method of self-killing secondary to grief or guilt) by starvation as they are prevented from killing themselves by other physical means. On the other hand, the main motivation behind hunger strikes of remanded prisoners is unfair – in their opinion – charge or refusal of application for bail. Finally, asylum seekers at an early stage of imprisonment communicate distress and their desire to change detention status through food refusal. Later, when it becomes apparent that they will be repatriated against their will, food refusal can be motivated by the desire to die rather than accept this tragic fate. Illegal immigrants most often use hunger strikes to express their outrage at having been treated as criminals when they do not perceive themselves as such. Although it is claimed from time to time that the main motivation behind hunger strikes is to draw media attention to the striker's problem (e.g., Lewey 1977, p. 416), most authors would generally agree that an unarmed individual has very few methods left to resort to if he or she wants to make a life or death decision (Oguz and Miles 2005). Thus, they think that the choice to refuse food in the case of hunger strikes in prisons can be an authentic, albeit lethal, expression of values that may end the person's life (Oguz and Miles 2005), although it cannot be excluded that prisoners sometimes seem to play with the system in undertaking their hunger strike, as Dryer suggests (2000) (Table 104.2).

104.3.3 Competence Testifying and Its Effect on Force-feeding of Hunger Strikers in Prisons

It is very important to say that the majority of cases in which prisoners refused nutrition were inspired by numerous reasons other than mental disorder (Brockman 1999) and hunger strikes are very rarely unjustified. It is therefore not surprising that society and the law now acknowledge that a competent prisoner, even with suicidal tendencies, may choose to self-starve. A prisoner's decision, regardless of

Table 104.2 Motivations behind food refusal among hunger strikers in prisons and anorexics

Motivation behind food refusal		
Hunger strikes among prisoners		Anorexics
Sentenced young prisoners	particularly in the case of a first lengthy sentence – self-starvation (which may be treated as a variant of self-harm) is used as a method of reducing tension or an attempt to precipitate change.	Distorted body image.
	self-starvation as a form of a suicide (which may be chosen as a method of escaping punishment, a means to exercise autonomy, or a method of self-killing secondary to grief or guilt), because they are prevented from killing themselves by other physical means.	An intense fear of weight gain, even when they are bordering on physical collapse.
Remanded prisoners	self-starvation as a form of protest against unfair – in their opinion – charge or refusal of their application for bail.	Efforts to exert control over their eating behavior.
Asylum seekers	At an early stage of imprisonment – food refusal as communication of distress and the desire to change detention status.	Egosyntonicity of anorexia nervosa, namely this condition is often highly valued by anorexics. This phenomenon refers to the sense, which many patients experience, of anorexia nervosa being part of themselves or of their identity.
	Later, when it becomes apparent to the asylum seeker that he will be repatriated against his will, food refusal can be motivated by the desire to die rather than accept this tragic fate. Through hunger strikes illegal immigrants most often express outrage for being treated as criminals when they do not perceive themselves as such. Although from time to time opinions are published suggesting that the main motivation behind hunger strikes is to draw media attention to their problem.	Communication of distress (usually a person is not fully aware of it) concerning adulthood, body, and especially, sexuality and the desire to manage it.
Sometimes prisoners seem to be playing with the system in undertaking their hunger strike.		

There are various motivations behind food refusal among hunger strikers in prisons and anorexics, including the desire to inflict self-harm, change one's detention status or die, escape punishment, communicate distress or play with the system (in prisoners); distorted body image, intense fear of weight gain, an effort to exert control overeating behavior, egosyntonicity, and communication of distress (in anorexics)

whether it appears to be foolish, cannot be overruled unless the individual is incompetent (Brockman 1999). When a prisoner refuses nourishment and is considered by the doctor to be capable of forming an unimpaired and rational judgment concerning the consequences of such voluntary refusal, he or she shall not be fed artificially (Kenny et al. 2004). The above attitude is further reinforced by the question of whether death by hunger strike is suicide, or simply exercising the right to self-determination (Williams 2001). Studies have shown that prisoners who go on hunger strikes have a high prevalence of depression or post-traumatic stress disorder but are not especially likely to be suicidal or incapable of making the decision to go on hunger strike (Oguz and Miles 2005, p. 170). Wynia (2007) underlines that suicide as a medical term has no place in discussing hunger strikes. Hunger strikers are not generally clinically depressed and would prefer not to die; the strikers are not suicidal, even if they are willing to die to achieve their political aims. Hernan Reyes of the International Committee of the Red Cross said that true hunger strikers do not want to die any more than soldiers charging a hill want to die (Table 104.3).

Table 104.3 Mental disability, capacity, and attitudes toward suicide among hunger strikers in prisons and anorexics

Mental disability, capacity, and attitudes toward suicide		
	In hunger strikers in prisons	In anorexics
Mental disability and capacity	Generally prisoners who go on hunger strikes are not incapable of making a decision to go on a hunger strike; food refusal by prisoners may be motivated by a variety of factors, most of which are not related to mental disorder.	According to the 1990 Mental Health Act anorexia nervosa does not meet the criteria of psychosis under the Act (so anorexics are generally competent) but this current legal conception of capacity, which is based on understanding and reasoning, does not capture the difficulty that arises from the impact of anorexia nervosa on the sense of personal identity, especially resulting in egosyntonicity.
Suicide	prisoners who go on hunger strikes have a high prevalence of depression or post-traumatic stress disorder but are not especially likely to be suicidal, suicide as a medical term, has no place in discussing hunger strikes; hunger strikers are not generally clinically depressed and would prefer not to die; they are not suicidal, even if they are willing to die to achieve their political aims.	Anorexics are genuinely terrified of the prospect of being overweight and some state openly that they would rather be dead than fat; in contrast to suicidal patients they do not explicitly discuss a desire to end their lives but their actions lead in that direction.

Generally, neither prisoners nor anorexics are incapable of making the decision to go on hunger strike but the current legal conception of capacity, which is based on understanding and reasoning, is completely inadequate for anorexia nervosa

104.3.4 Hunger Strikers' General Attitudes Toward Food Refusal

According to a blogger commenting on the situation of the Guantanamo prisoners who go on hunger strike, force-feeding not only violates US domestic and international laws but is also undisputedly perceived as cruel practice against human life and dignity (blog of rights, http://blog.aclu.org/2009/01/09/end-the-inhumane-force-feeding-of-guantanamo-prisoners/). In this vein, The World Medical Association Declaration of Malta concludes that forced feeding, unlike refusal to eat, is always accompanied by some form of physical or mental abuse and must therefore be perceived as degrading and inhuman (Wynia 2007). Most medical organizations advocate respect for a freely chosen decision to strike. Their disposition is mainly based on the concept of freedom of expression introduced by the International Covenant on Civil and Political Rights (Oguz and Miles 2005).

104.3.5 The Dilemma of the Physician Who Tries to Help a Hunger Striker in Prison

Although generally a doctor will not be neglecting his duty if he refrains from feeding a prisoner against his will, each time prisoners refuse food their doctors face a dilemma (Wynia 2007). Each case of hunger strike triggers the debate on legality and morality of force-feeding, which has continued through most of the history of prison medicine (Lewey 1977). Cases of force-feeding of prisoners (especially asylum seekers) by doctors result in great concern. When coming into contact with a prisoner on hunger strike, doctors should be aware of their professional, legal, and ethical obligations (Kenny et al. 2004). There are legal and social interests, reflecting profound ethical values, which militate against the prisoner's absolute right to die by means of hunger strike but it has been debated

whether a doctor may provide medical treatment once a hunger striker has reached the point where he is no longer capable of rational thought (Strauss 1991). Allowing the striker to die ratifies the charge that the authorities do not value the personhood of prisoners. Force-feeding to save life draws attention to the way the diminished quality of life has inspired the protest (Oguz and Miles 2005). Thus, the physicians find themselves between the rock and the hard place, where either decision is burdened with guilt (Lewey 1977). Any response by the state, including neglect, negotiation, and force-feeding, is a question of dialogue with the strikers and, consequently, is very problematic and difficult (Oguz and Miles 2005). Clearly, a physician who either respects the choice to hunger strike or force-feeds the striker is very often inevitably engaged in a political act (Oguz and Miles 2005). According to Oguz and Miles, such physicians ought to stay politically neutral and refrain from commenting in any way (positive or negative) on the striker's motifs as well as being respectful of the striker's right to exercise such a protest, by supplying him or her with essential updates on his or her condition without forcing them to terminate the protest (Oguz and Miles 2005). They should also be willing to take proactive action and provide information in advance so as to plan for loss of decision-making capacity, thus helping to delay death and reduce the risk of irreversible disabilities (Oguz and Miles 2005). Additionally, they should refrain from advocacy or criticism of the political aspirations of individuals under their care (Oguz and Miles 2005).

104.3.6 Consequences of Forcible Feeding Among Prisoners Who Undertake Hunger Strikes

Very little has been written about the consequences of forcible feeding in the case of hunger strikes in prisons. There are some reports of inquests where death was accelerated by force-feeding (due to pneumonia or syncope). Force-feeding can also lead to major infections, collapsed lungs, and other devastating health consequences, including serious digestive and pancreatic problems. Unfortunately, reports on the behavioral consequences of such forcible feeding are lacking. Evaluation of such consequences implies adopting a clear stance on values because, as was mentioned above, the strikers are not mentally disturbed, even if they are willing to die to achieve their political goals. Therefore, the physician must answer the following difficult questions: Is one individual's freedom of choice to be limited by another individual's moral obligations to benevolence? Or in this case, does freedom seem to be the highest human value? Those who value freedom of self-determination above all, even life itself, advocate noninterference. Others feel that when the choice leads to death, the human moral obligation to benevolence impels one to intervene – in a medical context, the physician must attempt to save life and preserve health (Lewey 1977). In such situations, the doctor has to apply a lesser evil to prevent a greater one. But what he shall consider to be a lesser evil is his arbitrary decision.

It is difficult to say precisely what a forcibly fed prisoner feels but there is no doubt that such intervention does not bring relief. On the one hand, forcible feeding saves life but on the other hand, as Oguz and Miles argue, for prisoners who, by and large, are deprived of means of exercising their political rights, hunger strikes convey a powerful and independent political message (Oguz and Miles 2005). Hence, forcible feeding seems to narrow their already diminished freedom.[2]

---

[2]Nowadays it is very difficult to bypass the dilemma with the so called "Cat and Mouse Act" under which hunger strikers were released from prison and then re-detained once they were fit again (Lewey 1977) because there were a lot of unintended consequences of the act. For example, the authorities experienced much more difficulty than anticipated in re-arresting the released hunger-strikers.

Table 104.4 Medical and behavioral implications of forcible feeding among hunger strikers in prisons and anorexics

Medical and behavioral implications of forcible feeding		
In hunger strikers in prisons		In anorexics
Medical	Pneumonia, syncope, major infections, collapsed lungs, serious digestive and pancreatic problems.	Pneumonia and over-hydration.
Behavioral	For prisoners, conventional means of political expression, such as voting, donating to political organizations, publishing, or national organizing are greatly diminished. They are obstructed, impracticable, or illegal. Under these circumstances, a hunger strike asserting bodily integrity is one of the few tools for strong political expression, thus forcible feeding seems to narrow already diminished freedom. Such intervention does not solve the problem of the hunger striker, for example it cannot change detention status of an asylum seeker, so not only does force-feeding not minimize his distress, it intensifies it.	Feeding alone is thought to be ineffective, and even counterproductive and antitherapeutic, and may be defined as mistreatment. Because the fundamental therapeutic aim in working with anorexia nervosa patients should be to facilitate the development of a secure, separate sense of self and minimize egosyntonicity of the condition, such behavioral treatment programs for anorexic patients are indeed paradoxical. Force-fed anorexics evidence no differences in recovery from anorexia's psychological aspects, satisfaction with treatment, or medical complication frequency compared with those who received oral kilocalories alone. In addition, such intervention clearly destroys the relationship of trust between patient and practitioner and jeopardizes the patient's prospects of long-term recovery. Force-fed patients with anorexia nervosa tended to perceive their figure and femininity more negatively than before hospitalization. Paradoxically, force-feeding may be connected with greater risk of death.

There are various negative biological and behavioral consequences of force-feeding among hunger strikers in prisons and anorexics, pneumonia being the most familiar biological consequence and failure to reduce distress being the most familiar behavioral consequence. Not only does force-feeding fail to reduce distress in prisoners, it actually exacerbates it. In anorexics, force-feeding leads to mental deterioration and may be connected with greater risk of death

Such intervention does not solve the problem of the hunger striker. For example, it cannot change the detention status of the asylum seeker and therefore force-feeding not only does not minimize his distress, it intensifies it even further (Table 104.4).

104.4 Anorexia Nervosa

104.4.1 Definition and Causes of Food Refusal in Anorexia Nervosa

It is common knowledge that anorexia nervosa is a serious psychiatric disorder characterized by distorted body image, which triggers intensive self-starvation (a person eats very small amounts of low caloric food) and – as a consequence – significantly diminished body weight. The very essence of this eating disorder is the staunch refusal to change (to gain weight) in conjunction with profound denial of illness (Harris et al. 2001). These patients often do not perceive themselves as sick (Gans and Gunn 2003). They do not want to eat and they typically manifest an intense fear of weight gain, even when they are bordering on physical collapse from malnutrition (MacDonald 2002) (Table 104.2). Clinicians working with patients suffering from anorexia nervosa must face not only the chronic but also the life-threatening (Patton 1988) nature of the illness and this is probably the most difficult aspect of their work. Although Beumont and Carney (2004) claim that patients express authentic terror at the thought of being overweight, with some of them going so far

as to claim they would rather be seen dead than fat, in contrast to suicidal patients, they do not explicitly discuss a desire to end their lives, yet their actions lead in that direction (Melamed et al. 2003, p. 622). Refusal of treatment that could look suicidal in another patient may, for the anorexic, be an affirmation of the only life she can conceive of living (e.g., Gans and Gunn 2003). Although anorexia nervosa is sometimes described as suicide in refractive or refracted (Lemma-Wright 1994; Malan 1997), the desire to assert autonomy and self-control is what eliminates the likelihood of suicide, replacing it with a process of starvation that is stretched over time (Lemma-Wright 1994). Anorexia is a paradoxical disorder in which the choice to starve is experienced existentially as the choice to be and every anorexic girl derives her fundamental meaning and satisfaction, her reason to live, from her efforts to become thin (Gans and Gunn 2003). Very often the anorexic person is unaware that her illness is a cry for help in the face of acute distress concerning adulthood, the body, and especially sexuality.

104.4.2   Egosyntonicity as the Main Feature of Anorexia Nervosa and Inadequacy of the Current Model of Capacity

Serpell et al. (2004) raise the issue of the egosyntonic nature of anorexia nervosa, which prompts people affected by the disorder to perceive it as a value (in contrast to bulimia nervosa, Serpell and Treasure 2002). Although egosyntonicity seems to be very important for the assessment of anorexic patients' capacity, its impact is still unaccounted for in the legal definition of capacity (Tan et al. 2003c). The authors (Tan et al. 2003c) suggest that personal identity should be considered a relevant factor in the assessment of competence to consent to, or refuse, treatment in anorexia nervosa, depending on how it affects an individual's sense of personal identity and her ability to make decisions. It is very important to say that the application of capacity in consideration of treatment refusal in anorexia nervosa can be problematic, especially because anorexic patients' difficulties concerning their ability to make treatment decisions, described above, are poorly captured by the concept of capacity currently in use that is based on understanding and reasoning (Tan et al. 2003a, b). The legal criteria of capacity are largely intellectual ones, based on the ability to believe and understand treatment information and to reason about it and they seem to be inadequate in the case of anorexia nervosa because anorexia affects patients' values rather than understanding and reasoning (Tan et al. 2003c). In this light, it is very controversial that, according to the 1990 Mental Health Act, anorexia nervosa does not fulfill the criteria of psychosis under the Act and therefore anorexic patients are generally competent and cannot be compulsorily hospitalized (if anorexic patients are temporarily disturbed or pose a risk to themselves, the Act allows them to be detained to facilitate emergency treatment as mentally disordered persons for a maximum of 3 days) (Lemma-Wright 1994; Griffiths et al. 1997) (Table 104.3).

104.4.3   General Attitudes Toward Forcible Feeding of Anorexic Patients

The deep existential motivation behind self-starvation in anorexia nervosa does not always seem to affect attitudes toward treatment of this condition because forcible feeding is still the main method of "helping" them in some hospitals. The strong conviction that many medical and highly dangerous complications of self-starvation may remit after re-nutrition (Corcos et al. 2003; Holtkamp et al. 2003) still lingers among some clinicians. According to MacDonald (2002), the main reason given

for rejecting the full implications of patient autonomy (for example in the case of forcible feeding) in the case of anorexia nervosa is that treatment promises both physical and psychological benefits. Many clinicians are convinced that if the treatment succeeds in inducing weight gain, the patient will be healthier physically (for example, she will have less risk of heart attack) and mentally (she will have less starvation-induced cognitive impairment). Thus the anorexic person, once admitted to hospital, very frequently may be subjected to a variety of treatment programs whose principal aim is to restore the anorexic to a normal weight (Lemma-Wright 1994). Such interventions should be deemed fundamentally improper.

104.4.4 Consequences of Forcible Feeding of Anorexic Patients

According to Draper (2000), feeding, unless administered to physically enable the patient to participate in therapy, is ineffective. Forcible feeding as a method of treating patients with anorexia nervosa may be counterproductive and antitherapeutic (Tan et al. 2003a). Thus, strict behavioral interventions (demanding, for example, that a patient eat 100% of her/his meal or be forcibly fed) may be defined as mistreatment in the case of anorexia nervosa (Treasure and Ramsay 2002), especially because of the surprising results reported by Finfgeld (2002) and Castro et al. (2004): nutritional abnormalities in adolescent anorexia nervosa persist after short-time recovery and both nonweight restored and some weight-restored individuals with anorexia nervosa experience chronic problems. Because treating patients with anorexia nervosa should be fundamentally aimed at rebuilding their stable, independent identity (Levens 1995), such behavioral treatment programs for anorexic patients are indeed paradoxical (Lemma-Wright 1994). This paradox is well exemplified by many very negative consequences of force-feeding in patients with anorexia nervosa. For example, involuntary nasogastric tube feeding (described earlier) of patients with anorexia nervosa is particularly problematic. Although according to Zuercher et al. (2003), patients who had received voluntary tube feeding gained significantly more weight per treatment week than those who received oral refeeding alone[3] and patients who had received tube feeding evidenced no differences in recovery from anorexia's psychological aspects, satisfaction with treatment, or medical complication frequency than those who received oral kilocalories alone, the effectiveness of (even voluntary) tube feeding in the treatment of anorexia nervosa is highly problematic. Such compulsory tube feeding destroys the relationship of trust between patient and practitioner and jeopardizes the patient's prospects of long-term recovery (Dresser 1984). Also literally forcing food into the mouths of sufferers decreases the chances of long-term recovery and is hardly in patients' best interest (Draper 2000, p. 121). A study conducted by Robb et al. (2002) showed that nasogastric feeding was a more effective alternative to less subtle forcible feeding as it resulted in faster and more substantial weight gain when applied over a similar period of time. A study by Mehran et al. (1999) into the perception of femininity, figure, diet, and clothing conducted before and after 3-month hospitalization also revealed a negative link between forcible feeding and patients' self-esteem: the force-fed patients evaluated both their femininity and figure in a more rejecting and unfavorable manner than before hospital admission (Figs. 104.1–104.4).

Gowers et al. (2000) find hospitalization unsupported by psychological help responsible for deterioration in patients' condition or even premature death while Draper argues that forcible feeding,

---

[3]Patients who received tube feeding for at least half of their length of stay gained 1 kg/week versus 0.77 kg/week for patients receiving oral re-feeding alone.

Fig. 104.1 Changes in perception of femininity in restricting-type anorexics (RAs) and bulimic-type anorexics (Bas) (Reprinted from Mehran et al. 1999. With permission)
Fig. 104.2 Changes in perception of figure in restricting-type anorexics (RAs) and bulimic-type anorexics (Bas) (Reprinted from Mehran et al. 1999. With permission)
albeit life-saving, does not address the underlying condition. Coupled with physical side effects of tube feeding such as pneumonia and over-hydration as well as a possible link between hospitalization and higher mortality, the reasons for forcible feeding as a form of treating anorexia nervosa do seem controversial for anorexia nervosa patients. These words sound especially tragic in the light of intriguing considerations of Zerbe (1993) and Levens (1995) that even clinicians' words are perceived by these patients as threatening; according to Zerbe (1993), they need "homeopathic" doses of therapy. Using cybernetic terms to portray the reciprocal relationship between forcible feeding and improvement of the anorexic patient's condition, one may say that the more food is given to patients compulsorily, the worse they feel (Table 104.4).

Fig. 104.3 Changes in perception of diet in restricting-type anorexics (RAs) and bulimic-type anorexics (Bas) (Reprinted from Mehran et al. 1999. With permission)

104.4.5 The Right to Die in the Case of Anorexia Nervosa?

In the context of deliberations on the chronicity of anorexia and illness-related suffering, the following question is inevitable: what is the sense of treatment and can treatment be replaced with palliative care? Draper (2000) is one researcher who has thoroughly examined the palliative care option for some anorexic patients. She maintains that abandoning treatment, however disturbing or gruesome in the case of an illness that seems easily curable, may be the only alternative for a person who refuses to be treated but cannot live without the illness either. Tan et al. (2003b) emphasize that some

patients, especially those who have been battling against anorexia for years, and some mothers, are of the opinion that if anorexia becomes chronic and does not respond to treatment, and if the sufferer exceeds a certain critical point, she should be allowed to leave. According to Manley and Leichner (2003), it is typical for a patient to experience, at one point in therapy or another, exhaustion and lack of strength to endure the struggle with the illness. As Draper (2000) says, such difficult cases are not typical, yet it should be noted that some people will never recover from anorexia or even maintain body weight stable (if low) enough to lead a normal life. Undoubtedly, when a person suffering from anorexia chooses death, this creates a serious ethical dilemma for the family and people involved in the treatment. Draper (2000) suggests that the palliative approach should be applied to patients who have been ill for a very long time (for longer than 1–8 years, i.e., the natural cycle of the illness), who have already been force-fed, are critical about making decisions concerning their own lives, are able to see the impact of anorexia on certain aspects of their lives, and whose lives are not at direct risk. According to the researcher, in such cases refusal of therapy is analogous to abandoning life-pro-longing therapy in the case of patients with disabling, chronic or acute terminal illnesses in favor of palliative treatment. When patients in full possession of their mental faculties refuse treatment, whether they are terminally ill or just choose to die, a doctor should accept the refusal (2000). An undoubtedly suggestive statement is the comparison proposed by Gans and Gunn (2003), referring to the difference between a 20-year-old woman that is secretly starving herself and a 50-year-old woman with chronic anorexia, exhausted by hospital and clinic stays and various medical appoint-ments. Gans and Gunn (2003) wonder whether there is a point when clinicians abandon hope that the patient will change her attitude and come to the conclusion that they are unable to continue in their treatment attempts that have always proved a failure? They may think this way: if no method of fully curing anorexia has been found so far, why should they hope that the next attempt is going to be suc-cessful? (Gans and Gunn 2003). Obviously, we can consider sending the patient to a better, private treatment center yet the question arises: who is going to pay for it? On the other hand, treatment of the long-term disability of anorexic patients is also expensive (Su and Birmingham 2003). Such questions seem to be highly problematic. Can we really resign from saving lives only because we feel discouraged or cannot always afford high-level therapy? Should we always do whatever is pos-sible to save somebody's life? Some researchers openly criticize the concept of palliative care of anorexic patients. Melamed et al. (2003) have no doubt that anorexia is a curable illness; frequently, therapy is only aimed at partial recovery and one must take recurrences into account, especially in chronic cases, but this is actually the reason why clinicians should focus on saving the lives of anorexic patients in the first place. The palliative care option is also considered disputable by Griffiths et al. (1997). They argue that in spite of the extreme difficulties of anorexia treatment, those who survive are deeply grateful to the doctors who have helped them. Gans and Gunn (2003) take an even more definitive stand on the issue, by saying that if an anorexic person dies, there will be no chance for recovery whatsoever.

104.4.6 Other Cases of Forcible Feeding

Forcible feeding is sometimes applied in the terminal phase of various illnesses, for example Alzheimer's disease (e.g., Sheldon 1997) or cancer (e.g., Higginson and Bruera 1996). Such patients may consistently refuse food and drink for both psychological and physical reasons. Sometimes doc-tors argue that patients who are terminally ill should be allowed to starve rather than be artificially fed. It is argued that force-feeding needlessly extends the dying phase, while starvation can offer a dignified death.

Table 104.5 Current knowledge on consequences of forcible feeding and its applications to other areas of health and disease

Current knowledge about consequences of forcible feeding	Its applications to other areas
Hunger strikes, especially among prisoners	Alzheimer's disease
Anorexia nervosa	Cancer cachexia-anorexia
	Widespread self-destructive behavior such as alcohol abuse

The behavioral implications of force-feeding in prisoners and hunger strikers may be helpful in the event of force-feeding of individuals who cannot eat for mental or bodily reasons, in the terminal phase of their disease, e.g. Alzheimer's disease or cancer cachexia-anorexia, and widespread self-destructive behavior such as alcohol abuse

Table 104.6 Key points concerning causes, problems, and consequences of forcible feeding

1. Food refusal may occur for a variety of reasons, for example it may be used as a method of exercising control over others (either at family or society level), a method of self-harm, and even committing suicide, only sometimes is it a symptom of mental illness.
2. Force-feeding always creates a difficult situation for the patient, the patient's family, as well as the hospital staff, especially physicians; however, it is sometimes essential to save a patient's life.
3. Although force-feeding, contrary to informed and voluntary refusal, is never ethically acceptable, and especially feeding accompanied by threats, coercion, force, or use of physical restraints is a form of inhuman and degrading treatment. Although previously force-fed patients, especially ones who have recovered from anorexia nervosa, are sometimes deeply grateful to the doctors who helped them, it must be underlined that using forcible feeding alone as a method of help either anorexics or self-starving prisoners may be counter-productive and may result in paradoxical effects (e.g. Brockman 1999; Draper 2000).

Food refusal may occur for a variety of reasons and it always creates a difficult situation for the patient and the social environment. In spite of the advantages of force-feeding, using it alone as a method of helping self-starving individuals may be counterproductive and may result in paradoxical effects.

104.5 Applications to Other Areas of Health and Disease

The attitude presented above may be helpful in situations described briefly in this chapter, namely in the event of force-feeding of persons, who cannot eat for mental or bodily reasons, in the terminal phase of their disease. If even in mentally and bodily healthy prisoners and generally healthy (except for the consequences of malnutrition) persons suffering from anorexia, forcible feeding may exacerbate the disease symptoms through organ damage and deepening of depression, this may also occur, but with greater intensity, in the event of patients suffering from terminal diseases. In addition, such undoubtedly self-destructive behavior as self-starvation, highlights other destructive behaviors, even those which are commonly recognized and do not qualify as mental disturbance, such as excessive alcohol consumption or nicotinism. It is worth considering whether and why only radical interventions aimed at the person's good are admissible here (Table 104.5).

104.6 Conclusion

Food refusal provokes many questions and proposed solutions. If doctors want to succeed in these difficult circumstances they should try to apply the golden mean in every situation. Both forcible feeding and such entirely different solutions as palliative care for people with anorexia or consent for a prisoner's death of malnutrition are highly inhuman; decisions in case of severe diseases such as Alzheimer's or neoplastic diseases seem to be even more difficult. In this situation, it is necessary to

clearly determine competence status in cases of anorexia whereas in prisoners, if mental disturbance is not suspected, detailed examination of mental status and exclusion of manipulation are essential in order to fulfill the requirements. Often, particularly in prisons, for example in the famous Guantanamo Bay case, force-feeding becomes one more repression or even torture technique. Of course it is not recommended to see such torture in every force-feeding event, although the prison metaphor is frequently used in existential approaches to anorexia (e.g., by Lemma-Wright 1994), but one should always carefully examine the deep-set motives underlying each case of deliberate food refusal because this is always an important message, which very rarely means a death-wish. The fact that, in spite of the extreme difficulties involved in the compulsory treatment of anorexia, survivors are very grateful to the doctors who helped them, should act as an additional incentive to undertake such efforts. This is why we should be very cautious when examining the possibility of palliative care for patients with anorexia, which in practice means permission to leave them alone. Obviously, we cannot always expect patients with anorexia, and especially prisoners, to be grateful for saving their life or to view doctors as Good Samaritans but it is always worth risking such action, knowing that we only have one life.

Summary Points

- Food refusal provokes many questions and solutions.
- Force-feeding seems to be a highly inhuman solution but is consenting to the death of another person as result of starvation not equally inhuman?
- A basic recommendation for people dealing with patients refusing food is thorough examination of their competence, which seems particularly difficult in anorexia nervosa because the capacity criteria prevailing in psychiatry are completely inadequate in case of this disease.
- You should remember that often, particularly in prisons, as for example in the famous case of Guantanamo Bay, force-feeding does not follow from the wish to help the prisoner but is yet another repression technique, sometimes a political one.
- The fact that people who refuse food are often very grateful to their doctors for saving their life (through forcible feeding among other things) should motivate us to seek the golden mean when dealing with people who refuse to eat. In this context, you should carefully examine the proposal of palliative care for people with anorexia, which practically permits us to leave them alone.

Definitions and Explanations of Key Terms

Anorexia nervosa: is a serious psychiatric disorder characterized by distorted body image, which triggers intensive self-starvation and – as a consequence – significantly diminished body weight. The very essence of this eating disorder is categorical refusal to change in conjunction with profound denial of illness.

Competence (capacity): – in psychiatry, ability to make rational decisions.

Egosyntonicity: – a phenomenon appearing in very few disorders, whose the main feature is that the afflicted person derives his or her sense of identity from the disorder.

Force-feeding: is the practice of feeding a person or an animal against their will.

Hunger strike: is a method of nonviolent resistance or pressure in which participants fast as an act of political protest, or to provoke feelings of guilt in others, usually with the objective to achieve a specific goal, such as a policy change.

Chapter 105
Psychological Stress, Diary Methods, and Eating Behavior

Daryl B. O'Connor, Fiona Jones, and Mark Conner

105.1 Introduction

A growing body of research indicates that psychological stress affects health through two distinct pathways: first, via autonomic and neuroendocrine responses; second, via changes to health behaviors (e.g., Jones and Bright 2001; O'Connor et al. 2000). Changes to dietary health behaviors such as high fat intake, or low fiber or fruit/vegetable intake may be one important mechanism whereby stress indirectly contributes to both cardiovascular disease (Van Horn and Kavey 1997) and cancer risk (Wong and Lam 1999) and is the focus of this chapter. Over the last 25 years, a large volume of research has been concerned with understanding the precise nature of the relationship between stress and eating behavior. Recent findings in this area have indicated that high levels of stress can be associated with both increased and decreased overall food intake (Wardle et al. 2000), while work on between-meal snacking has found stress to be associated with an increase in snacking in adults and adolescents (Conner et al. 1999; O'Connor and O'Connor 2004). This chapter provides an overview of research findings addressing the impact of stress on eating behavior in non-eating disordered human populations. Interested readers are also directed toward other reviews of this area by Greeno and Wing (1994), Adam and Epel (2007) and Nieuwenhuizen and Rutters (2008). Before reviewing the relevant literature, this chapter first introduces the conceptualization of stress as daily hassles and then focuses on the use of diary methods as an approach for exploring the effects of stress assessed in this way on eating behavior.

105.2 Conceptualization of Stress and Daily Hassles

Over the last 30 years, there have been three different approaches to the study of stress: the stimulus-based or engineering approach; the response-based or medicophysiological approach; and the psychological "interactional-appraisal" approach. The engineering approach views stress as a demand on an individual from their environment, which produces a strain reaction: the greater the strain the larger the reaction. This approach assumes that undemanding situations are not stressful. However, monotonous undemanding work environments very often are stressful. This engineering analogy is also

D.B. O'Connor (✉)
Institute of Psychological Sciences, University of Leeds, LS2 9JT, UK
e-mail: d.b.o'connor@leeds.ac.uk

problematic because it makes the assumption that individuals function both unconsciously and automatically, no consideration is given to the mediating psychological processes (e.g., cognitive appraisal), although such processes are very important in relation to stress. The response-based approach mainly considers stress in terms of the general physiological reaction to noxious events in a person's environment such as changes in blood pressure, heart rate, and stress hormones. Again this approach fails to take account of individual psychological processes. For this reason, much recent work has adopted a *transactional* (or interactional-appraisal) approach in order to explain the stress process. Such theories have contributed to our understanding of the variation in responses to similar noxious (or stressful) stimuli by emphasizing the importance of the intervening psychological processes.

105.2.1 Transactional Theory and the Daily Hassles and Uplifts Approach

The transactional approach was developed by Lazarus and Folkman (Lazarus and Folkman 1984). They define stress as "a particular relationship between the person and the environment that is appraised by the person as taxing or exceeding his or her resources and endangering his or her well-being" (Lazarus and Folkman 1984, p. 19). However, historically stress researchers focused their attention on the impact of life events, such as divorce, moving home, and unemployment, on physiological, psychological, and behavioral outcomes. This life events approach has been heavily criticized because of the focus on major life changes, which are comparatively rare, and ignores the fact that a great deal of stress stems from recurrent day-to-day problems or chronic conditions known as *daily hassles* (Lazarus and Folkman 1984). More specifically, daily hassles are events, thoughts, or situations which, when they occur, produce negative feelings such as annoyance, irritation, worry or frustration, and/or make you aware that your goals and plans will be more difficult or impossible to achieve (see Conner et al. 1999; DeLongis et al. 1982; Jones et al. 2007).

Lazarus (1966; Lazarus and Folkman 1984) suggested a new approach to stress based on his own Transactional Theory of Stress. Central to this theory and to his definition of stress is the notion of appraisal. In other words, stress is not a property of the environment (as implied by the life events approach), nor is it a property of the individual, rather it is a transaction between the individual and the environment. The focus is, therefore, on the process of appraisal and coping. In any potentially stressful transaction or encounter, a person may appraise the situation as involving harm or threat of harm, or alternatively they may see it in a positive, optimistic light and view it as a challenge (see Table 105.1). The type of appraisal will then determine the person's coping processes, which will in turn determine subsequent appraisals.

Table 105.1 Primary and secondary appraisal (Adapted from Lazarus and Folkman 1984)

Type of appraisal	Definition
Primary appraisal	*A person considers the quality and nature of the stimulus event. Three kinds of possible stressors*:
	1. Those which harm or lead to loss
	2. Those which threaten
	3. Those which set a challenge
Secondary appraisal	*The assessment of one's resources and abilities to cope with the stressor (coping potential)*:
	1. Internal resources (e.g. strength, determination)
	2. External (e.g. social support, money)

According to Lazarus and Folkman cognitive appraisal, which is central to their Transactional Theory of Stress, has two components – primary and secondary appraisal

This approach clearly has implications for the way stress is measured. In particular, Lazarus suggests that the search for a single satisfactory measure is "doomed to failure" (see Abraham et al. 2008). He argues that stress needs to be assessed by a series of different measures, which each capture different aspects of the stress process. Relevant measures, therefore, might include environmental inputs (e.g. daily stressors as well as life events), measures of individual differences, coping, physiological and psychological responses. A critical feature of this approach is that, because stress is a process, assessments should be repeated over time. This theory led to the development of a measure of daily stressors known as the Hassles Scale (e.g., Kanner et al. 1981) and subsequently a shorter Hassles and Uplifts Scale (DeLongis et al. 1982). Research informed by the Transactional theory has been associated with a growth in the use of daily assessments to tap the stress process. This typically uses "daily diaries," which contain rating scales, such as the Hassles scale as well as other formats that use open-ended free responses.

105.3 Diary Methods and Eating Behavior

As you will discover later in this chapter, research into the impact of stress on eating behavior has been overly reliant on laboratory-based, cross-sectional methodologies that have used single indices (i.e., assessed stressful life events over the previous year or 5 years) or "snap-shot" measurements of stress (i.e., assessed perceptions of stress over the past 2 weeks). Such approaches have ignored Transactional theory and the evidence showing that fluctuations in within-person stressful daily hassles are important in understanding stress-outcome processes. An early example of this approach comes from Kanner and colleagues (1981) who suggested that indices of (life) stress provide no understanding of what actually happens in day-to-day life and it is "day-to-day events that ultimately have proximal significance for health outcomes and whose accumulative impact…. should be assessed" (p. 3). The use of open-ended daily diaries allow respondents to record day-to-day minor life events or hassles that are part of everyday life and have the advantage of not constraining respondents to a limited number of events. There are essentially three different diary method protocols as shown in Table 105.2.

Table 105.2 Key features of different types of diary methods

Type of diary method	Description
Interval-contingent	The participant completes diary at prespecified intervals (e.g., end of each day). For example, if we wanted to know whether psychological stress on one day "predicts" symptom "flare-ups" on the next day in psoriasis patients. Interval-contingent protocols are especially useful for frequent behaviors without a definitive start and end
Event-contingent	The participant completes diary each time a specific event happens. For example, if we were interested in investigating whether the act of smoking moderates daily mood. Event-contingent protocols are especially useful to estimate event prevalence
Signal-contingent	The patient completes diary in response to random "alarms" or "beeps" from a palmtop computer or similar device. For example, if we wanted to establish whether negative mood is associated with the onset of pain episodes in arthritis patients. Signal-contingent protocols are especially useful for recording data on the distribution, frequency, and duration of events

Researchers have used three different diary method protocols. Each method varies according to the number and when each observation is recorded on a daily basis

105.3.1 How Should Diary Studies Be Analyzed?

The data from diary methods are essentially hierarchical as a consequence of the sampling and experimental procedures. As such multilevel modeling procedures are used to examine such data. If we wanted to know whether daily hassles influence eating behavior and whether this relationship is moderated by personality, we would set up a multilevel model at two levels. Level-1 would be the daily variation in daily hassles and eating behavior (within-subject variation) and Level-2 would be the between-subject variation in personality (e.g., O'Connor et al. 2008; Jones et al. 2007). In multilevel modeling, the outputs at one level (regression coefficients) become the parameters that are modeled/analyzed at the next level. Multilevel modeling should be used with hierarchical data sets to avoid certain erroneous conclusions based on the *ecological fallacy* (see below) and also to produce more accurate estimates of standard errors. Multilevel modeling procedures can be used to examine data with repeated assessments and physiological data. For a detailed introduction to multilevel modeling procedures, see Kreft and De Leeuw (2006).

105.3.2 Ecological Fallacy

The ecological fallacy is based on the inappropriate assumption that relationships at one level in a hierarchy apply at another. The problem occurs where people assume that relationships that are shown based on data for a group of people are necessarily true for individuals within the group. For example, imagine the Prime Minister finds that when considering the UK as a whole (i.e., country level), increasing per capita income is associated with reduced crime rates. If she/he draws the inference, at individual level, that increases in personal income will be related to improvements in crime rates, then he may be in danger of committing the ecological fallacy, given that within the UK (hypothetically speaking), higher crime rates may always be greater in individuals with lower incomes compared to individuals with higher incomes. Within the context of psychological research, the same problem can arise if we draw within-person inferences based upon aggregated data units from across-person associations. For example, the relationship between stress levels at an organizational level and job control may be negative indicating that higher job control is associated with lower stress. However, within the organization, this inference may fail to account for the employees who will always experience greater levels of stress when they have higher control over their job compared to employees with lower control.

105.3.3 Benefits of Using Diary Methods

There are a number of benefits of using diary methods. These are best summarized in the words of Affleck and colleagues (1999) who argue that daily diary studies allow researchers "(a) to capture as closely as possible the 'real-time' occurrences or moments of change (in study variables); (b) to reduce recall bias; (c) to mitigate some forms of confounding by using participants as their own controls, and (d) to establish temporal precedence to strengthen causal inferences" (p. 747). Diary methods can also be used not just to record on-going behavior patterns but also to examine how the covariation between patterns of behavior (e.g., stress and diet) varies as a function of an intervention. Moreover, using daily diaries permit researchers to use sophisticated statistical techniques (e.g., multilevel modeling) to examine day-to-day within-person effects *together* with the impact of between-person factors such as personality or gender (see Ferguson 2005 for a detailed review).

105.4 The Impact of Different Types of Stressors on Eating Behavior

As outlined in the Introduction, stress has been found to be associated with both increased and decreased overall food intake, However, less work has explored the impact of different types of stressors and whether some serve as key moderators of eating behavior, while others have little or no effect. A number of different types of stressors have been identified in this literature and these are summarized in Table 105.3.

Previous research has found stressors of an ego-threatening nature to have distinct effects from those that elicit physical fear. Heatherton and colleagues (1991, 1992) suggest that situations involving potential negative evaluation or task failure (ego-threatening) will lead to disinhibition (overeating) in restrained eaters or current dieters whereas physically threatening situations will not. In contrast, these authors found that fear of an electric shock led to a reduction in food intake in unrestrained participants. Moreover, the impact of interpersonal stress has also been investigated (e.g. Oliver et al. 2001; Tanofsky-Kraff et al. 2000). Tanofsky-Kraff and colleagues (2000) compared the effects of interpersonal stress with ego- and physically threatening stress on eating and found that in the interpersonal stress group, individuals with high levels of restraint consumed the most food.

More recently, using laboratory methods, Lattimore and Caswell (2004) and Wallis and Hetherington (2004) have also highlighted the importance of taking into account different types of stressors together with eating style variables (e.g., restraint, emotional eating). In particular, Wallis and Hetherington (2004) showed that cognitively demanding stressors (such as the incongruent Stroop task) as well as ego threats have the capacity to increase food intake. The incongruent Stroop task was found to increase chocolate intake by 15% relative to control. Moreover, dietary restraint was associated with greater intake after the cognitively demanding stressor as well as an ego-threatening stressor compared to the control condition. In contrast, emotional eating was related to greater intake only after the ego threat, relative to control. Wallis and Hetherington argue that their findings reveal differential effects of ego-threat and cognitive demand on stress-related eating in restrained and emotional eaters. The importance of distinguishing between psychological (e.g., reaction time tasks, delivering a speech) and physical stressors (e.g., the cold pressor task) has also been demonstrated by Lattimore and Caswell (2004) when considering stress–eating relations. These authors have suggested that reaction time tasks require active coping whereas cold pressor tasks require passive coping. Within this context, active coping involves a behavioral response where an individual is able to influence the outcome of a task. Passive coping involves passive sensory intake with no opportunity to influence the outcome of a task. In their study, Lattimore and Caswell (2004) found that restrained eaters consumed more than unrestrained following the active coping stressor

Table 105.3 Main different types of stressors/hassles

Type of stressor/hassle	Definition of stressor/hassle
Ego-threatening	Stress associated with a fear of failure and/or negative evaluation (e.g., sitting an exam)
Interpersonal	Stress associated with feeling a sense of social alienation and being interpersonally ill-equipped (e.g., argument with partner)
Physically threatening	Stress associated with threat of facing physical harm (e.g., fear of an electric shock).
Work-related	Stress associated with the work environment and work-related tasks (e.g., meeting a deadline)

Previous research has identified a number of types of stressors/hassles, which impact on individuals in different ways. For example, physically threatening stressors have been found to be associated with a reduction in food intake, whereas, ego-threatening stressors have been found to be linked with an increase in food intake

compared to the passive coping stressor and to a relaxation condition. Moreover, consistent with Wallis and Hetherington (2004), these findings indicated that stressors, which are cognitively demanding, but do not have an ego-threatening or social evaluation element, still have the capacity to induce increases in food intake.

As highlighted earlier, a large proportion of the previous research into the effects of stress on eating behavior has relied upon cross-sectional, laboratory-based methodologies. One of the few exceptions is a recent open-ended diary study that found strong evidence for the moderating effects of different types of daily hassles on the stress-snacking relationship (O'Connor et al. 2008). Ego-threatening, interpersonal, and work-related hassles were found to elicit a hyperphagic response, whereas, physical hassles were found to elicit a hypophagic response. The latter findings confirm the work by Heatherton et al. (1991) and demonstrate that the differential effects of stressors observed in the laboratory are generalizable to naturalistic settings. In contrast to earlier findings, this research also identified work-related hassles, and not ego-threatening or interpersonal hassles, as the type of hassles that exerted the strongest effects on between-meal snacking (cf., Heatherton et al. 1991, 1992; Oliver et al. 2001; Tanofsky-Kraff et al. 2000). Moreover, it is important to highlight that these effects were not limited to vulnerable individuals who were inhibiting their food intake per se (e.g., restrained eaters) as they have been elsewhere (Heatherton et al. 1991; Wardle et al. 2000). Instead, these results clearly show that daily hassles can directly influence snack food intake.

105.4.1 Work Stressors

The above evidence suggests the importance of the work environment and work hassles for health behavior. However, despite the well-established importance of health behavior for psychological and physical well-being (see Abraham et al. 2008), there is relatively little research on the relationship between work stress and healthy eating compared to other health behaviors and even less using a diary approach. Much of the research that does exist has been based on the Job Strain model (Karasek and Theorell 1990) or the expanded Demand, Control, Support model (Johnson and Hall 1988), which suggests that relatively stable characteristics of work, in terms of job demands and job control (and support) predict strain outcomes. A number of studies have examined the relationships between these variables and healthy eating and/or body mass index (e.g., Hellerstedt and Jeffery 1997; Lallukka et al. 2004). Within these studies, relationships are often complex and frequently differ for men and women. For example, Hellerstedt and Jeffery (1997) found that men in high-strain jobs reported consuming more calories from high-fat foods (based on an 18-item food frequency questionnaire) than did men in low-strain jobs. In contrast, Lalluka et al. found that high-strain work was associated with eating (smoking and physical activity) for women only. Some studies have found no effects, for example, Overgaard, Gyntelberg, and Heitmann (2004) reviewed evidence in relation to obesity and found little evidence to support a link between job strain and body mass index. Occasionally, reverse effects have also been found. For example, Niedhammer et al. (1998) found that men with high control and high social support at work weighed more than those with low control and support.

Some of these conflicting findings may be explained by variations between the occupational samples used and the moderating effects of other features of work. Healthy behaviors require maintenance on a regular, often daily basis and may be disrupted (or encouraged) by a range of more proximal influences arising from both work and nonwork. The Job Strain and Demand, Control, Support approaches are designed to tap relatively objective and stable job characteristics

and, therefore, do not take into account individual daily variations in factors such as perceptions of hassles, mood, or working hours. With the exception of O'Connor et al. (2008), discussed above, few studies have investigated the impact of work-related hassles on eating behavior on a within-subject basis. However, Steptoe, Lipsey, and Wardle (1998) looked at daily hassles in a sample of teachers and nurses and found that fast food was eaten more frequently in weeks that were rated higher in perceived stress in which greater numbers of work- and home-related hassles were experienced.

Work stress has also sometimes been conceptualized in terms of length of work hours. In a review of effects of work hours on health, Van der Hulst (2003) found links between work hours and a number of health behaviors but no evidence of links between work hours and snacking. However, she only reviewed two studies that addressed this (Nakamura et al. 1998; Nakanishi et al. 1999). These studies were inconsistent with research by Wardle et al. (2000) who looked at employees working in a large department store. They found that periods of high work stress (measured in terms of long work hours) were associated with greater calorific energy, saturated fat, and sugar intake compared to periods of low stress (shorter hours). Work hours have also been examined in relation to body mass index. Six such studies were included in Van der Hulst's (2003) review. Findings were inconclusive, with only two studies reporting significant effects, one of which was in a positive direction (Emdad et al. 1998) and the other negative (Nakanishi et al. 1999).

More recently, Jones et al. (2007) looked at hours worked (as well as using measures of the psychosocial work environment such as demands and control) and found that long work hours were associated with greater consumption of high-fat and high-sugar between-meal snacks in women only, whereas higher levels of negative mood were linked to snack intake in men. These differential findings for men and women are likely to be explained by the fact that women often have greater family responsibilities, which leaves less scope for self-care on long work days. In addition, these results highlight the need for researchers to consider the fact that the impact of stress on eating behavior operates differently for men and women, an issue we return to later within the context of moderators of the stress–eating behavior relationship.

Long work hours, together with a range of other factors such as a rise in dual career families, changes in work technologies (computers and mobile phones), and a demand for 24-h services have resulted in a trend toward the erosion of work–home boundaries (Major and Germano 2006). Thus, there are increasing concerns about a lack of work–life balance and greater reports of work–family conflict. Such conflict between work and home is a well-established predictor of a range of negative outcomes, including physical and psychological symptomatology. Conflict is a bidirectional phenomenon, whereby work may interfere with home and family life or family concerns may interfere with work life. However, evidence suggests that work-to-family conflict is more prevalent than family-to-work conflict (Hammer et al. 2004). Work–home conflict is typically conceptualized in terms of time-based conflict, where the time spent in one domain reduces time available to spend in the other, and strain-based conflict, where strain experienced in one domain impinges on the other. It is highly plausible that lack of time due to work hours will impact on ability to prepare nutritious food, and strains such as tiredness and preoccupation with work worries will lead to alterations in eating patterns. It is, therefore, surprising that there is little research on these issues. However, one notable exception is a study by Allen and Armstrong (2006), which looked at work interference with family and family interference with work for a range of eating variables. They found that work interference with family was related to eating fewer healthy foods while family interference with work was linked to eating more high-fat foods. While not directly focusing on eating behavior, Grzywacz (2000) also found that work interference with family was linked to obesity; however, in this study there were no effects for family interference with work.

105.5 Moderators of Stress–Eating Behavior Relationship

A number of moderators of the stress–eating relationship have been examined (e.g. the obese, restrained eaters, women; Greeno and Wing 1994; O'Connor et al. 2008) and these are summarized in Table 105.4.

The individual differences model of stress–eating relationships (Greeno and Wing 1994) suggests that differences in learning history, attitudes toward eating, or biology produce variations in vulnerability to the effects of stress. Those exhibiting vulnerability are assumed to respond to stress by changing their eating behavior. In contrast, those with low vulnerability are assumed to not respond to stress in a way that influences eating. A number of vulnerable groups have been proposed and the research supporting such vulnerability is reviewed next. These groups include differences between: the obese and nonobese; the restrained (i.e., those attempting to control their food intake or dieters) and unrestrained; women and men; emotional and nonemotional eaters.

105.5.1 Obese Versus Nonobese

Initial interest in the effect of stress on eating in humans began as an attempt to understand obesity. It was suggested that overweight individuals were more likely to respond to stressful or emotional stimuli by eating (Stunkard 1959). Such views arose from psychosomatic views of obesity, which suggested that obese individuals did not learn to distinguish between hunger and anxiety (Kaplan and Kaplan 1957). Such individuals were assumed to respond to stress as if it were hunger (i.e., by eating) rather than anxiety. In contrast, Schachter et al. (1968) suggested that unlike normal-weight individuals, obese individuals had not learned to label various physiological cues (e.g., gastric contractions) as hunger and that these cues reduce under stress. Therefore, the prediction was that stress should produce a reduction in hunger and eating in normal-weight individuals but have no impact on the feelings of hunger and eating behavior in the obese. Despite the clear and contrasting predictions of these two views, the evidence in support of each is disappointing.

Greeno and Wing (1994) reviewed 11 studies that addressed the effect of stress on eating in obese and nonobese groups. Schachter et al. (1968) produced the first laboratory test of this effect: anticipating a painful compared to a mild shock (high versus low stress) produced a decrease in eating in

Table 105.4 Main moderators of the stress–eating relationship

Moderator	Main issue
Obese status	Do obese individuals respond differently to stress compared to nonobese individuals?
Restraint	Do individuals who restrict their food intake through self-control processes respond differently to stress compared to those who do not?
Gender	Do males respond differently to stress compared to females
Emotional eating	Do individuals who have a tendency to eat more when anxious or emotionally aroused respond differently to stress compared to nonemotional eaters?
External eating	Do individuals who are more responsive to food cues in their environment respond differently to stress compared to internal eaters?
Disinhibition	Do individuals who have a tendency to overeat respond differently to stress compared to those who do not?

A moderating variable changes the impact of one variable (independent variable) on another variable (dependent variable). The main moderators of the stress–eating relationship are listed here

normal-weight participants, but had no effect on obese participants. This finding is consistent with the Schachter et al. model outlined above. However, only one of the other ten tests of this hypothesis reviewed produced a similar decrease in consumption in normal-weight individuals. Support for the psychosomatic account has also been mixed. Of the 11 studies reviewed by Greeno and Wing (1994), three demonstrated an increase in eating for obese individuals when stressed, three studies found that some obese individuals eat more when stressed; however, five further studies failed to find a relationship between stress and eating in obese individuals. Taken together, this is only relatively modest support for the psychosomatic account of stress–eating relationships in the obese. In addition, those studies only finding partial support for the psychosomatic account suggest an alternative interpretation of these relationships. For example, Baucom and Aiken (1981) demonstrated that rather than obesity it was dieting that was the key predictor of stress-related eating in their study. For both obese and non-obese groups, stress only produced increases in eating in the dieting group. Given the fact that many obese individuals are dieting in an attempt to control their weight, the failure to control for dieting may explain the contradictory findings across studies in the impacts of stress on eating in the obese. In effect, it may be the fact that dieting is more prevalent in the obese than the nonobese, which explains why stress leads to greater eating in the obese compared to the nonobese group.

105.5.2 Restrained Versus Unrestrained

The concept of restrained eating developed from the "set point" theory of obesity (Herman and Polivy 1975). Restrained eaters are assumed to restrict their food intake through self-control processes. When these self-control processes are undermined, disinhibition of eating occurs, and excessive food intake takes place. For example, restrained eaters appear not to adjust their food intake for previous food intake (Herman and Mack 1975). Unrestrained eaters adjust for consuming a "preload" of food by eating less in a subsequent eating test; restrained eaters do not appear to perform this adjustment and eat just as much as if they had not eaten the preload. It is believed that the preload disinhibits the restraint over eating they normally show. Stress is also expected to affect restrained eaters through disrupting the control normally exerted over eating. Thus, individuals with high restraint scores should be more likely to respond to stress by eating, while those low in restraint should show no change. Heatherton et al. (1991) and Schotte et al. (1990) both compared high- and low-restrained eaters, and found that not only did restrained women eat more than unrestrained women, but restrained women who were stressed, ate more than restrained women who were not stressed. A number of other studies have also produced consistent results (see Greeno and Wing 1994; see also Adam and Epel 2007 for a useful recent review); stress produces greater increases in eating in restrained compared to unrestrained eaters. However, the majority of studies to date have only demonstrated this effect in college-aged women. Interestingly, Wardle et al. (2000) showed that work stress lead to increased eating in both restrained women and restrained men.

105.5.3 Women Versus Men

Several studies have looked at differences between female and male eating in response to stress. For example, Grunberg and Straub (1992) examined differences between women and men vulnerable to stress-induced eating. Sweet, salty, and bland foods were provided for participants while watching a video, and for half the subjects the video was unpleasant (i.e., stress inducing). Results showed that

unstressed men consumed significantly more food than any other group. However, stressed women did consume twice as much sweet food as unstressed women, suggesting the importance of food type, at least in women. Although stress generally reduced eating in men, this effect was not significant. Furthermore, some studies have failed to show gender differences. For example, Stone and Brownell (1994) examined the relationship between stress and eating for married couples, who completed daily records of stress and eating. Results showed that both men and women were likely to eat less than usual in response to stress, and the tendency to eat less with an increasing severity of stress was particularly pronounced in women. It is not clear why increased levels of stress were associated with decreased rather than increased eating in this sample. Using a similar design, O'Connor et al. (2008) reported that stress was more strongly associated with between-meal snacking in women compared to men. Interestingly stress was associated with a reduction in consumption of food at meals in this study suggesting that the nature of the eating behavior examined may be key in determining whether stress decreases, increases, or has no effect on amount eaten.

105.5.4 Emotional Versus Nonemotional Eaters

Emotional eating refers to a tendency to eat more when anxious or emotionally aroused compared to nonemotional eaters who do not show such reactivity to emotion in their eating habits. Emotional eating is found to be generally higher in women than men (Van Strien et al. 1986). Stress is assumed to lead to increased eating in emotional eaters because they fail to distinguish between anxiety and hunger (i.e., they respond to stress as if it were hunger), while not affecting those low in emotional eating. The origins in psychosomatic approaches to understanding stress–eating relationships discussed earlier in relation to understanding obesity should be clear. Psychometric measures of emotional eating have been developed (e.g., Van Strien et al. 1986). Van Strien and colleagues (1986) found that stressful life events predicted weight gain in men over a period of 18 months, but only among those who were emotional eaters. In women, stress led to weight gain irrespective of their level of emotional eating. Other studies have reported a limited or lack of impact (e.g., Conner et al. 1999) of emotional eating on stress–eating relationships. More recently O'Connor et al. (2008) reported a strong impact of emotional eating on stress–eating behavior relationships. However, given the limited number of published studies with emotional eating, its impact on stress–eating relationships remains an issue for further study.

105.5.5 Multiple Moderators

A key issue that the above review reveals is the need for integration of the effects of the different moderators of the stress–eating relationship. This is particularly important given the known interrelationship of the various moderators. For example, restrained eaters are reported to be more likely also to be emotional eaters (Weissenburger et al. 1986) and external eaters (Heatherton and Baumeister 1991). One recent large-scale study has focused on testing the above moderators simultaneously. O'Connor et al. (2008) used a daily diary study to compare eating behavior on high- and low-stress days in a sample of 422 workers over 28 consecutive days. Stress was assessed in terms of number of hassles reported while the eating behavior was number of between-meal snacks consumed. Number of snacks was significantly positively correlated with number of hassles. Multilevel modeling indicated that, consistent with previous findings, restraint, emotional eating, external eating, disinhibition,
Fig. 105.1 The effects of low conscientiousness and diet status on changes in between-meal snacking. Low consci-
entiousness individuals who were currently trying to lose weight reported eating more between-meal snacks than usual
during the stressful period compared to the nonstressful period. Results are expressed as mean ± SEM, total *n* = 131
(Adapted from O'Connor and O'Connor 2004)

gender, and obesity all individually moderated the relationship between daily hassles and number of
between-meal snacks in a direction consistent with previous research. However, when considered
simultaneously only emotional eating emerged as a significant moderator of the stress–eating rela-
tionship. Moreover, an earlier study pointed toward the possibility that different moderators may
interact. For example, O'Connor and O'Connor (2004) showed that low conscientious (i.e., moderator 1)
individuals who were currently trying to lose weight (i.e., moderator 2) reported eating significantly
more between-meal snacks during a stressful period compared to a nonstressful period (see
Fig. 105.1). Taken together, these findings suggest the need for further studies to examine the simul-
taneous and interactive effects of multiple moderators of the stress–eating relationship using different
research designs. In addition, they highlight the value of further exploration of the influence of higher
order personality factors such as conscientiousness. Recent evidence suggests that conscientiousness
and its facets may influence health status directly via changes in eating behavior and indirectly
through influencing stress–eating behavior relations (see O'Connor et al. 2009).

105.6 Applications to Other Areas of Health and Disease

The research reviewed here has potential application to a number of other areas of health and disease.
For example, exploration of the impacts of stress on other health behaviors represents an important
application for this work. Given the potentially strong relationship between stress and various health
and disease outcomes we need to know more about these behavioral mediators. For example, is the
impact of stress on dietary behaviors more or less important than potential effects on exercise, smoking,
or drinking behavior (Jones et al. 2007) in relation to various health outcomes? These questions point
to the need to simultaneously consider the impacts of stress on multiple health-related behaviors. For
example, stress may simultaneously promote both health-protective and health-risking behaviors. In
addition, the methodologies developed in this area in relation to studying hassles through the use of
diary studies may have widespread application to understanding various other influences on health
and disease. This is an idea we develop further in the final section.

105.7   Conclusions and Future Directions

This review of research on the effects of stress on eating behavior indicates the considerable evidence that the impact of stress on eating behavior is an important pathway through which stress impacts on health outcomes. Stress can be associated with overall increases or decreases to the amount eaten as well as changes in the patterns of eating. The nature of the eating behavior and the stressor are crucial in determining the nature of the relationship. Considerable recent research has shown how stress is associated with *increases* in the consumption of high-fat and high-sugar foods particularly when consumed as fast food or between-meal snacks (e.g., O'Connor et al. 2008; Steptoe et al. 1998). Future research could usefully explore the impacts of stress on a broader range of eating behaviors simultaneously (e.g., meals and snacks) and use more precise measurements of food intake (e.g., 24-h recall). In relation to the stressor, ego-threatening, work, and interpersonal stressors appear to be particularly associated with increased eating (e.g., Wallis and Hetherington 2004), while physically threatening stressors are generally associated with decreased eating (e.g., O'Connor et al. 2008). Understanding of the stress–eating behavior relationship is further complicated by the presence of various important moderating effects. Here, evidence particularly suggests that stress–eating relationships are strongest among individuals high in restraint, disinhibition, external eating, or emotional eating. Only one significant study has considered these moderators simultaneously and this study identified emotional eating as the preeminent moderating variable (O'Connor et al. 2008). Future research could usefully replicate this simultaneous assessment of the effects of various moderators given their intercorrelation.

In addition to pursuing carefully designed studies in the laboratory, future research in this area should also consider using innovative multilevel, daily diary methods in the real world. Daily diary techniques can use interval-contingent (i.e., assessments completed at the end of each day), event-contingent, (i.e., assessments completed in response to an event), or signal-contingent methods (i.e., assessments completed in response to random alarms or beeps from a palmtop computer) in exploring interrelationships among important variables in real-world settings. In such designs, participants complete diaries at a fixed time point (e.g., evening), during each day triggered by stressful encounters, or in response to random signals. This methodology facilitates the use of the powerful multilevel random coefficient modeling techniques. This approach provides accurate analyses of multilevel data structures and allows the modeling of day-to-day within-person effects together with the impact of between-person factors such as potential vulnerability variables (emotional eating, restraint).

Future researchers might also usefully consider utilizing the day reconstruction method introduced recently by Kahneman and colleagues (2004). This method is a structured recall technique that enables participants to recall events, mood, and well-being indicators over the previous day. For example, Stone et al. (2006) have used the daily reconstruction method to explore the diurnal rhythms of emotions in a large-scale investigation and identified a number of specific patterns, which have not previously been observed. They argue that diary methods are frequently expensive, are associated with a heavy participant burden, and possibly interfere with daily activities. However, the daily reconstruction method does not allow us to investigate causal relations between study variables.

A final important area for development is exploration of the psychological and biological mechanisms underlying the stress–eating relationship. These mechanisms are likely to be complex to account for the complexity of findings reported. Interesting research has focused on various attentional biases that might explain some of these effects (e.g., Newman et al. 2008; Tapper et al. 2008). Advances are also being made in relation to understanding the biological mechanisms. For example, differences in cortisol reactivity appear to offer one explanation of some moderating effects on the stress–eating relationship (Fig. 105.2; Newman et al. 2007). However, further careful assessment of daily fluctuations in cortisol levels in relation to changing stress levels is required to clarify the
Fig. 105.2 Cortisol reactivity profiles of high and low reactors during a laboratory stress challenge. This figure shows individual differences in the cortisol response to stress that might represent a biological moderator of the stress–eating relationship. Results are expressed as mean ± SEM, *n* = 50 (Adapted from Newman et al. 2007)

importance of this pathway. Moreover, several of the studies reviewed here also point to diathesis–stress mechanisms that suggest that psychological vulnerabilities, when activated by stress, may result in negative outcomes. For example, coping styles (the behavioral and cognitive responses individuals use when they encounter stress), in particular, have been shown to have well-established moderating effects on an individual's response to a stressful encounter (cf., O'Connor and O'Connor 2004). It would, therefore, be beneficial for future research to assess the psychological factors (e.g., coping) associated with the cortisol response to stress and test whether this differs according to stressor type (e.g., ego-threatening, interpersonal, work-related).

Summary Points

- Research into the relationship between stress and eating has been dominated by laboratory studies using experimental designs and cross-sectional surveys. Such designs capture differences between individuals in the effect of stress on eating. Eating is a behavior that varies within an individual on a day-to-day basis and is affected by factors such as daily hassles, which may similarly vary within the individual. Daily diary methods are appropriate to capture these effects.
- Multilevel modeling approaches using diary methodology allow researchers to examine the impact of such daily fluctuations in stressors on eating behaviors, together with the between-subject effects of moderators such as gender or individual differences.
- Different types of stressor have different effects on eating. In particular physical threats seem to lead to a reduction in food intake whereas other types of stressors e.g. ego-threatening, interpersonal, and work-related are more likely to lead to an increase in food intake, particularly for those who are susceptible to stress-related eating.
- Daily stressors in the work environment, including long work hours have negative impact on eating, typically these lead to increases in fatty food consumption or greater consumption of fast food.
- The effect of stress on eating behavior is moderated by a range of factors, e.g. gender, obesity, and eating styles. The only study to examine a range of these moderators simultaneously found that emotional eating was the principal moderator.

Key Terms

Psychological stress: Stress is the condition that results when person/environment transactions lead the individual to perceive a discrepancy – whether real or not – between the demands of a situation and the resources of the person's biological or social systems.

Daily hassles: Hassles are events, thoughts, or situations which, when they occur, produce negative feelings such as annoyance, irritation, worry or frustration, and/or make you aware that your goals and plans will be more difficult or impossible to achieve.

Diary methods: Diaries allow respondents to record day-to-day minor life events or hassles that are part of everyday life and have the advantage of not constraining respondents to a limited number of events.

Multilevel modeling: This is a statistical technique that allows the researcher to examine day-to-day within-person effects *together* with the impact of between-person factors such as personality or gender.

Moderating variable: Moderators change the nature of the relationship between two variables, e.g., the stress–eating relationship. They may alter either the strength or direction of this relationship. For example, dietary restraint would be described as moderating the relationship between stress and between-meal snacking.

Chapter 106
Parental Restriction and Their Children's Food Choices and Intake

Harriëtte M. Snoek

Keywords Parenting • Child • Eating behaviour • Restriction

106.1 Introduction

The environment in which children grow up largely shapes the child's food preferences, since children like and eat what is familiar to them (Fisher and Birch 2002), what is available, and what their parents eat (Ritchie et al. 2005). This has an influence on the rest of the children's lives, since dietary habits formed in childhood are likely to persist into adulthood (Klesges et al. 1991; Kelder et al. 1994; Clark et al. 2007). Food habits during childhood and the family context are therefore widely assumed to be crucial in the establishment of healthy dietary habits (Wardle 1995). These parental influences are transmitted in several ways. Firstly, weight status, food choices, food preferences, and eating behaviors "aggregate" within families (Faith et al. 2004b; Rankinen and Bouchard 2006), which suggests modeling of all these factors. Secondly, parents can influence their children through food-related parenting practices, and these food-related parenting behaviors occur within the context of parents' general parenting styles. (See Table 106.1 for definitions of general and food-related parenting practices.) Parents also have a more direct influence on their offspring by making certain foods available and accessible and reducing access to other foods (Ritchie et al. 2005). Finally, biological parents shape their child's genetic makeup. The focus of this chapter is on general and food-related parenting behaviors (especially parental control and restriction) and their relation to childrens and adolescents' food intake.

106.2 General Parenting

General parenting style is the context in which parenting practices occur, and it is often operationalized by the dimensions control and support (Baumrind 1971). The control dimension varies from supervision and monitoring to more manipulatively suppressive control, while the support dimension refers to the affective and supportive behavior of parents (Lamborn et al. 1991; Finkenauer et al. 2005). Those two dimensions have been related to children's behaviors, including health risk behaviors and internalizing problem behaviors (Maccoby and Martin 1983).

Generally, behavioral control (active supervision of, and acquiring knowledge about, what children are doing) was found to be a protective factor for problem behavior while psychological control (harsh, suppressive, and manipulating control including behaviors such as guilt induction, love withdrawal, and excessive pressure for change) was a risk factor (Finkenauer et al. 2005). Furthermore, psychological control is suppressive and authoritarian and therefore more likely to undermine the child's autonomy and ability to self-regulate food intake. Parental support on the other hand has been associated with less problem behavior and emotional problems in children (Finkenauer et al. 2005). The support and control dimensions can also be combined into four parenting styles (see Table 106.2). An authoritative parenting style (high control, high support) is considered preferable to an authoritarian (high control, low support), permissive (high support, low control), or neglectful (low support, low control) parenting style in terms of child behavioral outcomes.

Studies on food intake, weight, and eating problems are generally in line with these findings. Lack of parental support and parental caring have been related to disordered eating and body dissatisfaction (McVey et al. 2002; Littleton and Ollendick 2003) as well as obesity (Lissau and Sorensen 1994). An authoritarian feeding style has been related to a higher fruits and vegetables consumption and (Kremers et al. 2003) and lower overweight status compared to the other parenting styles (Rhee et al. 2006). However, results are inconclusive as some studies found only weak and mostly insignifi-

Table 106.1 Definitions and explanations of key terms

General parenting	
Support	Affective and supportive behaviors and responsiveness of parents
Behavioral control	Active supervision of, and acquiring knowledge about, what children are doing
Psychological control	Harsh, suppressive, and manipulating control including behaviors such as guilt induction, love withdrawal, and excessive pressure for change
Food-related parenting	
Restriction	Parents' attempt to control their children's eating by restricting access to foods
Monitoring	Extent to which parents report watching their children's consumption of (energy-dense) foods
Pressure to eat	Prompting, pressure, or encouragement to eat more healthy foods or more food in general, particularly at mealtimes
Instrumental feeding	Using food as reward, bribe, comfort, etc.

Definition of general parenting practices and most commonly studied food-related parenting practices

Table 106.2 Parenting styles defined by the two parenting dimensions

		Support or responsiveness	
		Low (rejecting, unresponsive)	High (accepting, responsive)
Control	**Low (undemanding)**	Neglectful	Authoritarian
	High (demanding)	Permissive	Authoritative

As described in Maccoby and Martin (1983, p. 39) the dimensions of parental support and parental control can be combined into four parenting styles
Fig. 106.1 Percentages of parents in the four categories of parenting styles (Đ, authoritative; , authoritarian; , indulgent; , neglectful) in the four countries. Data were derived from the cross-sectional study of the Pro Children project, October–December 2003. Most parents used an authoritative or neglectful parenting style although percentages differed between the four European countries (Reprinted from de Bourdeaudhuij et al. 2009, p. 261. With permission)

cant associations between general parenting style and fruit and vegetable intake. For example a study by de Bourdeaudhuij et al. (2009) measured parenting styles in four European countries. Most parents used an authoritative or neglectful parenting style (see Fig. 106.1) although percentages differed between countries. However, no differences were found in fruit and vegetable intake of children with the parenting style of their parents.

In summary, surprisingly few studies addressed the association between general parenting style and food intake and the current results are inconclusive. A number of those addressed parenting styles rather than the separate dimensions (support and control), which has the advantage that interplay between the dimensions is taken into account. However, when focusing on parental control, this further complicates conclusions on the effectiveness and desirability of a controlling parenting style. Overall, there is still some way to go before we can conclude on whether general parental control is related to a healthier food pattern.

106.3 Food-related Parenting

General feeding style and feeding practices are related. For example, a permissive parenting style has been related to lower monitoring of children's unhealthy food intake (Blissett and Haycraft 2008). Most studies, however, address either general parenting or food-related parenting. Similar terms as with general parenting styles have been used to translate food-related behaviors into feeding styles. An authoritative feeding style was defined as the balance between an authoritarian (control with little regard for the child's choices and preferences) and permissive (no active involvement of parents in type or amount of food eating) feeding style. This style has been related to a more healthy food pattern in preschool children (Patrick et al. 2005). In line with this O'Connor et al. (2009) found three clusters of parents with regard to parenting practices specific to fruit and vegetable intake. Next to the permissive (low control in general) and high controlling groups one cluster of parents scored
Fig. 106.2 Reported use (proportion) of each parenting practice category by K-means derived parenting practices cluster: Head Start preschool children and their parents in Houston, Texas and northern Alabama, 2004–2005. Based on the different parenting practices, three clusters were identified: permissive (low control in general), high controlling (high on control in general) and nondirective (high on most parenting practices which exception of the firm discipline). This third cluster was most strongly related to fruit and vegetable intake (Reprinted from O'Connor et al. 2009, p. 7. With permission)

high on most parenting practices which exception of the firm discipline (see Fig. 106.2). As expected this cluster was most strongly related to fruit and vegetable intake although the relation was no longer significant after controlling for parental intake.

The majority of research on food-related parenting focuses on three types of control of food intake (again sometimes also named feeding styles): Pressure to eat, restriction, and monitoring. Most of these studies further focused on preschool and primary age children (Clark et al. 2007). Restriction over food intake is the parents' attempt to control their children's eating by restricting access to foods. Pressure to eat refers to prompting, pressure, or encouragement to eat more healthy foods or more food in general, particularly at mealtimes. Finally, monitoring food intake is the extent to which parents report watching their children's consumption of (energy-dense) foods.

A series of experiments by Birch and Fisher in young children (Fisher and Birch 1999b; Birch and Fisher 2000; Fisher and Birch 2000) showed that food restrictions were associated with unintended outcomes, such as higher preference for and intake of the restricted foods and lower ability to self-regulate intake. For example, during a 5 week period of restricted access to a specific food, children ($n = 31$) consumed more of that compared to control food in a free access setting in the lab. Before the restricted access period there was no difference in intake in the lab between the restricted and control foods. Similar results of positive associations between control and snacking were found by Brown and Ogden (2004), and Johannsen, Johannsen, and Specker (2006) found that fathers' controlling behavior was associated with higher body fat percentages in girls. Others found null results or negative associations between parental control and food intake (de Boudeaudhuij 1997) or weight status (Robinson et al. 2001). See Gubbels et al. (2009) for an overview of studies on the association between parenting practices and food intake and their contradictory results. Prospective data revealed either no significant longitudinal associations between restriction, monitoring, or pressure to eat and fat mass (Spruijt-Metz et al. 2006) or showed inconsistent findings (Faith et al. 2004a; Carnell and Wardle 2007). In line with the mixed finding of the empirical studies, review studies also have not been conclusive. Clark et al. (2007) concluded that

"restriction of children's eating has most frequently and consistently been associated with weight gain" and they also stated that there is substantial evidence of a causal relationship. Wardle and Carnell (2007), on the other hand, concluded that the results of the studies they reviewed suggest that greater parental control either leads to lower adiposity in the long-term or has minimal impact on weight for the majority of the children.

In summary, there is some evidence for unintended negative effects of (firm) parental restriction on intake of (specific) foods. Also, there is some evidence that an authoritative feeding style in which parents set rules and are not permissive but also respect children's choices and preferences is the most successful style. However, evidence in this area is contradictive as in some studies it was found that restriction relates to higher intake (forbidden fruit effect), whereas others found an association with healthier eating patterns, and finally also null effects have been found. Overall more research is needed in order to be able to give well-founded advice to parents and studies should make clear distinctions between type of control used.

106.4 The Measure of Parental Control over Food Intake

For the measure of parental control there are several methodological issues to consider. Ogden, Reynolds, and Smith (2006) stated that research on parental control is confusing and used a narrow conceptualization of the ways in which parents control what and when their children eat. In addition, different forms of control may influence different areas of eating behavior. Ogden and colleagues make a distinction between overt and covert control. They argue that most of the existing scales measure overt control, which is the limitation of the child's intake of unhealthy foods "in a way that can be perceived by the child". This type of control are specific behaviors exerted while eating and during meals. In contrast, covert control "remains undetected by the child but still results in restriction" (Ogden et al. 2006, p. 102). This includes availability and accessibility of (un)healthy foods in the household in general and for the children in particular. Overt and covert control were both related to higher fruit and vegetable intake and lack of covert control was related to higher unhealthy snacks intake.

In a review, Faith et al. (2004c) concluded that, compared to measurement in which maternal feeding restrictions were explicitly assessed, measures of global parental feeding styles (including controlling efforts) did not seem to be sensitive enough to detect associations between parental behaviors and children's weight. However, questionnaires for food-related control and children's weight or food intake are subject to methodological problems. One of the most commonly used questionnaires on food-specific parental restriction of children is the Child Feeding Questionnaire (CFQ) (Birch et al. 2001). Although the CFQ showed good psychometric characteristics in some studies (Carper et al. 2000), it is still an unresolved issue how scores on the CFQ are related to parents' actual behaviors in a naturalistic setting (Orrell-Valente et al. 2007). Moreover, no clear correspondence between child and mother's reports on the CFQ scales has been found indicating discrepancies between parents' reports and children's perceptions of their parents' behavior. Carper, Fisher, and Birch (2000) found that while only 26% of the parents indicated that they pressured their daughters to eat, 61% of the daughters reported to perceive some degree of parental pressure. This raises questions about whether mothers generally give a fair and realistic report of their behavior when it comes to complex behaviors like how they handle the food intake of their children. Observational designs might be a good alternative way to study mother–child interactions on food, especially since young children cannot adequately report on perceptions of their parents' behaviors (Table 106.5).

106.5 Observations of Parental Control

Two study settings have been popular in observing parent–child interactions over food choices. First, children's involvement in food shopping has been observed and their attempts to influence their parents as well as parental reactions. For example, O'Dougherty, Story, and Stang (2006) found that children were actively engaged in food shopping. Children's requests were for sweets or snacks in half of the cases. Parents refused just over half of the requests; this was done most often by ignoring the request, by explaining why not, or by a simple verbal no. Usually, children accepted their parent's refusal at once (O'Dougherty et al. 2006).

A second often-used method for mapping parent–child interactions over food choices are observations during family meals. Moens, Braet, and Soetens (2007) for example found that during family dinners, families with an overweight child showed twice as much maladaptive control strategies and less parental support. Orrel-Valente et al. (2007) observed preschool children and their parents during meals. They found that children were very rarely restricted, rather parents more often tried to get children to eat more. This is again an important issue to consider in the comparison of observational studies and surveys as questionnaires often address both restriction of snacks and during meals and have a strong focus on restriction of food (especially unhealthy snack). Parental behaviors during meals might thus considerably differ from their rules and parenting practices regarding snack foods. Children's compliance with parental strategies was most highly associated with neutral prompts as opposed to pressuring/demanding, reasoning, offer of food or play rewards, and threats to withhold food or toys (see Table 106.3). Interestingly, parenting practices varied according to sex of both the parents and the children and by SES (Orrell-Valente et al. 2007).

In our own work (Snoek et al. in preparation a, b), mother-reported and child-reported restriction measured with the CFQ did not differ between mothers of overweight and nonoverweight children and had little main or moderating effect on the children's food choices. An observational study showed that mothers do seem to be successful in influencing their children's food choices, since children's choices in company of their mothers were healthier compared to when the child was

Table 106.3 Correlation of parental strategies with children's eating compliance and eating refusal

Type of strategy	Correlation of frequency of use and child eating ($n = 117$)	
	Eating compliance	Eating refusal
neutral prompts	0.65*	0.16
pressure/demand to eat	0.39*	0.67*
reasoning	0.32*	0.23
Offer of food rewards	0.27*	0.09
praise	0.31*	0.05
Food restraint (portion control)	−0.04	−0.06
threat to withhold food	0.23	0.14
threat to withdraw play privileges	0.09	0.67*
Offer of play rewards	0.28*	0.18*
average of all strategies per meal	0.69*	0.63*

*$p < 0.05$

Parental strategies to influence children's food intake were correlated to children's compliance and refusal. The highest compliance was found for neutral prompts while pressuring/demanding, reasoning, offer of food or play rewards, and threats to withhold food or toys was highly correlated to refusals (Reprinted from Orrell-Valente et al. 2007, p. 43. With permission)

Table 106.4 Event coding for each comment by the mothers during the role play

	Description	Examples
	Event ratings	
Neutral	Not related to the assignment.	
Monitoring	Coaching without pushing towards certain products or food groups. Child is given the freedom to choose.	"What are we going to eat tonight?", "What else do we need?"
Directive control	Mother has a clear idea about which product or food group to buy (pressure) or not to buy (restriction) and pushes child in that direction. Child is still able to make choices within certain boundaries.	"Do we eat French fries on a normal day?" (restriction), "What do we always eat with our potatoes?" (pressure)
Enforcing Control	Mother gives an order, is commanding, points at one specific product, or takes the product herself to make the child buy (pressure) or put back (restriction) something.	"Put the pizza back.", "And now some carrots."
Support	Mother agrees with something the child does or encourages child.	"Well done.", "Yes, you can take that one."

During observation of the interaction, each event, that is if the mother was speaking without being interrupted by a pause or the child, was coded as monitoring, control (directive or enforcing) and support

alone while choosing. This is in accordance with previous studies that found positive effects of maternal presence or expected presence on children's food choices (Klesges et al. 1991). Results further showed that mothers used a range of controlling and encouraging behaviors to influence their children's food purchases (Table 106.4). Observation of maternal controlling behaviors of children's food intake revealed two underlying factors, namely "monitoring control" which included support, monitoring, and directive control (pressure and restriction), and "authoritarian control" which included enforcing control (pressure and restriction). This is in line with the distinction made between types of general parental control and also supports the critique on the CFQ that it includes both monitoring and more psychological control items and does not account for differences in controlling behaviors (de Boudeaudhuij 1997; Saelens et al. 2000; Brown and Ogden 2004). Pressure to eat was not a separate factor from restriction, which is in contrast to the distinction made in the Child Feeding Questionnaire. Overall, it seems that at least in relation to children's food choices there is still some way to go in the development of a behavior-validated questionnaire on food-related parenting. In a sample larger than ours, scores on the CFQ could be linked to the observed maternal controlling behaviors and this could help to validate and/or adjust parts of the questionnaire.

Further we found that children made more unhealthy choices in dyads in which mothers were highly permissive and children dominant. Our results thus provide additional evidence that a certain degree of control is necessary, and suggest that when children are dominant, parents should also actively be involved in food choices. The way parents enforce control does not seem to be of great importance as long as they do not withdraw from the interaction and allow children to take control and make their own choices. More studies are needed to replicate our findings and look at the long-term effects.

Observation studies in conclusion seem to have a valuable contribution to the research on parental restriction and food intake. Not only because of the lack of (behavior) validated questionnaires but also because they take into account children's reactions to parental behavior and ideally also interactions between the two. Current observational studies provide some evidence for the benefits of active involvement of parents and control of children's food intake.

Table 106.5 Key facts of mapping parent–child interaction over food intake

1. Monitoring food intake, restriction of food intake, and pressure to eat are measured by the child feeding questionnaire (CFQ).
2. Parenting can be reported by parents and children separately on different versions of the same questionnaires. However, there is no strong correspondence between parent and child reports of parenting.
3. Observation studies can be a good alternative to questionnaires. Especially for young children, when parent reports are subject to social desirability, and when the available questionnaires are not validated for behavior.
4. Indifferent of the method it is important to distinguish between different types of parental control: monitoring versus restriction and directive versus enforcing control.

This table lists the key facts of mapping interactions between children and parents over food intake and the different methods that can be used.

106.6 Implications for Treatment and Prevention

The influence of maternal control might depend not only on the type of control, but also on its level. Lack of sufficient control (permissiveness) is believed to have a negative influence on children's behavior, whereas over-control is not good either. Bruch (1973) already observed that for the development of healthy eating behavior, it appears to be essential for normal development that there is a balance between stimulation coming from outside and confirmation of impulses originating in the child itself. Parents of young children are often the focus of public health interventions aimed at reducing overweight risks and/or improving diets. However, the focus of prevailing interventions is on *what* parents feed their children and not on *how* they feed them (Clark et al. 2007). There is, however, little consensus among researchers on how this should be, especially regarding control. Our results provide additional evidence that a certain degree of control is necessary.

106.7 Additional Issues to Consider

A few factors complicate the associations between food-related parenting and children's weight and eating. First, the association between parenting and child's weight and eating is likely to be reciprocal: An overweight status or increase in weight can elicit certain parental behaviors (Ventura et al. 2009). For example, higher child adiposity is been related to higher restriction (Fisher and Birch 1999a). Similarly, Faith et al. (2004a) found that (among children predisposed to obesity) elevated child weight appears to elicit restrictive feeding practices, which in turn may produce additional weight gain. Parents may adopt child-feeding behaviors in response to child weight, or perceived child weight (Clark et al. 2007).

The influence of children's weight on parental behavior is further complicated by the fact that parents do not always have an accurate perception of their child's weight status and do not always recognize their children's overweight. For example, Etelson, Brand, Patrick, and Shirali (2003) found that parents of overweight children invariably underestimated their children's weight. Only 10.5% of parents of overweight children perceived their child's weight accurately compared with 59.4% of other parents. Perception of child's weight (and of parents' own weight) can be measured with a subscale of the CFQ and several studies addressed its relation to weight status and parental feeding behaviors (Birch and Ventura 2009).

Third, maternal restriction has been linked to various maternal characteristics, such as own weight concern and restrained eating (Clark et al. 2007). Fisher and Birch (1999a) found that parents' own

restrained eating was related to higher restriction of their 3–5 years old children. Similarly, mothers' dietary restraint was related to maternal control, which in turn was related to higher 24-h recall food intake and higher weight in 5-year-old daughters (Birch and Fisher 2000). So, in addition to maternal behaviors being a reaction to children's characteristics, these behaviors can also partly be a response to their own characteristics and weight preoccupations.

106.8 Conclusion

More research is needed on the relation between parental behaviors and food intake. General control and food-related control should both be addressed, and for food-related control a clear distinction between types of control is indispensable. Given the lack of (behavior) validated questionnaires for food-related parenting practices, observational studies can add valuable information to the commonly used surveys. So far, evidence favors an authoritative feeding style in which parents are not permissive but actively control their children's food intake but, do not impose strict/harsh control, leave room for their children's own choices and preferences, and acknowledge their children's possible ability to self-regulate their energy intake.

106.9 Applications to Other Areas of Health and Disease

Like for other health-related behaviors (Van Der Vorst et al. 2007) some degree of parental control seems necessary. However, unlike for example, smoking or alcohol use everyone has to eat. Obesity only results from a long-term unhealthy food pattern and is not caused by individual foods or eating moments. So, it is not about preventing or delaying one specific behavior. A second difference with other health (risk) behaviors is that there is some evidence that children might have an innate food intake regulation. Parents thus will have to find the balance between permissiveness which probably leads to unhealthier choices and over-control which will interrupt children's ability to self-regulate their energy intake.

Summary Points

- General parental support and an authoritative parenting style were related to healthier eating patterns in some but not all studies.
- Firm and harsh control might enhance liking of a food and might undermine children's ability to self-regulate energy intake.
- Food-related restriction has been related to higher intake of unhealthy foods, healthier eating patterns, or sometimes even null effects.
- Questionnaires on food-related restriction measure different types of restriction and have not been fully validated for behavior.
- Observational studies provide tentative proof that some degree of restriction is necessary in order for children to make healthy food choices.

Chapter 107
The False Memory Diet: False Memories Alter Food Preferences

Daniel M. Bernstein, Nicole L.M. Pernat, and Elizabeth F. Loftus

Abbreviation

FBPQ   Food and beverage preferences Questionnaire

107.1 Introduction

Consider this scenario. You are hunched over a toilet bowl (or flower pot), throwing up. You ate something that did not agree with you, and now you are suffering the consequences of it. As you are busy vomiting, you realize, or think you realize, what it was that made you sick: It was the egg salad. There is a good chance that you will avoid egg salad for a short time after the event. There is also a chance that you might altogether avoid egg salad permanently. Studies show that animals that repeatedly get sick after eating a particular food will avoid that food, and that even a single sickness experience after eating food can lead to a strong aversion to that food (Garcia and Koelling 1966; Gustavson et al. 1974; Gustavson and Nicolaus 1987). If a true food-related memory can produce these consequences, can a false memory do so too? We present evidence that false memories regarding food and alcohol can affect eating and drinking behavior.

In this chapter, we review new research, conducted over the last half decade, showing that we can plant false memories about a past experience with a particular food or alcohol. These have consequences for people; if the false memory is unpleasant, people avoid the food or drink. If the false memory is pleasant, they want the food or drink more. We discuss possible explanations for these findings. Moreover, we explore which kinds of people are more susceptible and which foods are particularly amenable to forming false food memories. We end with a discussion of applications to other areas of health and disease.

107.2 False Memory Primer

Memory is reconstructed, not a faithful replay of the past (Bartlett 1932). As a reconstruction, memory is prone to distortions, omissions, and deletions of details as well as construction of entire events that never occurred. We distinguish between two main types of false memories – those pertaining to

e-mail: daniel.berstein@kwantlen.ca

details (which we call false "detail" memories) and those pertaining to entire events (which we call *rich* false memories) (see Loftus and Bernstein 2005). False detail memories are commonplace. In fact, every memory of every event invariably contains some false detail memory. When recalling the past, we virtually never get all the details exactly right. We either subtly alter some details (we misremember that the culprit in a robbery wore a black shirt when, in fact it was grey) or grossly alter other details (we misremember that the culprit had a beard when, in fact, he was clean-shaven; for a discussion of false detail memory tasks, see Bransford and Johnson 1973; Loftus et al. 1978; Roediger and McDermott 1995). In contrast to such false detail memories for an event, we also sometimes wholly reconstruct memories for entire events that never occurred (we think we remember seeing an entire robbery when the robbery never actually occurred). Findings from studies on rich false memories demonstrate that simply imagining that an event happened in one's past makes one believe that the event actually happened (Garry et al. 1996; see also Hyman et al. 1995; Lindsay et al. 2004; Loftus and Pickrell 1995). Although less common than false detail memories, rich false memories do occur. Moreover, false detail memories and rich false memories likely share some of the same underlying processes; whatever makes us misremember details from the past also is responsible for making us misremember entire events.

Most research to date has focused on how false memories form. What has been less studied is the question of what happens after a false memory forms. False memories in the real world have real consequences for one's behavior (e.g., an adult who falsely remembers being abused by her grandfather may confront the grandfather, refuse to speak to the grandfather, or even sue the grandfather). Recent research in our laboratory has examined the behavioral consequences of false memories. In this research, we planted false memories about food and alcohol in order to provide a plausible and convenient context in which to explore the attitudinal and behavioral consequences of false memories.

107.3 False Food and Alcohol Memories

Using a combination of procedures, we and others have completed more than 20 experiments investigating false food and alcohol memories. Our studies show that people can be led to believe that they had either positive or negative experiences with food or alcohol in their past, and that these false memories affect not only their attitudes and preferences but also their behavior toward those foods and alcoholic beverages. We review this work here, starting with our basic procedure for planting memories and assessing attitudes and preferences. Next, we discuss several potential explanations of our findings. How do we know that our subjects really believe they got sick on a key food; perhaps they have guessed the true nature of our studies and are acting in accordance with how they think we want them to act? This is the age-old problem called demand characteristics. Another issue involves figuring out which subjects are most prone to developing false food memories. This refers to what is called individual differences. Finally, we discuss theoretical mechanisms involved in the formation of false food memories. For simplicity, we use the term *false food memories* to refer to both false food memories and false alcohol memories. We also use the term *false memory diet* as a shortcut to refer to the formation and consequences of false food memories. We are not proposing that this is a bona fide dieting technique, although our methodology might eventually be used for dieting purposes.

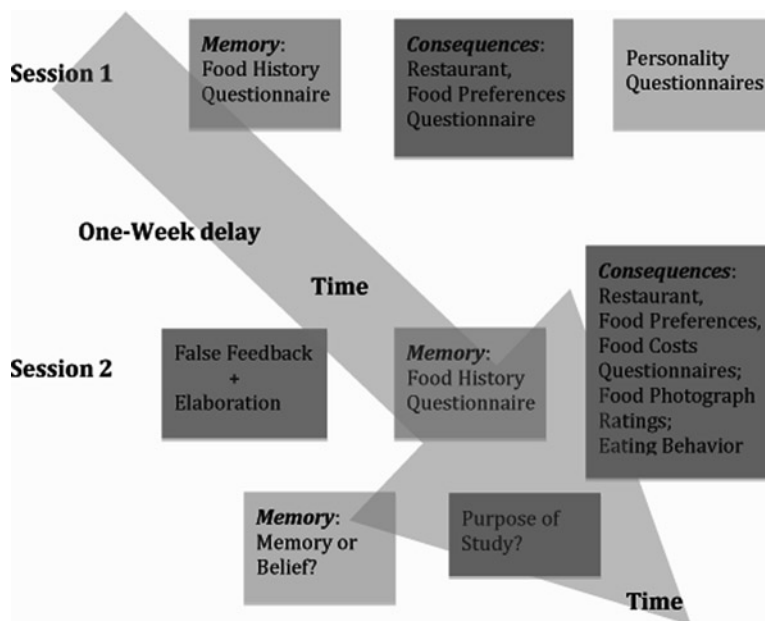
Basic procedure. Our basic procedure involves two sessions separated by 1 week, and a combination of different questionnaires designed to measure one's past experience with and preference for various foods and alcoholic beverages. We have used different combinations of these questionnaires in different studies, but here we present a comprehensive list of questionnaires to provide a broader picture of our studies to date. Briefly, in Session 1, subjects complete a series of questionnaires


Fig. 107.1 General procedure used in our false food memory studies. Subjects complete tasks over a 2-week period, in a fixed order (read from left to right). False memory formation is indicated with the word *Memory*, and is measured using the Food History Questionnaire and the Memory or Belief? Questionnaire. *Consequences* are measured using the Restaurant, Food Preferences, and Food Costs Questionnaires, in addition to the Food Photograph Ratings and Eating Behavior measures. See text for details

aimed at measuring their childhood experiences with and current preference for various foods and beverages. In Session 2, typically conducted a week later, subjects receive false feedback about their Session 1 responses that leads them to believe that they likely experienced a variety of food- and alcohol-related events in their past. Subjects then complete some of the same measures that they completed during Session 1. Figure 107.1 depicts our procedure.

In this research, we have been interested in two intertwined issues. First, we examine the formation of false food memories. Second, we examine the consequences of these memories. To answer the first question, we see if receiving false feedback about a critical food-related childhood event (e.g., "You got sick eating egg salad") increases subjects' confidence that they experienced that event sometime in their past. To answer the second question, we see if receiving false feedback about the critical food-related event alters subjects' attitudes and behaviors. We now explain our procedure in more detail.

In Session 1, subjects complete a series of questionnaires designed to measure one's food and beverage history and preferences. Specifically, to measure food and beverage *history*, subjects complete a Food and Beverage History Questionnaire in which they rate their confidence that various food and alcohol-related events occurred sometime in their childhood. Sometimes we ask about events occurring before the age of 10 or 12 years, and sometimes (particularly in the alcohol studies) we ask about events occurring before say the age of 16 years. To measure food and beverage *preferences*, subjects complete a Food and Beverage Preferences Questionnaire (see Fig. 107.2) in which they rate how much they like each of a large number of different foods and beverages (including some alcoholic drinks) and a Restaurant Questionnaire in which subjects rate the likelihood of their ordering various foods and beverages at an imaginary restaurant (see Fig. 107.3). All rating scales used are 8-point. Whatever our critical item is for a given study (e.g., "you got sick from egg salad") that food item appears on all food and beverage history and preference measures. This allowed us to

Food & Beverage Preferences Questionnaire

Please rate each of the following food and beverage items in terms of how much you enjoy it. Put your rating in the space to the left of the item.

1 = 'definitely don't like' (for whatever reason) to 8 = 'definitely like'

___Watermelon	___Tofu	___Coke
___Lemonade	___Apple pie	___French fries
___Taffy	___Chocolate bars	___Salad
___Steak	___Pepsi	___Rum
___Vanilla Ice Cream	___Celery	___Black beans
___Deviled eggs	___Bananas	___Doughnuts
___Iced-Tea	___Rice	___Red Wine
___Zucchini	___Tequila	___Asparagus
___Pasta	___Spinach	___Almonds
___Chocolate cake	___Granola	___Cranberry Juice
___Carrots	___Onion rings	___White Wine
___Vodka	___Orange Juice	___Mango
___Potato salad	___Cheetos	___Sprite
___Cole slaw	___Omelet	___Crackers
___Tortilla chips	___Garlic	___Potato chips
___Diet Coke	___Beer	___Diet Pepsi
___Tacos	___Ginger	___Roasted eggplant
___Pizza	___7-UP	___Gin
___Broccoli	___Cheddar cheese	___Pickled herring
___Kool-Aid	___Whiskey	___Vanilla pudding
___Egg salad	___Brownies	___Root beer

1 = 'definitely don't like' (for whatever reason) to 8 = 'definitely like'

Fig. 107.2 Food and Beverage Preferences Questionnaire (FBPQ). Food and beverage preferences questionnaire used in Clifasefi et al. (submitted). This is a modification of a task used previously in several studies (e.g., Bernstein et al. 2005b)

compare scores on the critical item before and after the manipulation, in order to discover any change in food preference.

During Session 1, subjects also complete several filler questionnaires purported to measure their personality and eating habits. We have used these questionnaires for different purposes in different studies. We have used these to disguise the true nature of our studies, and make the false feedback manipulation more credible. Toward the latter purpose, we recruit subjects for a Food and Personality study, and most subjects report at the end of the studies that they thought the study was about food and personality. Occasionally the questionnaires tap demographic or other information about the subjects, which we can use for our analyses of individual differences.

One week later, subjects return to complete Session 2. At the beginning of Session 2, subjects receive false feedback regarding their responses to the Session-1 questionnaires. In particular, we tell subjects that we entered their Session-1 responses into a computer with a sophisticated program that generated an individualized profile of their childhood experiences with food. All subjects receive the same feedback about three events that we chose (specifically because these events likely occurred in anyone's childhood, e.g., you disliked spinach). Moreover, experimental subjects receive one additional and critical piece of feedback. Depending on the study, experimental subjects might read in their profile that they became ill after eating dill pickles as a child or that they loved asparagus the first time they tried it, to take but two examples from different studies.

a

Restaurant Questionnaire
Imagine that you are at a nice restaurant for a special dinner. How likely are you to order each of the items on the menu below, assuming that price is not an object?

Fig. 107.3 (continued)

Next, control subjects read that the computer randomly selected one event for them to consider in greater detail, e.g., that they felt happy when a classmate brought sweets to school. Experimental subjects receive the same false feedback about the sweets item, in addition to a critical item. Control subjects are asked to imagine the sweets event and experimental subjects are asked to imagine the sweets event and the critical event in great detail, as indicated in the instructions, "Think about your memory of this experience. If you don't have a specific memory, imagine what *might have* happened. Then answer the following

questions, in some detail, regarding the item listed above: (1) How old were you? (2) Where did it occur? And what were you doing at the time? (3) Who were you with? (4) How did it make you feel?"

Immediately after receiving the false feedback and elaborating on it, subjects complete some of the same questionnaires that they completed in Session 1 – specifically, the Food and Beverage History Questionnaire, the Food and Beverage Preference Questionnaire, and the Restaurant Questionnaire. Subjects also complete what we call a Memory or Belief? Questionnaire in which they report on several events from the Food and Beverage History Questionnaire, including the critical item. Subjects choose one of the following for each event: Whether they have a specific memory for the event, believe that the event occurred but lack specific memory, or are positive that the event did not occur in their past. Subjects are also instructed to provide detailed reasons for making their selections. In many of our studies, we finish by asking subjects to report what they think the study's purpose was. In all of our studies, we run subjects in groups ranging in size from 2 to 40 people. This is our basic procedure that we have followed; however, in our most recent work on this topic, we add behavioral measures either at the end of Session 2 and/or to another session occurring up to 4 months later (Geraerts et al. 2008). In these studies, we give subjects actual foods or alcohol (including the critical item) to consume, and we measure how much they consume. At the end of all studies, we fully debrief subjects.

False food memory studies done to date. Using the aforementioned procedure, we can explore both the formation and consequences of false memory. To explore false memory formation, we compare subjects' responses to the critical item on the Food and Beverage History Questionnaire before and after receiving false feedback. In all of our studies thus far, we find that experimental subjects tend to increase their ratings more than control subjects do, indicating that the false feedback affected their confidence that the critical event happened in their childhood. Next, we examine subjects' responses to the critical item on the Memory or Belief? Questionnaire. We divide our experimental subjects into two groups, Believers versus Nonbelievers. To be considered a Believer, subjects must increase their confidence in the critical event after receiving the false feedback. Moreover, they must indicate on the Memory or Belief? Questionnaire that they have a memory *or* belief for the critical event. If they fail to meet both criteria, we consider them Nonbelievers.

To explore the consequences of false memory, we can compare Believers to Nonbelievers and controls (those subjects who did not receive false feedback about the critical item) in terms of their attitudes and behaviors toward the critical item. Specifically, we measure how much subjects increase or decrease their preference ratings, or the likelihood of ordering the critical item in a restaurant, or how much of the critical item they consume. In some studies, we have included additional measures to assess the consequences of false memory. These include ratings of photographs depicting various foods and beverages, and ratings of how much subjects would pay for various foods at a local grocery store.

Now that we have described our procedures in detail, what did we find? In our first study, we used two critical items, hard-boiled egg and dill pickle (Bernstein et al. 2005a). We told half the subjects that they "got sick" after eating a hard-boiled egg, while we told the remaining subjects that they "felt ill" after eating a dill pickle. As expected, those subjects who received the hard-boiled egg feedback increased their confidence in this event, while those who received the pickle feedback increased their confidence in this event. Importantly, the egg group did not increase their confidence in the pickle item, and the pickle group did not increase their confidence in the egg item. Thus, our false feedback manipulation worked, as intended. But did false memories have any measurable consequences for subjects' food preferences? The answer is yes. Subjects who met our definition of Believer (25% of Pickle subjects and 31% of Egg subjects) indicated less willingness to eat the "offending" food as adults. These findings show that people can be led to believe that they got sick after eating a particular type of food, and that they later appear less interested in eating that food.

Next, we wished to know if we could extend these effects to fattening foods, or foods that weight-conscious people might want to avoid. We first attempted to do this with potato chips (unpublished

data). We had little trouble getting subjects to believe that they had become sick after eating chips as children, but they didn't seem inclined to avoid chips now. Perhaps, we thought, this was because people eat potato chips too often. Perhaps, we could find consequences with more novel foods (also see Martins and Pliner 2005). We set out to test this idea on two fattening foods, one that is commonly eaten (chocolate chip cookies) and one that is not as commonly eaten (strawberry ice cream) (Bernstein et al. 2005b). Confirming our hunch, we could not convince many people that they had gotten sick eating chocolate chip cookies. Moreover, the false feedback about cookies had no impact on our subjects' self-reported preferences for chocolate chip cookies.

In stark contrast, the procedure worked with strawberry ice cream, the more novel food. In this study and all subsequent studies, we used a slightly different definition of Believer than we used in our first study. We added one more constraint to our criteria before labeling someone a Believer; subjects had to provide low confidence during Session 1 on the Food and Beverage History Questionnaire. In other words, subjects had to begin the study relatively confident that they had *not* gotten sick eating strawberry ice cream as children. With this new definition, nearly 40% of our subjects became Believers and indicated that they had gotten sick eating strawberry ice cream. In addition, Believers reported less willingness to eat strawberry ice cream at a party and reported lower general preference for strawberry ice cream. These results indicate that people can be led to avoid a fattening novel food like strawberry ice cream but not a fattening common food like chocolate chip cookies. These results also indicate that stronger manipulations may be needed to make people believe that they got sick eating a familiar food and make people avoid that food.

Given that our false food feedback technique made our subjects less willing to want to eat a fattening food (a potentially healthy consequence of a false memory), we wondered whether we could use this same technique to get people to eat *more* of a healthy food (also a healthy consequence of a false memory). We chose asparagus as the critical item, because it has a distinct flavor and is relatively novel and unfamiliar.

In our first study to examine the consequences of false memory for a positive, rather than a negative food-related experience, we told some of our subjects that they loved asparagus the first time they tried it (Laney et al. 2008a). We found that approximately 50% (48% in Experiment 1 and 53% in Experiment 2) met our definition of Believer. As in our previous studies, we wished to know whether there were consequences associated with believing our false feedback. In this study, we added two new tasks to our arsenal of consequence measures. These new measures included a Food Costs Questionnaire and a Food Photograph rating task. On the Food Costs Questionnaire, subjects indicated how much they would pay for a variety of foods at the grocery store, including the critical item, "a pound of asparagus." Subjects indicated their answers by circling one of seven price options. In the Food Photograph task, subjects rated photographs depicting a variety of foods and beverages (see Fig. 107.4).

Recall that half our experimental subjects in this study came to believe that they loved asparagus the first time they tried it. In comparison to control subjects (those not exposed to false feedback), Believers indicated (a) greater preference for asparagus, (b) greater willingness to pay more for asparagus at the grocery store, and (c) that photographs of asparagus were more appetizing and less disgusting. Thus, false positive memories about a food also had consequences. Specifically, coming to believe that one loved asparagus the first time one tried it had positive and healthy consequences for one's attitudes toward asparagus. These encouraging result left us with two unanswered questions: How long do the false memories last? Do false food memories affect what people actually eat, as opposed to what they think they might want to eat?

To address these questions, we used two experimental groups, a "love" and a "hate" group who received false feedback about either loving or hating asparagus the first time they tried it, respectively. We found that our basic false food memory formation and consequence results persisted up to

Fig. 107.4 Food photographs. Photograph task used in Experiment 2 by Laney et al. (2008a). Subjects rated each food in terms of how appetizing and disgusting it was. Subjects also rated the artistic quality of each photo and whether a novice, amateur, or expert photographer took the photo. *Note*: original photographs were in color

2 weeks after subjects received the false suggestion. We also contacted subjects by email 1 week after they had completed Session 2, telling them that we would feed them during their final laboratory visit 1 week later. We asked them to rank order a list of sandwiches and vegetables (including asparagus) that they would like us to provide during their final visit. Subjects did, in fact, return to the laboratory for the final session, but we did not feed them as promised. Instead, we asked them to complete our standard self-report consequence measures during this final session. We found that Believers in the Love group (34% of Love experimental subjects) indicated via the email questionnaire that they wanted to eat asparagus upon returning to the lab (Laney et al. 2008c).

Although the subjects in these previous studies changed what foods they reported wanting to eat, we never examined what they actually ate. Two studies have since examined actual eating behavior. Each study was conducted without knowledge of the other, further lending credence to the results. In one study, we suggested to some subjects that they had gotten sick after eating egg salad as children (Geraerts et al. 2008). We then measured actual behavior at two different time points. The first occurred shortly after subjects completed our standard Session 2 measures.

Subjects were taken to another room where they received a bogus debriefing. Subjects learned that the researchers wanted to thank them for participating by providing drinks and sandwiches. The sandwiches contained five different fillings, including egg salad, tuna salad, chicken salad, cheese, and ham. While the subjects listened to the bogus debriefing, they helped themselves to the food. An experimenter recorded the type of sandwiches the subjects chose. The second way that we measured behavior was that we re-contacted subjects 4 months later and invited them to participate in what they thought was an unrelated study. Eighty-five percent of subjects returned and completed a taste test in which they tasted and rated five drinks and five sandwiches in terms of appearance, smell, flavor, and preference. After this rating exercise, subjects learned that we would be throwing away the food. We invited them to eat as much as they liked. After 15 min, the experimenter removed the food, and re-administered our Session 2 materials in a different format so as to disguise the link between this session and Session 2.

In comparison to control subjects, subjects who received and believed the false feedback about egg salad (35% of subjects) ate fewer egg salad sandwiches (a) shortly after receiving the false feedback *and* (b) 4 months later (see Fig. 107.5). Believers also gave lower ratings to the appearance and
Fig. 107.5 Mean number of egg-salad sandwiches consumed by Believers, Non-Believers, and control subjects in the second and third sessions. Error bars represent standard errors of the means (Figure and caption reprinted from Geraerts et al. (2008). With permission from publisher)

flavor of egg salad than did control subjects. These results show that subjects can be led to create false food memories with real and long-lasting behavioral consequences.

Another study conducted in a different country also demonstrates the power of false suggestion in shaping actual eating behavior (Scoboria et al. 2008). Experimental subjects received both a personalized profile indicating that they very likely became ill after eating peach yogurt as children, and they received a bogus government report indicating that numerous people had become ill after eating peach yogurt that had been contaminated by *E. coli* bacteria. Experimental and control subjects then returned 1 week later for what they thought was an unrelated multi-site marketing study. During this later session, subjects completed an elaborate taste test of different crackers and yogurts in which they rated each in terms of appearance, odor, taste, and texture, in addition to how much of each food they would like to eat (food perception scores). At the end of the taste test, subjects were told that all remaining food would be discarded, so they were free to eat as much of it as they wished. After 10 min, the experimenter removed the food and weighed it to determine how much of each type of cracker and yogurt was consumed by the subjects. As expected, subjects who were exposed to the false suggestion about peach yogurt indicated lower food perception scores for peach yogurt only, in comparison to controls. More importantly, experimental subjects ate less yogurt overall (of all types presented) than did controls, even though the two groups ate equal amounts of crackers. Thus false food memories affect what people actually eat.

False alcohol memory. Because false suggestion worked so well with food, we wondered whether it also would work with alcohol. To find out, we suggested to some subjects that they had become sick after drinking rum (or vodka) in the past (Clifasefi et al., submitted). Many of these subjects came to believe the false feedback and indicated less preference for drinks containing rum (or vodka) in comparison to control subjects.

In another project involving wine, we examined real behavior by measuring actual wine consumption after subjects received false feedback concerning their past experience with white wine. We suggested to some subjects that they previously got sick after (or loved) drinking white wine. As expected, both types of false suggestion (sick, loved) increased subjects' confidence that this event occurred in their past. Moreover, false positive memories were accompanied by increased self-reported and acutal preference for white wine (Wudarzewski et al. 2009) Thus, false alcohol memories, just like false food memories, affect attitudes and behaviors.

False beliefs versus false memories. Several important questions arise from these studies. One question involves the extent to which our findings relate to memory or mere suggestion. It is possible that merely suggesting to people that they got sick on a particular food in the past is sufficient to alter preferences and eating behavior. Perhaps they don't need to develop a false memory. We have data that speak directly to this question. In nearly every experiment that we have conducted on this topic, we find that Believers show more consequences than do Nonbelievers or controls. If the suggestion itself is sufficient to elicit attitudinal and behavioral consequences, then the Nonbelievers should also show consequences because they too received the false suggestion. Thus, mere suggestion does not seem sufficient to produce the kinds of results we typically see.

In discussing our results we have used the terms "belief" and "memory." Most investigators distinguish between these constructs as follows. Beliefs pertain to ideas (which may or may not be accurate) that we have about the past in the absence of specific detail that can be recalled. For example, we know and believe that we were born, but we do not remember the event itself. Memories, in contrast to beliefs, pertain to recollected details of past experiences. For example, many of us can recall details about our first kiss. Using this distinction, we can examine the formation of false beliefs and false memories. At the end of our studies, we ask subjects whether they have a general belief in or a specific memory for the event. In our studies, the vast majority of subjects (sometimes more than 90%) report a belief rather than a memory (see Table 107.1). Thus, most subjects are forming false beliefs rather than false memories in our studies. The reason that we have not distinguished these subgroups in this chapter is because the two groups are largely indistinguishable in terms of their confidence that the critical event occurred (as measured by their responses to the Food and Beverage History Questionnaire) or the consequences that we measure. Thus, because false beliefs and false memories similarly affect attitudes and behaviors in our studies, we combine false beliefs and false memories into Believers and then compare these subjects to Nonbelievers and control subjects (but see Table 107.1 to differentiate the percentage of Believers who reportedly form a false memory and the respective context).

Table 107.1 Key features of false memory studies: proportion of believers who reported memory rather than a belief for a given critical item, across studies

Aversion vs. preference	Critical item	Believers reporting memory		Study
		Proportion	Percent (%)	
Aversion	Exp 1: Ill from strawberry ice cream	1/7	14	Bernstein et al. (2005a)
	Exp 1: Ill from chocolate chip cookies	0/4	0	Bernstein et al. (2005a)
	Exp 2: Ill from strawberry ice cream – Elaboration Group[a]	1/24	4	Bernstein et al. (2005a)
	Exp 2: Ill from strawberry ice cream – Scenario Group[a]	1/13	8	Bernstein et al. (2005b)
	Exp 2: Ill from dill pickles	4/22	18	Bernstein et al. (2005b)
	Exp 2: Ill from hard-boiled eggs	5/28	18	Laney et al. (2008a)
	Ill from egg salad	3/35	7	Geraerts et al. (2008)
	Hated asparagus	17/46	37	Laney et al. (2008c)
Preference	Loved asparagus	7/35	20	Laney et al. (2008c)
	Exp 1: Loved asparagus	10/22	45[b]	Laney et al. (2008a)
	Exp 2: Loved asparagus	11/21[b]	52	Laney et al. (2008a)
Total		**60/257**	**23**	

Exp experiment

[a]Elaboration group was asked to elaborate on and answer questions about the suggested critical event (sick from strawberry ice cream); Scenario group was asked to choose between two possible scenarios depicting the suggested critical event

[b]Believers reporting a memory differ from Believers reporting a belief on Food and Beverage History Questionnaire (False Memory subjects also rate asparagus photo as more appetizing than False Belief subjects)

One last question arises concerning whether we can know that our manipulation produced a false memory or whether it triggered a true memory of the food experience. Without knowing the actual past of each of our subjects, we cannot be sure. However, there is a clue in one study that argues against the idea that we triggered a true memory. In that study, parents of subjects were contacted and asked to verify whether the critical event (got sick eating egg salad) did or did not occur in their child's past. Notably, of those subjects who entered the study denying the event and postmanipulation developed a memory for it, none of their parents corroborated the event. Readers might wonder whether parents would be expected to recall this event even if it had happened. In fact, many subjects who appeared to have true memories of getting sick on egg salad had parents who corroborated this event (Geraerts et al. 2008).

Demand characteristics. Demand characteristics correspond to situations in which subjects try to guess the true nature of the experiment, and in turn, act according to how they think they should act to be "good" subjects (Orne 1962). If our subjects figure out the true nature of our experiments (investigation of false food memories and their consequences), then they might pretend to form false memories for the suggested event and show consequences of those false memories. Several lines of evidence argue against this possibility. First, we ask subjects at the end of our studies what they think the purpose of the study was. Very few subjects guess the true nature of our studies. When we exclude subjects who guessed the purpose of the study, our overall findings do not change (see Laney et al. 2008b). Second, in some of our studies (e.g., Bernstein et al. 2005b) our false feedback works for one item (e.g., strawberry ice cream) but not another (e.g., chocolate chip cookies). If subjects are responding to demand, one would think they would form false memories for both events. Thus, we do not think that demand characteristics are responsible for our effects.

Boundary conditions. So, false memories can be planted and they have consequences for people. For some foods, like potato chips and chocolate chip cookies (two commonly eaten, and perhaps overeaten junk foods), our procedure did not seem to work. Thus, our false food memory technique does not work with all foods. Just as our technique does not work with all foods, it doesn't work for all people. Typically fewer than half of our subjects come to form false memories (i.e. become Believers). Thus, some subjects are more prone than others to forming false memories (Hyman and Billings 1998). Although we have frequently included measures of individual differences in our studies, they generally have not been related to the likelihood of developing a false memory.

Theoretical considerations. What is the mechanism behind the false memory diet? In two unpublished studies, we ruled out the possibility that behavioral consequences were due to simple positive or negative associations with target foods. When subjects trained to merely *associate* certain critical foods (e.g., asparagus, broccoli) with positive or negative words (e.g., love, hate), self-reported preference for the critical foods did not change, unlike when false memory procedures were used.

Mazzoni, Loftus, and Kirsch (2001) proposed a three-step model to account for the formation of false memories. Elsewhere, we have expanded on aspects of this model (Bernstein et al. 2009). Here, we extend the model to include the consequences of false memories. According to the original model, (1) an event comes to be seen as plausible in the culture of the rememberer (Plausibility); (2) one obtains a personal belief that the event likely occurred to him/her (Autobiographical Belief); and (3) one interprets thoughts and images about the event as memories (Autobiographical Memory). Mazzoni and colleagues have added a step to this model in which a person views an event as personally plausible before believing that the event likely occurred to her/him (Scoboria et al. 2004).

We hypothesize that the probability that an individual comes to believe that an event is generally plausible and that it likely occurred in his/her remote past depends partially on the ease with which the event is processed. Researchers typically define ease of processing as speed, and speed of processing as fluency, because processing speed is easily measured with reaction time. However, fluency can also be the integration, coherence, or well-formedness of perceptual detail, or the perception of ease

independent of the speed of processing (Whittlesea and Leboe 2003). Fluency can be enhanced by different stimulus variables such as repetition, clarity, and presentation duration (see Alter and Oppenheimer, in press 2009). When people are unaware of the source of their fluency, they may mistake that fluency for familiarity. Put another way, when people experience fluent processing of some material, they sometimes mistakenly believe that the material is familiar to them.

We propose that fluency and familiarity precede plausibility in the formation of autobiographical beliefs and memories (see Fig. 107.6). Moreover, we argue that the consequences that we have observed in our work depend on the formation of autobiographical beliefs and memories, although it is possible that consequences like food and alcohol preferences and eating behavior also link directly to fluency, familiarity, and plausibility. For example, Scoboria et al. (2008) demonstrated such a link between plausibility and eating behavior. In their study, subjects ate less peach yogurt after reading a phony government report aimed at boosting the plausibility that they got sick eating peach yogurt as children. In fact, in that study, eating behavior was unrelated to false autobiographical beliefs and memories, thus providing further evidence for a direct link between plausibility and eating behavior.

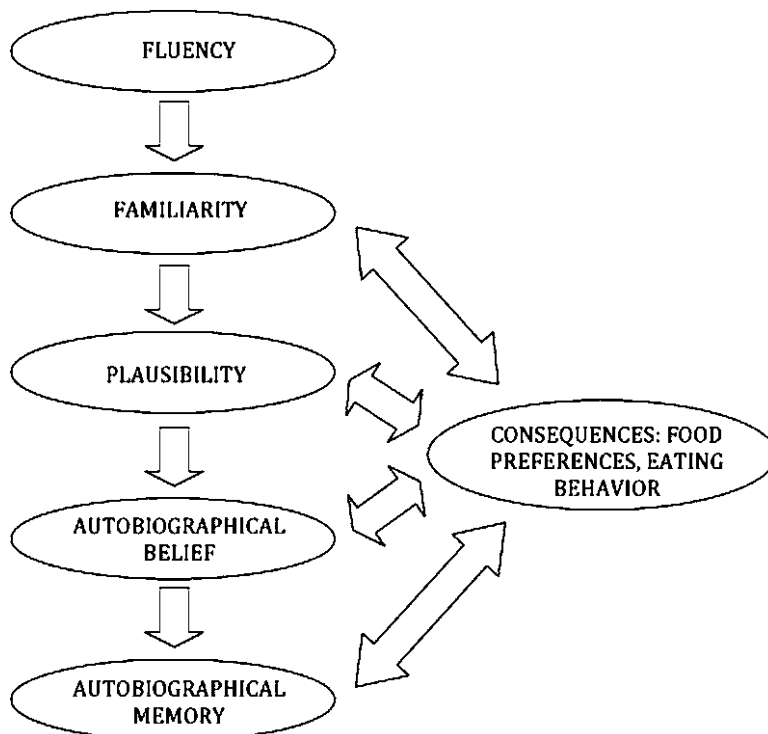
Why should the plausibility of a food-related experience matter? The more familiar a person is with a food, like chocolate chip cookies, the more difficult it is to make that person believe that she/he got sick from eating chocolate chip cookies in the past and the more difficult it is to change her/his preference for chocolate chip cookies. From an evolutionary perspective, familiar objects tend to be more preferable, likely because familiar things are perceived as safer than unfamiliar things (see Bornstein 1989; Bronson 1968). It is less plausible that a familiar food would be unsafe and capable


Fig. 107.6 Hypothesized steps in false memory formation and consequences. Fluency (ease of processing) produces feelings of familiarity, which increase plausibility, autobiographical belief and autobiographical memory pertaining to a food-related experience (e.g., one loved or hated asparagus in childhood). Familiarity, plausibility, autobiographical belief, and autobiographical memory affect and are affected by food preferences
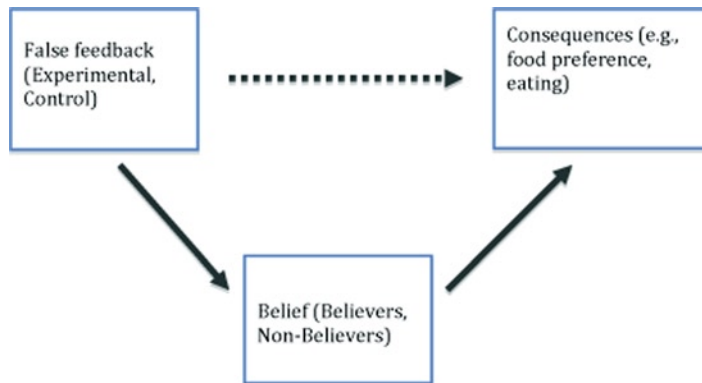

Fig. 107.7 Hypothesized model of the effect of false feedback on food preferences and eating behavior. False feedback (experimental versus control subjects in our studies) may produce consequences directly. Belief in the false feedback (Believers, Nonbelievers) partially mediates this effect. Believers and Nonbelievers are those who do and do not believe the false feedback, respectively. *Dashed arrow* denotes a weaker link than a *solid arrow*

of causing sickness. Thus, if a food is more familiar, it will be more preferred (Loewen and Pliner 1999; Mennella et al. 2001; Pliner 1982; Sullivan and Birch 1994). This explains the observation that familiarity of a food (how frequently it is eaten) enhances preference for it, apparently making it more difficult to develop false memories for having become sick from that food (Bernstein et al. 2005b). These mechanisms can help us understand food preferences, which, as we will see, is useful when it comes to therapeutic applications.

We end this section with a hypothetical model to explain the consequences of false food memories. Figure 107.7 depicts a model whereby exposure to false feedback (e.g., you got sick eating egg salad in the past) has consequences for eating behavior (e.g., you eat less egg salad now). Moreover, we propose that belief in the false feedback partially mediates this link between false feedback and consequences. Work is underway to test this model.

107.4 Applications to Other Areas of Health and Disease

In this section on applications of false memory research to eating behavior, we outline how false food memories could be utilized to influence our eating habits. We then discuss neophobia, lack of dietary variety, and obesity, followed by a therapy called covert sensitization, as well as several ethical concerns. We suggest possible applications of implementing false memories of food experiences for therapeutic means. However, we emphasize that such suggestions are cautious, in light of the scant literature on the ethics and safety of utilizing false memories for eating behavior.

There are two general ways by which false food memories could be utilized to positively influence our general eating habits. One is to increase preference for healthy foods and the other is to introduce aversion to unhealthy (junk) foods. Regarding the former, ideally people would come to believe that they enjoyed a range of food items, or at least, as in the "asparagus love" study, that they enjoyed a particular vegetable. This method would be beneficial for people who do not already consume enough vegetables and fruits in general.

In order to reduce or eliminate certain foods from the diet, aversion to those foods via false food memories could be implemented. Both preference-inducing and aversion-inducing applications of false food memories could be especially useful for people who have a tendency to avoid novel foods (neophobia) or

have health conditions requiring them to be vigilant about their diets. Obesity is one such condition, and may actually be related to neophobia. In each case, a goal is to increase healthy food intake and simultaneously decrease junk food consumption. We now consider the problems of neophobia and obesity.

Food Neophobia and Obesity. Food neophobia is the fear of trying new foods. Having evolved as omnivores with an interest in novel foods, humans historically avoided novel foods because such foods could be dangerous (Rozin 1976; Rozin and Fallon 1987). However, novel foods are rarely dangerous in our current society, reducing our need for neophobic tendencies. Furthermore, by definition, food neophobia has a constraining effect on dietary variety (Falciglia et al. 2000). This could limit the variety of nutrients consumed (Martins 2002), reducing overall health. Indeed, neophobic children tend to have poorer overall diets than non-neophobic children, consuming less vitamin E and more saturated fat (Falciglia et al. 2000). Increased dietary variety in early life increases willingness to try novel foods (Mennella et al. 2001). Thus, if a neophobic or other person who had limited childhood dietary variety formed false memories of having tried different foods as a child, they might increase their food variety in general, alongside the new penchant for eating the food for which they have the false memory.

Evolutionarily speaking, humans are presumably adapted to seek out high fat, sugary, salty foods (Galee 1996). When neophobia is coupled with the abundance of these foods, as found in North America, such foods would conceivably become the mainstay of neophobic people (Birch 1999). Indeed, as mentioned, neophobic children have higher saturated fat intake (Falciglia et al. 2000). This suggests that one answer to the burgeoning problem of obesity may lie in addressing not only the food preferences in obesity itself, but also the underlying neophobia (if present). To this end, a false memory diet (the formation and consequences of false food memories) could be used by training individuals to avoid eating fatty, sugary foods while simultaneously increasing vegetable intake.

Despite memory modification's prospects, Pezdek and Freyd (2009) object to the generalizability of Geraerts et al.'s (2008) findings, including the efficacy in treating obesity. Pezdek and Freyd assert that false memories probably will not be able to produce aversion to (a) foods that do not naturally elicit disgust already and (b) commonly eaten and enjoyed foods. Regarding obesity, they rightly remind us that no one food is responsible for obesity. Moreover, because becoming sick would be a rare occurrence for many of the culprit foods (which tend to be familiar, fatty, and sugary or salty), this event would be implausible. Thus people would be more likely to resist false memory formation for the target event (Pezdek et al. 1997). However, these objections may not be as widely applicable as Pezdek and Freyd suggest.

With regard to (a) and (b), the following foods have been used to date in published false food memory studies: Hard-boiled eggs, dill pickles, strawberry ice cream, chocolate chip cookies, asparagus, egg salad, and peach yogurt. With the exception of chocolate chip cookies, the rest of these foods produced consequences such as lowered food preference, taste ratings, and actual consumption. With the exception of hard-boiled eggs and egg salad, none of the other foods listed here is typically associated with a disgust reaction. Moreover, two of these foods are eaten regularly, including ones that do not naturally elicit disgust (i.e., peach yogurt, dill pickles), yet subjects still formed false food memories for these foods.

What we can say so far is that foods *most* amenable to the false memory diet seem to be less common foods (Bernstein et al. 2005b) – and by extension, less preferred foods, as well as foods that are naturally more disgusting. Prima facia, the potential ease of applying a false food diet to disgusting foods appears related to the plausibility of those foods inducing illness (Pezdek and Freyd 2009). Considering disgust in particular, people tend to be disgusted by meat or fat (Martins and Pliner 2006, 2005; Martins et al. 1997; Scott and Downey 2007), and bitter vegetables (Scott and Downey 2007), as well as certain textures, such as slimy substances (Martins and Pliner 2006; Scott and Downey 2007). With this in mind, we could take advantage of the disgust factor for reducing fat intake, since disgust-inducing foods – with the exception of bitter vegetables – often tend to be animal-based which are usually higher

in fat that non-animal-based foods. Regarding other fatty foods in general, the non-disgust-inducing common ones seem to be resistant to memory modification. In addition, a possible solution to modifying those tenacious memories for less common foods may be to use stronger manipulations such as photo-doctoring, whereby subjects see themselves eating the culprit food (see Wade et al. 2002). There is, however, another tentative method for the modification of nutritional behavior, called covert sensitization. Unlike the false memory diet, it does not include false belief or memory formation per se, though like the false memory diet, it is based on detailed visualization of a given script.

Covert Sensitization: A solution to alcoholism and obesity? First introduced by Cautela (1966), covert sensitization is a modification of aversion therapy, which originally used physical conditioning by way of chemical or electrical means to induce nausea and disgust associated with a particular behavior (see Davidson 1974 for review). In covert sensitization, the physical stimulus and undesirable stimulus are actually absent (hence "covert"), and are instead imagined by the patient. Sensitization occurs as the aversion intensifies across sessions (see Table 107.2). When this reaction remains consistent over time, therapy is considered successful.

Covert sensitization is supposedly rapid and has appeared useful in treating some forms of overeating, including snacking between meals, and chocolate addiction (Kraft and Kraft 2005). However, other studies have brought its efficacy into question (Little and Curran 1978). Whereas the false food memory diet that we discuss here often modulates the overall amount of food consumed, covert sensitization (assuming that it works) requires complete abstinence; this is fine if one's goal is to completely eliminate, say, cookies from one's diet. However, this is not ideal if one still would like to enjoy the occasional dessert; strawberry ice cream and vomit do not make an appealing combo. Furthermore, there may be ethical issues to consider in applying covert sensitization or false memory diets to individuals suffering from eating disorders such as anorexia or bulimia. The same could be said for false memory diets.

Ethical considerations. As asserted by Davidson (1974), whenever a therapy involves intentional change in behavior, ethics must be considered carefully. In this chapter we suggest not only solutions for eating behaviour alteration, but a possible, new way of doing so via memory modification. We know that memories are naturally fluid, subject to reconstruction, including false details. Yet when it comes to purposeful, complete fabrication of memories, one must ponder the ethics involved and whether the potential benefits outweigh the costs. A few false memories of loving asparagus or getting sick from strawberry ice cream may or may not outweigh the ethics involved in planting these memories.

Table 107.2 Procedure for covert sensitization (Amalgamated from various sources – Anant 1967; Cautela 1967; Cautela and Kearney 1986)

1. Physical relaxation and deep breathing
2. 3 steps in the imagined scene
    (a) Imagine setting
    (b) Imagine taking 1 or 2 drinks
    (c) Imagine taste changing, nausea, and vomiting
3. Incrementally introduce aversion to alcohol
    (a) 1st stage: Imagine 3 steps (above), in certain settings, and at home
    (b) 2nd stage: Imagine more scenes, different settings (Cautela 1967; Anant 1967)
    (c) 3rd stage: Imagine smell of liquor inducing nausea and vomiting
    (d) 4th stage: Imagine that the desire to drink leads to sickness
    (e) 5th session: Learn differentiation between liquor (as sickness inducing) and nonalcoholic beverages (as comfort-maintaining)
4. Session stops when therapist notices that patient's appearance becomes indicative of "disgust and nausea" (e.g., facial discoloration) (Anant 1967, p. 20)
5. Patient repeats critical procedure 10–20 times, twice per day (Cautela and Kearney 1986)
6. Patient advised to implement procedure whenever temptation arises (Cautela and Kearney 1986)

This table lists the covert sensitization procedure, using alcohol as the example target substance

Summary Points

- Thesis: False memories for a food or alcohol-related experience can affect diet and food preferences.
- Some foods are more amenable than others to false memory formation.
- Uncommonly eaten foods, even if fatty and sugary (e.g., strawberry ice cream) appear to be more amenable to false memories of sickness.
- Commonly eaten foods (e.g., cookies) seem less amenable to false memories of sickness, yet some commonly eaten foods have been shown to be amenable to false memories of sickness (e.g., yogurt, pickles).
- By definition, "Believers" tend to develop false food memories that result in attitudinal and behavioral consequences.
- By definition, "Nonbelievers," tend not to develop false food memories that show attitudinal and behavioral consequences.
- In nearly every experiment, Believers show more behavioral consequences than do Nonbelievers or control subjects.
- A minority of subjects develop false food memories.
- A "false memory diet" (i.e., false food memories and their consequences) may be applied to (a) increasing preference for healthy foods, such as asparagus and (b) creating aversion to potentially unhealthy substances like alcohol and fatty foods.
- A false memory diet could be applied to several food-related health issues such as neophobia, obesity, alcoholism.
- Covert sensitization, like false food memories, may be useful in manipulating food preferences.
- Unlike covert sensitization, false food memories can generalize to other types of similar foods.
- Future research may identify (a) a larger range of foods amenable to memory modification, (b) why some foods are more amenable than others, (c) new methods to accommodate the difficult foods, and (d) who could benefit from a false memory diet.
- Ethical considerations include (a) misuse of covert sensitization or a false memory diet by sufferers of anorexia or bulimia, (b) the sensitive nature of purposefully modifying someone's memory, and (c) the notion of intentional behavioral modification in general.

Key Terms

Believers: Subjects who incorrectly believe that a suggested event occurred to them in the past.
False belief: Incorrect belief that an event occurred, but inability to recall specific details about the event.
False food memories: Refers here to both false food memories and false alcohol memories.
False memory: Memory for a particular event that never actually occurred.
False memory diet: The formation and consequences of false food memories.
Food neophobia: Fear of trying new foods.
Food neophilia: Seeking and enjoying new foods.
Fluency: Ease of processing, which can mean speed (operationally defined as reaction time), integration, coherence, or well-formedness of perceptual detail, or the perception of ease independent of the speed of processing.
Nonbelievers: Subjects who correctly believe the false feedback to be false.
Subject: A person who participates in a research study. Participation is always voluntary, as monitored by research ethics boards.

Abbreviations

ASGB	Adjustable silicone gastric banding
VBG	Vertical banded gastroplasty
RYGBP	Roux-en Y-gastric bypass
BPD	Biliopancreatic diversion
BED	Binge eating disorder

108.1 Bariatric Surgical Interventions

Two different types of bariatric operations are currently in use – operations that restrict energy intake and operations that cause intestinal absorption limitation of the energy-rich substrate. Restriction operations are: adjustable silicone gastric banding (ASGB), vertical banded gastroplasty (VBG), and gastric bypass (RYGBP) (Favretti et al. 2007; Mason et al. 1998; MacLean and Shibata 1977). The operations aimed at limiting intestinal absorption are: biliopancreatic diversion (BPD) and its variances (Scopinaro et al. 1998; Marceau et al. 2007).

108.1.1 Operations Causing a Reduction of Food Intake

In the ASGB operation, a silicone band is strapped around the upper part of the stomach resulting in a small gastric proximal pouch, with the distal outlet, which can be adjusted to individual needs (Fig. 108.1). VBG consists in a stapled pouch with an externally banded conduit into the stomach proper (Fig. 108.2). The small size of the pouch and the small diameter of the outlet physically limit the amount of food that can be consumed during any single meal. In gastric bypass, the stomach is transected into two pouches. The proximal pouch is of very minute size and is attached to a loop of the proximal jejunum, while the distal one, which represents the near entirety of the stomach, is completely bypassed by the transit of food (Fig. 108.3). After RYGBP, food intake is reduced for

Fig. 108.1 Schematic representation of adjustable silicone gastric banding. A silicone band is strapped around the upper part of the stomach resulting in a small gastric proximal pouch, with the distal outlet which can be adjusted to individual needs. The proximal gastric pouch is rapidly filled after having introduced little amount of food, and the operated subject is compelled to stop eating, so that the overall food intake reduces

mechanical reasons due to gastric restriction as well as because of the action of specific entero-hormones, causing early satiety, which are produced by the small bowel in contact with food that is yet to be digested. Weight loss after ASGB and VBG ranges between 30% and 50% of the initial surplus weight, and long-term studies indicate the tendency toward weight regain over years (Favretti et al. 2007; Mason et al. 1998). The variances in weight loss and maintenance among different populations suggest that the weight loss/gain outcome is more dependent on individual factors than on the operation itself. RYGBP entails a weight loss of 50–60% of the initial surplus weight, with satisfactory weight maintenance, though regaining of weight throughout the years is not an unlikely finding (MacLean and Shibata 1977).

Gastric restriction procedures work by causing nausea, pain, discomfort and potentially vomiting and by forcing the individual to stop eating when the amount of food assumed exceeds the small quantity allowed by the size of the small proximal gastric pouch. After RYGBP limitation of food intake can also be accounted for by the true early satiety elicited by the action of gut hormones produced by the proximal jejunum in contact with undigested food, contributing along with gastric
Fig. 108.2 Schematic representation of vertical banded gastroplasty. Vertical banded gastroplasty consists in a proximal stapled little pouch with an externally banded conduit into the stomach proper. The proximal gastric pouch is rapidly filled after having introduced little amount of food, and the operated subject is compelled to stop eating, so that the overall food intake reduces

restriction to the limitation of food intake. The decrease in food consumption leads to weight loss, which in turn causes the reduction of the subject's energy expenditure. When the decreased energy expenditure matches the amount of energy assumed nutritionally via the restricted stomach, the weight loss halts and body weight stabilizes at a reduced level. If habitual food intake does not change over time, body weight naturally remains stable in the long run.

Postoperation, the patient has the ability "to get around" gastric restriction and to continue to consume large amounts of food. If the frequency of eating increases, the overall amount of food ingested remains unchanged in spite of gastric restriction and early satiety, and body weight does not change or rather increases. Eating capacity increases when soft aliments are assumed, or when liquids are ingested immediately after solids. Furthermore, gastric restriction does not represent an obstacle for high-calorie beverages or heavy dressings, which may be freely ingested without the provocation of adverse effects. Though eating large amounts of food provokes marked epigastric distress and vomiting short-term, frequent overeating leads to over distension and dilatation of the gastric pouch, which completely nullifies the mechanical effects of gastric restriction.

For these reasons, weight results of the gastric restriction procedure are strictly dependent on the individual's postoperative eating habits. If eating behaviors fitting the new gastric anatomo-functional conditions created by the operation are adopted, the patient succeeds in reaching and maintaining a satisfactory body weight long term. This is no longer true when the individual assumes a behavior that overrides the effects of gastric restriction and the guidelines of the "gastroplastic diet" are not followed. Adequate changes in eating habits and behavior are therefore mandatory for obtaining satisfactory weight results; both for short and long term after gastric restriction procedures.
Fig. 108.3 Schematic representation of Roux-en-Y gastric bypass. In gastric bypass, the stomach is transected into two pouches. The proximal pouch is of very minute size and is attached to a loop of the proximal jejunum, while the distal one, which represents the near entirety of the stomach, is completely bypassed by the transit of food. The size of the proximal gastric pouch and the production of entero-hormones producing early satiety contribute to the limitation of food intake little

108.1.2 Operations Causing Limitation of Intestinal Absorption

Biliopancreatic diversion and its variances consist in a nearly complete separation in the intestinal tract of the combined transit of digestive juices and food, which thus produces limitation of the intestinal absorption of energy-rich substrates, while the uptake of essential nutrients (with little or no need of digestion) is nearly fully preserved (Fig. 108.4). Because of the new anatomo-functional conditions that cause the delayed meeting of food and digestive juices, subjects who have been operated on have permanent and selective maldigestion and then malabsorption of fat and starches. The rearranged gastrointestinal system presents an absorption threshold for energy-rich substrates of about 1,600 kcal/day, and the excess of calories ingested is not absorbed and is eliminated via stool (Scopinaro et al. 2000). Following the operation, body weight reduces and subsequently stabilizes when body energy expenditure matches energy intestinal absorption. When actual dietary energy intake overtakes the intestinal threshold, over-energy is eliminated and body weight does not change. Therefore, weight loss and maintenance after BPD is totally independent of individual food consumption and eating behavior, thus explaining the highly satisfactory weight loss outcome for long and very long term following intervention. The vast majority of subjects operated on lose more than 70% of their initial surplus weight, and body weight remains substantially stable at long and very long term in nearly all cases (Scopinaro et al. 1998).
Fig. 108.4 Schematic representation of biliopancreatic diversion. Biliopancreatic diversion consists in a nearly complete separation in the intestinal tract of the combined transit of digestive juices and food, which thus produces limitation of the intestinal absorption of energy-rich substrates. Due to the permanent and selective limitation of intestinal absorption of energy-rich substrates, weight loss occurs regardless of energy intake, and body weight becomes independent from eating behavior and food consumption

108.2 Feeding Pattern Prior to Bariatric Intervention

As aforementioned, in severe cases of obesity bariatric surgery is the only therapeutic method that allows for satisfactory weight loss that is maintained in the long term. However, due to the great prevalence of severe obesity, only a small minority of severely obese patients have the opportunity to be treated via bariatric surgical intervention.

108.2.1 Characteristic of Obese Patients Requiring Bariatric Surgery

Studies carried out in recent years have shown that severely obese patients requesting bariatric surgery are metabolically more compromised and that, contrary to current opinion, they present a lower prevalenMce of binge eating, night eating, and other aberrant eating behaviors than their counterparts enrolled in conservative treatment groups (Ronchi et al. 2008; Munoz et al. 2007). A decade ago, obesity surgery was widely considered as an extreme therapy, and physicians and nutritionists were reluctant to recommend bariatric procedures for fear of complications and adverse side effects. Therefore, only few patients with very high degree of motivation caused by a drastically deranged

body image and/or seriously abnormal eating habits submitted to bariatric surgery (and in most cases against their physician's or family's advice). In recent years, the common attitude toward obesity and bariatric surgery has changed progressively and profoundly, and today severe obesity is no longer regarded as a condition arousing personal guilt and engendering social blame. It is however thought of as a severe metabolic disease, not to be stigmatized, and carrying a high risk for cardiovascular disease resulting in increased mortality. The general belief moreover has developed that with respect to severe obesity conservative therapy is without efficacy in the vast majority of the cases, with subsequently more realistic and operational attitudes toward obesity treatment and bariatric surgery. In fact, because of this, in recent years, obese patients applying for bariatric surgery are those with the highest degree of obesity and with compromised metabolic and/or cardiovascular conditions, regardless of any individual eating behavior or psychological status. The more realistic social attitudes toward severe obesity have improved the possibilities for successful treatment for a larger quantity of patients.

108.2.2 Role of Preoperative Variables in Prediction Postoperative Clinical Outcome

Though bariatric surgery is actually the only effective procedure for the treatment of severe obesity, positive results are not always obtained. In some patients weight reduction is insufficient or unsatisfactory, in others the weight loss is partially or completely gained back over the long term, and it may be that few years after intervention, body weight is higher than initially (before the procedure). In addition, those individuals who have been operated on are at risk of complications because of the surgical procedure itself, specifically the bariatric operation. Furthermore, in some cases, the operation is followed by unpleasant side effects that negatively influence the postobese subject's quality of life. In order to improve clinical results and to obtain satisfactory weight results with no complications in the greatest possible number of severely obese patients, preoperative factors were investigated, which can predict successful weight outcome and the occurrence of complications. Furthermore, a predictive factor was investigated that could provide information for the individualization of the type of operation (gastric restriction or limitation of intestinal absorption) offering the best chance of success for each individual obese patient. Unfortunately, no biological, behavioral, or psychosocial preoperative factor has unequivocally proven to be effective in predicting postoperative clinical results (Hsu et al. 1998; Bocchieri et al. 2002a; Herpertz et al. 2004; Sarwer et al. 2005). As expected, the greater the initial weight, the more substantial the weight loss: however, the initial degree of obesity is not predictive of the long-term weight results: in other words, the initial body mass index value cannot differentiate the weight-losing patients from those doomed to regain in the long term the weight lost in the first postoperative phases.

108.2.3 Cognitive Restraint and Surgically Obtained Weight Loss

As said above, some individuals who have been operated on contrast and cancel the mechanical effects of gastric restriction on food intake by consuming energy-dense food or beverages, or by eating frequently, resulting in poor weight loss and maintenance. It has therefore been suggested that snacking in between meals and a preference for sugary, high-calorie foods can be a predictive factor for poor weight loss following the gastric restrictive procedure (Sugerman et al. 1989). Accurate and

complete longitudinal investigations, however, could not find association between any preoperative eating habit or behavior and weight loss and maintenance (Hudson et al. 2002). It has been hypothesized that severely obese patients with high levels of cognitive restraint may easily succeed in achieving a permanent reduction in food intake, and then most likely achieve a positive weight loss outcome (Sarwer et al. 2005, 2008;Chevallier et al. 2007). On the other hand, to be considered are those individuals who already restrict their food intake at higher levels and may have little space for additional restriction. These individuals may be looking at poor postoperative weight results (Lindroos et al. 1996). It is therefore not surprising that correlations have not been made between weight loss and maintenance after gastric restriction operations and preoperative energy expenditure, food consumption, or cognitive restraint (Camerini et al. 2001; de Zwaan et al. 2003).

108.2.4 Disinhibition and Surgically Obtained Weight Loss

The tendency to lose control over food intake is a dietary attitude frequently observed in severely obese patients undergoing bariatric surgery. It has been suggested that high preoperative disinhibition can be a predictive factor of poor weight loss results particularly following gastric restriction operations. The disinhibition in fact may undoubtedly lead individuals to eat rapidly and frequently, and to drink highly caloric beverages, which cancel out the mechanical effects of gastric restriction on the amount of food consumed. Furthermore, the intake of a large quantity of food in one sitting could provoke dilatation of the gastric outlet, thus impairing the function of the gastric restriction mechanism itself. Finally, a high level of disinhibition could potentially reflect poor emotional conditions and an underlying eating disorder. On this perspective, obese patients with high disinhibition levels could be in a psychological state that prevents their ability to adapt themselves to the novel eating and behavioral conditions created by the operation. Some studies have suggested that high disinhibition is associated with reduced weight loss after bariatric surgery (Dymek et al. 2001; Hsu et al. 1996, 1998; Kalarchian et al. 2002). Patients with binge eating disorder (BED) who underwent RYGBP lost significantly less weight at 6 months than individuals who prior to the operation did not have this disorder (Dymek et al. 2001). Moreover, reported or current binge eating is likely associated with weight gain in patients long term after bariatric surgery (Dymek et al. 2001; Hsu et al. 1998). For these reasons, BED has been considered as a specific contraindication for gastric restrictive procedures in the treatment of severe obesity. In contrast to these reports, other longitudinal studies failed to find any relationship between weight loss and a preoperative binge eating status as assessed in clinic and via self-report, and weight outcomes in BED patients have been quite similar to those obtained in their non-binge counterparts (Powers et al. 1999; Malone and Alger-Mayer 2004; Busetto et al. 2005; Lang et al. 2002).

   Though it has been reported that patients suffering from depression after surgery tend to have less weight loss and a poorer postsurgery quality of life, in most prospective studies, specifically investigating the effects of personality traits and preoperative psychological distress has demonstrated that these variables are not a negative predictor of weight loss (Larsen et al. 2004; Herpertz et al. 2009; Norris 2007).

108.2.5 Conclusions

Taking all documentation into consideration globally, it can be noted that after bariatric surgery, dietary attitudes or behavioral or psychological factors do not exist, which can effectively predict weight loss outcome or can individualize the type of operation.

As said above, the steady weight loss obtained by bariatric operations is followed by a sharp and nontreatment-induced improvement of psychological state, emotional condition and the quality of life (Herpertz et al. 2009). Though specific studies on this topic are still unavailable, clinical experience suggests that these marked positive changes are due to subjective factors together with environmental influences. The appearance of a new physical efficiency because of the weight loss with the disappearance or improvement of complications related to the obese status undoubtedly increases individual auto-efficacy, moving postobese subjects toward true psychological well-being. Furthermore, after weight loss, somatic morphology returns within normal ranges and social stigmatization is a memory. This fact undoubtedly has a substantial positive effect on the postobese subject's psychological state and emotional condition.

In the Western World, social stigmatization deeply affects the psychological state and emotional condition of each severely obese individual in different ways. Understanding, therefore, the true personality and psychological condition of these patients regardless of their obese status might be a nearly impossible task. For each subject, psychological functioning and emotional state is deeply affected by the individual/environment relationship. The type of relationship postobese subjects have with the environment after reversion to normal somatic morphology (which is changed because of the new socially accepted somatic morphology) is completely unpredictable. Furthermore, it is impossible to know what will happen to the operated subject in the future and how the subject will cope with different situations throughout the years. The lack of any preoperative predicting factors with respect to postoperative psychological conditions is therefore not at all surprising.

108.3 Changes in Feeding Behavior After Bariatric Surgery

It is quite understandable that the effects on eating habits of a surgical procedure, which reduces the intestinal absorption of energy-rich substrates, are substantially different from those caused by an intervention aimed at restricting food intake. Patients who have undergone BPD lose weight and are able to maintain a reduced weight with a completely free diet with no limitations of food consumption. However, for those who have had gastric restriction procedures, a free diet is no longer possible. For these patients, a positive outcome in terms of weight can only be obtained with sufficient and permanent changes in eating habits and behaviors.

108.3.1 Feeding Behavior After Biliopancreatic Diversion

After BPD, in those obese patients with normal eating habits and behavior no postoperative changes were observed, while in patients with disordered eating patterns dramatic behavioral improvement was observed. The amount of food consumption remained substantially similar at the preoperative stage with a slight increase observed in only a few patients (Scopinaro et al. 1998). Furthermore, a sharp drop in the Restraint Scale and Eating Disorder Examination score was verified (Adami et al. 2001, 2002), while in postoperative subjects, long-term mean values of the Cognitive Restraint subscale score of the Three Factor Eating Questionnaire were substantially similar to those observed prior to surgical intervention (Adami et al. 1993).

These findings support two important considerations with respect to psychological construct cognitive restraint, which is frequently observed in severely obese patients. Cognitive restraint does not

necessarily correspond to a decrease in food consumption; however, in most cases represents only a psychological requirement for food intake reduction, which the subject does not or cannot put into action. In addition, postBPD findings support the hypothesis that two different types of cognitive restraint exist. Rigid and drastic restraint rapidly subsides when body weight reduces, body morphology normalizes, and the dire need to lose weight ceases. While the more flexible and reasonable cognitive restraint noted via the Three Factor Eating Questionnaire is part of the eating habits of a "normal" person regardless of his or her degree of obesity. It is therefore only minimally affected by the obese status and by weight loss.

More interestingly, after BPD patients tend to lose their tendency toward disinhibition over food intake that frequently accompanies the obese status. After surgical intervention in fact a marked decrease (leading towards normality) of the disinhibition score of the Three Factor Eating Questionnaire was observed (Adami et al. 1993). In addition, all subjects having a BED preoperatively, report completely normal eating patterns long term after intervention. (Adami et al. 1996). Moreover, although after BPD intervention, the patient can eat without gaining weight, no patients have been observed binge eating, and the preoperative normal eating pattern remains quantitatively and qualitatively unmodified by the operation (Scopinaro et al. 1998). It has been suggested therefore that BPD be considered the choice procedure for the treatment of severe obesity associated with BED. The effects of BPD on the tendency toward disinhibition with respect to food intake may have two explanations. The dissatisfaction with one's own somatic morphology leads an individual to restrain food intake cognitively with the goal of losing weight and achieving a more socially acceptable body shape. According to the counter-regulation theory, drastic and rigid cognitive restraint leads to disinhibition (Herman et al. 2005). Thanks to the limitation of intestinal absorption, subjects who have undergone BPD succeed in achieving normal or nearly normal somatic morphology with a completely free diet. It must therefore be assumed that the aforementioned patients have abandoned all concerns about weight, food, and diet, and that dieting behaviors are no longer engaged in postoperatively. This would be the reason the tendency toward disinhibition over food intake weakens or disappears. On the other hand, in recent years, the tendency toward disinhibition and binge eating has been regarded more as an index of psychological distress and emotional disturbance than as a direct effect of rigid dieting, and this psycho-behavioral construct should therefore not be simply considered as a consequence of the forced and drastic cognitive limitation on food consumption (Bryant et al. 2007; Dingemans et al. 2002). As mentioned above, in the vast majority of cases, the surgically obtained stable normalization of body weight and somatic morphology results in a marked improvement of the quality of life and psychological state (Herpertz et al. 2009; Adami et al. 2005), and this marked improvement may well correspond to a reduction of the tendency toward disinhibition regarding food and to the disappearance of binge-eating episodes. In conclusion, whatever the cause, after BPD normal eating patterns do not change. Disinhibition however reduces or disappears and abnormal or atypical eating habits and behaviors are replaced with normal eating habits and behaviors (Herpetz et al. 2009; Adami et al. 1996, 2005; Wadden et al. 2001; Sarwer et al. 2005).

On the contrary, those obese patients who reported night eating, and who had a normal disinhibition score of the Three Factor Eating Questionnaire prior to BPD, continued this behavior for a long term after surgical intervention, with body weight steady at nearly normal levels and concerns about weight, food, and diet completely forgotten (Adami et al. 1999a). Furthermore, in obese patients with night eating, a characteristic neuroendocrinal pattern was observed, with specific alteration in the melanocortin metabolism (Birketvedt et al. 1999). Metabolic and postsurgery data clearly indicates that night eating should not be merely considered as a component of the case history of BED, and suggests however that this behavior can lead to weight gain regardless of disinhibition and the loss of control over food intake.

108.3.2 Feeding Behavior After Gastric Restriction Procedures

As aforementioned, weight outcome following BPD is substantially accounted for by the limitation of intestinal absorption of energy-rich substrates and therefore completely regardless of eating pattern changes. PostBPD subjects therefore represent a very good experimental model for understanding eating behavior and its relationship with body weight and dieting. By contrast, after gastric restriction operations, weight loss is strictly dependent on new eating habits and behaviors adopted. As a result, eating behavior modifications after gastric restriction surgery take on a profoundly different meaning. In large groups of patients undergoing gastric restriction, the simple fact of having changed individual eating habits in the postoperative period represents the strongest predictor of weight outcome at 1 and 2 years postoperation (Sarwer et al. 2008; Chevallier et al. 2007). In addition, in subjects who have lost weight after RYGBP, cognitive restraint increases long term and remains at higher levels than initially observed, while a marked decrease in self-reports of hunger and disinhibition has been observed (Chevallier et al. 2007). These findings prove that after gastric restriction procedures, postoperative changes in eating habits are mandatory for a satisfactory weight loss outcome.

Following gastric restriction procedures, overall postoperative improvement in eating behavior has been documented in some studies (Sarwer et al. 2008; Silver et al. 2006; van Hout et al. 2007; Bocchieri et al. 2002b), while in other research a sharp increase in the tendency to disinhibition as well as the frequency of binge eating was observed, so that BED was regarded as a contraindication for ASGB, VBG, and RYGBP (Kalarchian et al. 2002; Saunders 2004; Lang et al. 2002; Colles and Dixon 2006). It has been suggested that following the gastric restrictive procedure, the prevalence of BED is greatly diminished solely because of the mechanical impediment preventing the consumption of an objectively large amount of food in a single sitting (Colles and Dixon 2006; Busetto et al. 1996). Because of this, the feeling of loss of control over food intake could persist. The patient would binge eat if possible, however, he or she is physically unable to do so because of the surgery. Any attempt to binge eat could result in vomiting (Powers et al. 1999), which obviously does not represent purge behavior. Both prior to and following bariatric surgery, an eating behavior that is commonly termed "grazing" has been reported, involving the consumption of smaller amounts of food over extended periods of time (Saunders 2004; Colles et al. 2008). Preoperative binge eaters may be at high risk of conversion to postoperative "grazers," and after the operation, grazing could fulfill a similar function to that of binge eating (Saunders 2004). It has been observed that in severely obese patients, grazing is common and nearly all preoperative "grazers" continue this eating pattern after the gastric restrictive procedure has taken place (Saunders 2004). After gastric restriction intervention, a noteworthy increase in grazing prevalence was observed when compared to baselines, and noted was that most subjects began grazing behavior only after the operation. This was most likely induced by the gastric restriction. Globally considered, nearly one third of those severely obese patients who submitted to gastric restriction operation make reference to grazing behavior (Colles et al. 2008). Finally, it has been observed that grazing is associated with poor postoperative psychological adjustment and with the presence of emotional distress. In this sense, grazing likely represents a marker of impaired psychological function (Saunders 2004; Colles et al. 2008). Though grazing does not predict weight results for a long term following gastric restriction, it is not surprising that postoperative grazing is associated with poor weight loss or long-term weight regain. Eating small amounts of food "permanently" renders gastric restriction useless and allows for the overall intake of a large quantity of food (Colles et al. 2008).

Contrary to postBPD, the incidence of night eating unexpectedly increases after the gastric restriction procedure. On this topic, however, longitudinal as well as cross-sectional comparisons are

Table 108.1 Key feature of eating pattern and bariatric surgery

1. Bariatric surgery, also known as weight loss surgery, refers to the various surgical procedures performed to treat obesity by modification of the gastrointestinal tract to reduce nutrient intake and/or absorption

2. Surgery should be considered as a treatment option for patients with a BMI (body weight in kg divided by stature in meters) of 40 kg/m^2 or greater who instituted but failed an adequate exercise and diet program (with or without adjunctive drug therapy) and who present with obesity-related comorbid conditions, such as hypertension, impaired glucose tolerance, diabetes mellitus, hyperlipidemia, and obstructive sleep apnea.

3. The loss of the initial excess weigh after gastric restriction procedures and after biliopancreatic diversion is 40–60% and 70%, respectively.

4. After biliopancreatic diversion a satisfactory weight loss occurs at a completely free diet, while in the other cases a good weight outcome is dependent on the individual adaptation to the gastric restriction: in these patients an eating behavior modification program could be advisable.

This table gives the accepted indication for the bariatric surgery and the weight loss results usually obtained; furthermore, the differences in eating pattern following the gastric restriction operations and those that reduce intestinal absorption are outlined

currently thwarted by inconsistent diagnostic criteria (Bocchieri et al. 2002; Colles et al. 2007). For a clear understanding of the clinical importance of night eating, agreement on behavioral features and diagnostic criteria is required. Prospective studies should explore the clinical significance of night eating and its impact on the outcome of weight loss therapies. This is of particular importance with respect to bariatric surgery, given the great prevalence of night eating observed among surgical candidates (Adami et al. 1999a).

108.4 The Role of the Behavior Assessment and Behavior Modification Treatment Prior to and Following Bariatric Surgery

As mentioned previously, no psychological or behavioral variable has found to be predictive of weight outcome or the occurrence of complications after bariatric surgery. Therefore, a behaviorally oriented preoperative evaluation would theoretically be completely useless. However, an initial psychological assessment of candidates for bariatric surgery is of a great importance to the clinical work-up of patients (Wadden and Sarwer 2006). The primary aim of the interview is to inform candidates regarding the nature of the operation they plan to have, about its potential risks and benefits, as well as the changes they must make in eating and lifestyle habits (short and long term). The likelihood of experiencing vomiting, dumping, and related complications, and how they are motivated is also discussed. Furthermore, the candidate must be well aware of the great importance of being present for regular follow-ups. For surgical intervention that determines intestinal absorption limitation, follow-up is mandatory to the prevention of calcium and vitamin deficiencies and to ensure intervention upon onset of the first symptoms of possible protein malnutrition, a serious life-threatening complication, which affects 1% of patients operated on. Subjects must acknowledge that they will need supplementation for the rest of their lives, and that intervention could cause undesirable side effects. Side effects that they must accept in exchange for stable weight loss, or with which they must learn to cope by adopting a specific behavior. Patients undergoing gastric restriction procedures must be fully aware that by necessity, feeding behavior will change after surgical intervention because of the gastric restriction in the ASGB and VBG subjects and because of early satiety in the RYGBP ones. All subjects must be informed that long-term weight outcome is substantially dependent on the changes that will come into play in eating behavior. If the patient learns to use gastric restriction and/ or early satiety to reduce food intake permanently, he or she will succeed in reaching and maintaining

a reduced weight for a long term. If on the contrary, the subject assumes behavior after the operation that nullifies the mechanical or functional effects of the operation on food transit in the upper gastro-intestinal tract, only poor weight loss results will be obtained.

Furthermore, the presence of an eating disorder together with the patient's psychosocial status must be evaluated. Those patients who are severely obese may be unwilling to accept a true psychological assessment: in these cases, it must be clearly stated that the evaluation is not the first phase of psychotherapy, but simply helps the person to decide whether bariatric surgery is the right choice. Evaluation is usually carried out with self-report questionnaires and/or structured or semistructured interviews addressing the following areas:

1. *Weight and dieting history*: The interview should be devoted to the investigation of the age of obesity onset, difficulties with food intake and body weight control throughout the subject's lifetime, as well as the maximum weight reached. As to be expected, the great majority of surgery candidates have made multiple and significant efforts at losing weight. As already mentioned, past dieting could have the opposite effect on the postoperative weight outcome. On one hand, significant weight fluctuation could lead to a global decrease in energy expenditure, preventing satisfactory postoperative weight loss even when food intake is reduced. On the other, significant past weight loss could indicate the good capability of sticking to a dietary plan, thus predicting satisfactory weight loss and maintenance. So, generally speaking, past dieting behavior cannot predict weight outcome after surgery.

2. *Expectations from surgery*: Obese patients must be informed that after gastric restriction procedures, most individuals lose nearly 30–40% of their initial weight and that this reduction requires adequate changes in eating patterns. Unrealistic expectations with respect to weight loss and other postoperative outcomes could lead to psychological distress. Instead of focusing on weight loss per se, candidates are required to measure their success by means of other improvements in health or activities linked to daily living, such as being able to play with their children or to sit comfortably in an airplane (Wadden and Sarwer 2006).

3. *Eating pattern*: Inquiries are made during the interview about the foods typically eaten and favorite foods with the goal of identifying changes required in food intake after surgery. These issues are discussed in greater detail with the program's dietician, who provides an overview of the postoperative diet, as prescribed. Eating behavior must furthermore be investigated in order to detect the presence of aberrant alimentary patterns. As noted previously, given the absence of data to warrant this practice, patients with BED and night eating are not routinely deferred from surgery. However, they are warned against the potential effects of their eating disorder on adherence to the postoperative diet, and persons of significant concern are provided a referral for cognitive behavioral therapy. Current evidence suggests that binge eating is most likely to reoccur 18–24 months after RYGBP or ASGB (Kalarchian et al. 2002; Sarwer et al. 2005; Wadden and Sarwer 2006).

4. *Psychological conditions*: Among severely obese patients, the prevalence of depression may be higher than in individuals of normal weight, and though the prevalence of depression usually decreases after surgery, subgroups of patients who remained depressed even at long-term follow-up (after surgically obtained weight loss) were observed (Mitchell et al. 2001). Clinical evaluation and Beck Depression Inventory data has revealed that more than three quarters of bariatric surgery candidates report minimal to mild symptoms of depression which are not generally of clinical concern and that disappear within the first postoperative year (Wadden et al. 2006). Only patients with potential suicidal ideation and impaired sleep, concentration, cognition (including self-critical thoughts), and social function may need psychiatric or psychological support. A small minority of surgery candidates could have severe psychiatric disorders which are independent

from the obese status, such as psychosis, bipolar disease or addiction, and as a result must be excluded from the bariatric program

5. *Family members*: The decision to turn to bariatric surgery is significant for the patient's family. The preoperative interview inquires about patient living arrangements, spousal (partner) and other intimate relationships, and whether family members and friends support his or her decision.

Theories have been made that true cognitive-behavioral intervention prior to bariatric surgery might make patients more receptive to postoperative changes in eating behavior and as a result could improve weight reduction and maintenance. This hypothesis however has not been verified due to the very poor adherence to preoperative cognitive behavioral intervention (Leahey et al. 2009).

108.4.1 Cognitive Behavioral Factors Promoting Weight Loss After Gastric Restriction Operations

As mentioned earlier, satisfactory weight results following gastric restriction surgery are substantially dependent upon adequate postoperative long-term changes in eating habits and behavior. After classic behavior modification therapy for obesity, true and permanent changes in eating patterns are very difficult to obtain. As a result, after initial weight loss, recurrence represents the rule as verified in support groups. On the contrary, after gastric restriction surgery, most of the subjects operated on achieve in maintaining a satisfactory reduced weight for a long term, thus revealing adequate postoperative eating habit changes that are steadily maintained throughout the years. Consequently, the action of powerful factors should be considered, which promote eating habit changes following the operation. Gastric restriction represents a powerful and nearly unavoidable aversive stimulus against overeating; a stimulus that is felt each time the subject eats. This fact progressively induces the individual to reduce food intake via the classical mechanism of conditioning. Following a gastric restriction procedure for a short term, for anatomical or functional reasons, the patient is unable to resume eating with patterns which are similar to habitual patterns before the operation took place. Therefore, the so-called resistance to change is completely abolished. In other words, patients engaged in a conservative weight loss program must actively avoid resuming initial eating habits starting with the first phases of treatment. Patients who have been operated on, however, are immediately compelled by gastric restriction to adopt new eating habits and behavior without the possibility of return to the preoperative state. From a cognitive-behavioral point of view, there is a third factor promoting positive long-term results during the first postoperative months. Subjects who have undergone intervention lose weight because of the liquid diet in addition to the metabolic factors resulting from surgical invention. Therefore, individuals who have been operated on begin behavior modification programs with a body weight that has been reduced, and, according to the model of operant conditioning, this represents a powerful positive reinforcement for acquiring new and appropriate eating habits and behaviors. According to the cognitive-behavioral approach, all of these factors can explain why dietary changes after gastric restriction operations take place spontaneously without any specific therapy and are more important and persistent than those observed following standard behavior modification as a form of obesity therapy. In other words, gastric restriction represents an important mechanical and/or physiological perturbation on the upper gastrointestinal tract, and as a direct result, the individual's eating habits unavoidably changes. In order to achieve satisfactory weight loss and maintenance, subjects operated on must assume new eating patterns, which entail a reduction in food intake, by means of the artificial stimuli derived from the anatomical and/or functional modifications resulting from the gastric operation.

108.4.2 Eating Behavior Modification After Gastric Restriction Operations

If the patient is able to make changes, a positive weight loss result will be achieved. If, however, the effects of the operation are contrasted negatively by rapid or frequent eating, the consumption of juices or liquid calories and by consumption of dressings or high-calorie beverages, eating behaviors will change in the opposite sense, and poor weight loss results will be unavoidable. As aforementioned, it has been demonstrated that strict postoperative dietary adherence can predict positive postoperative weight results (Chevallier et al. 2007), and that participation in support groups is far better when done following rather than prior to the bariatric operation (Leahey et al. 2009). It must therefore be hypothesized that postoperative support driving patients to assume adequate eating habits and to avoid compensatory ones could lead to an overall reduction in food intake and then might significantly improve weight loss and maintenance. It is therefore advisable that all postgastric restriction patients be enrolled in specific eating behavior modification programs. Behavioral intervention should be affected according to a methodology similar to standard eating behavior modification used in conservative obesity therapy, with bi-weekly group sessions supervised by a psychologist or a dietician with experience in the field. As in the standard approach for obesity, food logs are obtained and reviewed during sessions and appropriate feedback is given. Cognitive-behavioral techniques should be used to reduce binge-eating frequency, the tendency to loss of control while eating, and grazing. Participants should furthermore be encouraged to use cognitive restructuring techniques to replace maladaptive cognitions with more adaptive thoughts, to increase their awareness of internal sensations, including early satiety and external cues, to modify environmental cues and to improve coping skills (Sharon and Irvin 2003; Fichter et al. 1998). While the classic program is simply aimed at reducing food intake, the postgastric restriction program should be mainly devoted to inducing postoperative patients to avoid those eating behaviors apt at canceling out the effects of the gastric restriction itself. Patients must therefore be specifically trained to identify early satiety at each meal, and to do away with such behavior as eating rapidly and frequently or consuming high-calorie beverages and fluid foods. Furthermore, patients must learn to use the weight loss obtained in the first postoperative phases as a powerful positive reinforcement for making adequate changes in their eating patterns. Gastric restriction subjects should receive more training on adopting adequate feeding behaviors than on consuming a healthy diet.

108.4.3 Eating Behavior Modification After Biliopancreatic Bypass

Owing to the permanent and selective limitation of intestinal absorption of energy-rich substrates, after BPD, patients experience highly satisfactory weight loss and maintenance independent of changes in food intake (which in the majority of the cases remains substantially similar to preoperative food intake) (Scopinaro et al. 1998). Furthermore, maladaptive eating behavior spontaneously disappears with respect to the diminishing of cognitive restraint and/or the sharp improvement of psychological and emotional conditions (Adami et al. 1993, 1995, 1996). The stable achievement of normal somatic morphology represents very strong positive reinforcement of changes in eating patterns and lifestyle. The simple instructions of the surgeon or dietician are therefore usually sufficient to obtain postoperative eating behavior suitable for the prevention of deficiency complications and to eliminate or minimize unpleasant side effects of the operation. In this sense, a structured

program of behavior modification after BPD is useless in the vast majority of patients who have been operated on.

As mentioned above, after BPD satisfactory weight loss and maintenance is accompanied in the vast majority of the operated subjects by a marked improvement of psychological functioning and emotional conditions. However, in a few patients who have been operated on, psychological status does not improve or even worsens. Because preoperative parameters that can predict psychological improvement after the operation do not exist, these infrequent cases are completely unforeseeable. Stable weight reduction corresponds in the vast majority of the cases to a normalization of the body image, demonstrating that in severely obese patients body image derangement is substantially secondary to somatic morphology that is far different from the socially accepted standard (Adami 2001; Adami et al. 1996). Nevertheless, a number of postobese subjects are still dissatisfied with their bodies in spite of normal or nearly normal body weight and morphology. Because these individuals have difficulty recognizing psychological needs (Adami et al. 2001), they usually request additional weight loss. In these cases, dieting is clearly useless. As mentioned above, the new gastrointestinal apparatus that BPD subjects have entails intestinal threshold absorption of energy-rich substrates, and the energy consumed in excess is eliminated via stool (Scopinaro et al. 2000). Therefore, when dietary intake of energy-rich substrates is greater than the intestinal threshold, as is obviously the rule in healthy postoperative long term BPD subjects long term, the amount of energy actually absorbed and then disposable for the body, and above all accounting for the individual's body weight, is only determined by an intestinal factor, and completely independent of food consumption. As a consequence, the decrease of food intake is completely without effect on body weight, and this could very well create cognitive dissonance and increase psychological distress. Therefore, generally speaking, a subject after BPD long-term who asks for additional weight loss first and foremost needs careful psychological evaluation. There are a very few patients who, in the extreme, and despite having reached normal or nearly normal body weight, are so dissatisfied with their body image that they require revisional surgery to regain the weight lost and return obese.

As said above, BPD subjects have seriously modified both their gastrointestinal systems as well as somatic morphology, and necessarily require adaptation of eating habits as well as lifestyle. While in the vast majority of cases adequate modification occurs spontaneously without need of therapy, a minority of patients do not possess emotional, technical, or cultural skills to cope with these changes that deeply affect their internal and/or external world. This fact may strongly and negatively influence overall psychological conditions and quality of life. The marked weight loss experienced following BPD undoubtedly represents a "catastrophic" change for severely obese patients; a change that means radical modifications. Therefore, from a dynamic point of view, low-grade transient depression in the first postoperative phase is unsurprising. However at longer term and when the markedly positive effects of the weight loss and maintenance become evident, the prevalence of depression usually decreases sharply. Only a small minority of patients remain depressed after having reached a normal or a nearly normal weight. Those postobese subjects who remain depressed refer a quality of life which is at times worse than at the preoperative stage when they were still obese. These patients undoubtedly need psychological and/or psycho-behavioral therapy, which must be effected with standard techniques based on the therapist's experience and the patient's cultural and social characteristics. Most of these individuals have alexithymic-type personality traits that are not changed by weight loss and recovery of a socially accepted somatic morphology (Adami et al. 2001). Clinical practice has shown that bariatric surgery is experienced by patients with a great deal of emotion, and represents an occurrence of pivotal importance in their lives. Consequently, many significant events happening in the postoperative period are specifically accounted for by the operation itself. It is therefore not surprising that most patients, and specifically those with personality traits

with alexithymic characteristics, refer their symptoms and their distress to the surgeon and/or to the dietician, without requiring specific psychological, psycho-behavioral or psychiatric help. These subjects however must be referred to professionals with specific experience. In other cases, subjects operated on with severe emotional or psychological discomfort primarily seek out psychological or behavioral help. The therapist must be sure to remember that these subjects are not responsible for their obese status. Bariatric surgical intervention is the only effective therapeutic method for severe obesity. Surgically obtained weight loss is accompanied by an improvement in psychological conditions in the majority of cases and that having undergone a bariatric operation should not represent a personal source of shame. Besides the specific complications that require specific therapy and disappear within a limited period, BPD entails negative side effects that in some cases can be eliminated or improved by ad hoc behavioral modifications. Other cases of complications are the unavoidable consequence of the reduced intestinal absorption that justifies long-term weight maintenance. In some cases, the main goal of postoperative modification intervention should be to help the patient adopt behavior which can eliminate or attenuate these effects. In all cases, the principle aim of the therapy should be to encourage patients to adapt themselves to this condition, while avoiding criticism regarding the intervention or the personal decision that lead the patient to turn to bariatric surgery.

108.5 Conclusions

Severe obesity is a multifactorial chronic disease that is largely dependent on still unknown genetic and metabolic factors. Psychological and behavioral dysfunctions are essentially secondary to the obese status. Any surgical intervention, moreover, involves technological procedures directed more at the body than the individual. For those patients who have undergone any surgical procedure, the establishment of a good therapeutic relationship has undoubtedly been of only limited significance, good results being mainly dependent on the skill of the surgeon. However, bariatric surgery profoundly influences food intake as well as body weight, fundamental aspects of individual life. Therefore, to have positive clinical work as well as a satisfactory overall outcome, strict cooperation of the clinical surgeon with the psychologist or with a professional who has a history of caring for the individual as a whole is mandatory.

The psychologist or the behavior professional may initially have a substantial role in the initial assessment, when the patient's capacity to understand the risks and benefits of surgery as well as the consequences of the operation and weight loss must be evaluated. It is furthermore necessary that the presence of serious psychiatric problems, such as schizophrenia, bipolar disorder, or addiction be excluded, which could contraindicate the bariatric procedure. Finally, a careful appraisal of eating behavior is required, as well as clinical assessment of the patient's ability to adapt (including feeding pattern and lifestyle) to the new anatomo-functional and morphological changes derived from the operation and the weight loss. With multiple surgical procedures available, it is imperative that the patient be matched with the most appropriate procedure. This could be the most important task of the psychologist working with a bariatric surgery team. According to the clinical guidelines mentioned, patients with more severe cases of obesity, with deranged eating patterns, with low cultural and intellectual levels, and/or who are believed to have little capacity to change would be addressed to BPD. The younger and more highly motivated patients however can undergo gastric restriction surgery with a greater chance of successful weight loss results. Although psychological evaluation is advocated, there is currently no standard evaluation protocol or predicting factor able to exclude the choice of bariatric surgery or individualize the

type of operation most suitable. The challenge of this approach is to improve weight loss results and predict therapeutic response based on preoperative variables. Clinical findings could guide surgeons in selecting the most appropriate operation for a candidate or allow dieticians and mental health professionals to provide pre- or postoperative counseling to improve the long-term weight loss outcome and quality of life. Until such data is obtained, a patient-oriented behavioral evaluation provides candidates for bariatric surgery with an invaluable opportunity to discuss their often life-long struggle with their weight and the distress it has caused them. While after BPD psychological support is only seldom required, after gastric restriction operations postoperative routine behavior modification therapy may be advisable and could significantly improve the weight loss outcome, particularly long term. Clearly, the main goal of this support should be to encourage healthy eating patterns. Subjects must be instructed and conditioned to accept gastric restriction and to use early satiety as a means to permanently decrease food intake. In doing this, they achieve and maintain satisfactory long-term weight loss. This type of behavioral intervention has still not been schematized or formalized, and prospective results are not yet available. However, specific postoperative support theoretically represents reasonable methodology for improving the overall results of the gastric restrictive operation. From this it is clear that generic competence is not sufficient, and in-depth knowledge of bariatric surgery and related psychological problems is required of the psychologist or psychiatrist working in this field. This must obviously go hand in hand, not of least importance, with the mandatory complete abandonment of any personal blame related to obesity and obese individuals.

108.6 Applications in Other Areas of Health and Disease

In the western developed world, the prevalence of severe obesity is sharply increasing and therefore over the next few decades an even greater number of patients will undergo obesity surgery. Bariatric operations interfere with the main aspects of the subject's life such as food intake and somatic morphology. The bariatric surgery team therefore requires the direct involvement of a psychologist or a professional with experience in behavioral modification. Generic competence is not sufficient, and along with the complete lack of any personal stigmatization toward obesity, in-depth knowledge of bariatric surgery and related psychological problems is required.

Summary Points

- Two different types of bariatric operations are available, those aimed at reducing food intake (gastric restriction procedures) and those limiting intestinal absorption of energy-rich substrates (biliopancreatic diversion and its variants).
- Gastric restriction obstructs the transit of food in the upper gastrointestinal tract and food intake is then forcedly reduced. When gastric restriction leads to a decrease in habitual food intake, satisfactory weight loss results are obtained.
- After biliopancreatic diversion highly satisfactory weight loss and maintenance is achieved by the permanent limitation of the intestinal absorption of fat and starches. Weight results are therefore achieved independently from changes in food intake and behaviors.
- After any surgically obtained weight loss, as a rule sharp improvement in psychological state and eating behavior is observed, indicating that these alterations are substantially secondary to the obese status.

- For the purpose of improving weight loss results, behavioral intervention is envisaged with the aim of matching individual eating habits with gastric restriction without use of compensatory practices.
- After biliopancreatic diversion, the subjects whom have been operated on, easily and without therapy, adapt lifestyle and eating behavior to the anatomo-functional changes in the gastrointestinal tract resulting from the operation and to the new body morphology resulting from the weight loss.

Definitions of Key Terms

Full recovery from obesity: This is the steady reduction of body weight within the physiological range and the disappearance of comorbidities specifically due to the obese status.

Postobese subjects: They are formerly obese patients who steadily normalized or nearly normalized body weight.

Gastric restriction: It is a mechanical impediment of food transit due to the new anatomical condition created by gastric banding or vertical gastroplasty. The subject stops eating after having ingested only a small amount of food in order to prevent nausea, discomfort, and epigastric pain or vomiting.

Early satiety: After the gastric bypass, indigested food directly passes into the distal intestine, and this promotes the secretion of entero-hormones producing satiety. This phenomenon contributes along with gastric restriction to the reduction of overall food consumption.

Threshold for intestinal absorption: While absorption capacity of the intact intestine is not limited, the new gastrointestinal apparatus resulting from biliopancreatic diversion can absorb only a fixed amount of energy-rich substrates, and the fat and starches ingested in excess are eliminated via stool. This results in highly satisfactory weight loss and maintenance independent of food intake.

Compensatory eating behaviors after gastric restriction: They refer to behaviors engaged in consciously or unconsciously by patients who have been operated on, and which render the gastric restriction inefficient. If the subject eats rapidly or frequently, ingests fluid food, high calorie beverages or heavy dressings, drinks during meals or overeats until vomiting, food transit is unaffected and the overall food intake remains at a high level, with the obvious consequences on body weight.

Grazing: Grazing involves consumption of smaller amounts of food over extended periods. In postgastric restriction subjects, this behavior may fulfill a similar function to binge eating, likely representing a marker of impaired psychological function.

Binge eating: Episodes represented by eating large quantities of food within a limited period with the clear feeling of loss of control. After biliopancreatic diversion, binge-eating episodes disappear thanks to the renunciation of concern for diet, food, and weight, and to the sharp improvement of psychological conditions.

Body image: The body image construct defines the picture of our body we form in our mind, that is to say the way in which the body appears to us. Body image derangement is quite common in severely obese patients and as a rule, after surgically induced weigh loss sharp improvement moving toward normality of this psychological construct is observed.

Alexithymia: Alexithymia denotes an individual's difficulty to express emotions and turn emotions into symbols to facilitate interindividual communication. Alexithymic personality traits are common in eating disordered patients and in severely obese subjects.

Abbreviations

ACh   Acetylcholine
BED   Binge-eating disorder
DA   Dopamine
D1   Dopamine type 1 receptor
D2   Dopamine type 2 receptor
D3   Dopamine type 3 receptor
DSM-IV   Diagnostic and Statistical Manual of the American Psychiatric Association, Fourth
           Edition
mRNA   Messenger ribonucleic acid
NAc   Nucleus accumbens

109.1 Introduction

Obesity is presently one of the greatest threats to public health in the US. It is estimated that by the year 2030, half of the population will be obese (Wang et al. 2008). Presently, in addition to the 33% of the population that is obese, about 55% are overweight (Flegal et al. 1998). Obesity and being overweight have serious physical, emotional, psychological, societal, and economic risks. Depression, substance abuse, and susceptibility to other illnesses are examples of some common comorbidities seen with obesity.

Despite the wealth of information, public warnings, and availability of diet drugs and healthly foods, people often remain overweight. Of particular note is the number of youth who are overweight. This has contributed to the rise in the incidence of Type-II diabetes among children, which has been estimated to have increased up to tenfold over the past 20 years (American Diabetes Association 2000), and it will undoubtedly result in additional health problems as these children age.

Several questions arise when considering these statistics. Why are so many individuals overweight? Why can't some people stop eating unhealthy food? Why do some people have a penchant for sugary or fat-rich foods, which are also high in calories?

109.2 What Is a Food Addiction?

The theory of food addiction posits that, for some individuals, food is like a drug of abuse. There have been several clinical accounts in which people claim to be "addicted" to certain foods, and this addiction manifests as excessive overeating, a feeling of distress when palatable food is not available, and craving of certain foods (Ifland et al. 2009). These food addictions tend to focus on highly palatable, calorically dense foods, or for some people, refined carbohydrates. Much like the relationship that emerges between a person addicted to drugs and their drug of abuse, those who feel they are addicted to certain foods can find it difficult to stop overeating, which can ultimately result in body weight gain or an eating disorder. Interestingly, a recent study has discovered that many advertisements for highly palatable snack foods targeted at children contain images of the food having drug-like properties (Page and Brewster 2009). This finding highlights the commonalities between some foods and drugs of abuse, and it reinforces the notion that the concept of food addiction permeates through our culture.

Although the term food addiction is often used colloquially, its scientific definition is now emerging, and evidence is accumulating to suggest that repeated exposure to certain foods can, indeed, produce behaviors and changes in the brain that resemble an addiction-like state. One may wonder how something as innocuous as a palatable food, which many people consume on a regular basis with no adverse effects on health or well-being, could be akin to a drug of abuse. In this chapter, we discuss instances in which a palatable food can act as an addictive substance. Although foods and drugs are vastly different in their roles in society, they rely on a common underlying brain circuitry, and thus can be quite similar in their effects on the brain, as described below.

109.3 Possible Origins of Food Addiction

The rapid rise in the overall number of adults and children who are overweight is too abrupt to suggest a genetic cause. Environmental and/or behavioral changes are more likely the source of the problem.

From an evolutionary standpoint, food is necessary for survival, and there exist innate biochemical processes that reinforce feeding behavior when one is hungry. Similarly, other "natural" behaviors, such as sexual behavior, are necessary for the survival of our species, and are thus powerful reinforcers. Some of our ancestors survived to procreate by spending their time hunting for food and then engaging in opportunistic binge eating due lack of refrigeration and the scarcity of their next meal. However, in the modern-day environment of industrialized countries food is plentiful. Those skills that were previously needed for survival may lead to detrimental behavior that affects the brain and subsequent feeding behaviors. Thus, there may exist an innate drive to overeat when food is available, and in our present environment, that may mean that people indulge on a regular basis (Stephens et al. 2004).

This drive to consume food is motivated by the release of neurochemicals that are associated with a feeling of euphoria and pleasure. As described next, palatable foods are especially strong reinforcers, sending these systems intended to motivate food consumption for survival into over-drive. It is important to note that much like the development of drug addiction, food addiction is not seen in all people and it may become most apparent in a subset of genetically susceptible individuals.

109.4 Binge Eating: A Behavioral Criterion of Food Addiction

The Diagnostic and Statistical Manual of the American Psychiatric Association (Fourth Edition, Text Revision) (DSM-IV) defines binge eating as a series of recurrent binge episodes during which one eats a larger amount of food than normal during a short period of time (usually within any 2-h period) and shows three or more of the following: (1) eating until feeling uncomfortably full, (2) eating large amounts of food when not physically hungry, (3) eating much more rapidly than nor-mal, (4) eating alone because one is embarrassed by how much s/he is eating, (5) feeling dis-gusted, depressed, or guilty after overeating, or (6) marked distress or anxiety regarding binge eating (American Psychiatric Association 2000). Meeting these criteria can lead to a diagnosis of Binge-Eating Disorder (BED), an eating disorder that affects approximately 6% of the population (Hudson et al. 2007). In addition to BED patients, there are individuals who engage in binge-eat-ing behavior that is associated with other eating disorders; e.g., bulimia nervosa. Although binge-eating behavior is traditionally associated with eating disorders, it has also been linked to obesity, and it may be a predictor of body-fat gain among children, leading to a high risk for adult obesity (Tanofsky-Kraff et al. 2006). Binge eating is also associated with increased frequency of body weight fluctuation, depression, anxiety, and substance abuse (Ramacciotti et al. 2005; Galanti et al. 2007; Grucza et al. 2007).

People usually binge on palatable, highly caloric foods, which also happen to be high in fats, sugars, or often both, and are thus normally meant to be consumed in moderation (Hadigan et al. 1989; Kales 1990; Guertin and Conger 1999). Data derived from normal-weight, binge-eating women indicate that binge episodes most often contain bread or pasta, followed in frequency by sweets, fatty foods, or salty snacks (Allison and Timmerman 2007). Individuals with a preference for bingeing on sweet foods tend to binge more frequently. Thus, there may be some property of palatable "snack" or "comfort" foods rich in sugar and/or fat that promotes binge eating.

Although the word "addiction" does not appear in the DSM-IV, substance abuse is clearly defined as an instance "when an individual persists in use of alcohol or other drugs despite problems related to use of the substance" (American Psychiatric Association 2000). A diagnosis of substance abuse is given when recurrent substance use (1) results in a failure to fulfill major obligations at work, school, or home; (2) occurs in situations in which it is physically hazardous; (3) produces related legal prob-lems; and (4) is continued despite social or interpersonal problems caused or exacerbated by the effects of the substance. Using laboratory animals, we have adapted some established procedures that are used to classify substance dependence with respect to drugs of abuse, and applied them to the study of food addiction in our model of sugar bingeing. Others have recently taken the criteria from the DSM-IV pertaining to substance abuse and applied them to describe food addiction in humans, thereby creating a food addiction scale that can be administered in a clinical setting (Gearhardt et al. 2009).

109.5 An Animal Model of Binge Eating: A Focus on Sugar Bingeing

We acknowledge that binge eating is a multifaceted behavior, with emotional and cultural components that are difficult to model in laboratory animals. Nonetheless, animal models of binge eating are integral to understanding the physiological and neurochemical basis of this behavior. Other models of binge eating are available and of great interest, as each has its own particular relationship to human behavior, such as stress-induced eating and fat bingeing (Boggiano et al. 2005; Corwin 2006; Berner et al. 2008). We chose to focus on sugar bingeing because, under normal conditions, rats and people have a pleasurable reaction to the taste of a sugar solution, sugar is ubiquitous in our society, and it has been associated with the rapid rise in the incidence of obesity.

We have developed a model in our laboratory in which food restriction and refeeding is used to precipitate daily bingeing behavior. Rats are maintained on daily 12-h food deprivation, followed by 12-h access to a 25% glucose or 10% sucrose solution (similar to the sugar concentration of a soft-drink) and rodent chow (Avena et al. 2008b). After just a few days on this schedule, the animals begin to binge on the sugar, as indicted by an increase in their intake of the sugar solution during the first hour of access. We also have data suggesting that these animals take voluntary binges throughout their 12-h access period. Animals that have unrestricted access to the sugar solution and chow consume an amount similar to that consumed by the bingeing animals, but their consumption is spread over 24 h, and these rats do not engage in bingeing episodes.

109.6 Behavioral Evidence of Sugar Addiction

In the following sections, we will describe the empirical data that suggest addiction-like brain and behavioral changes using our animal model of binge eating. The data described below have been summarized in previous reports (Avena et al. 2008b, 2009a), as well as in Table 109.1.

Table 109.1 Summary of features of food addiction

1. Bingeing is characterized by consuming a larger than normal or intended amount of food in a discrete period of time. In addition to sugar, animals will binge on pure fat, which suggests that binge eating is not exclusive to sweet taste. The combination of sweet and fat activates multiple taste receptors, postingestive signals, and neuropeptide systems. Sugar/fat combinations, in the form of cookies or sugar-fat mixtures, have been used by researchers to induce binge eating in laboratory models. Our model of sugar-bingeing produces alterations in the mesolimbic DA system and opioid systems that are consistent with the effects of substances of abuse.
2. A negative state can result when an abused substance is no longer available. In particular, opioid withdrawal has a clearly defined behavioral profile. Sugar-bingeing rats show signs of opiate-like withdrawal when sugar is removed, or when withdrawal is precipitated with an opioid antagonist. Concomitant changes in DA and ACh release in the NAc are observed, which are consistent with the findings observed during withdrawal from some drugs of abuse.
3. Craving is characterized by a profound desire to procure an abused substance. One way to examine craving after abstinence is to test for the "deprivation effect." Rats that are bingeing on sugar will lever press 23% more for it after 2 weeks of abstinence than they did prior to abstinence, while a control group with 0.5-h daily access to sugar did not show this enhanced response. These results suggest a change in the motivational impact of sugar that persists throughout a prolonged period of abstinence, leading to enhanced intake. Others have shown that responding for a cue previously associated with sugar grows with duration of abstinence, suggesting the gradual emergence of long-term changes in the neural circuitry underlying excessive motivation that results from sugar self-administration and abstinence.

This table lists key concepts and symptoms associated with food addiction, including bingeing, withdrawal, and craving that have been shown using animal models. References are included in the text below.

109.6.1 Escalation of Intake and Bingeing Behavior with Limited Daily Access to Sugar

Escalation of intake is a characteristic of drugs of abuse. Increased intake with subsequent exposures to a drug may be due, in part, to a tolerance to the drug, indicated by needing more of the substance in order to produce the same euphoric effects. Often, escalating intake is coupled with a "binge" upon access to a substance of abuse.

   As described above, our model of sugar bingeing demonstrates that rats given daily intermittent access to a sugar solution, along with rat chow, escalate their sugar intake and increase their intake during the first hour of daily access, which we define as a "binge" (Colantuoni et al. 2001). This binge-like behavior is one sign of dependence. However, what makes this model unique is that it results in multiple signs of dependence, including withdrawal, craving, cross-sensitization, and drug substitution, as described next.

109.6.2 Sugar Bingeing Results in a Withdrawal-Like State

Animals can show signs of opiate withdrawal after repeated exposure to an opiate when the substance is removed, or the opioid receptors are blocked. In rats, opiate withdrawal has clear and well-defined behavioral signs, including somatic indicators of distress, decrease in body temperature, aggression, and anxiety, as well as a motivational pattern characterized by dysphoria and depression (Martin et al. 1963; Way et al. 1969).

   We have observed similar signs of opiate-like withdrawal in rats that have been bingeing on sugar (Fig. 109.1). When administered the opioid antagonist naloxone, somatic signs of withdrawal, such
Fig. 109.1 Percent of time spent on the open arms of an elevated plus maze in sugar-binging rats versus ad libitum chow rats. Rats that had previously been bingeing on sugar spent significantly less time on the open arm of the plus maze after 36 h of fasting compared with a group previously maintained on ad libitum chow that was also fasted for 36 h. This indicates that sugar abstinence can cause anxiety ($^*p < 0.05$) (Reproduced with permission from Avena et al. 2008a)

as teeth chattering, forepaw tremor, and head shakes occur (Colantuoni et al. 2002). These animals are also anxious, as measured by reduced time spent on the exposed arm of an elevated plus maze. Signs of opiate withdrawal also emerge spontaneously without the use of an opioid antagonist, when all food is removed for 24–36 h (Colantuoni et al. 2002; Avena et al. 2008a). Therefore, our data suggest that bingeing on a sugar solution releases opioids in the brain, with resultant neural adaptations that are manifest as a dependency. Other researchers have obtained supportive findings that suggest opiate-like withdrawal using similar models of sugar bingeing. For example, signs of anxiety have been reported in rats with limited access to a high-sucrose diet (Cottone et al. 2008). The mere removal of sugar has been reported to decrease body temperature (Wideman et al. 2005). Also, signs of aggressive behavior have been found during withdrawal of a diet that includes intermittent sugar access (Galic and Persinger 2002).

109.6.3 A Dietary History of Sugar Bingeing Precipitates Increased Responding for Sugar Following Abstinence: A Possible Sign of Craving

Craving in laboratory animals can be defined as enhanced motivation to procure an abused substance (Koob and Le Moal 2005). After self-administering drugs of abuse and then being forced to abstain, when the drug again becomes available animals will take more than they did prior to abstinence (Sinclair and Senter 1968). Also, animals will often persist in unrewarded operant responding (i.e., resistance to response extinction), and over time increase their responding for cues previously associated with the drug (Ciccocioppo et al. 2001; Grimm et al. 2002; Lu et al. 2004). This increase in motivation to obtain a substance of abuse mimics the condition observed with humans, and may contribute to the likelihood of relapse.

We measured lever pressing for sugar after abstinence in rats that had been previously bingeing on sugar. Sugar-bingeing rats lever press for 23% more sugar in a test after 2 weeks of abstinence than they did before (Avena et al. 2005), while a control group with 0.5-h daily access to sugar did not show the effect. The results suggest a change in the motivational impact of sugar that persists throughout a prolonged period of abstinence, leading to enhanced intake. The results further suggest that relatively brief exposures to sugar are not sufficient to result in enhanced intake following abstinence, but rather, limited access in the form of prolonged daily binge eating is needed to produce the effect.

Additionally, as described above for drugs of abuse, the motivation to obtain sugar appears to grow with the duration of abstinence. Sucrose seeking increases during abstinence in rats that have a history of intermittent access for 10 days, and it is greater after 30 days of sugar abstinence compared with 1 week or 1 day, suggesting the gradual emergence of long-term changes in the neural circuitry underlying motivation as a result of sugar self-administration and abstinence (Grimm et al. 2005).

109.6.4 Sugar-Bingeing Rats Show Locomotor Cross-Sensitization to Psychostimulant Drugs

When animals become sensitized to some addictive drugs, it is evidenced as a lasting, growing tendency toward hyperlocomotion during abstinence in response to a low, challenge dose of a
Fig. 109.2 Locomotor activity following amphetamine shown as percent of baseline photobeam breaks. Sugar-bingeing rats (Daily Intermittent Sucrose and Chow) were hyperactive 8 days following the cessation of sugar access in response to a low dose of amphetamine compared with control groups. This suggests sensitization of the dopamine system as a result of sugar bingeing ($^{**}p < 0.01$, $^{*}p < 0.05$) (Reproduced with permission from Avena and Hoebel 2003b)

psychostimulant. Additionally, cross-sensitization, whereby sensitization to one drug makes an animal susceptible to the effects of another drug, has been demonstrated (Robinson and Becker 1986; Antelman and Caggiula 1996).

We find that sugar-bingeing rats become sensitized to amphetamine. Such animals are hyperactive in response to a low, challenge dose of amphetamine that has little or no effect on naïve animals (Avena and Hoebel 2003b). This was observed after 8 days of abstinence from sugar. Rats maintained on the sugar-feeding schedule but administered saline were not hyperactive, nor were rats in control groups (e.g., allowed to binge on chow only, or with ad libitum access to sugar and chow, or ad libitum access to chow only) that were given the challenge dose of amphetamine (Fig. 109.2). Conversely, rats sensitized to amphetamine show locomotor cross-sensitization to a small meal of sugar (Avena and Hoebel 2003a). Other laboratories have reported that intermittent sucrose access cross-sensitizes with cocaine (Gosnell 2005) and facilitates sensitization to the dopamine (DA) agonist quinpirole (Foley et al. 2006). Collectively, these results support the theory that the DA system is sensitized by intermittent sugar access, as evidenced by cross-sensitization. This is important since enhanced mesolimbic dopaminergic neurotransmission plays a role in the behavioral effects of sensitization as well as cross-sensitization (Robinson and Berridge 1993).

109.6.5 Sugar Bingeing Acts as a "Gateway" to Increased Alcohol Intake During Sugar Abstinence

Sensitization to one drug can lead not only to hyperactivity, but also to subsequent increased intake of another drug or substance (Henningfield et al. 1990; Nichols et al. 1991; Volpicelli et al. 1991; Hubbell et al. 1993; Liguori et al. 1997; Ellgren et al. 2007). In the clinical literature, when one drug leads to taking another, it can be known as a "gateway effect".
Fig. 109.3 Ethanol intake in grams per kilogram of bodyweight. Rats with a history of binge access to sugar and chow (Intermittent Sugar and Chow) consumed more 9% ethanol than rats in either the Ad libitum Sugar and Chow group or the Ad libitum Chow group ($^*p < 0.05$). In comparison with rats in the Ad libitum Chow group, rats in the Intermittent Chow group also consumed more ethanol ($^‡p < 0.05$) (Taken with permission from Avena et al. 2005)

When rats are bingeing on sugar and then forced to abstain, they subsequently show enhanced intake of 9% alcohol (Avena et al. 2004) (Fig. 109.3). This suggests that intermittent access to sugar can be a gateway to alcohol use. Others have shown that animals that prefer the sweet taste of saccharin will learn to self-administer cocaine more readily than usual (Carroll et al. 2007). Presumably underlying this behavior are neurochemical features of the brain that are inborn or learned, such as adaptations in DA and perhaps opioid functions, as described in the next section.

109.7 Neurochemistry of Food and Reward

Food is a natural reward that activates neurochemical pathways in the brain that evolved to reinforce this behavior by making it pleasurable and motivating. Non-natural reinforcers, including many drugs of abuse, exert their powerful reinforcing effects by usurping these brain pathways. Overlaps in the circuitry and brain regions regulating food and drug intake have been suggested and have inspired the model of sugar addiction that is described in this chapter. While several neurotransmitters and hormones have been studied in these brain regions, this chapter will focus on DA, the opioids, and acetylcholine (ACh) in the nucleus accumbens (NAc) shell, which so far, are the neurotransmitters that we have found to be involved with the reinforcing effects of food addiction.

109.8 Neurochemical Evidence of Sugar Addiction

The evidence described above suggests that sugar bingeing can produce behaviors that are similar to those observed in drug-dependent rats. In this section, we describe neurochemical findings that may result in, or perpetuate, these behaviors.

109.8.1 Sugar Bingeing Alters the DA System in the NAc

Drugs of abuse can alter DA receptors and DA release in the mesolimbic regions of the brain. In response to cocaine, there is an upregulation of Dopamine type 1 (D1) receptors (Unterwald et al. 1994) and increase in D1 receptor binding (Alburges et al. 1993; Unterwald et al. 2001). Conversely, Dopamine type 2 (D2) receptor density is lower in the NAc of monkeys that have a history of cocaine use (Moore et al. 1998). Drugs of abuse can also produce changes in gene expression of DA receptors, with morphine and cocaine decreasing accumbens D2 receptor messenger ribonucleic acid (mRNA) (Goeders and Kuhar 1987; Turchan et al. 1997; Georges et al. 1999), and increasing Dopamine type 3 (D3) receptor mRNA (Spangler et al. 2003). These findings with laboratory animals support clinical studies, which have revealed that D2 receptors are downregulated in cocaine addicts (Volkow et al. 1996a, b, 2006).

We have found similar changes with our animal model of sugar bingeing. Autoradiography reveals increased D1 receptor binding in the NAc and decreased D2 receptor binding in the striatum relative to chow-fed rats (Colantuoni et al. 2001). Others have reported a decrease in D2 receptor binding in the NAc of rats with intermittent access to sucrose and chow compared with rats fed restricted chow only (Bello et al. 2002). Rats with intermittent sugar and chow access also have decreased D2 receptor mRNA in the NAc, and increased D3 receptor mRNA in the NAc and caudate-putamen compared with chow-fed controls (Spangler et al. 2004).

One of the strongest neurochemical commonalities between sugar bingeing and drugs of abuse is their effect on extracellular DA. The repeated increase in extracellular DA is a hallmark of drug that are abused (Di Chiara and Imperato 1988), whereas normally during feeding the DA response fades out after repeated exposure to food as it loses its novelty (Bassareo and Di Chiara 1997). However, when rats are bingeing on sugar, the release of DA is more like that of a drug of abuse than a food. Rats that are bingeing on sugar apparently release DA every day, as measured on days 1, 2, and 21 of access (Fig. 109.4) (Rada et al. 2005). Control rats fed sugar or chow ad libitum, rats with intermittent access to just chow, or rats that taste sugar only two times, develop a blunted DA response that is typical of a food that loses its novelty. These results are supported by findings of alterations in accumbens DA turnover and DA transporters in rats maintained on an intermittent sugar-feeding schedule (Hajnal and Norgren 2002; Bello et al. 2003).

109.8.2 Sugar Bingeing Affects Endogenous Opioids

In addition to the effects on DA, opioid systems are also affected by sugar bingeing in a manner that is consistent with the effects of some drugs of abuse. Laboratory animal studies reveal that mu-opioid receptor binding is upregulated in the NAc, caudate-putamen, and cingulated cortex in response to chronic access to cocaine and morphine (Unterwald et al. 2001; Vigano et al. 2003; Bailey et al. 2005). In the striatum and the NAc, enkephalin mRNA is decreased in response to repeated injections of morphine (Uhl et al. 1988; Turchan et al. 1997; Georges et al. 1999). Similar changes have been observed by brain imaging in cocaine-dependent humans (Zubieta et al. 1996).

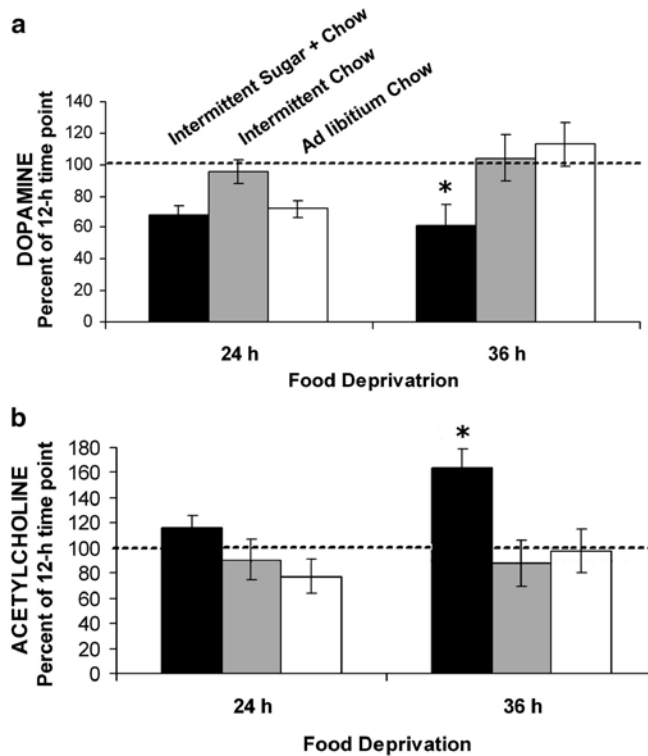
Sugar bingeing also produces a significant decrease in enkephalin mRNA in the NAc (Spangler et al. 2004), as does limited daily access to a sweet-fat, liquid diet (Kelley et al. 2003). Perhaps in response to decreased enkephalin production, mu-opioid receptor binding is significantly enhanced in sugar-bingeing rats, in the NAc shell, cingulate, hippocampus, and locus coeruleus, compared with chow-fed controls (Colantuoni et al. 2001) (Fig. 109.5).
Fig. 109.4 DA release relative to baseline in sugar-bingeing rats and control rats. Sugar-bingeing rats release a surge of accumbens DA in response to drinking sucrose for an hour on day 21 of daily access. DA release, measured using in vivo microdialysis, increases for the sugar-bingeing rats (Daily Intermittent Sucrose and Chow) on days 1, 2, and 21. On the other hand, DA release was attenuated by day 21 in the control groups. The bar indicates the hour during which sucrose or chow was available during the microdialysis tests. These results suggest that repeated surges of DA may be involved in generating sugar dependency ($^*p < 0.05$) (Reproduced with permission from Rada et al. 2005)
Fig. 109.5 Mu-opioid receptor binding in sugar-bingeing rats compared to controls. Animals exposed to intermittent 25% glucose and chow (*black bars*) show increases in mu-receptor binding in the NAc shell, cingulate cortex, and the CA1 pyramidal layer of the hippocampus (Hippo CA1) relative to chow-fed controls (*white bars*) ($^*p < 0.05$) (Taken with permission from Colantuoni et al. 2001)


Fig. 109.6 Extracellular DA and ACh in the NAc following 24 and 36 h of fasting. (**a**) After 36 h of fasting, DA release in the intermittent sugar + chow group (*black bar*) was significantly less than both the intermittent chow (*grey bar*) and ad libitum chow (*white bar*) control groups. (**b**) Extracellular ACh was significantly increased in the intermittent sugar + chow group at the 36 h fasting point compared with both control groups. *p < 0.05 compared with both intermittent chow and ad libitum chow (Taken with permission from Avena et al. 2008a)

109.8.3 Withdrawal from Sugar Bingeing Upsets DA/ACh Balance in the Accumbens and is Opioid Mediated

Behavioral signs of drug withdrawal are usually accompanied by alterations in DA/ACh balance in the NAc; DA decreases while ACh increases. This imbalance has been shown during chemically induced withdrawal from several drugs of abuse, including morphine, nicotine, and alcohol (Rada et al. 1996, 2001, 2004).

Rats bingeing on sugar also show this neurochemical imbalance in DA/ACh during withdrawal. This result occurs both when rats are given naloxone to precipitate opiate-like withdrawal (Colantuoni et al. 2002) and after 36 h of food deprivation (Avena et al. 2008a) (Fig. 109.6).

109.9 Supporting Evidence of Food Addiction

109.9.1 Other Animal Models Show Evidence of Food Addiction

The literature suggests that, like sugar, there may be evidence of a similar addiction-like state that emerges with access to a fat-rich diet. Le Magnen (1990) noted that naloxone could precipitate withdrawal in rats on a cafeteria-style diet, which contains a variety of fat- and sugar-rich foods. Teegarden and

Bale (2007) showed that mice exposed to diets high in fat or carbohydrate for 4 weeks, and then forced to abstain, endured an aversive environment to gain access to their preferred food. They conclude that withdrawal of such a diet elevates a stress state and reduces reward, and that exposure to a high-fat diet reduces this stress and contributes to dietary relapse. We have not found signs of withdrawal or anxiety-like behaviors in rats withdrawn from a high-fat diet (Avena et al. 2009b); however, it is clear that further studies are needed to fully understand the differences between sugar and fat bingeing and their subsequent effects on behavior. Withdrawal is not necessary for drug craving, just like hunger is not necessary for food craving (Pelchat et al. 2004). Moreover, different classes of drugs (e.g., DA agonists vs. opiates) result in specific behavioral and physiological withdrawal signs. Thus, it may be that different macronutrients may also produce specific withdrawal syndromes, some of which may be more easily quantified than others. However, as of now, it appears that sugar is the only palatable substance for which bingeing, withdrawal, abstinence-induced enhanced motivation, and cross-sensitization have all been demonstrated in an animal model.

We began this chapter with a discussion relating binge eating to obesity. Indeed, the findings with animal models that have been presented suggest that binge eating sugar, and possibly even fat, may have some addiction-like properties. However, in our animal model, sucrose bingeing does not affect body weight; the rats compensate for the excess calories obtained in the sugar binge by consuming less rodent chow. But, a combination of sweet-fat does result in increased body weight (Berner et al. 2008). Thus, sweet taste may be largely responsible for producing addiction-like behaviors including a withdrawal syndrome, whereas fat may be the macronutrient that results in excess body weight. The combination of these two macronutrients constitutes a large proportion of the snacks and desserts on which people tend to over indulge, possibly contributing to the desire to overeat and, consequently, gain weight.

109.9.2 Clinical Studies Suggestive of Food Addiction

In addition to the complementary research from animal models, there is clinical support for the theory of sugar addiction. Others have speculated that obesity and eating disorders, such as bulimia and anorexia, may have properties of an "addiction" in some individuals (Gillman and Lichtigfeld 1986; Marrazzi and Luby 1986; Mercer and Holder 1997; Davis and Claridge 1998; Riva et al. 2006). The auto-addiction theory proposes that some eating disorders can be an addiction to endogenous opioids (Marrazzi and Luby 1986, 1990; Heubner 1993). In support, appetite dysfunctions in the form of binge eating and self-starvation can stimulate endogenous opioid activity (Aravich et al. 1993). Bulimic patients will binge on excessive amounts of noncaloric sweeteners (Klein et al. 2006), suggesting that they derive benefits from sweet orosensory stimulation. This finding is related to our result with sugar bingeing and purging. Using the sham feeding preparation, in which rats can binge on sugar that is then "purged" via an open gastric cannula, we have shown that the taste of sugar releases DA and hinders the release of the satiety-associated ACh in the accumbens (Avena et al. 2006). Also, the findings that sugar bingeing cross-sensitizes with amphetamine and cocaine, and fosters alcohol intake, may be related to the documented comorbidity between bulimia and substance abuse (Holderness et al. 1994). Rats will substitute a sweet taste for cocaine when the drug becomes difficult to obtain (Comer et al. 1996), and they may even prefer sweet taste to intravenous cocaine (Lenoir et al. 2007). Similarly, some drug addicts engage in binge eating early in recovery, and report using food as a substitute for drug use to satisfy drug cravings (Cowan and Devine 2008).

New studies have begun to characterize food addiction in humans. The Yale Food Addition Scale, for example, is one of the first psychometrically validated scales used to target food addiction, by identifying feeding behaviors that are paramount to dependency. This tool provides an operationalized

definition of food addiction, and brings it into the clinical realm (Gearhardt et al. 2009). Other studies have shown that self-identified refined-food addicts use food to self-medicate; they eat when they feel tired, anxious, depressed, or irritable in order to escape a negative mood state (Ifland et al. 2009).

Imaging studies in humans have supported the idea that aberrant eating behaviors, including those observed in obesity, may have similarities to drug dependence. Craving-related changes in fMRI signal have been identified in response to palatable foods, and are similar to those seen during drug craving (Pelchat et al. 2004). Similarly, PET scans reveal that obese subjects show a reduction in striatal D_2 receptor availability that is associated with the body weight of the subject (Wang et al. 2004b), and is similar in magnitude to the reductions reported in drug-addicted subjects (Wang et al. 2001). Binge eaters have also been shown to have a "gain of function" of the mu-opioid receptor gene, which correlates with higher scores on a self-report measure of hedonic eating (Davis et al. 2009). Exposure to especially palatable foods, such as cake and ice cream, activates several brain regions including the anterior insula and right orbitofrontal cortex (Wang et al. 2004a), which may underlie cognitive aspects of craving food (Rolls 2006).

109.10 Applications to Other Areas of Health and Disease

Discovering the underlying basis of food addiction will not only alter society's perception of those who are obese and overweight, but it may also impact long-standing policies and traditions regarding health and nutrition. Programs may also incorporate what is known about food addiction's neurochemical basis to help those who are at great risk for developing an addiction. Thus, knowing the underlying reasons behind food addiction will play an important role in preventing some maladaptive feeding behaviors and may even help treat those who are already afflicted.

109.11 Conclusion

This chapter presents and overview of the evidence for the concept of food addiction. The focus is on an animal model of sugar bingeing that can result in addiction-like behaviors. This model suggests that sugar bingeing shares many behavioral and neurochemical similarities with drug abuse. As such, it has implications for the further study and treatment of binge eating, with distinctions between different diets and the role of addiction in generating and perpetuating obesity.

Summary Points

- Food is a natural reinforcer that activates neural pathways that are usurped in cases of drug abuse. Studies suggest that aberrant feeding patterns, such as binging on palatable foods, can produce behaviors and changes in the brain that resemble an addiction-like state.
- Animal models of binge eating are used to study the addiction-like properties of palatable food. This chapter focuses on sugar binge eating. If given a pattern of feeding and deprivation, animals will develop binge eating behavior.
- Behavioral changes indicative of binge eating include withdrawal when the sugar is no longer available, an enhanced motivation to obtain it during abstinence, as well as cross-sensitization to other drugs or drug substitution.

- Neurochemical changes are observed in sugar-bingeing rats that are indicative of an addicted state. These include alterations in DA and opioid receptor binding and mRNA expression, repeated release of DA with repeated binges, and altered DA and ACh release during opiate-like withdrawal.
- Clinical studies have complemented the findings with laboratory animals and have given stronger validity to the concept that food addiction is a condition that exists in some individuals.

Key Terms

Addiction: A state in which the animal comes to depend on a substance for normal functioning. Addiction is characterized by tolerance to the abused substance suggested by (1) increased consumption, with sensitization of certain neurotransmitter systems (2) withdrawal signs in the case of substances that affect opioid systems; and (3) craving measured as excessive ideation or efforts focused on obtaining the substance. This cognition and behavior may become self-destructive in its intensity, and be described in terms of impulsive or compulsive acts.

Binge eating: Series of episodes during which one eats a larger amount of food than normal in a short period of time, while presenting at least three of the following: (1) eating until feeling uncomfortably full, (2) eating large amounts of food when not physically hungry, (3) eating much more rapidly than normal, (4) eating alone due to feelings of embarrassment, (5) feeling disgusted, depressed, or guilty after overeating, or (6) marked distress or anxiety after a binge.

Withdrawal: A negative physical state precipitated by the removal of an addictive substance or by blocking its action in the brain.

Craving: An intense desire for a substance, quantified in animal studies by how hard an animal is willing to work to obtain the desired substance.

Obesity: A condition of extreme overweight. In humans, a person with a body mass index (weight in kilograms divided by height in meters squared) of over 30 is considered obese. Obesity is associated with comorbid illnesses, including heart disease and diabetes. The incidence of obesity has dramatically risen over the past 20 years, and it continues to climb in the industrialized countries of the world.

Chapter 110
The Lingering Impact of Negative Food Experiences: Which World War II Veterans Won't Eat Chinese Food?

Brian Wansink, Koert van Ittersum, and Carolina Werle

Abbreviation

MRE   Meal-Ready-to-Eat is a self-contained, individual field ration in lightweight packaging bought by the United States military for its service-members for use in combat or other field conditions where organized food facilities are not available

110.1 Introduction

How do long-term negative experiences shape long-term food habits? Napoleon famously said, "An army marches on its stomach," yet relatively little attention has been devoted to food in contrast to the tactics and strategies of great battles. There is abundant research demonstrating the immediate short-term influences various environmental cues have on food preferences (Wansink 2006). In contrast, very little research has invested the long-term impact of how a person's food preferences are shaped by their first experience with a food. To better understand and predict people's preferences for different types of foods, it is important to understand the origin of their preferences. This chapter investigates some of the responses American soldiers had to foods they ate during World War II and how their preferences and consumption of these foods changed after they returned to their homes.

This chapter is structured as follows. Using archived survey data collected during World War II, we will determine the most favored and least favored foods served to soldiers in combat, along with how much of them they consumed. Following this, we will review a longitudinal analysis of food consumption patterns of soldiers who were exposed to unfamiliar (Chinese) food while in combat. The combination of the two patterns of data will provide insights as to how food preferences might change under the stress of combat as well as the lingering consequences it might have on preferences and food intake (Wansink et al. 2008).

110.2 Familiar Foods Among Combat Soldiers in World War II

Perhaps the best record of the eating habits of soldiers in World War II was included in an in-depth sociological investigation of training, living, adjusting, and recovering, which was sponsored by the US War Department's Information and Education Division. It was a system of over 150 classified stratified questionnaires covering five or six times as many issues. Parts of it were subsequently published in *The American Soldier* (Stouffer et al. 1949).

Part of the research investigated preferences for various food items that were included in either K-rations, food served in platoon-sized groups of 30, or food items that were included in C-rations, food served in individual field servings. Whereas K-rations were usually prepared in a field kitchen, C-rations were individually eaten, and were more similar to the Meals-Ready-to-Eat (MREs) eaten by today's soldiers.

In two surveys, one conducted with 402 soldiers in September 1944 (S-160-B) and another conducted with 2,549 soldiers in November–December 1944 (S-177), soldiers were asked about their preference for these items. To assess the types of foods eaten, how much they liked those foods, and how much of those foods they consumed, the raw data from the surveys was obtained from the Department of Defense and they were reanalyzed.

When meals were prepared in Army Field Kitchens, the foods were canned, but were frequently prepared and served hot. When asked if they generally received enough food to eat, 11% of the participating soldiers replied "Always," 49% replied "Usually," 39% replied "Usually not."

When asked about the most common items found in these meals, soldiers were asked to indicate which they liked best and which they liked least. For each food they were then asked to indicate whether they generally ate all of it, part of it, or none of it.

The most and least favorite foods are indicated in Table 110.1. The favorites included cheese (31%), chopped ham and eggs (27%), and beef and pork loaf (11%). The least favorite were crackers and biscuits (25%), cheese (17%), and a three-way tie with chopped ham and eggs, beef and pork loaf, and pork loaf with carrots and apple flakes (7%).

Except for three evocative foods – beef and pork loaf, pork and egg yolk, and pork loaf with carrots and apple flakes – the data in Table 110.2 also show how much these soldiers usually ate of each items.

Although chocolate bars were not in the top 3 of best liked food items, it is a food item that is most likely to be completely consumed (76%), followed by cheese (60%) and cheese and bacon (59%).

Table 110.1 The preference of combat (K) rations served from army field kitchens (in percentages)

Food	Which food items do you like best and which food items do you like least?	
	"Like the best"	"Like the least"
Cheese	31	17
Chopped ham and eggs	27	7
Beef and pork loaf	11	7
Biscuits	7	25
Chocolate bar	6	2
Fruit bar	5	3
Cheese and bacon	3	0
Pork and egg yolk	2	3
Pork loaf with carrots & apple flakes	2	7

This table shows the percentage of soldiers who indicate which food item of the list they "like the best" and which food item they "like the least." Because of non-response, not all columns sum to 100%

Table 110.2 The intake of combat (K) rations served from army field kitchens (in percentages)

| | Do you generally eat all of it, part of it, or none of it? | | |
Food	"Eat all"	"Eat part"	"Never eat"
Chocolate bar	76	12	7
Cheese	60	24	7
Cheese and bacon	59	22	7
Fruit bar	47	12	15
Biscuits	42	46	6
Chopped ham and eggs	39	12	15

This table shows for each food item the percentage of soldiers who generally consume the entire food item ("eat all"), the percentage of soldiers who only eat part of it ("eat part"), and the percentage of soldiers who never eat the food item ("never eat"). Nonresponses would bring each row total to 100%
Fig. 110.1 The most favored WWII combat foods are also the least favored. This figure visualizes the relationship between the percentage of soldiers who favor food items the most and the percentage of soldiers who favor food items the least

The least liked food item, biscuits, is also the food item most likely to be only partly consumed (46%), followed by cheese (24%) and cheese and bacon (22%). Finally, there are two food items that stand out as items soldiers indicate they never eat, fruit bars (15%) and chopped ham and eggs (15%). Interestingly, enough, this latter food item is also among one of the best liked food items as well. A couple observations are notable in this data.

First, the same foods were often the most favorite and the least favorite among soldiers. While cheese, chopped ham and eggs, and beef and pork loaf were the three most favorite foods, two of them were also among the least favorite. Many of the other less valenced foods inspired neither love nor hate. Indeed the correlation between a food being the most favorite and it also being the least favorite is 0.45 ($P < 0.05$) (see Fig. 110.1). This strongly suggests there are different segments of background and taste preferences being represented in this data.

There is an expression that one man's meat is another man's poison. These data suggest that the inherent food quality of these items is acceptable to good. What causes cheese to be the most favorite of 31% of the soldiers and the least favorite of 17% probably has less to do with the cheese than with the background, taste preferences, and food associations of the soldiers.

A second observation from these data in Tables 110.1 and 110.2 is that those foods that were the most favorite were also those with relatively high nutrient density. Foods that we would think would be quite tasty – such as chocolate bars and fruit bars were among the most consumed foods in the sample (76% reported eating their entire chocolate bar). In contrast, however, these foods were not among the most favorite. While a reinvestigation of marginal notes in the data revealed no explanation, we might hypothesize that either the overriding need of protein or of the comfort of hot food would trump that of only taste.

Similar results were found with C-Rations, which are the rations soldiers carried into the field by themselves. In the individual rations – the canned C-Rations – soldiers' favorite foods were the ones highest in protein and not those that we would have otherwise assumed tasted the best. Their most favorites were meat and beans (51%), spaghetti and meat (13%), beef stew (6%), chocolate (5%), hash (5%), and ham and eggs (2%). The least favorite were hash (32%), beef stew (19%), biscuits 10%), meat (9%), beans (5%), and corned beef (2%).

In this situation, we have been discussing how a combat soldier responded to foods that were – to a great extent – foods they were familiar with before leaving for combat. In other words, their impression and preferences of these foods had already been formed, and there were associations they had that were independent of the new associations (either negative or positive) that were formed overseas in combat. What we will next examine is the long-term responses to novel or new foods that soldiers were exposed to while in combat.

The soldiers' preference for foods served in combat seems to be related to their previous habits but also to combat-related needs, which explains a preference for energy-dense foods. Energy-dense foods are more satiating providing the energy soldiers needed to accomplish their daily tasks while in the army. But the influence of the army on veteran's lives was not only on the short-term preferences for energy-dense foods; the veteran's experiences during war shaped their food preferences in the long-run. Previous research on the food preferences of children reveals that bad experiences due to the consumption of a food (such as nausea) may lead to food aversion for many years. Our research demonstrates that the context in which a food is consumed can influence adult's food preference and aversion in the long term.

110.3 The Lingering Determinants of Food Preference

Being overseas in World War II opened up the culinary world for many Americans. Indeed, Italian, French, and German food may have tasted fairly good for many returning veterans. They found jobs, started families, and the idea of spaghetti or a bratwurst was not as strange – not as "foreign-sounding" – as it was 5 years earlier (Wansink 2002). Yet compared to the taste of the meat and potato-like cuisine of the Europeans, learning to appreciate Asian cuisines, such as Chinese and Japanese food would have seemed more extreme (Scott and Downey 2007). Asian food was unlike anything most of them had ever eaten (Chin 2005). Why then, did some Pacific veterans learn to love Chinese food and others hated it – even 60 years later?

Part of this could be related to a person's food adventurousness (Stallberg-White and Pliner 1999) or to food neophobia (relative aversion to new foods). Yet another part, however, could be related to country-specific associations (Brunstrom 2005). More specifically, animosity towards foreign countries – the remnants of antipathy related to previous or ongoing military, political, or economic events – may influence different people in different ways. For instance, Klein and Ettenson (1998a, b) found animosity influenced willingness to buy Japanese products in the Chinese city of Nanjing,

where 300,000 civilians were killed by the Japanese in World War II. Similar results from World War II were found by Nijssen et al. (1999), who examined the animosity of Dutch consumers toward Germans. Such visceral experiences may also lead to biased preferences toward these relatively unfamiliar foods.

What is not clear is what causes these biases. There are numerous anecdotal accounts of Vietnam veterans returning to the US with newfound preferences for Asian foods. Yet there are also many accounts of other Vietnam veterans having a powerful aversion to any casserole or meal containing rice. This aversion might be less related to a veteran's personality (such as his adventurousness) than about his experience in the war.

Consider how Chinese food might have been perceived by American veterans of World War II. Although China was an American ally during the war, Chinese food was an unfamiliar food that many Pacific veterans may have largely associated with battles against Japan (Stouffer et al. 1949). For such veterans, the associations they have with Chinese food may have been viscerally influenced by whether their experience in the Pacific are recalled as favorable or unfavorable (Nordgren et al. 2006). For instance, those experiencing intense or frequent combat may let this unfavorable experience negatively bias their long-term perception of Chinese food, or of any Asian food they see as similar (Japanese, Thai, Korean, and so forth). For those who were more removed from the negative associations with combat, there should be less stigma. In contrast, combat experience for a European veteran should have little influence on their perception of Chinese food because there were no proximate negative associations with it.

110.3.1 Investigating Food Preferences in World War II Veterans

To examine the long-term consequences of combat experience on preferences for unfamiliar foods, the homogeneous focus of the sample was American World War II veterans (Wansink et al. 2009). A random selection of 5,000 names of veterans born before 1928 was obtained from US census data. In the year 2000, each veteran was sent a survey, a cover letter, and a business reply return envelope. The cover letter asked them to complete the survey. In return, a small donation was made to the World War II Memorial, they were sent a copy of the major findings of the project, and they were invited to a symposium – Consumer Camp™, then at the University of Illinois at Urbana-Champaign (now at Cornell University) – that discussed the results of the project.

To determine their experience in combat, respondents were first asked to indicate whether they had experienced combat while serving during World War II. Those who responded "Yes," were then asked to note the frequency (1 = infrequent; 9 = frequent) and the intensity (1 = low intensity; 9 = high intensity) of their combat experiences. Veterans were classified as having had a high level of combat experience if the average of their summated score was higher than the mean (6.1 out of 9).

Veterans were then asked to indicate their preference toward Chinese food and their preference toward Japanese food (1 = dislike very much; 9 = like very much). To be able to examine these preferences independent of their general predisposition for variety and adventure, respondents were asked to rate their general level of adventurousness immediately following the war and at the current time (1 = not adventurous; 9 = adventurous). An index for adventurousness was calculated using the average of these two measures. Last, demographic questions were asked.

While there are likely to be memory biases that can affect responses, efforts were made to minimize these biases (Bradburn et al. 2004). Based on a pre-study, questions were worded in a way where they could be answered with the least effort and greatest accuracy.

110.3.2 Is Food Preference Related to Combat Experience?

Of 2,376 surveys that were not returned and were assumed to be delivered, 493 veterans personally responded (20.7%). Among these veterans, 76% were between 76 and 80 years of age, 31% had attended at least 1 year of college, 42% were born in a town with less than 10,000 inhabitants, and 41% currently lived in a town with less than 10,000 inhabitants.

The hypotheses were tested using univariate analysis of variance. As indicated in Table 110.3, the preference for Chinese food was higher among Pacific veterans with low combat experience (little to none) than with the Pacific veterans with high combat experience (5.4 vs. 4.2; F = 8.4; p < 0.001). For European veterans, their combat experience had no impact on their preference for Chinese food (p > 0.05). As expected, previous experiences influenced food preference among Pacific veterans, but not among European veterans.

The same analysis of the liking scores for Japanese food provide further support for the view that combat experience affects long-term food preferences. As expected, Pacific veterans with high combat experience had a less favorable opinion about Japanese food than those with little or no combat experience (2.8 vs. 3.5; F = 3.0; p < 0.05). As was expected, this was not the case with European veterans. Their preferences for Japanese food were unaffected by their level of combat experience (see Table 110.3). The general preference of all veterans for Japanese food was much smaller than towards the more commonly available Chinese food (p < 0.05). Figure 110.2 summarizes the main findings.

When aggregating their responses, 31.8% of the veterans generally liked Chinese food (7–9 on the 9-point scale) and 29.2% disliked it (1–3 on the 9-point scale). Their opinions toward Japanese food were generally more negative: 58.4% of disliked it while only 12% liked it.

One's preference for Chinese food or Japanese food could also be partly explained by personality variables such as one's level of adventurousness. Veterans with a higher level of adventurousness may have a higher preference for foreign food in general. It was unclear whether this personality trait would be sufficient to overcome combat experience.

To examine this, combat experience and self-rated adventurousness were regressed upon preferences toward Chinese food and toward Japanese food. The results in Table 110.4 show that both factors are significant predictors of preference for Chinese food for Pacific Veterans. Combat experience remained an important predictor for Pacific Veteran's preference for Chinese food even when accounting for adventurousness. It is important to note, however, that combat experience and adventurousness still explains only 6.1% of the variance of Pacific veterans' preference for Chinese food 60 years after the war. Nevertheless, it is higher than the variance explained among European Veterans (Adj. R^2 = 0.004). The same analysis for Japanese food was not statistically significant for either group of veterans.

Table 110.3 How World War II combat influenced long-term preference for Asian food

	Low combat experience		High combat experience			
	Mean	SD	Mean	SD	F test value	Sig.
Preference for Chinese food

110.4 Applications for Food Preference Development

After accounting for demographic differences, there is an egalitarian tendency in nutrition, as in public health, to assume all people's experiences and preferences are equal. This is often not effective. For instance, it has been shown that fruit lovers have dramatic psychographic differences

compared vegetable lovers (Wansink and Lee 2004), and telling someone to "eat your fruits and vegetables" will backfire with both segments. Similarly, this paper illustrates that the most loved foods of World War II combat soldiers were also the most hated foods by others. This underscores the critical power of segmentation. Another finding shows that the most preferred foods were those that are higher in proteins, suggesting a preference for energy-dense foods among soldiers. This short-term preference for proteins could be explained by their energy needs due to the army activities. Still the army also influenced the long-term food preferences of veterans.

In the development of long-term food preferences, demographic differences are unlikely to explain anything but the most obvious. People from the South like spicy food; people from poor, rural areas like chicken. Instead, the powerful insights are more likely to be based on psychographic differences and experiences.

Of those veterans who enjoyed Chinese and Japanese food and still ate it with some frequency, there were no characteristics they had in common. Before the war, some had lived in big cities, some on farms. Some had graduated from college, others had never seen a 9th grade classroom.

What did explain their preferences was the level of combat they had experienced as soldiers. When analyzing the profiles of those Pacific veterans who liked Chinese food, we did not find Marines who had been at Iwo Jima or infantry soldiers at Guadalcanal. What we found were mechanics, clerks, engineers, and truck drivers – enlisted men who did not experience the War from the front line. Although their wartime experience was a sacrifice, they did not come home with terrible associations that tainted the taste of food even 50–60 years later. It appears the feelings we have when we first eat a food can follow us for a lifetime.

While there is abundant research demonstrating the immediate effects of environmental cues on food consumption, research investigating the potential long-term effects of contextual experiences with a food on preference remains scarce. Research generally examines the effect of specific food characteristics and for instance personality characteristics on food preferences, largely ignoring the very first experiences people had with a food. Ignoring these early experiences may be an oversight. To really understand food preference and the associated consumption behavior, a thorough and complete understanding is desirable. The importance of the first experience with an unfamiliar food on long-term preferences indicates that extra care must be taken when planning the introduction of new foods and new recipes. Changing initial food perceptions is difficult and understanding the influence of the context of the initial exposure to an unfamiliar food may give insights for improving the healthfulness of the food we eat.

Today people are more exposed to foreign foods in their daily lives; it is easy to find a Chinese or a French restaurant in almost every American city. As a consequence, preference for these foods can integrate into an individual's habits easily. Even so, the context in which a food is consumed for the first time may influence food preferences durably. This is the case when there is immigration. When someone chooses to immigrate to a country the relation established with the food of the new country may be more positive than when this immigration is imposed by political or economical reasons. Further research should look into the effects of immigration experiences and acculturation on food consumption.

Summary Points

- There is abundant research demonstrating the immediate effects of environmental cues on food preference and consumption (Wansink 2006).
- Research on the long-term effects of the context in which people first consume a food on long-term food preference is scarce.

- It is critical to understand all factors shaping food preference.
- The army influenced veteran's short-term food preferences for energy-dense foods and long-term food preferences for foreign food.
- This research demonstrates that traumatic combat experiences shape long-term food preferences, even 60 years after the very first experience with a food.

Definitions and Explanations of Key Terms and Words

Animosity towards foreign countries: The remnants of antipathy related to previous or ongoing military, political, or economic events.

C-ration: An individual canned, precooked or prepared wet ration intended to be issued to US military land forces when fresh food or packaged unprepared food prepared in mess halls or field kitchens was impractical or not available and when a survival ration was insufficient.

Food adventurousness: The self-reported frequency of trying unfamiliar foods on a scale ranging from "never" to "most of the time."

K-ration: An individual daily combat food ration which was introduced by the US Army during World War II.

Long-term food preference: An individual's enduring liking of a particular food.

Mood: A relatively long lasting, affective or emotional state.

Neophobia: The fear of new things, foods or experiences.

Ration: The food allowance for 1 day (especially for military service personnel).

Stress: A state of mental or emotional strain or suspense.

Key Facts About Food Preferences

1. There is abundant research demonstrating the immediate effects of environmental cues on food preference and consumption (Wansink 2006).
2. Research on the long-term effects of the context in which people first consume a food on long-term food preference is scarce.
3. It is critical to understand all factors shaping food preference.
4. Immediate energy needs seem to influence short-term food preferences.
5. This research demonstrates that traumatic combat experiences shape long-term food preferences, even 60 years after the very first experience with a food.

NT	Nontasters
PROP	6-n-propylthiouracil
PTC	Phenylthiocarbamide
T1, T2	Beginning and end of the WRS
VAS	Visual analog scale
WRS	Weight reduction session

111.1 Introduction

Our research on food neophobia and associated food behavior has been undertaken in the context of our studies on adaptation and adaptability of taste perception, which may shed light on relationships that were not previously observed.

Food neophobia, the reluctance to eat new foods, evolved in mammalian species in the context of environmental survival (Rozin and Vollmecke 1986). This primitive behavioral trait is genetically determined in humans as shown by twins and family studies (Cooke et al. 2007; Knaapila et al. 2007). Large variation among individuals has been observed (Potts and Wardle 1998; Pliner and Salvy 2006), of which at least two-thirds is accounted for by genetic factors. Neophobia varies from childhood to adulthood with a maximal intensity from 2 to 6 years old (cf. review by Dovey et al. 2008). Nowadays, the environment in Western societies provides a large diversity of food choices. However, the environmental context of food variety does not necessarily imply

individual large food repertory. There is evidence that food neophobia affects diet variety, notably by reducing fruit and vegetable consumption (Galloway et al. 2003) – replaced by less healthy high-caloric foods – thus favoring the development of obesity and noncommunicable diseases (Falciglia et al. 2000). Although neophobia is largely determined by genetic factors, part of the variation of this complex behavioral characteristic should be explained by the influence of external (environmental) factors. Accordingly, investigating to what extent food neophobia is likely to vary according to these external influences can help to induce more healthy food behavior especially in subjects at risk.

Sensory factors are also important determinants of food choice (Pasquet et al. 2002). Taste perception, the result of long term coevolution between animals and plants, allowed individuals to differentiate beneficial versus toxic or antinutrient natural substances. Although reflecting partly the taste system, the relationship between taste recognition thresholds for various compounds illustrates this dichotomy (Hladik et al. 2003). The ability to perceive sugars and to prefer high caloric foods, leading to accumulation of body fat, is an adaptation to cope with environmental pressure (i.e., seasonal variation, Hladik 1988), which, as for neophobia, can be presently maladaptive. In the same vein, it has been assumed that bitter taste evolved as a defense mechanism to detect potentially harmful toxins in the environment (Wooding 2006). Bitter taste perception – especially for compounds including the N-C=S chemical group such as phenylthiocarbamide (PTC) or 6-*n*-propylthiouracil (PROP) – is genetically determined, discriminating tasters from nontasters (Blakeslee 1932). High sensitivity levels for these compounds may reduce food preferences, notably for green vegetables, and hence induce lower variety in food choices, so that the perception of bitterness might be considered a genetic marker for food preferences in humans (Drewnowski 2000; Dinehart et al. 2006). Since the food behavior of both neophobic and individuals with an increased sensitivity to detect the bitter taste show similar characteristics, it is paramount to investigate relationships between individual taste sensitivity and food neophobia.

In this chapter, we first present a review of current knowledge on the relationship between food neophobia, food preferences, and taste perception. Referring to this conceptual framework, we report the results of a recent study focusing on changes in food neophobia, food use, and food preferences in obese adolescents during a long-term weight reduction session in a residential medical center near Paris, considering their individual taste acuity. One application of this study was to adapt dieting to participants in the medical center and then to improve individual protocols designed to reduce obesity prevalence among children.

111.2 Possible Relation Between Food Neophobia, Food Preferences, and Sensory Perception

111.2.1 *Food Neophobia as a Personality Trait*

Food neophobia is an adaptive behavioral trait evolved in animal species to cope with the presence of toxic substances in several plant or animal products eventually used as food (Rozin and Vollmecke 1986). For instance, a mouse in the presence of a new type of food (potentially poisonous) will hesitate and eat just a bite, thus minimizing the risk of being poisoned. If this "trial" is followed by sickness, the new food will be totally avoided. However, in the cultural context of human societies, the adaptive value of food neophobia might be totally neglected since food choices result essentially from education.

One study (Rigal et al. 2006) has shown that when adolescents are exposed during 10 months in a residential institute out of their family food environment, their food neophobia score, measured with the declarative FNS scale, does not reduce differently from that of a control group staying in their usual environment during this period. This showed that food neophobia as a personality trait (a global response, differing from the neophobia state measured in a context of food presentation) is slowly changing throughout lifetime, when comparing childhood, adolescence, and early adult life (Skinner et al. 2002, Nicklaus et al. 2005). The variation in food neophobia can be represented by an individual trajectory into which changes could be difficult to include. In this vein, Reverdy et al. (2008) showed that at the end of a sensory education program in France, the declared food neophobia decreased significantly in the educated group compared to the control group. Nevertheless, these effects disappeared 10 months later. Thus, sensory education can influence children's food neophobia, but does so only temporarily.

111.2.2 Genetically Determined Taste Perception and Food Preferences

Taste perception has been shaped in an evolutionary context in plants and animal species allowing them to differentiate between beneficial and toxic or antinutrient natural substances (Hladik and Simmen 1996; Dong et al. 2009). In humans, the genetically determined basis of taste perception has been clearly demonstrated for some bitter substances such as thiourea, PTC, and PROP (Reed et al. 2006). The application of psychophysical and anatomical measurements to taste genetics allowed researches to identify supertasters, individuals who live in a "particularly intense taste world" (Bartoshuk 2000; Reedy et al. 1993).

The relationship between food preferences and the genetically controlled taste sensitivity was first explored by Fisher et al. (1961), who found a positive correlation between bitter sensitivity to PTC or to quinine, and the percentage of food dislikes in a list of 118 items. Later investigations were focused on the perception of the bitter compounds analogous to those present in natural foodstuffs (cruciferous vegetable containing the N-C=S chemical group). Taster preschool-aged children have also been reported to rate spinach (Turnball and Matisoo-Smith 2002) or raw broccoli (Bell and Tepper 2006) as less palatable than do nontaster children. The nontaster children (Bell and Tepper 2006) consumed more vegetables, particularly the vegetables that were bitter tasting (olives, cucumber, and broccoli) than did the taster children during a free-choice intake test. Thus PTC or PROP sensitivity could be used as a genetic marker for feeding behavior in the perspective of dietary prevention of chronic diseases (Drewnowski and Rock 1995; Drewnowski 2000; Hung et al. 2004; Tepper et al. 2008). Taking into consideration the PTC/PROP tasting status of individuals could be relevant to healthier dietary patterns, by promoting the consumption of a wider array of foods in sensitive subjects (Tepper 1998, Drewnowski and Rock 1995).

Perceived taste intensities for sweet and/or fatty compounds have also been studied in various age groups in relation to food preferences (Monneuse et al. 1991) considering the risk factors for obesity, metabolic diseases (Reed et al. 2006), and cancer (Liu 2004) related to the consumption of high calorie diets. However, the relationship between nonbitter taste perception and food behavior is still a matter of debate (Reed et al. 2006). Genes coding for sweet taste receptors have been identified (Montmayeur and Matsunami 2002), but without a clear connection with food behavior phenotypes, especially in humans (Kim et al. 2006). Authors have argued that PTC/PROP perception status must be considered prior to any investigation on taste sensitivity and hedonic responses to other taste stimuli when analyzing sensory determinants of food behavior (Pasquet et al. 2002; Yeomans et al. 2007).

111.2.3 A Case Study in Tunis

The relationships between taste sensory responses and food preferences and acceptance were studied in a sample of Tunisian subjects sharing a homogeneous cultural background (Pasquet et al. 2002). It was found that most subjects with a high sensitivity to PROP showed higher preferences for known foods (appreciated in the local cultural context) than the subjects with low taste sensitivity, but they had a reduced food repertory, thus suggesting difficulties at overcoming an inherent neophobia in most PROP-sensitive subjects.

In this study, taste recognition thresholds for sucrose, fructose, sodium chloride, quinine hydrochloride, citric acid, tannic acid, oak tannin, and PROP were determined by presenting, in a semirandomized order (blind-test), a series of graded aqueous solutions of each product. Subjects (random sample of 123 adults of both sexes, aged 19–59) also tasted and rated the pleasantness/unpleasantness of 4 supra-threshold solutions of sodium chloride and sucrose. All subjects completed a checklist of 43 food items representative of Tunisian diet rated in terms of flavor, on a Labeled Affective Magnitude (LAM) scale.

According to underlying distribution of PROP taste recognition thresholds, the subjects were separated into three categories: "nontasters" (NT), "medium-threshold tasters" (MTT), and "low-threshold tasters" (LTT) (Fig. 111.1). Results bring out the specificity of most sensitive subjects (PROP LTT), as exhibiting greater taste sensitivity for most tested substances compared to the other subjects. A relationship was found between PROP thresholds and food preferences. PROP LTT status is linked to higher food preference ratings for many currently consumed food items on the list. Mean preference rating for the presented list is also higher in LTT subjects, irrespective of sex, age, and sociocultural influences (Table 111.1).

When focusing on the list of food consumed by all subjects, there was no difference in dislikes between groups. However, when given orally solutions of sodium chloride – generally rated as aversive – the degree of dislike increases from the least sensitive (NT) group to the most sensitive group (LTT). Besides, when considering the food list including all consumed and not consumed foods, most sensitive subjects exhibited a higher percentage of unknown and not consumed food than other subjects (Fig. 111.2).
Fig. 111.1 Distribution of 123 Tunisian subjects in three groups according to PROP recognition thresholds. A range of 12 PROP solutions (1.9×10^{-6}–3.8×10^{-3} M) was used. All subjects with an actual estimated threshold above 1.68×10^{-4} M (equivalent to observed threshold at solution #8) have been classified as "nontasters" (*NT*) and subjects with a threshold below 2.1×10^{-5} M (equivalent to observed threshold at solution #5 have been classified "low threshold taster" (*LTT*)

Table 111.1 Values of the *t* test of the differences between groups of PROP tasters for preference ratings for Tunisian food items

	(LTT + MTT) Versus NT (*t*)	LTT Versus (MTT + NT) (*t*)
Barley bread	–0.60	2.17**
Chorba	–2.82**	–0.26
Aubergine	–1.28	2.95**
Oranges	0.89	2.01*
Liver	1.20	2.90**
Offal	0.29	2.01*
Eggs	0.58	3.22**
Milk	2.47*	–1.17
Lben (curdled milk)	–0.74	2.24*
Sman (rancid butter)	–1.26	2.23*
Arise	2.47*	2.02*
Chili	–1.28	2.33*
Mint	0.20	2.20*
Green tea	–2.40*	–0.92
Mean of the preference ratings	–0.25	3.17**

*$p < 0.05$;**$p < 0.001$

Low threshold tasters (LTT) tend to rate preference for foods higher than the other subjects (MTT + NT). For all other foods in the list of 43 items, no significant difference is observed
Fig. 111.2 Percentage of food items unknown or not consumed in the list by the most sensitive subjects (LTT) compared to all other subjects (MTT + NT). LTT actually consume a significantly lower number of food items ($p < 0.05$) than all other subjects

111.2.4 PROP Perception in Relation with Temperamental Traits

Few studies have investigated the relationship between PTC or PROP taste sensitivity with temperamental traits and psychometric variables. In the 1960s, Fischer moved away from the focus on genetics and began to consider the behavioral implications of genetic variation in taste. He found associations between PROP tasting and drug sensitivities (Fischer et al. 1965), personality type, food preferences, and smoking habits (Fischer et al. 1963). Mascie-Taylor et al. (1983) showed that PTC nontaster students were significantly more "placid", "relaxed", "practical" and scored higher on IQ tests than their

taster counterparts. The same relationship with IQ was observed in children in a recent paper (McAnally et al. 2007). Other studies indicated that a high PROP/PTC sensitivity generally corresponds to pickiness or to an anxious temperament, as in early infancy (Chiva 1985). Conversely Ullrich et al. (2004) did not find more subject with food adventurousness (a proxy of food neophobia) among PROP tasters than among PROP nontasters but their results suggest that, together, taste sensitivity and food-adventurousness statuses could reveal consumer likes and dislikes.

111.3   *Case Study:* Changes in Food Neophobia and Food Preferences During a Weight Reduction Session (WRS)-Relationships with Taste Acuity

According to the foregoing, it appears that investigations should be conducted to describe more directly the relationship between food neophobia and taste sensitivity.

111.3.1   *Investigating Taste Perception, Food Neophobia, Food Familiarity, and Liking in Obese Adolescents*

The relationship between taste acuity and food neophobia, and food familiarity and liking has been studied in French obese adolescents of both sexes: 28 girls and 11 boys aged 10.5–17.5 years (mean 14.7 years) in the context of a longitudinal protocol of WRS in a residential place near Paris (Monneuse et al. 2008). Mean body mass index (BMI) was 39.5 kg/m^2 (ranging from 30.9 to 51.6) at T1 and 29.7 kg/m^2 (ranging from 22.1 to 42.1) at T2. BMI for age was expressed in terms of Z-scores using the sex-specific CDC BMI for age reference curves (Centre for Disease Control and Prevention 2000). The figures are 2.47 (ranging from 2.02 to 2.99) at T1, and 1.75 (ranging from 0.48 to 2.59) at T2. The obese adolescents ate all of their meals at the clinical centre, where consumption of a wide variety of foods was encouraged with a long-term exposure to multiple food experiences (Rigal et al. 2006). Although most foods served are known by the subjects in the French cultural context, some of them may not be usually served at the family table, where a limited repertoire represents specific habits. As in most French collective systems for children, the food served during the WRS covers a very broad range.

Determination of taste recognition thresholds was carried out using a series of four pure chemicals in solution in a commercial drinking water selected for its low mineral content: sucrose, citric acid, sodium chloride, and PROP (Simmen et al. 2004). The testing procedure was the staircase-method. The four series of solutions were presented one after another, in a random order to which the subject was blind. Once the taste of two successive concentrations was recognized successfully, the subject was given the highest previously unrecognized concentration (first reversal). This up-and-down procedure was performed twice until the taste of two increasing stimuli was correctly named. The actual recognition threshold was calculated as the mean of the lowest concentrations recognized in each ascending run.

Although PROP-sensitivity could be considered a marker of global taste acuity (Pasquet et al. 2002; Hong et al. 2005), considering the moderate correlations found by Hladik et al. (2002) between taste recognition thresholds for various taste compounds, we drew also an individual global taste acuity score (GTAS). It was determined by grouping threshold data for each tested substance into

terciles and attributing, respectively, score 3, 2, and 1, for the first, the second, and the third tercile. The GTAS was then calculated as the sum of the score values. Thus, in contrast to threshold concentrations, lower GTAS scores reflect poorer taste acuity. The study sample was finally divided into three categories of subjects with increasing GTAS for testing relationships with neophobia.

Supra-threshold-perceived intensities have been measured for solutions of various concentrations provided in a random order for sodium chloride, sucrose, and PROP. The perceived intensity of each solution was marked by the subject on a nine-point scale (VAS) labeled at the extremities with "no taste" [1] and "extremely intense taste" [9], and the intensity values obtained for the concentrations of each taste were then added. According to these scores, the study sample was divided into three groups of increasing taste perceived intensity for each tested substance.

Food neophobia was measured on FNS scales, slightly modified in comparison to the one first developed by Pliner and Hobden (1992), at the beginning (T1) and at the end (T2) of the WRS. Food familiarity and likes or dislikes for different food categories were assessed. Each subject rated, at least 2 h after their last meal, a 60 items *ad hoc* food familiarity and liking questionnaire (FFLQ). The FFLQ includes seven food categories which differ by the frequency of exposure to adolescent subjects throughout the WRS. Among these categories, fruit and vegetables, calorie-reduced foods, and breakfast foods represent three categories frequently offered and for which variety is probably larger than in the participants' home. Foods rarely served were tested through two categories: animal products and relatively high energy foods. The list also included foods never served because of their very high caloric density or because of their unusual occurrence in the French adolescents' diet. We also included spices as one category because of our parallel interest in flavor responses. Different scores were calculated for each subject from the FFLQ: (a) number of unknown foods (sum of "No" responses to the familiarity question); (b) mean food liking (mean of all liking scores given for the foods that have already been tasted); and (c) food category likings (mean liking scores for each of the seven food categories). Higher scores indicate higher likings.

111.3.2 Influence of Taste Acuity on Food Neophobia and Food Liking Changes During the Weight Reduction Session (WRS)

Globally, FNS scores decreased between T1 and T2 (Monneuse et al. 2008) as previously reported in the 72-subject larger sample (Rigal et al. 2006). During this period, WRS have allowed new foods experiences as attested by the familiarity and liking results, namely a significant decrease in the number of unknown foods in the FFLQ and an increase in the scores for three food category likings (fruits and vegetables, breakfast foods, and calorie-reduced foods). Interestingly, both the decrease in food dislikes and the increase in liking for fruits and vegetables were correlated with a decrease in the BMI for age.

We found in this sample a low proportion of PROP "nontasters": six adolescents (all girls) out of 39. Obese adolescents did not differ in BMI according to PROP status. Significant correlations were observed between taste thresholds for sucrose and sodium chloride, for sucrose and PROP, for sodium chloride and citric acid, and for sodium chloride and PROP.

No significant relationships were observed at T1 between taste variables and food neophobia. However, significant relationships were observed between taste acuity data and food-related behavioral changes during the WRS. GTAS was associated positively with the change of FNS and negatively with the change in liking for fruits and vegetables: "high GTAS" category subjects (with high taste acuity) were characterized by limited reductions in FNS (T2-T1) (Fig. 111.3) and less sensitive subjects showed greater increase in the acceptability of healthy foods, especially fruits and vegetables (not shown).
Fig. 111.3 Changes in food neophobia score of obese adolescents during a WRS according to the global taste acuity score (three categories of GTAS). The study sample is divided into three groups of subjects ($n = 11$, 14, and 14, respectively) of increasing taste acuity including, respectively, 5, 11, and 12 girls. Differences between subjects grouped according to GTAS were assessed using a Student's *t*-test. Box and whisker plot: mean and SE

As regards supra-threshold perceived intensities, PROP data gave better correlations with food-related behavioral changes than did sucrose and NaCl. PROP perceived intensity was related positively with changes in food neophobia scores (lower ratings, greater declines), and negatively with changes in liking for fruit and vegetable (lower rating, greater increase, Fig. 111.4) and for spices, consistent with the general direction of associations observed with the threshold measures.

Therefore, taste perception, especially PROP sensitivity, may reduce the likelihood and/or magnitude of food-related attitudinal changes, particularly vis-à-vis neophobia and liking for fruit and vegetable. It appears to be a predictor of the magnitude of changes in food behavior achieved during a WRS of obese adolescents.

Thus, among obese subjects participating in a WRS, those with greater taste acuity have more difficulties in overcoming food neophobia, and accepting healthy foods, notably fruit and vegetables. Conversely, subjects with low taste sensitivity can significantly improve their food behavior, increase their food repertory, and hence change their own trajectory of food neophobia.

111.3.3 Analysis of the Relation Between Taste Perception, Food Neophobia, and Food Likings

According to the results of the Tunis study, we would have expected to observe a relationship between taste (especially PROP taster status) and neophobia at the beginning of the WRS. The absence of such relationship in our study could be due to the specificity of our sample, namely subjects with metabolic disorders, that could have consequences in taste acuity levels (Pasquet et al. 2007).
Fig. 111.4 Changes in the liking for fruit and vegetable score of obese adolescents during a WRS according to the perceived intensity of supra-threshold PROP solutions. The study sample is divided into three groups of 13 subjects of increasing PROP-perceived intensity including, respectively, 7, 10, and 11 girls. Differences between subjects grouped according to supra-threshold rating scores were assessed using a Student's *t*-test. Box and whisker plot: mean and SE
Fig. 111.5 Key features of food neophobia: hypothetical model to explain changes in food preferences, (especially for fruit and vegetables) according to taste perception differences among individuals. *Plain lines* represent the non-tasters, *dotted lines* represent the tasters

However, taste responsiveness, whether determined on the basis of taste recognition thresholds or supra-threshold intensity ratings, appears to change the attitude to food during WRS for obese adolescents. Our study is, to our knowledge, unique in showing a relationship between taste acuity and changes in attitude to food following a change in available foods, meal structure, and educational context. Greater taste acuity seems to make it more difficult to overcome food neophobia, and to accept healthy foods, notably fruit and vegetables as illustrated in a model of interaction of key features of food neophobia (Fig. 111.5).

If one considers food neophobia as a temperamental trait (at least when measured by FNS; Rigal et al. 2006), the relationship that we found between gustatory perception and changes in food neophobia highlights the relationship between psychological traits and sensory factors.

Another relationship may be suggested by the results of psychophysical studies of young and middle-aged adults (Goldstein et al. 2005; Simchen et al. 2006) showing that individuals least sensitive – either considering PROP status or global taste acuity – have higher BMIs than more sensitive individuals. Thus, lower taste acuity could favor weight gain through higher adaptability to an eating environment promoting excessive calories consumption, as in Western affluent societies. In the same way, the environmental context of our study (dieting program) and the "plasticity" of less sensitive subjects may explain the important positive changes in food-related behavior. Obese adolescents with high taste sensitivity may be less likely to benefit from WRS programs, and probably need an adapted weight reduction protocol.

Since neophobic or taste-sensitive individuals share the same tendency toward a narrow food repertory with healthy foods being under-represented, it would be necessary to investigate any possible interaction or additive effect of these parameters of food behavior. In our sample, the few adolescents that were both nontaster and non-neophobic were much more prone to liking fruit and/or vegetables at the end of WRS than did the other subjects (unpublished data). However, although this finding is consistent with current views on the relationship between sensory factors and food related attitudes, the small sample size does not allow us to draw a definitive conclusion on any interaction of both parameters. More research is necessary to propose, at the beginning of the WRS, a preventive screening of obese patients that would include the FNS questionnaire together with taste evaluation to maximize the changes of success in weight reduction and behavioral changes.

In conclusion, the results of this study suggest that taste sensitivity, especially PROP sensitivity, may reduce the likelihood and/or magnitude of food-related attitude to changes, particularly vis-à-vis neophobia and liking for fruits and vegetables. This should be taken into account in attempts to optimize the outcomes of weight reduction programs in obese adolescents.

111.3.4 Applications to Other Areas of Health and Disease

Concerning application to other areas of health and disease, in attempts to optimize the outcome of weight reduction programs in obese adolescents, taste sensitivity should be considered to adapt the program of a WRS to individual characteristics.

Indeed, in the context of our study focusing on massively obese adolescents, those who have high taste sensitivity among these obese adolescents may be less likely to benefit from the WRS, and probably need an adapted weight reduction program. To detect these individuals, quantification of fungiform papillae or taste pores and determining a global taste score as GTAS in our study would be more tedious than a rapid and simple screening test with PROP. A filter paper disk method has showed to be a reliable screening tool for assessing sensitivity to PROP (Zhao et al. 2003).

Lifestyle intervention is effective in motivated obese children to reduce excess weight and improve the cardiovascular risk factor profile. Therefore, all diseases related to obesity should be treated with lifestyle intervention in this age group whenever possible. Since genetic variations influence outcome in respect of both excess weight reduction and improvement of cardiovascular risk factor, unsuccessful children should not be blamed. Putting together genetic research and clinical intervention studies represents a new promising field to prove the impact of genetic variants on body weight and to understand the different outcomes.

Summary

- Food neophobia, the reluctance to eat new foods resulting from a long-term co-evolution of animals and plants, is genetically determined as a temperamental trait that, in humans, varies slowly throughout lifetime according to individual characteristics, but would not much vary in response to external influences.
- The genetically determined taste perception of bitter substances (such as thiourea, PTC, or PROP), as a marker of taste acuity, mediates food dislikes.
- Most subjects with a high sensitivity to PTC or PROP show higher preferences for known foods (appreciated in the local cultural context) than subjects with low taste sensitivity, but they have a reduced food repertory, thus suggesting inherent neophobia in most sensitive subjects.
- There is a relationship between sensitivity to PTC or PROP and some temperamental characteristics, a low sensitivity corresponding to relaxed or placid temperaments, whereas high sensitivity generally corresponds to pickiness and anxious temperament.
- Subjects with a low sensitivity to PROP or PTC tend to be overweight. It can be hypothesized that lower taste acuity, together with temperamental traits such as neophilia and placidity, could favor weight gain through a higher adaptability to an eating environment promoting excessive calorie consumption, as in Western affluent societies.
- Among obese subjects participating to a weight reduction session (WRS), subjects with high taste sensitivity have difficulties overcoming food neophobia.
- Among obese subjects participating in the WRS those with low taste sensitivity can significantly improve their food behavior, increasing food repertory, thus partly overcoming food neophobia.
- In the environmental context of the WRS, "plasticity" of less- sensitive subjects may explain the important positive changes of food behavior and preference for fruits and vegetables. However, additional or interactive effects of taste and neophobia statuses on food-related behavioral changes remain to be demonstrated.
- Application to other areas of health and diseases: Taste sensitivity (and perhaps neophobia) status should be determined in order to adapt weight reduction programs to individual characteristics.

Definitions

Aqueous solutions: Ranges of concentrations of solutions usually used in our studies are sucrose and fructose (10 solutions: 2.0–1,000 mM), citric acid (8 solutions: 0.20–25 mM), NaCl (12 solutions: 1.77–1,000 mM), PROP (15 solutions: 0.001–3.2 mM), quinine hydrochloride (11 solutions: 0.4–400 μM), tannic acid (12 solutions: 4–8,000 μM), oak tannin (9 solutions: 0.02–6 g/l).

BMI: Body mass index is a commonly used index of relative weight. BMI is calculated as weight divided by height squared, thus expressed in kg/m². An adult who has a BMI between 25 and 29.9 is considered overweight. An adult who has a BMI of 30 or higher is considered obese.

BMI for age and sex: It is expressed in terms of Z-scores using growth charts, such as the sex specific CDC BMI for age reference curves.

FFLQ: It is a food familiarity and liking questionnaire used to measure the food familiarity (food use) and food preference on liking scales. In our study it was composed of 60 food items, a few of them supposed to be unfamiliar for adolescents.

Food preference: It is the selection of some food items over others. Food preferences data are usually collected from answers to questionnaires with food lists adapted to age and cultural context. The food lists are presented in random order on a booklet, each item on separated sheet with a scaling system used to determine food likes and dislikes.

Food use: It is a food item that has already been tried and is known. For example, a labeled box, inserted above each preference scale, is to be filled by participants with a binary response (Yes/No) to answer the question: "Have you already tasted this food?." It is a measure of food familiarity.

Food neophobia: It is the fear of tasting a new food. It is considered a biological reflex evolved to minimize the risk of ingesting toxic foods.

FNS: Food neophobia scale is a paper and pencil measure of the trait of food neophobia (first a 10-item test). For the obese adolescents, we used a French validated translation of the declarative standard questionnaire of the FNS including 13 items.

FNS score: In our study, it was equal to the mean of ratings for 13 items/4 points (disagree a lot, disagree, agree, agree a lot, respectively from 1 to 4) scale questionnaire. According to the phrasing of the original questionnaire, seven items were reverse-scored, so that higher scores are indicative of a greater neophobia.

LAM: Labeled Affective Magnitude scale is one of the scales used to determine food preference: each sheet includes a food item presented with an 11-point labeled vertical scale.

Perceived taste intensity: It is the intensity perceived when tasting supra-threshold solutions starting from threshold to the highest concentration. It is evaluated with a scaling system.

Preference rating: It is the score of pleasantness/unpleasantness of solutions or of food items indicated on specific hedonic scales.

PROP: Genetic sensitivity to the bitter tasting 6-*n*-propylthiouracil (PROP) is considered a marker for preferences/aversions, especially foods with bitter taste.

Taste recognition threshold: It is the lowest concentration of a taste stimulus in an aqueous solution for which the subject is able to recognize the right taste. The subject is informed of various taste categories proposed before each ascending run. Taste recognition thresholds have been determined by presenting, in a semi-randomized order (blind-test), a series of graded aqueous solutions of each product.

VAS: Visual Analog Scale is one of the scales used to indicate perception intensity or liking of a taste stimulus in an aqueous solution or of a food item. For example, the 9-point scale labeled from "I don't perceive at all" (1) to "I perceive a lot" (9) or/and "I don't like at all" (1) to "I like a lot" (9).

WRS: Proposed in a residential context, it is a weight reduction session of 10 months mean duration (T1 the beginning, T2 the end) and aims at encouraging participants to consume a wide variety of foods, including fruit, vegetables, and reduced energy products. Variety is also encouraged for breakfast that should account for about 20% of daily energy intake.

FDA	Food and Drug Administration

112.1 Introduction

Neural and hormonal communication between the gut and brain modulate appetite, feeding, and digestion (Bray 2000; Sanger and Lee 2008). In an integrated gut–brain–energy axis, gastrointestinal (GI) motility, gastric acid secretion, digestion, and defecation are coordinated with appetite, satiation,

and metabolism. Indeed, complex disorders linked with digestion including functional dyspepsia (FD), gastroesophageal reflux disease (GERD), eating disorders, gastroparesis, and irritable bowel syndrome (IBS) are associated with diverse symptoms affecting the entirety of the GI tract such as nausea, vomiting, abdominal discomfort, and early satiety. In this chapter, we illustrate the links between gastric function and appetite and their dysregulation in dyspeptic disorders. In addition, we discuss how an understanding of the relationship between the gut–brain–energy axis can be used to develop novel therapies that address the polysymptomatic nature of functional GI disorders.

112.2 Dyspeptic Disorders

Dyspepsia as defined by the Rome III criteria (Drossman 2006) requires the presence of one or more of the following symptoms: postprandial fullness, early satiety, and epigastric burning or epigastric pain (Talley et al. 2008) (Tables 112.1 and 112.2). Unexplained nausea with vomiting and heartburn were included in other categories (Table 112.3) (Drossman 2006; Tack et al. 2006; Talley et al. 2008).

Dyspepsia is associated with a variety of organic and functional disorders. Organic causes of dyspeptic symptoms include peptic ulcer, cholelithiasis, reflux disease, or malignancy. In patients initially presenting with dyspepsia, about 33–50% have an underlying organic disease (Allescher 2006). However, routine clinical evaluation and procedures do not reveal the cause of symptoms in the majority of patients with dyspepsia. If these symptoms persist for greater than 3 months with symptom onset of at least 6 months, affected patients are categorized as having FD. Functional Dyspepsia, a functional gastroduodenal disorder (FGDD) (Table 112.3) (Tack et al. 2006; Talley et al. 2008) or functional gastrointestinal disorder (FGID) (Drossman 2006), has previously been

Table 112.1 Key features of dyspepsia

1 The characteristic symptoms of dyspepsia are postprandial fullness, early satiety, and epigastric burning or epigastric pain
2. Dyspepsia is associated with a variety of organic and functional disorders
3. Dyspeptic symptoms caused by organic disorders include peptic ulcer, cholelithiasis, reflux disease, and malignant disease
4. When the routine clinical diagnostic procedures reveal no reasonable explanation for their dyspeptic symptoms, the majority of patients are categorized as having FD

This table lists the key facts of dyspepsia including the characteristic symptoms and causes

FD Functional dyspepsia

Table 112.2 Dyspeptic symptoms defined by Rome III (Adapted by permission from Elsevier Limited, Tack et al. 2006; Drossman 2006)

Symptom	Definition
Postprandial fullness	An unpleasant sensation akin to the prolonged persistence of food in the stomach
Early satiation	A feeling that the stomach is overfilled soon after starting to eat. This feeling is out of proportion to the size of the meal and results in the patient being unable to finish the meal
Epigastric pain	Pain located between the umbilicus and sternum in the midline of the torso. The pain is a subjective and unpleasant feeling but difficult to describe. Some patients may describe feelings of tissue damage or chest pain
Epigastric burning	Pain located in the epigastrium that has a burning quality but does not radiate to the chest

Table 112.3 Rome III criteria for functional gastroduodenal disorders (FGDD) (Adapted by permission from Elsevier Limited, Tack et al. 2006)

B			FGDD
	B1		Functional dyspepsia
		B1a	Postprandial distress syndrome
		B1b	Epigastric pain syndrome
	B2		Belching disorders
		B2a	Aerophagia
		B2b	Unspecified excessive belching
	B3		Nausea and vomiting disorders
		B3a	Chronic idiopathic nausea
		B3b	Functional vomiting
		B3c	Cyclic vomiting syndrome
	B4		Rumination syndrome in adults

referred to as nonulcer dyspepsia (NUD), essential dyspepsia, or idiopathic dyspepsia. Nausea, vomiting, and heartburn were previously considered in the diagnostic criteria of FD, but, because appetite is influenced by these symptoms as well as dyspepsia, we broadly consider all of these symptoms.

112.3 Physiologic Aspects of the Gut–Brain Axis

The gut and brain are highly integrated and communicate bidirectionally through neural and hormonal pathways (Jones et al. 2006). For example, psychosocial factors can influence digestive function, symptom perception, disease presentation, and outcome. Conversely, visceral pain can affect central pain perception, mood, and behavior.

112.3.1 Neural Aspects

The cephalic phase of eating prepares the gut to receive, digest, and absorb food (Sanger and Lee 2008), and this provokes significant changes in GI motor functions and the secretory response to eating. These stimuli are transmitted to the gut via the vagus nerve (Zafra et al. 2006). Thoughts of appetizing food, and the sight, smell, and taste of food, all help to initiate the cephalic phase. As the esophagus and stomach receive food, their motility changes. Completion of a meal then leads to satiation, defined as a feeling of having consumed enough or a sensation of fullness. After the stomach and upper small intestine are emptied of their contents, a fasting phase of motility is re-adopted and the migrating motor complex (MMC) returns. MMC is a cyclic pattern of motility and secretion that begins in the stomach or small intestine and terminates in the distal regions of the small intestine including the terminal ileum. Within the small intestine, the MMC exhibits three phases. Phase I is a period of near-quiescence; phase II involves short- or nonpropulsive contractions occurring with an irregular frequency; and phase III is a relatively short burst of high-amplitude propulsive contractions (Husebye 1999). The MMC is also accompanied by cyclic variations in gastric and pancreatic secretion, gallbladder emptying and splanchnic blood flow. The phase III MMC is thought to clear the stomach and intestine of undigested material, thereby preventing bacterial overgrowth in the upper gut; it may also promote sensations of hunger. Gastric, biliary, and pancreatic secretions are also affected by the MMC, and the MMC may help to prepare the gut for the consequences of eating. Finally, MMC activity is terminated upon meal ingestion.

Many upper gut functions depend on signaling by the vagus nerve. The vagus nerve extensively innervates the upper GI tract, and most of the nerve fibers are unmyelinated afferent C-fibers that function in mechanosensation (signaling muscle stretching and contraction) and chemosensation (monitoring the chemical environment of the gut lumen) (Powley et al. 2005). Most afferent nerves from the gut terminate in the nucleus tractus solitarius (NTS) in the dorsal brainstem, but several nerve fibers project to the area postrema (AP), a circumventricular organ within the brainstem. From the NTS, nerve fibers project to motor nuclei (e.g. the dorsal motor vagal nucleus (DMVN)) and higher regions of the brain including the parabrachial nucleus, hypothalamus, amygdala, and insular cortex (Andrews and Sanger 2002). The combination of projections of afferent vagal fibers in the brain and the extensive distribution of vagal terminals in the gut helps the vagus nerve fulfill its functions to regulate normal physiologic responses (e.g. the cephalic phase of eating and the subsequent response during feeding), mediate different vago-vagal reflexes (e.g. transient lower esophageal sphincter (LES) relaxation and gastric accommodation), and regulate the strength of antral propulsive contractions and other basic functions (e.g. secretion, motility, and pancreatic function). Additionally, the vagus nerve mediates pathophysiologic sensations and reflexes including nausea, early satiety, and vomiting (Powley et al. 2005; Andrews and Sanger 2002). Among the best examples of the close relationship between the vagus and the enteric nerves is gastric accommodation. This process is initiated as a vago-vagal reflex following oropharyngeal stimulation and gastric exposure to an ingested meal. Efferent vagal neurons activate inhibitory nerve pathways within the enteric nervous system (ENS) through nitric oxide signaling pathways to first promote "receptive accommodation" and then maintain this relaxation through "adaptive accommodation" (Takahashi and Owyang 1997).

112.3.2 Hormonal Aspects

A number of different hormones are secreted by the gut and adipose tissues during feeding, digestion, or fasting that can profoundly affect the GI tract (Sanger and Lee 2008). Some hormones directly affect secretory function along the GI tract (e.g. gastrin stimulates acid secretion by parietal cells), and major sites of hormone action also include the enteric and vagal neurons and the AP. The AP has a greatly reduced or absent blood–brain barrier. Consequently, the AP is one of the main sites within the central nervous system where blood-borne signals (e.g. hormones, cytokines, toxins) can directly affect the brain by initiating signaling from the AP along nerve projections to the adjacent NTS and higher regions of the brain. Additionally, some hormones can cross the blood–brain barrier including those with specific transporters such as leptin and insulin (Banks 2006). Hormones released from the gut both act on the ENS to contribute to the development of the MMC cycle and act on the CNS to promote the gradual reestablishment of appetite. Other hormones are released during fasting that are not associated with any particular phase of MMC activity. The concentrations of leptin and glucagon-like peptide 1 (GLP1) are low during fasting while those of ghrelin and orexin are high. Much research has focused on the hormones whose plasma concentrations increase during fasting, and it is hypothesized that these hormones strongly affect sensations of hunger and energy expenditure. In addition to these systemic effects, it is becoming increasingly clear that fasting-associated hormones can also strongly affect a myriad of GI functions, possibly to prepare for the reception of food. Indeed, such a role has been proposed for ghrelin, the first orexigenic hormone identified that is produced in and released from the stomach. Ghrelin has a well-established role in increasing appetite and food intake and stimulating gastric emptying and acid secretion, and it at least partly mediates these functions through a vagal nerve pathway (Date et al. 2002; Masuda et al. 2000). Table 112.4 summarizes the hormones released from the gut with known GI activity.

Table 112.4 Major hormones released from the gut with known GI activity (Adapted by permission from Nature Publishing Group, Sanger and Lee 2008)

A. Hormones released during fasting

Hormone	Release site(s) and stimuli	Functions
Ghrelin	Stomach (where the largest amounts are found) before a meal; the duodenum, small intestine, arcuate nucleus and other sites produce smaller amounts	• Increases appetite and stimulates feeding when peripherally and centrally administered • Increases the secretion of growth hormone and, to a lesser extent, the release of other hormones including prolactin, adrenocorticotropic hormone and cortisol • Stimulates gastric motility and emptying
Orexin A and B	Cells throughout the GI tract including the myenteric plexus, mucosal endocrine cells, and endocrine pancreas	• Depolarizes enteric and vagal afferent neurons and inhibits small intestinal MMC activity when locally applie • Stimulates rat gastric emptying and acid secretion
Motilin	The jejunum and duodenum during phase III of the MMC	• Initiates MMC phase III-like activity and increases gastric emptying

B. Hormones released during feeding/digestion

Hormone	Release site(s) and stimuli	Functions
Gastrin	Upper gut (antrum and duodenum) in response to food in lumen	• Stimulates gastric acid secretion by binding CCK-2 receptors on parietal cells • Also reduces lower esophageal sphincter pressure and promotes gastric emptying
CCK	Duodenum and jejunum in response to fat and protein intake	• Reduces feeding and slows gastric emptying by signaling through CCK-1 receptors on vagal mechanoreceptive nerve terminals • Reduces feeding, slows gastric emptying, and decreases nausea and vomiting by signaling through CCK-2 receptors in the AP • Stimulates gall bladder contraction and exocrine pancreas secretion
PYY	Small intestine postprandially	• Acts as an "ileal break" by reducing food intake • Slows gastric emptying, intestinal fluid and electrolyte secretion and intestinal meal transport
GLP1	Small intestine and colon after a meal containing fat or carbohydrates	• Reduces gastric emptying and small intestine transit through vagus nerve signaling • Reduces food intake in humans and stimulates insulin release
PP	The pancreas in response to food intake in a vagal cholinergic dependent manner	• Inhibits gastric emptying, acid secretion, pancreatic exocrine function, gallbladder contraction, and food intake • Alters patterns of hypothalamic gene expression suggesting a role of PP in modulating gut function and food intake over time; distinguishes the actions of PP from those of CCK
Oxyntomodulin	The pancreas in response to food ingestion, especially the presence of fatty acids in the lumen of the intestine	• Reduces food intake, gastric emptying and gastric acid secretion; may act via the GLP1 receptor
Amylin	The pancreas in response to food; co-secreted with insulin	• Decreases hunger (anorectic effects) via the AP • Slows gastric emptying (probably via the AP) • Antagonism accelerates gastric emptying of liquids in rats

GI Gastrointestinal, *MMC* Migrating motor complex, *CCK* Cholesystokinin, *AP* Area postrema, *PYY* Peptide YY, *GLP1* Glucagon-like peptide 1, *PP* Pancreatic polypeptide

112.3.3 Gut Hormone Signaling Pathways

Hormones are released during fasting that modulate vagal activity, and, via communications between the brainstem and hypothalamic areas such as the arcuate nucleus, affect brainstem activity and the sensation of hunger (Fig. 112.1a). Released hormones contribute to the development of the MMC cycle and the gradual reestablishment of appetite. Motilin, for example, may play a role in the initiation of phase III MMC activity, and increased blood concentrations of ghrelin and orexin stimulate enteric or vagal neurons to promote the sensation of hunger and prepare the stomach for the reception of food. Gut-derived signals can be transmitted to the brain via GI vagal afferents that predominantly terminate in the brainstem at the NTS. Alternatively, gut-synthesized hormones can enter the bloodstream and alter the activity of the AP, a region without an appreciable blood–brain barrier that directly communicates with the NTS. Together, these areas communicate with the DMVN, from which vagal efferents project back to the gut. Gut-released ghrelin may also directly act on the hypothalamus to increase gastric emptying and promote feeding, but this requires its transport across the blood–brain barrier.

During eating and digestion, decreases in concentrations of hormones that stimulate the appetite and promote eating are seen. In contrast, there are increased levels of hormones that contribute to satiety and regulate the rate of food transit out of the stomach and along the intestine. The arrival of food in the lumen of the gut stimulates the release of hormones from endocrine cells of the duodenum and jejunum. These hormones modulate vagal activity and affect brainstem function either directly via the vagus or, after entering the circulation, through the AP. The net result is to reduce appetite, enhance satiety/fullness, and delay gastric emptying, and this is illustrated for cholecystokinin (CCK) (Fig. 112.1b). Other hormones including peptide YY (PYY), glucagon-like protein 1 (GLP1), pancreatic polypeptide (PP), amylin, and apolipoprotein A-IV are released from distal regions of the intestine such as the pancreas and/or endocrine cells of the intestine. These hormones regulate the speed at which food exits the stomach and transits the intestine, and they also contribute to the development of satiety. A primary mechanism to achieve satiety is a reduction in gastric emptying induced by GLP1 and CCK through both vagal stimulation and modulation of AP activity following release into the circulation.

112.4 Pathological Aspects of the Gut–Brain Axis in Dyspepsia

Both organic and FGID alter the physiologic factors regulating feeding. These may affect not only gastric motility (reflux, accommodation, mixing, and emptying), but these disorders may also influence food preference, appetite, and eating behaviors (Sanger and Lee 2008).

112.4.1 Neural Aspects

A disturbance in any portion of the feeding process results in decreased food intake, and a disrupted cephalic phase of eating (e.g. taste and food aversions) may lead to an eating disorder. It is thought that declines in the senses of taste and smell may contribute to the anorexia of aging. Although the etiology of FD remains unclear, a number of factors are postulated to play a role in the development of FD symptoms (Allescher 2006) (Table 112.5). Visceral hypersensitivity is
Fig. 112.1 Signal networks of gut hormones released during fasting (**a**) or during eating and digestion (**b**) (Reprinted by permission from Nature Publishing Group, Sanger and Lee 2008)

Table 112.5 Postulated mechanisms leading to the development of dyspeptic symptoms in patients with functional dyspepsia (Adapted by permission from Elsevier Limited, Allescher 2006)

- Visceral hypersensitivity
  ○ Increased perception of distention
  ○ Impaired or altered perception of acid
  ○ Visceral hypersensitivity secondary to chronic inflammation
- Motility disorders
  ○ Postprandial antral hypomotility
  ○ Reduced relaxation of the gastric fundus
  ○ Decreased or impaired gastric emptying
  ○ Changes of the gastric electric rhythm
  ○ Gastroesophageal reflux
  ○ Duodenogastric reflux
- Changes in acid secretion
  ○ Hyperacidity
- *Helicobacter pylori* infection
- Stress
- Psychological disorders and abnormalities
- Genetic predisposition

currently thought to be a key factor in causing FD through increased perception and processing of GI neural inputs (Mearin et al. 1991). In a study of experimentally induced gut distention, a majority of patients with FD developed greater discomfort than matched healthy controls. Changes in gut motility, acid secretion, and distension may all be affected by increased gut sensitivity, and this may explain many of the symptoms of FD. Patients with FD often have concomitant abnormalities in GI motility and psychiatric illness. Whether these disorders are an epiphenomenon or are related to the underlying disease remains unclear. Symptom development and exacerbation in patients with FD are often linked to stressful life events leading the patient to seek medical help at that time. Thus, patients seeking care are more likely to have active life stressors than those who do not, leading to bias in the sample population. Additionally, stress could affect intestinal function, which in connection with the observed visceral hypersensitivity, could lead to increased symptom perception.

112.4.2 Hormonal Aspects

The circulating levels of hormones related to appetite regulation are altered in dyspetic disorders. For example, plasma ghrelin levels are increased in some patients with FD, especially those with dysmotility-like FD (Suzuki et al. 2006), and elevations in the acylated form of ghrelin were significantly associated with the subjective symptom score in FD patients (Shinomiya et al. 2005). Increased ghrelin concentrations are also seen in patients with duodenal or gastric ulcers, suggesting a possible relationship with mucosal injury (Suzuki et al. 2006). Similarly, patients with dysmotility-like dyspepsia have higher serum leptin concentrations, and this was associated with the presence of gastritis and *H. pylori* infection (Lankarani et al. 2004). When considered together with our knowledge that

leptin is produced within the stomach, its ability to activate vagal nerve terminals, reduce appetite, and increase mucin secretion suggest that leptin may have a role in protecting the upper gut during states of injury (Sanger and Lee 2008).

112.5 Therapeutic Aspects of Dyspepsia

The therapies currently available for the treatment of dyspepsia, and for FD in particular, target the underlying hypothesized pathophysiology of the disease, including increased gastric acid sensitivity, delayed gastric emptying, and *H. pylori* infection. However, only a small proportion of patients experience symptom relief using these treatments (Cremonini et al. 2004). New treatment modalities targeting impaired gastric accommodation, visceral hypersensitivity, and central nervous system dysfunction are currently under development. There are several pharmacologic and nonpharmacologic approaches for the treatment of FD. Some treatments modulate established or putative physiologic disturbances, and others provide symptom relief in the absence of a well-defined pathophysiologic target (Table 112.6). Serotonergic modulators, CCK-1 antagonists, opioid agonists, *N*-methyl-d-aspartate (NMDA) receptor antagonists, neurokinin (NK) antagonists, capsaicin-like agents, ghrelin or motilin receptor agonists, and antidepressants are among the agents currently under investigation (Table 112.7).

Table 112.6 Overview of therapeutic targets and pharmacologic and nonpharmacologic treatments in functional dyspepsia (FD) (Adapted by permission from Elsevier Limited, Cremonini et al. 2004)

Targets	Agents
Acid secretion	• Proton pump inhibitors
	• H2-receptor antagonists
	• *Helicobacter pylori* eradication
Delayed emptying	• Prokinetics
Impaired accommodation	• Serotonergic agents: 5-HT1, 5-HT4 agonists
	• CCK-A antagonists
	• Opioid agonists
	• Octreotide
	• Nitrergic drugs
	• Motilin receptor agonists
	• Ghrelin receptor agonists
Visceral hypersensitivity	• Tachykinin receptor antagonists
	• Opioid receptor agonists
	• Capsaicin-like
	• NMDA receptor antagonists
	• Antidepressants (TCA and SSRIs)
Psychological factors	• Psychotherapy
	• Hypnotherapy

GI Gastrointestinal, *H2* Histamine 2, *5-HT* Serotonin, *CCK* Cholesystokinin, *NMDA* *N*-methyl-d-aspartate, *TCA* Tricyclic antidepressants, *SSRIs* Selective serotonin reuptake inhibitors

Table 112.7 Novel agents for the management of functional dyspepsia (FD). Overview of the pharmacodynamics, proposed mechanisms of action, and available clinical data (Adapted by permission from Elsevier Limited, Cremonini et al. 2004 and Nature Publishing Group, Sanger and Lee 2008)

Site of action	Agent	Pharmacodynamics	Proposed mechanisms	Clinical data	Refs
Serotonergic agents	Sumatriptan	5-HT 1 antagonist	Relaxes fundus, reduces visceral sensitivity	Failed to relieve postprandial symptoms	Boeckxstaens et al. (2002)
	Alosetron	5-HT3 antagonist	Modulates gastric accommodation, Accelerates gastric emptying, Reduces visceral sensitivity	Provided adequate relief of pain or discomfort in female patients	Talley et al. (2001a) Kuo et al. (2002)
	Tegaserod	5-HT4 partial agonist	Accelerates gastric emptying	No difference in time with symptom relief versus placebo	Cremonini et al. (2004)
CCK receptor antagonist	Dexloxiglumide	CCK-1 antagonist	Modulates gastric accommodation and duodenogastric reflexes	Reduced post-lipid infusion symptom scores during gastric distension	Feinle et al. (2001)
Opioids	Fedotozine	κ-agonist	Reduces visceral sensitivity	Reduced global dyspepsia severity and individual symptoms of pain, nausea and fullness	Read et al. (1997)
	Asimadoline	κ-agonist	Reduces visceral hypersensitivity	No patient data, reduced postprandial fullness and delayed the onset of satiety in healthy volunteers	Delgado-Aros et al. (2003)
	Alvimopan	μ-antagonist	Stimulates gastric motor function	No data in FD, relieved postoperative ileus	Taguchi et al. (2001)
NMDA modulators	Dextromethorphan	NMDA antagonist (low affinity)	Reduces visceral hypersensitivity	Reduced visceral hypersensitivity healthy volunteers	Kuiken et al. (2002)
	Ketamine Memantine	Selective NMDA antagonist	Reduces visceral sensitivity	No data in FD	
Vanilloid receptor	Capsaicin	VR1 agonist	Reduces visceral sensitivity	Reduced severity of global dyspepsia and symptoms of pain and fullness	Bortolotti et al. (2002)
Tachykininergic agents	Aprepitant	NK-1 antagonist	Provides visceral analgesia, Reduces the motor response to noxious stimuli	Approved by FDA for chemotherapy-associated nausea and vomiting	Poli-Bigelli et al. (2003) Chawla et al. (2003)
	Talnetant	NK-3 antagonist	Provides visceral analgesia	No data in FD	Giardina et al. (2003)

Target	Drug	Mechanism	Description	Notes	References
Antidepressants	Amitriptyline, Desimipramine, Mianserin, Clomipramine, Sertraline, Paroxetine	TCA and SSRIs (Blockade of serotonin transporter)	Treats comorbid psychiatric conditions, Provides visceral analgesia, Modulates gastric motor functions	Amitriptyline reduced symptoms in FD Sertraline failed to alter perception thresholds in healthy volunteers	Mertz et al. (1998)
Motilin receptor	Mitemcinal (GM-611)	Motilin receptor agonist	• Stimulates motility similar to phase III of the MMC • Increases gastric emptying of a meal over a sustained period of time	• Phase II • Reported to improve symptoms in patients with diabetic gastroparesis, compared with placebo	McCallum and Cynshi (2007)
	PF-045480434 (KOS-2187)	Motilin receptor agonist		• Preclinical • Effective as a gastric prokinetic in dogs	Peeters (2006)
	ABT-229	Motilin receptor agonist		• Trial terminated • Failed to improve symptoms in patients with FD or with type 1 diabetes mellitus • These data argue against the use of such drugs in the treatment of these disorders or alternatively, given the potential worsening of symptoms in these trials, questions the selectivity of action of this compound and the doses used; ABT-229 is, for example, reported to be effective in rats, a species in which a functional motilin receptor is not thought to exist, and, despite having a 20-h plasma half-life, ABT-229 was given twice daily	Talley et al. (2000) Talley et al. (2001b) Tack and Peeters (2001)
Ghrelin receptor	TZP-101	Ghrelin receptor agonist	• Stimulates motility and acid secretion • Increases energy intake and meal appreciation • A defensive role in the upper gut	• Phase II • Pilot study showing symptom improvement in diabetic gastroparesis after intravenous administration	Ejskjaer et al. (2009)

Summary Points

- Dyspepsia is defined by the Rome III criteria and requires the presence of one or more of the following symptoms: postprandial fullness, early satiety, and epigastric burning or epigastric pain.
- Dyspepsia is associated with a variety of organic and functional disorders. However, a majority of patients with dyspeptic symptoms have no identifiable causes of their symptoms on routine exam and are classified as functional dyspepsia (FD).
- The gut and the brain are highly integrated and communicate in a bidirectional fashion largely through the nervous and endocrine systems.
- The vagus nerve plays an essential role in the regulation of normal physiologic responses in the gut.
- Numerous hormones are secreted by the gut and adipose tissues during feeding, digestion, or fasting that can profoundly affect gut functions. Hormones can directly affect gut secretory functions, or they may act through the enteric and vagal neurons and the area postrema (AP).
- A disturbance at any point in the feeding process results in a decline in food intake. Although the etiology of FD is still unclear, several factors and mechanisms are hypothesized to cause this disorder including visceral hypersensitivity, abnormalities in GI motility, stress, and underlying psychiatric disorders.
- Hormone concentrations in the circulation are altered in patients with dyspeptic disorders. Currently available treatments for dyspepsia, particularly FD, are based on putative underlying pathophysiologic mechanisms, including gastric acid sensitivity, slow gastric emptying, and *H. pylori* infection.
- Serotonergic modulators, CCK-1 antagonists, opioid agonists, NMDA receptor antagonists, NK antagonists, capsaicin-like agents, ghrelin or motilin receptor agonists, and antidepressants are among the agents currently under investigation for the treatment of FD.

Definitions, Key Terms and Words

Dyspepsia: A medical condition characterized by chronic or recurrent pain in the upper abdomen, upper abdominal fullness, and feeling full earlier than expected when eating.

Postprandial: After eating a meal.

Satiety: The satisfied feeling of being full after eating.

Epigastric: Of or relating to the upper central region of the abdomen.

Vagus nerve: The tenth cranial nerve, which originates in the medulla oblongata, a part of the brain stem, and wanders all the way down from the brainstem to the colon

Armamentarium: The total therapeutic assets of a physician or medical facility, including medicines and equipment.

Chapter 113
Overnutrition in Mothers and Appetite Regulators in Offspring

Hui Chen and Margaret J. Morris

Abbreviations

AgRP	Agouti-related protein
ARH	Arcuate nucleus
CART	Cocaine- and amphetamine-regulated transcript
G	Gestational day
HFD	High fat diet
MC3/4R	Melanocortin 3/4 receptor
MSH	Melanocyte-stimulating hormone
mTOR	Mammalian target of rapamycin
NPY	Neuropeptide Y
Ob-Rb	Long form of the leptin receptor
P	Postnatal day
POMC	Proopiomelanocortin
PVH	Paraventricular nucleus of the hypothalamus
SOCS	Suppressor of cytokine signalling
STAT	Signal transducer and activator of transcription

113.1 Introduction

The World Health Organization formally recognized the obesity epidemic in 1997; however, as obesity continues to rise exponentially, it has now reached pandemic proportions. Increasingly around the world, obesity is no longer restricted to adults. Childhood obesity is currently rising, with 20 million children under five estimated as overweight in 2005 (WHO 2006). In the USA, the number of overweight children has doubled and the number of overweight adolescents has tripled since 1980. It is increasingly accepted that obesity results from a combination of genetic and environmental factors. This chapter reviews recent experimental work in rodents and nonhuman primates that investigate the impact of maternal obesity and early postnatal overfeeding on hypothalamic appetite circuits and appetite control (Table 113.1).

Table 113.1 Key points of maternal obesity

As the obesity epidemic widens, maternal obesity is becoming a greater threat to the long-term health of offspring. Nutritional changes in utero are known to impact on subsequent disease risk, a process known as programming- Animal studies demonstrate that the hypothalamic circuits important in appetite control develop around the time of birth, and are influenced by the level of maternal obesity, as well as circulating levels of leptin, insulin and lipids. Thus the circuits are said to be 'plastic'

Offspring of obese mothers show increased adiposity and increased food intake, and often these changes persist in the long term. Alterations in hypothalamic appetite regulators are observed. Animal studies are important to provide information regarding the underlying mechanisms, as such, research is difficult to carry out in humans and the neural circuits involved in energy homeostasis are well preserved across mammalian species

Key information regarding the influence of maternal obesity on appetite control and risk of obesity

113.2 Impact of Maternal Nutrition on the Risk of Metabolic Disorders in Offspring

Overconsumption of energy-rich food and a sedentary lifestyle make significant contributions to the rising rate of childhood obesity. However, apart from the social and environmental factors that influence children's behaviour (Nielson et al. 2006), the prenatal maternal condition is also critical to offspring body composition, and can predispose the foetus to the development of obesity after birth. Increasing evidence suggests that both maternal phenotype and nutritional state during gestation, as well as nutrition during the lactation period, are important in promoting obesity in offspring. Human studies suggest that intrauterine factors may be more important than genetic factors in determining the individual changes in gene expression in response to consumption of a high-fat diet (HFD) (Tremblay and Hamet 2008). Thus intrauterine factors may have a longstanding influence.

Early research revealed an inverse relationship between low birth weight due to gestational malnutrition and the increased risks of obesity and cardiovascular disease (Fall et al. 1995; Painter et al. 2005). Barker first proposed the 'foetal origins' hypothesis in 1990, which posits that adverse environmental factors early in life cause disruption of normal growth and development, leading to a more susceptible adult phenotype prone to metabolic disorders, such as cardiovascular disease (Barker 1990).

However, under the current obesity pandemic, maternal overnutrition during gestation arguably has become a more prominent modulating force in foetal development. The observation of a 'U-shaped' relationship between birth weight and later obesity (Curhan et al. 1996) with increased risk in those who are born small and large for gestational age, means that we must now consider the potential detrimental impact of maternal overnutrition/obesity and increased birth weight on the risk of disease in childhood and in adulthood. A range of experimental approaches have been used, exploring overnutrition during different developmental windows, from maternal overnutrition prior to and/or during gestation, during lactation, and early in postnatal life.

Maternal obesity and hyperglycemia during pregnancy can lead to high birth weight, increased circulating insulin, glucose, free fatty acids and triglycerides, and glucose intolerance, as well as obesity in offspring (Armitage et al. 2005; Boney et al. 2005; Franke et al. 2005; Chen et al. 2009; Elahi et al. 2009). Offspring of obese mothers are at higher risk of becoming obese and developing insulin resistance and cardiovascular disease later in life, as evidenced in both human and animal studies (Plagemann et al. 1992; Samuelsson et al. 2007; Elahi et al. 2009).

A simple increase in body weight gain during pregnancy and lactation due to hyperphagia induced by pharmacological inhibition of melanocortin 3/4 receptors (MC3/4R) leads to the development of obesity in offspring over time (Heinsbroek and van Dijk 2009). Animal work suggests that overnutrition either starting prior to gestation, or during both gestation and lactation, exert similar effects on

Table 113.2 Parameters in P20 rat offspring of lean and obese rat dams

Offspring from	BW (g)	Fat mass (g)	TG (mM)	Glucose (mM)	Insulin (ng/ml)	AUC
Lean dams	33.1 ± 0.3	102.7 ± 6.2	0.74 ± 0.07	7.90 ± 0.29	0.22 ± 0.04	0.47 ± 0.09
Obese dams	47.4 ± 1.4*	136.5 ± 7.3	1.55 ± 0.18*	9.49 ± 0.34*	0.51 ± 0.06*	0.25 ± 0.04*

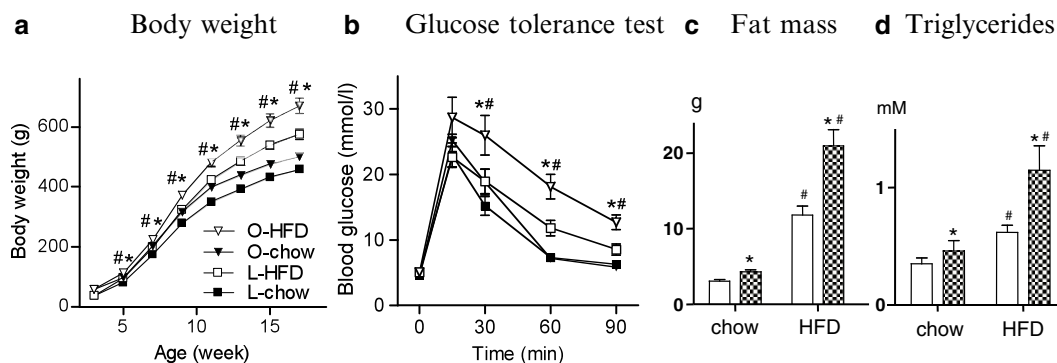
Body weight (BW), fat mass, circulating triglyceride (TG), glucose, and iusnilin, as well as area under the curve AUC of glucose tolerance test in offspring from lean or obese dams (*$P < 0.05$). Dams were fed for 6 weeks prior to mating (data based on Chen et al. 2008).


Fig. 113.1 Parameters in chow and high-fat diet (*HFD*)-fed 18 week old rats from lean and obese mothers. (**a**) Body weight trajectory, (**b**) glucose tolerance test, (**c**) white fat mass, (**d**) plasma triglyceride levels in chow and HFD-fed 18 week old rats from lean (*open bars*) and obese (*checked bars*) mothers. *, #, $P < 0.05$ maternal and post-weaning diet effects, respectively. L-chow: pups from lean mothers on chow diet; L-HFD: pups from lean mothers on high fat diet; O-chow: pups from obese mothers on chow diet; O-HFD: pups from obese mothers on high-fat diet (Modified from Chen et al. 2009)

the development of obesity and hyperinsulinemia in offspring (Howie et al. 2009). Offspring from rat dams who have established obesity induced by HFD consumption prior to gestation developed adiposity and impaired glucose and lipid metabolism as early as postnatal day (P) 20 (Table 113.2) (Bayol et al. 2007, 2008; Chen et al. 2008), and these were maintained until adulthood (Fig. 113.1) (Chen et al. 2009; White et al. 2009). Overnutrition during the suckling period can also cause an obese phenotype, even in genetically obesity-resistant rats (Gorski et al. 2006). When these obesity-resistant rats were cross-fostered by obese dams with rich milk, they went on to develop obesity when challenged by HFD after weaning (Gorski et al. 2006). Increased milk availability through litter size reduction also leads to an obese phenotype in the rat (Velkoska et al. 2005; Chen et al. 2008). Rats over-fed during the suckling period displayed persistence of overweight and hyperphagia throughout their lifespan (Bassett and Craig 1988; Plagemann et al. 1992). Furthermore, overfeeding during the suckling period showed additive effects with maternal obesity, with the combination promoting more severe adiposity and glucose intolerance at weaning (Chen et al. 2008). Thus, both maternal obesity and early postnatal overfeeding can promote an obese phenotype in offspring.

Effects of maternal overnutrition on diet preference in offspring have also been observed. Maternal consumption of a typical western 'junk food' diet, such as biscuits, chocolate, muffins, potato crisps, and sweets, in pregnancy and lactation promoted an exacerbated preference for these 'junk foods' in offspring in adulthood (Bayol et al. 2007). Maternal overnutrition has also been shown to induce greater hyperphagia and increased feeding efficiency when offspring were challenged by HFD consumption; offspring of obese dams had more severe weight gain and adiposity, as well as insulin resistance in adulthood (Chen et al. 2009; Nivoit et al. 2009).

113.3 Development of Energy Homeostasis Circuitry in the Hypothalamus

Appetite is regulated by a complex and redundant but highly reliable network. The central neural pathways involved in appetite regulation and energy metabolism are well conserved across species. The hypothalamus plays a key role in energy homeostasis. The most commonly studied circuit involves two groups of neurons concentrated in the arcuate nucleus (ARH) located in the ventral part of the hypothalamus, one expressing the appetite stimulators, neuropeptide Y (NPY) and agouti-related protein (AgRP), and the other expressing the appetite suppressors α-melanocyte stimulating hormone (αMSH) derived from proopiomelanocortin (POMC) and cocaine- and amphetamine-regulated transcript (CART), which interact with each other to match caloric intake to energy expenditure. These NPY/AgRP and POMC/CART expressing neurons project to the paraventricular nucleus (PVH) and other hypothalamic areas to exert their effects (Morton et al. 2006).

NPY is the most robust appetite stimulator, produced predominantly in the ARH. Physiologically, hypothalamic NPY concentrations are elevated before a meal to stimulate appetite, and continuous or repeated central administration of NPY leads readily to obesity. Activation of the Y1 receptor (major NPY orexigenic receptor) can increase food intake even when NPY expression is inhibited (Shintani et al. 2001). POMC derived αMSH counteracts NPY to inhibit feeding and promote negative energy balance (Morton et al. 2006). Leptin, an adipose-derived hormone, can directly access the hypothalamic ARH, to suppress NPY/AgRP and activate POMC/CART expression to inhibit feeding and increase energy expenditure via the long form of the leptin receptor (Ob-Rb). Leptin resistance is commonly observed in dietary obesity (Levin et al. 2004). The hypothalamic NPY/AgRP and POMC/CART expressing neurons are plastic, being modified by chronic overconsumption of HFD, associated with the development of metabolic disorders, such as adiposity, hyperlipidemia, hyperinsulinemia, and glucose intolerance.

In the rat, differentiation of the neuronal systems regulating energy homeostasis begins during gestation, and continues until weaning (Grove et al. 2005). In adults, the adipose hormone leptin signals fat stores; however, in rodents between P4 to 16, there is a marked increase in circulating leptin levels, which is called the '*leptin surge*' (Fig. 113.2). Leptin reaches peak levels at P9 to 10. Increased leptin is necessary to support the development and maturation of these brain neurons
Fig. 113.2 Postnatal leptin surge in mice. Leptin surge in female C57BL/6J mice from P4 to P42 (Modified from Ahima et al. 1998. With permission)

involved in the regulation of appetite and energy metabolism (Ahima et al. 1998). The role of leptin in neural development in neonatal rodents was shown to be independent of its role in energy homeostasis, given that exogenous leptin does not reduce body weight, milk intake, or metabolic rate during the first two postnatal weeks (Ahima et al. 1998; Mistry et al. 1999; Pinto et al. 2004).

Both leptin deficiency and an abnormally high leptin surge can alter neural development, thus affecting feeding and energy metabolism, contributing to obesity (Pinto et al. 2004; Yura et al. 2005; Bouret et al. 2006; Kirk et al. 2009). The lack of *ob* gene results in leptin deficiency in *ob/ob* mice, whereas higher levels are present in mice with restricted intrauterine nutrition. Leptin deficiency in *ob/ob* mice results in a lower hypothalamic neuron density, which is thought to contribute to the obese phenotype (Bouret et al. 2004; Pinto et al. 2004). The high leptin surge due to restricted intrauterine nutrition has been shown to be linked to an increased density of hypothalamic neurons (e.g. NPY) involved in feeding and energy metabolism, leading to increased weight gain and adiposity when mice were fed a HFD after weaning (Yura et al. 2005). Thus, any abnormality in the leptin surge will likely disturb energy homeostasis.

The ontogeny of the NPY and POMC system has been most extensively studied in rodents and nonhuman primates by Grove and colleagues (Grove et al. 2003, Grove and Smith 2003). There are significant differences between rodents and the nonhuman primate. In the rat, differentiation of the neuronal systems that regulate appetite and energy expenditure begins during the last week of gestation, with development continuing until weaning (Grove et al. 2005). Therefore, in rodents, projections of ARH NPY- and POMC-expressing neurons throughout the hypothalamus do not fully mature until the second and third postnatal weeks; whereas in nonhuman primates and humans, these neural projections are fully developed at birth (Grove et al. 2003, Grove and Smith 2003). Initial studies demonstrated that NPY was not only abundantly expressed in the ARH, but transient expression of NPY was also observed in other hypothalamic regions, including the dorsomedial hypothalamic nucleus, PVH, lateral hypothalamus, and the perifornical region, where NPY is not evident in adulthood (Singer et al. 2000). NPY levels in all areas were low at P2, increased rapidly to peak at P15–16 and returned to levels observed in adulthood in the ARH, while in the other areas NPY was no longer apparent after P30 (Singer et al. 2000; Grove et al. 2003, Grove and Smith 2003). This process is more complete at birth in humans and primates. In nonhuman primates, NPY mRNA was expressed in the ARH, PVH, and dorsomedial nucleus of the hypothalamus as early as gestational day (G) 100 (Grayson et al. 2006). ARH NPY/AgRP projections to the PVH were initiated by G100, but were limited and variable. However, by G130 there was a modest increase in density and number of NPY-expressing neurons (Grayson et al. 2006). By G170, ARH NPY/AgRP fibre projections to efferent target sites were completely developed, but the density continued to increase in the postnatal period, a feature similar to the rodent (Grove and Smith 2003; Grayson et al. 2006). There were minimal αMSH fibres at G100 and G130, but they were moderate at G170.

113.4   Impact of Maternal Nutrition on Neural Development

The brain is clearly affected by the nutrition state during gestation, which may have a role in producing the long-term behavioural and physiological changes observed in offspring after weaning, including an increase in food intake, preference for fat, hyperlipidemia, and greater body weight. The use of animal models can provide a fundamental understanding of the developmental aspects of these neural circuits, while modelling maternal obesity in rodents and other species is needed to explore the programming mechanisms at play in utero and during the suckling period. As discussed above, projections from the ARH of the hypothalamus play a key role in regulating energy balance (Elmquist

et al. 2005) and changes in their development is thought to be involved the programming associated with variations in maternal nutrition.

As elucidated below, several studies have shown that exposure of pregnant rat dams to a HFD results in changes in hypothalamic neuronal development and gene expression of hypothalamic neuropeptides regulating energy balance in the offspring, even though the birth weight was not different in offspring of obese and lean mothers (Chen et al. 2008; Morris and Chen 2009). Thus, modifications to the hypothalamic circuitry may be a fundamental mechanism underlying the increased risk of obesity induced by overnutrition during critical windows of early development. Most work to date has examined gene expression or protein levels, and more work is needed to examine transmitter release and synaptic density.

113.4.1 *Impact of Maternal Obesity on Intra Uterine Neural Development*

In rats, maternal HFD-feeding from G6 increased hypothalamic proliferation of different orexigenic peptide-expressing neurons, changes that were evident at birth (Chang et al. 2008). Programming of foetal neural development due to maternal overnutrition with HFD occurred within days of overfeeding, as more active neurogenesis was evident from G11 to 15 (Chang et al. 2008). Proliferation of neuroepithelial and neuronal precursor cells of the embryonic hypothalamic third ventricle was evident in offspring of HFD-fed rat dams. Maternal HFD-feeding also increased the number of neurons expressing orexigenic peptides in offspring (Chang et al. 2008). Importantly at P15, the changes in hypothalamic peptides remained in those offspring of HFD-fed obese dams that were suckled by dams consuming control diet, suggesting prenatal exposure to HFD had persisting effects on hypothalamic peptide expression. Site-specific effects were observed, as increased expression of the orexigenic peptides, galanin, enkephalin, and dynorphin were seen in the PVH, and orexin and melanin-concentrating hormone in the perifornical lateral hypothalamus. However, the ARH expression of these genes, including AgRP, was downregulated in offspring from HFD-fed obese dams (Chang et al. 2008). Established maternal obesity that predated conception was also associated with reduced AgRP staining in the PVN of offspring as compared to offspring from control dams (Kirk et al. 2009).

Experiments using genetically obese prone rats suggested that genetic background has an important influence on the ability to form ARH projections. However, some hypothalamic neurons involved in energy homeostasis were permanently disrupted by maternal HFD consumption, particularly those involving αMSH (Bouret et al. 2008).

In term, foetus of HFD-fed obese rat mothers, plasma leptin levels were higher than those in offspring of lean dams (Gupta et al. 2009). However, at P1, without the support of foetal-placental circulation, blood leptin levels were reduced in offspring from obese rat dams, relative to those from lean dams (Morris and Chen 2009). Interestingly, the hypothalamic mRNA expression of most of the appetite regulators, NPY, AgRP, POMC, MC4R, and Ob-Rb were increased in the foetus of obese dams whereas the protein level of the downstream target of leptin, signal transducer and activator of transcription (STAT)3 was reduced (Gupta et al. 2009). However, at P1, we observed lower hypothalamic NPY, MC4R, POMC, mTOR mRNA expression in offspring from obese rat mothers (Morris and Chen 2009). Furthermore, mRNA expression of Ob-Rb, STAT3, and the inhibitor of STAT3, suppressor of cytokine signalling (SOCS)3 in the hypothalamus was also downregulated by maternal obesity (Morris and Chen 2009). The difference in mRNA expression between term foetus and newborn could be due to differences in circulating leptin levels. While different observations between laboratories may relate to strain differences, type of diet used and the extent of maternal obesity, alterations in maternal nutrition appear to permanently affect the hypothalamic processes that regulate food intake.

Several hypotheses have been advanced to explain the alterations in hypothalamic circuitry in response to maternal obesity. Chief among these are changes in circulating hormones such as leptin and insulin (Gorski et al. 2007; Chen et al. 2009). Chang et al. (2008) reported that increased neurogenesis and neurite growth in offspring of HFD-fed dams was closely associated with increased blood lipids, and these authors suggest that lipids may contribute to altered neurogenesis. We (Chen et al. 2008) and others (Srinivasan et al. 2006) have also reported increased triglycerides in offspring of obese dams. A study in nonhuman primates demonstrated that even if mothers did not develop obesity, the developing foetus is highly vulnerable to excess lipids; exposure led to increased liver triglycerides, increased markers of oxidative stress and premature gluconeogenic gene expression, promoting nonalcoholic fatty liver disease (McCurdy et al. 2009).

113.4.2 Impact of Maternal Obesity on Early Postnatal Development

At P9, leptin levels were observed to be 6 times higher in offspring from obese rat dams with greater fat mass compared with those from lean mothers (Fig. 113.3, H. Chen and M. J. Morris unpublished data). Maternal milk offers an important source of leptin and milk leptin level was shown to be higher in HFD-fed rat dams (White et al. 2009). However, the higher leptin levels in offspring from obese mothers were correlated with their fat mass (Fig. 113.3), suggesting that plasma leptin levels may be independent of milk leptin levels. Nevertheless, milk leptin has been suggested to protect the infant against several chronic diseases later in life, and particularly against obesity and related medical complications (Pico et al. 2007; Palou and Pico 2009). Oral leptin supplementation in rats during lactation was shown to improve leptin and insulin sensitivity at adulthood by increasing the hypothalamic leptin receptor, Ob-Rb, and reducing the inhibitory signal SOCS-3 (Vickers et al. 2005; Pico et al. 2007; Sanchez et al. 2008; Palou et al. 2009). Although leptin injection during the prenatal period has been shown to reverse the risk of obesity and its related metabolic disorders in rats subjected to intrauterine undernutrition (Vickers et al. 2008), to our knowledge such an approach has not yet been carried out in animals undergoing intrauterine overnutrition.

Nevertheless, leptin resistance may already exist in neonatal offspring from obese mothers as reflected by a 24% reduction of phosphorylated-STAT3 immunoreactive cell numbers upon leptin injection at P10 (Fig. 113.4) (Bouret et al. 2008), suggesting leptin signalling in hypothalamic neurons is impaired during postnatal development in offspring of obese rats. The trophic action of leptin on ARH neurons is also reduced in neonates from obese dams, reflected by reduced neurite growth after 36h in vitro incubation with leptin (Bouret et al. 2008).

By P12, ARH projections to the PVH appeared fully developed in the offspring of lean dams. In rats from obese dams, there were two to four times fewer labelled fibres compared with lean offspring at this time (Fig. 113.5). Reduced fibre densities in the PVH were still evident at P16 in offspring of

Fig. 113.3 Plasma leptin and fat mass at P9. Plasma leptin concentrations and retroperitoneal white fat mass in 9-day-old pups from lean (*open bar*) and obese (*checked bar*) mothers. (*, $P < 0.05$ maternal effect, H. Chen and M. J. Morris unpublished)
Fig. 113.4 Response of arcuate nucleus (*ARH*) neurons to leptin in lean and obese mothers. Leptin-induced phospho-STAT3 immunoreactivity in the ARH of pups from lean and obese mothers on P10. Neonates from obese mothers show a 24% reduction in the number of phospho-STAT3 cells in the ARH following leptin administration as compared to pups from lean mothers. *DIO* diet-induced obese, *DR* diet-resistant, *V3* third ventricle (Reprinted from Bouret et al. 2008. With permission)
Fig. 113.5 Neural projections from the arcuate nucleus (*ARH*) to paraventricular nucleus (*PVH*) in offspring of lean or diet-induced obese dams. Dams were fed chow or high-energy (*HE*) diet throughout pregnancy and lactation. Maternal obesity permanently disrupted the projections from ARH to PVH in rat offspring at P12 (*upper panels*) and P16 (*lower panels*). *DIO* diet-induced obese, *DR* diet-resistant (Reprinted from Bouret et al. 2008. With permission)

obese versus lean dams (Bouret et al. 2008; Kirk et al. 2009) (Fig. 113.5). Thus AgRP/NPY neuron density and innervation are likely influenced in adulthood, while no effect on projections of α-MSH expressing neurons was observed (Bouret et al. 2008; Kirk et al. 2009).

Normal or increased ARH Ob-Rb expression has been observed in juvenile offspring from obese dams (Gorski et al. 2007; Chen et al. 2008); hypothalamic STAT3 mRNA expression was also observed to be upregulated by maternal obesity (Chen et al. 2008). However, both increased leptin sensitivity (Gorski et al. 2007) and leptin resistance has been reported in young offspring from obese mothers (Ferezou-Viala et al. 2007), assessed by the alteration of hypothalamic phosphorylated-STAT3 in response to leptin injection. A recent report describes resistance to the anorexigenic effects of leptin administration in offspring of obese mothers at as early as 30 days of life (Kirk et al. 2009). Also, offspring of obese dams had elevated hypothalamic MC4R, NPY Y1 and Y5 receptor mRNA expression (Gorski et al. 2007).

At P20 (normal weaning age) under a free feeding state, offspring from obese rat mothers had reduced NPY and increased POMC mRNA expression in the hypothalamus, in the face of reciprocally altered hypothalamic NPY Y1 receptor and MC4R mRNA expression (Chen et al. 2008). However, hunger is the major drive for ingestive behaviour. After overnight (14 h) fasting, in rat offspring from obese mothers, the reduced hypothalamic NPY and AgRP mRNA expression was returned to similar levels as those in rats from lean mothers (Chen and Morris 2009). The already higher NPY Y1 receptor expression in the free feeding state was further increased after overnight fasting (Chen and Morris 2009). Changes in NPY receptor may also underlie the exaggerated feeding response to NPY injection into the lateral brain ventricle in offspring from HFD-fed dams (Kozak et al. 2000). Although POMC mRNA expression was not altered by fasting, the downregulation of MC4R and its downstream mediator Sim1 was absent in rats from obese mothers. We propose that this could directly lead to increased milk consumption during the sucking period, as well as a higher daily energy intake immediately after weaning (Chen and Morris 2009). Furthermore, this could also contribute to an exacerbated preference for 'junk food' in offspring following maternal consumption of a 'junk food' diet in pregnancy and lactation (Bayol et al. 2007), although further work would be necessary to test this.

Maternal obesity has been shown to cause reductions in hypothalamic glucose sensor mammalian target of rapamycin (mTOR) and glucose transporter 4 expression in offspring at P20. As a result, after overnight fasting, hypothalamic NPY signalling in pups from obese dams was more active than that of those from lean dams (Chen and Morris 2009). This was accompanied by increased milk intake during the suckling period and energy intake immediately after weaning (Chen and Morris 2009), which could directly contribute to greater body weight, circulating triglycerides, glucose, and insulin levels in these animals both at weaning (Chen et al. 2008) and later on in adulthood (Chen et al. 2009). Therefore, we hypothesize that activation of hypothalamic mTOR may be a useful strategy to reduce the adiposity and glucose tolerance in offspring from obese mothers, especially when they consume a HFD. A summary of some of the changes induced by maternal obesity is presented in Fig. 113.6.

113.4.3 Early Postnatal Overnutrition

The early postnatal period is also a 'critical period' of development. A number of studies have demonstrated that environmental influences during the early postnatal period in humans (Fall et al. 1995) and rodents (Velkoska et al. 2005; Chen et al. 2008) can also influence body weight and energy homeostasis in adulthood.

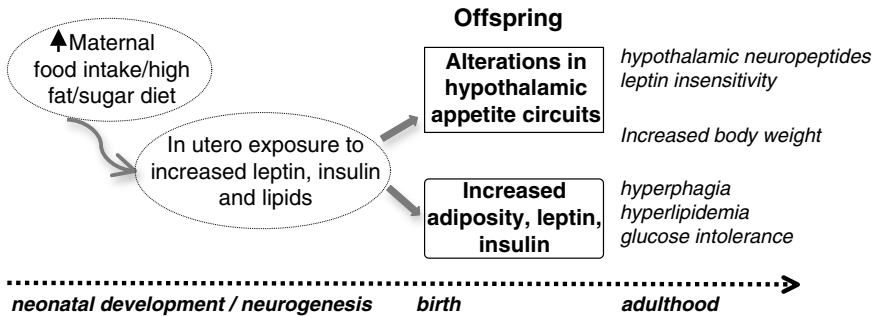
Rodents overfed during the postnatal period induced by reducing litter size, show increased early weight gain and fat deposition, hyperleptinemia, hyperinsulinemia (Plagemann et al. 1999b), and central leptin resistance at the hypothalamic ARH (Schmidt et al. 2001). Although NPY concentration


Fig. 113.6 Schematic model of effects of maternal obesity on offspring. Summary of the changes that occur in offspring of mothers exposed to overnutrition and obesity. The changes that occur in offspring are shown at right; experimental data describing these effects are presented in this chapter

was only slightly increased in the PVH in overfed rats during the suckling period, NPY neuron density was significantly increased in the ARH (Plagemann et al. 1999b). This may suggest a lack of inhibition on NPY and an acquired resistance of the hypothalamic NPY system to increased leptin levels in early postnatally overfed rats. Hypothalamic galanin is a stimulator of food intake and body weight gain. On P21, in over-fed rats, the number of galanin neurons was increased in the ARH, positively correlated to their body weight, which persisted even until adulthood (Plagemann et al. 1999a). Furthermore, male rats overfed during the suckling period exhibited a decrease in hypothalamic mRNA levels of Ob-Rb in the face of hyperleptinemia, contributing to their leptin resistance (Lopez et al. 2005). Moreover, this obese model showed an increase in the mRNA expression of CART, NPY and AgRP in the ARH (Lopez et al. 2005). These changes led to the lifelong persistence of overweight and hyperphagia in those rats overfed during the suckling period (Bassett et al. 1988; Plagemann et al. 1992; Voits et al. 1996), which may suggest a permanent disturbance of weight regulation.

The impact of maternal obesity appears to be amplified by early postnatal overfeeding, as pups from obese dams showed exaggerated adiposity and glucose intolerance at weaning if they were raised in small litters (Lucas 1998; Chen et al. 2008). This was closely linked to an alteration in hypothalamic NPY and POMC expression, as well as their functional receptors (Chen et al. 2008).

In summary, research into the long-term impact of maternal obesity on hypothalamic appetite control has grown in the last decade. Animal models can provide critical data regarding the potential mechanisms underlying the link between maternal obesity and offspring disease risk. Many questions remain, and care must be exercised when considering the clinical implications of this work. Nonetheless the appetite regulatory pathways are well conserved across species, and the models discussed here provide critical insight into hypothalamic regulation of appetite that cannot be obtained in humans. A critical distinction needs to be drawn between effects observed in response to consumption of HFD, and to established maternal obesity. Given the breadth of the obesity epidemic, attention should focus on developing strategies to ameliorate the impact of overnourishment in early life.

113.5 Applications to Other Areas of Health and Disease

Obesity represents a major public health concern and is a major risk factor for cancer, liver disease, metabolic diseases including type 2 diabetes, and cardiovascular disease. Childhood obesity is increasing in most continents. Although adult lifestyle factors undoubtedly contribute to the incidence of obesity, it is now recognized that the adaptations that occur as a result of early exposure to nutritional excess, such as

that induced by maternal obesity, may result in increased susceptibility to the development of a range of diseases. Urgent measures are required to stem the increase in childhood obesity.

Summary Points

- Earlier work showed that undernutrition in pregnancy is associated with greater risk of obesity and cardiovascular disease in offspring.
- Over the past three decades, the prevalence of obesity in both adults and children has increased around the world.
- Obesity is also increasing among women of reproductive age, and this may have consequences for the next generation.
- Obesity during pregnancy is associated with large birth weight, increased circulating insulin, glucose, free fatty acids and triglycerides in offspring.
- The impact of maternal overnutrition on the risk of metabolic disorders in offspring has been examined in both human and animal studies.
- The brain circuits that control appetite are immature at birth, and are influenced by circulating leptin, insulin and possibly lipids; leptin is critical to allow hypothalamic neuropeptide projections to form.
- Maternal obesity in the rodent has been shown to disrupt the normal postnatal surge in leptin, and to lead to changes in neuronal development and expression of transmitters important in regulating appetite.
- In rodents, leptin resistance and glucose intolerance is observed in offspring of obese mothers; whether this occurs in humans needs to be determined.
- Overfeeding in the early postnatal window also increases obesity risk in the long term, and the combination of maternal obesity and early postnatal overfeeding appears to exert additive detrimental effects.
- Further work is needed to improve our understanding of the consequences of maternal obesity and nutrient excess on the next generation. While much of the experimental work presented here was conducted in the rodent, these observations provide useful insights into avenues for future research into developing preventive measures to curb the obesity epidemic.

Definitions and Explanations of Key Terms

Anorexigenic: Inhibits feeding behaviour.

Arcuate nucleus: Key hypothalamic area that integrates peripheral signals of energy balance (e.g. adiposity signals).

Energy homeostasis: The physiological processes whereby energy intake is matched to energy expenditure.

Hypothalamus: A brain region critical in the regulation of feeding, it contains many orexigenic and anorexigenic transmitters.

Leptin: A hormone produced in the adipose tissue that acts in the hypothalamus to decrease appetite and food intake.

Maternal programming: The participation of maternal genotype or phenotype in foetal development.

Orexigenic: Inducing feeding behaviour.

Chapter 114
Sex Hormones and Appetite in Women: A Focus on Bulimia Nervosa

Sabine Naessén and Angelica Lindén Hirschberg

Abbreviations

CCK   Cholecystokinin
ER   Estrogen receptor
HPG   Hypothalamic–pituitary–gonadal axis
OC   Oral contraceptive
PCOS   Polycystic ovary syndrome
PMS   Premenstrual syndrome

114.1 Introduction

Appetite is the sensation of hunger or desire for specific food. The behavioral response to this sensation is food intake, which eventually leads to satiety. Eating behavior, however, is a complex phenomenon encompassing many factors like meal size, rate of eating, and frequency of eating episodes. Environmental and psychological inputs but also social and cultural stimuli affect eating behavior.

Many factors are involved in the regulation of appetite and food intake, both on a meal-to-meal basis and longer term. These factors may be divided into central and peripheral mechanisms (Hirschberg 2001). The hypothalamus has a key function in the central feeding system, controlling input from several neurohumoral factors and absorbed nutrients, such as glucose and free fatty acids. The peripheral feeding system involves a cascade release of gastrointestinal hormones regulating food intake in response to a meal. These peptides chemically recognize the presence of nutrients in the gastrointestinal tract and they influence gastrointestinal motility, thus signaling to the brain that the stomach is full, which leads to termination of food intake. Several gastrointestinal peptides have been suggested as putative satiety agents.

Sex hormones, i.e. estrogen, progesterone, and androgens, play an important role in the regulation of appetite and energy metabolism (Asarian and Geary 2006). In most species, food intake and

S. Naessén (✉)

Department of Obstetrics and Gynaecology, Karolinska University Hospital, SE-171 76 Stockholm, Sweden
e-mail: sabine.naessen@karolinska.se

reproductive function are closely related. The most pronounced physiological changes in appetite and body composition occur during pregnancy and lactation. Sex hormones are known to interact with gastrointestinal peptides and neurotransmitters in the central control of appetite, whereas the effects on energy expenditure seem to be mainly caused by peripheral metabolic effects in adipose tissue (Hirschberg 2001; Asarian and Geary 2006).

Eating disorders, both anorexia and bulimic behavior, are associated with sex hormone abnormalities causing menstrual disturbances and metabolic consequences. Sex hormone changes may be primary or secondary to abnormal eating. There is increasing knowledge about the role of sex hormones in disturbed eating behavior.

114.2 Sex Hormones and Eating Behavior

Eating disorders are much more common in women than in men (Andersen 1999), suggesting a possible role for sex hormone signaling in the etiology of disturbed eating. In females of many species, feeding is closely associated with hypothalamic–pituitary–gonadal (HPG) axis function. Rodents and primates eat less during estrus (time prior to and following ovulation when animals have increased sexual receptivity) (Asarian and Geary 2006). A similar decrease in eating during the ovulatory phase, when estradiol levels are high, has been demonstrated in cycling women (Fong and Kretsch 1993; Johnson et al. 1994).

Estradiol is known to inhibit feeding by reducing meal size in animal experiments (Lindén et al. 1990; Geary 2001). Several mechanisms seem to be involved including increased activity of the satiety signal cholecystokinin (CCK) released from the small intestine in response to food intake (Lindén et al. 1990; Geary 2001). In contrast, the eating-stimulatory potency of the gastric hormone ghrelin is decreased (Clegg et al. 2007). Furthermore, estradiol increases the activity of the anorectic factor corticotropin-releasing hormone in the hypothalamus, and decreases the action of the hypothalamic appetite-stimulating factor neuropeptide Y (Pelletier et al. 2007).

In the hypothalamus, both estrogen receptor (ER) a and ERb are expressed (Laflamme et al. 1998). It has been demonstrated that ERb is the receptor in the central nervous system regulating the anorectic action of estrogen in mice (Liang et al. 2002). However, ERa mechanisms also seem to be involved but the site of action is not fully elucidated (Asarian and Geary 2006). Until now only a few variants of the ERβ gene have been reported and characterized with regard to allele frequency. Polymorphisms in the ERb gene have been associated with ovulatory dysfunction (Sundarrajan et al. 2001). Recently, an association of ERb gene polymorphisms with bulimia was demonstrated (Nilsson et al. 2004). This finding points to a possible role of ERb in the etiology of bulimic disease.

In contrast to estrogen, progesterone seems to stimulate appetite. Several studies in women have demonstrated a distinct increase in food intake in the premenstrual period of the menstrual cycle, when progesterone levels are high (Dye and Blundell 1997; Cross et al. 2001; Bryant et al. 2006). It has been suggested that brain serotonin is involved in the mechanisms (Cross et al. 2001). Furthermore, intake of specific macronutrients may be affected as well. Thus, there seem to be a preference for foods containing high amounts of both fat and sugar before menstruation (Cross et al. 2001).

Testosterone is known to stimulate appetite (Asarian and Geary 2006) and to impair impulse control (Eriksson 2000). These effects of testosterone are considered to be centrally mediated but the exact mechanisms are not known (Asarian and Geary 2006). Women with high androgen levels and polycystic ovary syndrome (PCOS) have a greater craving for sweets and a tendency of binge eating (Hirschberg et al. 2004; Klein et al. 2006). It has therefore been suggested that high androgen levels may promote bulimic behavior by influencing food craving or impulse control.

114.3 Sex Hormone Disturbances in Women with Bulimia Nervosa

Bulimia nervosa is associated with menstrual dysfunction although most women with bulimia are of normal body weight. The occurrence of amenorrhea in bulimic women has been reported within the range of 7–40% (Copeland et al. 1995) and 37–64% of the patients may have irregular bleedings with long intervals (oligomenorrhea) (Cantopher et al. 1988). In comparison, the prevalence of secondary amenorrhea in the general population is between 2% and 5% (Münster et al. 1992).

Different mechanisms may interact in the etiology of menstrual dysfunction in bulimia. In anorexia nervosa, amenorrhea is explained by hypothalamic inhibition of the reproductive system due to starvation (Chan and Mantzoros 2005). Low levels of estradiol and gonadotropins, indicating hypothalamic inhibition of the HPG axis, have also been reported in bulimic women (Gendall et al. 2000). Furthermore, low levels of thyroid hormones, considered to be a consequence of the temporary starvation periods associated with the disease, have been demonstrated in bulimia nervosa (Gendall et al. 2000; Naessén et al. 2006a).

In addition, an association between bulimia and PCOS has been suggested. PCOS is the most common hormonal aberration in women of fertile age, with a prevalence of 5–10%, and is associated with menstrual disturbances due to oligo- or anovulation, clinical symptoms of hyperandrogenism, and polycystic ovaries (Fig. 114.1) (Ehrmann 2005). Furthermore, the syndrome is often associated with insulin resistance and abdominal obesity. The diagnostic criteria for PCOS are shown in Table 114.1. A genetic predisposition is required for the development of the syndrome, though there is also a link with environmental factors (Ehrmann 2005).

There are several similarities between PCOS and bulimia nervosa. Women with PCOS, like in bulimia nervosa, show disturbed appetite regulation, increased craving for carbohydrates, and impaired meal-related secretion of CCK (Hirschberg et al. 2004; Moran and Norman 2004). On the other hand, an increased frequency of PCOS symptoms has been demonstrated in bulimic women in

Fig. 114.1 Ultrasound picture of a polycystic ovary

Table 114.1 The diagnostic criteria for PCOS according to Rotterdam Consensus 2004

Diagnostic criteria for PCOS
1. Oligo-or anovulation
2. Clinical and/or biochemical signs of hyperandrogenism
3. Polycystic ovaries on ultrasound

Two out of three criteria are necessary for diagnosis

Table 114.2 Frequency of PCOS symptoms in bulimics and healthy women (Adapted from Naessén et al. 2006)

Criteria	Bulimics $n = 77$	Controls $n = 59$
1. Oligo- or anovulation (%)	31.2[***]	1.7
2. Clinical and/or biochemical hyperandrogenism (%)	27.3[*]	11.9
3. Polycystic ovaries on ultrasound (%)	7.1	6.8
PCOS diagnosis (%)	16.6[*]	1.7

[*]$p < 0.05$

[***]$p < 0.001$

comparison with healthy controls (Table 114.2). Thus, increased occurrence of polycystic ovaries, acne, hirsutism, and elevated serum levels of androgens have been reported in bulimic women (McCluskey et al. 1992; McSheery 1992; Sundblad et al. 1994; Jahanfar et al. 1995; Cotrufo et al. 2000; Monteleone et al. 2001; Morgan et al. 2002; Naessén et al. 2006b).

What is the etiological connection between bulimia and PCOS? It has been suggested that polycystic ovaries may be secondary to abnormal eating behavior (Morgan et al. 2002). Another explanation for an association between bulimia and PCOS may be that hyperandrogenism is the primary condition, which predisposes for the development of bulimic behavior and associated psychiatric comorbidity. Testosterone is appetite-stimulating (Asarian and Geary 2006) and high androgen levels in women have been associated with impaired impulse control, irritability, and depression (Eriksson 2000). These symptoms are common features in women with bulimia (Eriksson 2000). Furthermore, bulimic women are more sexually experienced and sexually experimental than control women (Abraham 1998). This may also be related to increased androgen activity since androgens have well-known stimulatory effects on female sexuality (Flöter 2009).

It could be concluded that bulimia nervosa is associated with several hormonal aberrations, which may be primary or secondary to abnormal eating. Menstrual disturbances may be caused by hypothalamic inhibition of the reproductive axis due to periods of starvation. An alternative explanation is essential hyperandrogenism like PCOS, which may promote bulimic behavior since androgens have appetite-stimulating effects and could impair impulse control.

114.4 Oral Contraceptives and Appetite

Oral contraceptives (OCs) containing the combination of a synthetic estrogen and progesterone (progestin) are used by numerous women for birth control, but OCs are also frequently used for medical treatment. Dysmenorrhea, bleeding disorders, endometriosis, hypogonadism, and PCOS are common indications for treatment with OCs. The treatment is generally well tolerated with few side effects. However, there is a small risk for thromboembolic events. Some women may experience changes in

Table 114.3 Pharmacological profile of progestins in combined oral contraceptives

Drospirenone	-	+	+
Progesterone	-	(+)	+

+ agonist action, (+) weak agonist action, - no effect

appetite and weight, although studies evaluating body weight all show no significant change in average weight and body composition by combined OCs (Gallo et al. 2008). The progestin component in combined OCs and particularly high-dose progestins are associated with increased appetite and weight gain (Hirschberg et al. 1996; Maltoni et al. 2001). However, despite extensive clinical experience of OC treatment, little is known about effects of different types of OCs on appetite and body weight.

Combined OCs usually contain ethinylestradiol as synthetic estrogen, whereas the type of progestin varies between different OCs. The progestins used mainly belong to two chemical families: derivates of 19-nortestosterone and derivates of 17-α-hydroxyprogesterone. Derivates of 19-nortestosterone have varying degrees of androgenic activity, whereas derivates of 17-α-hydroxyprogesterone, that are structurally related to progesterone, lack androgenic effects and may also exert antiandrogenic activity (Table 114.3). Progestins with androgenic activity in combination with ethinylestradiol seem to be associated with a lower risk of vascular thromboembolism than other combinations (Lidegaard et al. 2009; van Hylckama Vlieg et al. 2009). However, side effects like acne, increased appetite, and weight gain are more common when androgenic OCs are used. In contrast, OCs with antiandrogenic properties could be used for treatment of acne and hirsutism (Pekhlivanov et al. 2006).

Levonorgestrel and norethisterone belong to the older progestins and are derived from testosterone. They have potent antigonadotropic effects and androgenic activity by binding with high affinity to the androgen receptor (Sitruk-Ware 2006) (Table 114.3). OCs containing levonorgestrel seem to have limited influence on the coagulation system and are therefore in some countries recommended as the first choice for contraception (Lidegaard et al. 2009; van Hylckama Vlieg et al. 2009).

Later generations of progestins were developed to reduce undesirable androgenic side effects. Desogestrel is one of those but still binds to the androgen receptor and could exert weak androgenic actions (Table 114.3). Cyproterone acetate is a very potent antiandrogenic progestin and is used in combination with ethinylestradiol for treatment of acne, seborrhea, and hirsutism (van Hylckama Vlieg et al. 2009).

Drospirenone belongs to the new generation of progestins and is the first with antimineralocorticoid activity together with considerable antiandrogenic effects (Sitruk-Ware 2006) and thus differs from other synthetic progestins currently used in OCs. The antimineralocorticoid effect of drospirenone may help prevent sodium retention and a rise in blood pressure in susceptible women. Furthermore, a small reduction in body weight has been demonstrated in users of OCs containing drospirenone. Drospirenone exerts direct antiandrogenic activity due to competitive binding to the androgen receptor (Sitruk-Ware 2006). In addition, drospirenone alone or in combination with ethinylestradiol will suppress androgen production from the adrenals and ovaries. OCs containing drospirenone have been successfully used for treatment of hyperandrogenic symptoms in women with PCOS (Pekhlivanov et al. 2006).

Theoretically, OCs with antiandrogenic properties could be beneficial for bulimic patients by influencing food craving and impulse control.

114.5 Sex Hormone Treatment in Bulimia

Cognitive–behavioral therapy in combination with antidepressant medication is currently the standard treatment for bulimic women, but several cases are resistant to this therapy. Furthermore, the risk of relapse is high and about 35% (Olmsted et al. 2005). Thus, there is a need for additional treatments for bulimia and for new strategies to prevent relapse.

The associations between endocrine status and eating behavior presented above suggest that treatment with estrogenic and/or antiandrogenic activity may be effective as an additional therapy for bulimic women. In support of this hypothesis, treatment with the androgen receptor antagonist flutamide has been shown to reduce symptoms in bulimic patients (Bergman and Eriksson 1996; Sundblad et al. 2005). However, this medication has been associated with adverse liver effects (Osculati and Castiglioni 2006), which would limit the long-term use of the drug.

Recently, it was also demonstrated that treatment with an antiandrogenic OC (30 µg ethinylestradiol + 3 mg drospirenone) improved eating behavior and reduced meal-related appetite in women with bulimia nervosa (Naessén et al. 2007). The decrease in compensatory behavior and reduced hunger response was significantly related to decreased testosterone levels following treatment (Fig. 114.2). Furthermore, bulimics who responded with decreased bulimic behavior had higher pretreatment levels of testosterone and higher frequency of binge eating and of compensatory behavior than those who did not (Naessén et al. 2007). These findings are in line with previous reports on associations between high androgen levels on the one hand and increased appetite, reduced postprandial CCK secretion, deranged appetite regulation, and impaired impulse control on the other (Sundblad et al. 1994; Hirschberg et al. 2004).

Thus, treatment with an antiandrogenic OC, which is widely used and generally well tolerated with few side effects (Pekhlivanov et al. 2006), showed similar beneficial effects as treatment with an androgen receptor antagonist. The ethinylestradiol/drospirenone combination is also reported to reduce premenstrual symptoms (PMS; Brown et al. 2002). As in bulimics, increased levels of testosterone have been reported in women with PMS (Eriksson 2000). These women also suffer from increased craving for food during the premenstrual phase, where also bulimics may experience aggravation of their symptoms (Eriksson 2000).

To conclude, treatment with an antiandrogenic OC may improve meal-related appetite responses in women with bulimia nervosa and reduce bulimic symptoms. The results support the notion that androgens play a role in bulimic behavior. Hypothetically, bulimia may in some cases be a manifestation of a hormonal constitution rather than a primary psychiatric illness. Antiandrogenic OC treatment may develop into a new management of women with bulimia nervosa, particularly in those with hyperandrogenic symptoms. However, large scale placebo-controlled studies are needed to corroborate this concept.

114.6 Application to Other Areas of Health and Disease

Apart from treating bulimic behavior, menstrual disturbances and clinical signs of hyperandrogenism should be evaluated in bulimics in order to provide adequate medical care and treatment. Menstrual disturbances in women with bulimia may be caused by hypothalamic inhibition of the reproductive axis due to periods of starvation. Another mechanism may be essential hyperandrogenism like PCOS, since hirsutism, acne, and polycystic ovaries are common features in bulimic women. Androgens may promote bulimic behavior by stimulating appetite and influencing impulse control. Combined OCs with antiandrogenic properties could be beneficial for bulimic patients with hyperandrogenic symptoms.

Fig. 114.2 Levels of free testosterone, frequency of compensatory behavior, and subjective hunger response in bulimics before and during treatment with an antiandrogenic oral contraceptive. There were significant decreases of all three variables (free testosterone $p < 0.01$; compensatory behavior and subjective hunger $p < 0.05$, respectively). Horizontal lines indicate 10th, 25th, 50th, 75th, and 90th percentile (Adapted from Naessén et al. 2007)
Summary Points

- Sex hormones play an important role in the regulation of appetite and energy metabolism. Estrogen is known to inhibit feeding, whereas progesterone and testosterone may stimulate appetite. Altered sex hormone activity may be involved in disturbed eating behavior.
- Bulimia nervosa is frequently associated with sex hormone disturbances, which may be secondary or primary to abnormal eating. Menstrual disorders and low estradiol levels are common although most bulimic women are of normal weight. Hypothalamic inhibition of the reproductive axis due to periodic starvation could be one underlying mechanism of menstrual disturbances in women with bulimia.
- Increased androgens, acne, hirsutism, and polycystic ovaries are also frequent among bulimics. PCOS, which has a genetic background, may therefore be an alternative cause of menstrual disturbances in bulimic women.
- Testosterone is appetite-stimulating and high androgen levels in women have been associated with impaired impulse control, irritability, and depression. It has been suggested that androgens may promote bulimic behavior.

- Antiandrogenic OC treatment seems to reduce meal-related appetite and improve bulimic behavior in relation to reduced androgen levels in women with bulimia nervosa.
- The findings support the notion that androgens play a role in bulimic behavior. Hypothetically bulimia may in some cases be a manifestation of a hormonal constitution rather than a primary psychiatric illness. Antiandrogens may develop into a new therapeutic approach in women with bulimia nervosa, particularly in those with hyperandrogenic symptoms.

Key Terms

Amenorrhea: No menstrual bleeding for 3 months or more.

Androgens: Male sex hormones.

Anovulation: Absence of ovulation due to hormonal or gonadal disorder.

Combined oral contraceptives (OCs): Medication for birth control, containing estrogen and progestin, also used for medical treatment of different disorders. The mechanism of action is suppression of ovulation and endogenous sex steroid hormone production.

Hirsutism: Increased body and facial hair growth of male type.

Hyperandrogenism: Condition of excessive production of androgens associated with increased body hair growth and acne.

Hypothalamic–pituitary–gonadal (HPG) axis: The endocrine system in women regulating ovarian function. The hypothalamus secretes gonadotropin-releasing hormone, the pituitary releases the gonadotropins luteinizing hormone and follicle-stimulating hormone, and in response the ovary secretes estradiol, progesterone, and androgens. In turn, ovarian steroid hormones modulate hypothalamic and pituitary output.

Polymorphism: The genetic variation within a population of two or more alleles of a gene, where the frequency of the rarer alleles is greater than can be explained by recurrent mutation alone.

Polycystic ovaries: Enlarged ovaries with increased number of follicles identified by gynecologic ultrasound.

Polycystic ovary syndrome (PCOS): The most common hormonal disorder in women of reproductive age, characterized by menstrual disturbances, symptoms of excess androgen, and polycystic ovaries. Insulin resistance, diabetes type 2, and abdominal obesity are associated with the syndrome. Genetic and environmental factors are important for the development of PCOS.

Progestin: Synthetic progesterone used in contraceptive pills.

Key Points

Hyperandrogenism may explain several symptoms in bulimic women. High testosterone levels in women have been associated with:

- Menstrual disturbances
- Polycystic ovaries
- Hirsutism, acne
- Increased appetite
- Impaired impulse control
- Irritability
- Depression

Chapter 115
Dietary *n*-3-Polyunsaturated Fatty Acid Deprivation and Cytokine Signaling Pathways in the Brain

Sophie Laye, Virginie F. Labrousse, and Veronique De Smedt-Peyrusse

Abbreviations

15d-PGJ2	15-deoxy-delta 12,14-prostaglandin J2
AA	Arachidonic acid
ALA	Alpha linolenic acid
BBB	Blood brain barrier
CNS	Central nervous system
COX	Cyclooxygenase
cPLA2	Calcium-dependent phospholipase A2
DHA	Docosahexaenoic acid
DPA	Docosapentaenoic acid
EPA	Eicosapentaenoic acid
ERK	Extracellular signal-regulated protein kinase
GFAP	Glial fibrillary acidic protein
HEPE	Hydroxyeicosapentaenoic acid
IKK	IκB kinase
IL-1	Interleukin 1
IL-10	Interleukin 10
IL-1R	Interleukin 1 receptor
IL-1ra	Interleukin 1 receptor antagonist
IL-1RAcP	Interleukin 1 receptor accessory protein
IL-6	Interleukin 6
IL-6R	Interleukin 6 receptor
iPLA2	Calcium-independent phospholipase A2
IRAK	Interleukin-1 receptor associated kinase
IκB	Inhibitor of κB
JAK	Janus kinase

e-mail: sophie.laye@bordeaux.inra.fr

JNK	c-Jun N-terminal kinase
LA	Linoleic acid
LOX	Lipoxygenase
LPS	Lipopolysaccharide
LT	Leukotriene
LTP	Long-term potentiation
LXA4	Lipoxin A4
LXR	Liver X receptor
MAPK	Mitogen associated protein (MAP) kinase
MHCII	Class II major histocompatibility complex
MK	MAPK-activated protein kinase
MyD88	Myeloid differentiation primary response gene (88)
NEMO	NFκB essential modulator
NFκB	Nuclear factor kappa B
NIK	NFκB inducing kinase
PAMP	Pathogen-associated molecular patterns
PC	Phosphatidylcholine
PE	Phosphatidylethanolamine
PG	Prostaglandin
PGE2	Prostaglandin E2
PGI	Prostacyclin
PPAR	Peroxisome proliferator-activated receptor
PUFA	Polyunsaturated fatty acid
RXR	Retinoid X receptor
SAMP8	Senescence-accelerated prone mouse
STAT	Signal transducers and activators of transcription
TACE	TNFα cleavage enzyme
TLR4	Toll-like receptor 4
TNFR	Tumor necrosis factor receptor
TNFα	Tumor necrosis factor alpha
TRADD	TNFR1-associated via death domain
TRAF-6	TNF receptor associated factor 6
TX	Thromboxane
Tyk	Tyrosine kinase 2

115.1 Introduction

The central nervous system (CNS) has long been considered a privileged organ from the point of view of immunity, as the blood brain barrier (BBB), thanks to its tight junctions, limits the entry of immune cells, notably lymphocytes, into the brain. Research in neuroimmunology has shown that the brain possesses its own system of defense, which, in addition to being activated by immune stimuli, is closely linked to the immune system. Inflammatory cytokines, which are important mediators of communication within the immune system, also act in the brain, in particular by activating the innate immune cells of the brain that in turn produce inflammatory cytokines. The synthesis of brain cytokines is finely regulated, allowing them to return to basal levels without leading either to a rupture of the BBB or to cerebral lesioning. On the other hand, when these factors are synthesized in large quantities or in a chronic manner by the brain, they have toxic effects on neurons, resulting in

substantial neuronal dysfunction that can lead to cell death. The fragilization of neuronal function due to cytokines is also seen during aging, where microinflammation, characterized by microglial reactivity and the chronic production of low levels of inflammatory cytokines, is seen to occur. Numerous epidemiological studies show a correlation between the expression levels of inflammatory cytokines and the incidence of functional alterations (cognitive or mood disorders) in elderly subjects. This microneuroinflammation, which increases the vulnerability of the aging brain to immune stimuli, is characterized by the increased production of brain cytokines and the risk of developing delirium and/or neurodegenerative disorders with an inflammatory component, such as Alzheimer's disease. Limiting the development of chronic neuroinflammation is a key element in the protection of the brain against neurodegenerative disorders.

In this context, diet constitutes a strategy of choice, since it is an environmental factor to which individuals are exposed throughout life. Increasing attention has been paid to ω3 and ω6 polyunsaturated fatty acids (PUFAs), micronutrients that are essential since they cannot be synthesized de novo by the organism. An increasing store of information attests to the powerful immunomodulatory effects of the PUFAs. Thus, ω3 PUFAs form the basis of lipid derivatives (neuroprotectins and resolvins) with anti-inflammatory properties, whereas ω6 PUFAs are the precursors of the proinflammatory prostacyclins, and stimulate the production and activity of inflammatory cytokines. In addition, the brain is extremely rich in PUFAs. Their accumulation takes place during the perinatal period, in proportions dependant on maternal dietary levels. Conversely, their levels diminish as the individual ages, but can be corrected by appropriate nutritional strategies. During the last few decades, the lifestyle of Western societies has evolved towards a decrease in energy expenditure mainly related to our sedentary life style, and a change in our dietary habits towards the consumption of energy-rich foods with high levels of saturated fats, ω6 PUFAs, and sugar, and poor in vitamins and micronutrients. The dramatic reduction in the dietary supply of ω3 PUFAs and the corresponding increase in ω6 PUFAs, by leading to an imbalance in the ω6/ω3 ratio, estimated at between 12 and 20 in developed countries at present (the current recommended ratio is 5), could contribute to the fragilization of the brain with respect to inflammatory cytokines, and thus to the development of neurodegenerative disorders.

115.2 The Innate Immune System of the Brain

115.2.1 Glial Cells

Microglial cells are the resident macrophages of the brain and constitute the first line of immune defense of the brain (phagocytosis, antigen presentation, and secretion of proinflammatory cytokines). Microglial cells have a ramified morphology when quiescent and an ameboid morphology when they are activated and produce cytokines. Ramified microglia cells generally do not display phagocytic activity and weakly express ligands and receptors involved in macrophage function. These ramified microglial cells, disseminated throughout the brain parenchyma, use their processes to receive signals such as inflammatory cytokines from their microenvironment, which reveal the existence of a lesion or the presence of a pathogen. In order to do this, microglial cells express several membrane receptors, including those for the inflammatory cytokines IL-1β, TNFα, and IL-6, as well as those that allow the recognition of PAMPs (pathogen-associated molecular patterns) such as the bacterial endotoxin receptors TLR4 and CD14. Microglia cells are involved in the pathophysiology of neurodegenerative disorders. Thus, during infection, there is a massive infiltration of peripheral immune cells, notably neutrophils, into the brain, along with an aggravated inflammatory response. During aging, the accumulation of damaged DNA activates parenchymatous microglia, which proliferate, become reactive

(a phenomenon called microglial "priming"), and produce inflammatory cytokines (reviewed in Dyerberg and Bang 1979). This microglial dysfunction is responsible for the exacerbation of the microglial reaction in response to an inflammatory stimulus, and for a massive recruitment of cells of the myeloid lineage, which, by infiltrating the parenchyma, reinforce the inflammation of the CNS, or neuroinflammation. These phenomena together contribute to the development of disorders with an inflammatory component linked to aging, such as Alzheimer's disease.

Astrocytes also participate in brain immunity and in the maintenance of tissue integrity in the nervous system. In fact, any pathological or injury-related inflammatory state leads to an astrocytic reaction, called reactive astrogliosis. Astrocytes proliferate, hypertrophy, and undergo an increase in new protein synthesis, including that of GFAP (glial fibrillary acidic protein). These phenotypic changes of astrocytes in response to inflammation constitute a physical and biochemical barrier that isolates the lesion site from the remaining, healthy tissue. The astrocytic response is regulated by growth factors and inflammatory cytokines that are liberated by the lesioned cells (astrocytes, neurons, etc.) as well as by microglial cells. Astrocytes, by virtue of expressing cytokine receptors, are in fact sensitive to the effects of cytokines. Numerous studies carried out in vitro and in vivo demonstrate that these cells produce inflammatory and anti-inflammatory cytokines. During aging, astrocytes become reactive and produce inflammatory cytokines. In addition, these cells partially lose their neuroprotective properties with age, thus contributing to the exacerbation of neuronal lesions participating in age-related neurodegeneration (reviewed in Pertusa et al. 2007). These phenomena together contribute to the development of neurodegenerative disorders with an inflammatory component linked to aging.

115.2.2 Inflammatory Cytokines, Their Receptors, and Their Signaling Pathways in the Brain

115.2.2.1 Inflammatory Cytokines and Their Receptors

The IL-1 family consists of two agonists, IL-1α and IL-1β, and one antagonist, IL-1ra. IL-1α and IL-1β are synthesized as inactive precursors which are cleaved by the calpains and by caspase-1 respectively to generate active peptides of 17 kDa. They bind to type I (IL-1R1) and type II (IL-1R2) receptors, of which the latter is a decoy receptor. These receptors all exist as soluble forms, which, by trapping IL-1, negatively regulate its actions. IL-1RAcP is an accessory protein that is indispensable for the intracellular signal transduction of IL-1 by IL-1R1. Association of IL-1 to its receptors enhances the receptors' affinity for the ligand. Nevertheless, when IL-1ra binds to IL-1R1, the IL-1R1/IL-1RAcP complex dissociates, explaining the absence of a biological effect of IL-1ra (reviewed in Rothwell and Luheshi 2000). Studies in rodents have revealed that IL-1 binding sites are very dense in the hippocampus and hypothalamus. IL-1R1 is expressed by neurons in the mouse hippocampus, and by cells of the choroid plexus and cerebral vasculature in the rat (Ericsson et al. 1995; Konsman et al. 2004).

TNFα is synthesized as a 26 kDa precursor that, after proteolytic cleavage by the metalloprotease TACE (TNFα converting enzyme), yields a 17 kDa peptide. The extracellular soluble form of TNFα is a homotrimer of the 17 kDa peptide. TNFα is the agonist of the type 1 (TNFR1 or p55) and type 2 (TNFR2 or p75) TNF receptors. The soluble forms of these receptors constitute decoy receptors for TNFα. Etanercept, a fusion protein that combines the p75 fraction of the soluble TNFα receptor with the Fc fragment of human immunoglobulin G1, is used in the treatment of rheumatoid arthritis, and is currently undergoing trials for use in Alzheimer's disease. TNFR1 is expressed by microglial cells

and astrocytes in culture. In rodents, TNFR1 is expressed by the circumventricular organs, the choroid plexus, and blood vessels. In the human brain, constitutive expression has been described in neurons and in blood vessels (reviewed in McCoy and Tansey 2008).

IL-6 is synthesized as a precursor, and released after proteolytic cleavage by as yet unidentified proteases. IL-6 binds to its receptor, IL-6R, which associates with a 130 kDa transmembrane glycoprotein, gp130. The IL-6/IL-6R/gp130 active complex is a hexamer composed of an IL-6 dimer, an IL-6R dimer, and a gp130 dimer. The formation of a gp130 homodimer leads to the activation of IL-6-related signaling pathways. The soluble form of IL-6R bound to IL-6 interacts with gp130 to trigger agonistic effects, whereas the soluble form of gp130 neutralizes the effects of IL-6. In rodents, IL-6R mRNA is expressed by neurons and glial cells in the hippocampus, the hypothalamus, and certain zones of the cortex. A weaker expression pattern is also detected in several circumventricular organs, where it is rapidly upregulated during inflammatory states. Neurons that express gp130 but not IL-6R are sensitive to IL-6 as a result of the soluble receptor (reviewed in Jones et al. 2005).

115.2.2.2 Signaling Pathways Associated with the Activation of the Cytokine Receptors

IL-1β and TNFα mainly activate the NFκB and MAP kinase (MAPK) signaling pathways. Activation of the NFκB pathway through the p50–p65 complex leads to the formation of NIK (NFκB inducing kinase), IKK (IκB kinase) α and β, and NEMO (NFκB essential modulator). This complex of kinases phosphorylates IκB, the inhibitor of NFκB, which is then degraded by ubiquitination. NFκB is then translocated to the nucleus and activates the transcription of target genes involved in inflammation (inflammatory cytokines, chemokines, eicosanoid pathway enzymes, endotoxin receptors, etc.). The MAPKs ERK 1/2 (extracellular signal-regulated protein kinase 1/2), p38, and JNK (c-Jun N-terminal kinase) catalyze the phosphorylation of the MKs (MAPK-activated protein kinases). While ERK 1/2 and JNK are implicated in cell proliferation and differentiation, p38 is essential for immune and inflammatory responses. The cascade of intracellular events that leads to the activation of NFκB and the MAPK pathways by IL-1 requires the recruitment of MyD88, IRAK, and TRAF-6 (Fig. 115.1). On the other hand, the activation of the same pathways by TNFα requires the adaptor protein TRADD and the death domain (DD). In this case, the activation of the NFκB pathway is initiated by the binding of the adaptor protein RIP (receptor interactive protein) to TRADD. The activation of TRAF2 (TNF receptor associated factor)-dependant MAPK or FADD (Fas associated death domain) caspases follows (reviewed in Liu 2005). IL-1β activates NFκB and MAPK signaling pathways in neurons and glial cells (Nadjar et al. 2003). In the aging brain, the activations of the JNK/p38 and caspase-3 pathways depend on IL-1β and its receptor, the synthesis of which is augmented in the hippocampus (Lynch and Lynch 2002). The overactivation of these pathways participates in the increase in neuronal death in the aging brain. Additionally, the overproduction of IL-6 by microglial cells in old mice is linked to the prolonged activation of NFκB (Ye and Johnson 2001).

The binding of IL-6 to its receptors leads to their phosphorylation by the Janus kinases (JAK1, 2 and Tyk). This leads to the recruitment of the STAT (signal transducers and activators of transcription) transcription factors, mainly STAT1 and STAT3, which are in turn phosphorylated. The phosphorylated forms of STAT form homo- or heterodimers via their SH2 domains, and subsequently migrate into the nucleus to activate the synthesis of target genes (Fig. 115.2). The constitutive expression of STAT1 and 3 proteins in the CNS has been demonstrated during postnatal development and in adulthood (reviewed in Dziennis and Alkayed 2008). In the adult brain, STAT3 is activated in astrocytes and endothelial cells in response to the administration of lipopolysaccharide (LPS) or IL-6 (Gautron et al. 2002; Harré et al. 2002). In the aging brain, IL-6 inhibits hippocampal long-term potentiation (LTP) through the intermediary of the ERK 1/2 pathways (Tancredi et al. 2000).

115.3 Polyunsaturated Fatty Acids and Their Role in the Control of Innate Cerebral Immunity and Its Behavioral Effects

Polyunsaturated fatty acids (PUFAs) of the ω3 or ω6 families are essential nutrients, since they cannot be generated *de novo* in mammals. In plants, they exist as precursors (linoleic acid (18:2ω6, LA) and α-linolenic acid (18:3ω3, ALA)) that are metabolized by a series of elongation and desaturation steps into arachidonic acid (20:4ω6, AA) in the first case and eicosapentaenoic acid (20:5ω3, EPA) and docosahexaenoic acid (22:6ω3, DHA) in the second. These PUFAs are incorporated into cell membranes as phospholipids. The liver is the principal site of conversion of the precursors LA and

ALA into long-chain PUFAs, although other organs such as the brain also express the necessary elongases and desaturases. Since the two series of PUFAs compete for the use of the enzymes necessary for their biosynthesis, and because they have distinct physiological properties, the ω6/ω3 ratio in the diet is of particular importance. Foods previously consumed by humans were rich in ω3 PUFAs (products of hunting), while those consumed today are poor in these nutrients. Thus, since the industrial revolution, the ratio of ω6/ω3 PUFAs in the diet has increased from 1 to almost 20 in industrialized countries like the USA, leading to a significant deficiency in ω3 PUFAs (reviewed in Simopoulos 2009).

The dietary deficiency in ω3 PUFAs, by decreasing their intracerebral levels, promotes neuroinflammation and consequently the development of CNS disorders with an inflammatory component. Indeed, the low incidence of inflammatory disorders (psoriasis or asthma) as well as the total absence of multiple sclerosis in Eskimos from Greenland, whose dietary supply of ω3 PUFAs is high due to the consumption of fish, points to the importance of the interaction between ω3 PUFAs and inflammation (Dyerberg and Bang 1979). On the other hand, the effect of ω3 supplementation is subject to debate. Certain clinical studies have reported anti-inflammatory effects of ω3 PUFAs administered in the context of chronic and autoimmune inflammatory disorders, while other studies have failed to reproduce these findings. Conversely, dietary supplementation with fish oil rich in EPA and DHA

leads to an amelioration of symptoms in patients with rheumatoid arthritis, chronic inflammatory intestinal disorders, or multiple sclerosis.

In this chapter, we will discuss the effects of the deficiency of ω3 PUFAs on neuroinflammation, and its behavioral consequences.

115.3.1 Consequences of the Decrease in ω3 PUFAs on Neuroinflammation Related to the Activation of Innate Immunity

After adipose tissue, the brain and retina are the organs that contain the highest levels of fatty acids (50–60% of the dry weight of the brain consists of lipids), which are principally PUFAs (35% of the lipids of the brain). The principal PUFAs of the cell membranes of the nervous system are AA and DHA, which are mainly incorporated into the phospholipids phosphatidylethanolamine (PE) and phosphatidylcholine (PC) in neuronal membranes. Neurons do not contain the elongases or desaturases necessary for the synthesis of long-chain PUFAs from their precursors LA and ALA. Most of the DHA and AA incorporated into neuronal membranes thus need to be provided by the diet in the form of presynthesized PUFAs. Nevertheless, a portion of these PUFAs can be derived from the precursors LA and ALA, mainly in the liver. Such biosynthesis is minimal in the brain, where the activity of desaturase corresponds to a mere 6% of that measured in the liver (Bourre and Piciotti 1992). Endothelial cells convert ALA into EPA, and astrocytes produce DHA from EPA in order to supply it to neurons. Recent studies in the rat demonstrate that when 4.6% of ALA is provided by the diet (considered an adequate supply), the conversion of ALA into DHA by the liver is sufficient to meet the DHA needs of the brain. When the diet is poor in ALA, the synthesis of DHA by the brain in increased. Conversely, the expression of iPLA2 (calcium-independent phospholipase A2), which mobilizes the DHA associated with phospholipids, is inhibited in the brain, thus increasing the half-life of DHA in this organ (reviewed in Rapoport et al. 2007). In rodents, a dietary deficiency of ω3 PUFAs leads to a decrease in the brain concentration of DHA, and a corresponding increase in AA and the ω6 equivalent of DHA in terms of the number of carbon atoms – docosapentaenoic acid (DPAω6, 22:5n-6) (Table 115.1). This substitution takes place to the detriment of the specific biophysical properties of DHA, leading to various functional disturbances that can be seen both at the level of synaptic transmission and at the behavioral level.

In vitro, ω3 PUFAs efficiently inhibit the synthesis of the inflammatory cytokines IL-1β, TNFα, and IL-6 (Fig. 115.3) and their signaling pathways, in particular the NFκB and MAPK pathways. However, results obtained in vivo are more controversial. In rodents, supplementation with fish oil either decreases or increases the production of IL-1β, TNFα, and IL-6 by monocytes and macrophages

Table 115.1 Impact of DHA deficiency in diet on DPA (22:5 n-6) and DHA (22:6 n-3) levels in brain cortex phospholipids of mice

| | PUFA (%) in phosphatidylethanolamine (PE) | |
	Control	N-3 deficiency
22:5n-6 (DPA, n-6)	0.5 ± 0.0	$13.8 \pm 1.0^{***}$
22:6n-3 (DHA, n-3)	26.4 ± 0.3	$11.1 \pm 0.5^{***}$

Mice were fed with either n-3/n-6 (control) and n-6 (n-3 deficiency) diet. DHA was strongly decreased in cortex PE of mice fed the n-6 diet as compared with the n-3/n-6 diet while DPA was increased. Data are mean ± SEM values, expressed as weight percentage of total fatty acids ($n = 4$)

$^{***}p < 0.001$ n-3/n-6 versus n-6 groups (Data from Dr S. Layé group)
Fig. 115.3 Docosahexanenoic acid (*DHA*) inhibits lipopolysaccharide (*LPS*)-induced Interleukin-1beta (*IL-1β*) and Tumor Necrosis Factor alpha (*TNFα*) expression in BV-2 cells. BV-2 cells (microglia cell line) were treated or not with 30 μM DHA for 24 h and then stimulated with LPS (1 μg/mL) or its solvent (control) for 6 h. IL-1β expression normalized to actin (Δ of control) was measured by quantification of western blots. TNF-α levels were measured in cell supernatants by ELISA. Results are expressed as mean ± SEM, $n = 3$. **$p < 0.01$, ***$p < 0.001$ (Data from Dr S. Layé group)

ex vivo. EPA and DHA, by reducing the availability of AA, decrease the production of prostaglandin E2 (PGE2), which is anti-inflammatory at low doses and proinflammatory at high doses (reviewed in Calder 2006). In vivo, the synthesis of the inflammatory cytokines IL-1β, TNFα, and IL-6 is weaker, whereas that of anti-inflammatory cytokines is higher in rodents subjected to a diet enriched in fish oil. Similar results have been reported in healthy human volunteers. Thus circulating leukocytes stimulated ex vivo by LPS produced less IL-1β, TNFα, and IL-6 when they were derived from subjects who had consumed fish oil capsules. However, these results were not reproduced by another supplementation study with doses less than or equal to 1.7 g/day of EPA and DHA. Other studies using supplementation with higher doses of EPA and DHA also demonstrated no effect on the production of cytokines by blood leukocytes (reviewed in Calder 2006). Nevertheless, a prospective study carried out in a sample of 1,123 subjects has shown that the levels of total circulating ω3 PUFAs (ALA, EPA, and DHA) are inversely correlated to the concentrations of TNFα and IL-6, whereas the ω6/ω3 ratio is inversely correlated to the level of IL-10 (Ferrucci et al. 2006).

The symptoms of the disorder (social withdrawal, piloerection, etc.) as well as the elevation of plasma IL-6 induced by the administration of IL-1β in the rat are attenuated by a diet enriched in fish oil (Miguelez et al. 2006). Nevertheless, other studies demonstrate an increase in plasma TNFα in response to LPS in mice fed with oils rich in ω3 PUFAs (Chavali et al. 1998). In humans, dietary supplementation with fish oil capsules for 3–4 weeks attenuates the febrile response but does not affect plasma concentrations of cytokines in healthy volunteers given an intravenous injection of LPS (Michaeli et al. 2007). However, the intravenous administration of fish oil 24–48 h before LPS injection attenuates the production of plasma TNFα and aggravates the fever (Pluess et al. 2007). In addition, a diet rich in EPA attenuates the alterations in spatial memory induced by a central injection of IL-1β in rats (Song and Horrobin 2004). A dietary deficiency of ω3 PUFAs also reduces the DHA content of the brain and increases the peripheral and central production of IL-6 in response to LPS. However, this overproduction of IL-6 does not induce behavioral changes, since the STAT3 signaling pathway in the brain is only weakly activated (Fig. 115.4) due to mechanisms that remain to be elucidated (Mingam et al. 2008). The inhibitory effects of LPS on hippocampal LTP disappear in rats given a diet rich in EPA, or when hippocampal slices are treated in vitro with EPA, in which case this effect is associated with a decrease in the production of IL-1β in the hippocampus (Kavanagh et al. 2004). The protective effects of EPA on the LTP alterations induced by the amyloid β peptide

Fig. 115.4 STAT3 signaling pathway is altered in *n*-3 PUFA depleted mice. The *n*-3 PUFA deficient diet reduces the LPS-induced STAT3 activity in mice hippocampi. STAT3 activity was determined by quantification of western blot. Data are given as the mean of phosphorylated STAT3 on tyrosine 705 to STAT3 ± SEM. * $p < 0.05$ (Data from Dr S. Layé group)
(Aβ) are associated with the inhibition of the expression of IL-1β in the hippocampus (Minogue et al. 2007). These data, taken together, suggest that dietary ω3 PUFAs limit the central effects of inflammatory cytokines under conditions of innate immune system stimulation.

115.3.2 Consequences of the Decrease in ω3 PUFAs on Age-related Neuroinflammation

During aging, the level and replacement of brain PUFAs decrease, particularly in the hippocampus, cortex, striatum, and hypothalamus. Brain levels of DHA and AA diminish in aging rats that display alterations in cognition and in LTP in the hippocampus (Favrelière et al. 2003; McGahon et al. 1999a). In transgenic SAMP8 mice, in which aging is accelerated, DHA decreases with age whereas lipid peroxidation increases (Petursdottir et al. 2007). In addition, the conversion of the precursors LA and ALA into their long-chain derivatives becomes less efficient. In fact, the activity of the desaturases responsible for the conversion of LA and ALA into their respective long-chain derivatives, and the activity of the Δ6 desaturase in particular, decreases with age in the liver and the brain. Phospholipid synthesis pathways are also altered with age, thus reducing the incorporation of PUFAs into membranes. The combination and interaction of these different alterations associated with aging contributes to a reduction in the level of DHA, i.e. a reduction in the index of membrane fluidity, in the brain of elderly people. In old animals that display a decrease in the membrane content of AA in the hippocampus, LTP is attenuated, but can be reestablished by a diet containing AA (McGahon et al. 1999b). These data serve to accentuate the importance of the dietary supply of DHA in aged subjects.

The expression of markers of microglial activation (CD68, MHCII and CD11b) increases with age in animals, as does the number of microglia in the brain of humans, attesting to the occurrence of age-related neuroinflammation (Godbout et al. 2005). Microglial cell reactivity is involved in the age-dependant increase in the production of inflammatory cytokines, as demonstrated by the inhibition of inflammatory cytokine overexpression by minocycline, an inhibitor of microglial reactivity, in aged rats (Griffin et al. 2006). In this context, the anti-inflammatory effect of long-chain ω3 PUFAs in the developing and aged brain could be due to their antioxidant activity. DHA and EPA are powerful antioxidants due to the presence of double bonds that are capable of capturing free radicals. It has been shown, notably, that DHA protects neurons in culture against the oxidative stress induced by methylmercury (Kaur et al. 2008), and that dietary supplementation with fish oil for 14 days reduces the levels of nitric oxide induced by cerebral ischemia, while promoting the activity of antioxidant enzymes such as sodium oxide dismutase and glutathione

peroxidase (Bas et al. 2007). In a cohort of elderly subjects, depressive individuals with an elevated plasma ω6/ω3 ratio present higher levels of TNFα and of IL-6 (Kiecolt-Glaser et al. 2007). Additionally, ω3 PUFA supplementation in elderly subjects reduces the levels of inflammatory cytokines produced by blood leukocytes stimulated in vitro (Meydani et al. 1991). The production of PGE2 by monocytes is inversely correlated to the EPA content of leukocytes obtained from aged subjects after the consumption of dietary complements containing different doses of EPA (Rees et al. 2006). To the extent that the level of peripheral cytokines reflects that of cytokines in the brain, these results, taken together, suggest that dietary ω3 PUFAs modulate neuroinflammation in elderly individuals. In rats, microglial activation, the production of IL-1β and alterations in hippocampal LTP with age are attenuated by EPA (Lynch et al. 2007). These data suggest that dietary ω3 PUFAs affect the inflammatory status of elderly subjects, and could thus modulate the associated cognitive deficits.

Epidemiological studies reveal the importance of ω3 PUFA levels in the development of age-linked neurodegenerative disorders. Thus, the plasma and brain levels of DHA decrease in patients with Alzheimer's disease. These results, however, remain controversial, since other studies demonstrate an increase or an absence of variation in brain DHA levels. Nonetheless, the risk of dementia is augmented in elderly subjects presenting low levels of circulating EPA. The use of a mouse model of Alzheimer's disease, the Tg2576 mouse, has demonstrated that a dietary supply of DHA leads to a reduction in the formation of amyloid plaques. However, the administration of dietary supplements containing DHA to patients with Alzheimer's disease or mild cognitive impairment has not yielded conclusive results (reviewed in Calon and Cole 2007).

115.4 Mechanisms of Action of Polyunsaturated Fatty Acids in Neuroinflammation

115.4.1 Lipid Derivatives of the PUFAs and Neuroinflammation

The hypothesis that the PUFAs regulate neuroinflammation relies on their previously described role in the control of inflammation in the periphery. In this chapter, we will review the pro- and anti-inflammatory properties of the PUFAs and their occurrence in the brain. It is well established that ω3 and ω6 PUFAs exert opposing effects on the regulation of inflammation. However, their effects are more nuanced. Thus ω6 PUFAs, AA in particular, are the precursors of the eicosanoids, which have proinflammatory effects, whereas ω3 PUFAs have weaker inflammatory effects. The PUFAs are released from membrane phospholipids principally by calcium-dependant phospholipase A2 (cPLA2), which is activated under inflammatory conditions. The released PUFAs enter two distinct metabolic pathways, the cyclooxygenase (COX) pathway leading to the formation of prostaglandins (PGs), prostacyclins (PGIs), and thromboxanes (TXs); and the lipoxygenase (LOX)/leukotriene synthase pathway leading to the formation of leukotrienes (LTs) (Fig. 115.5).

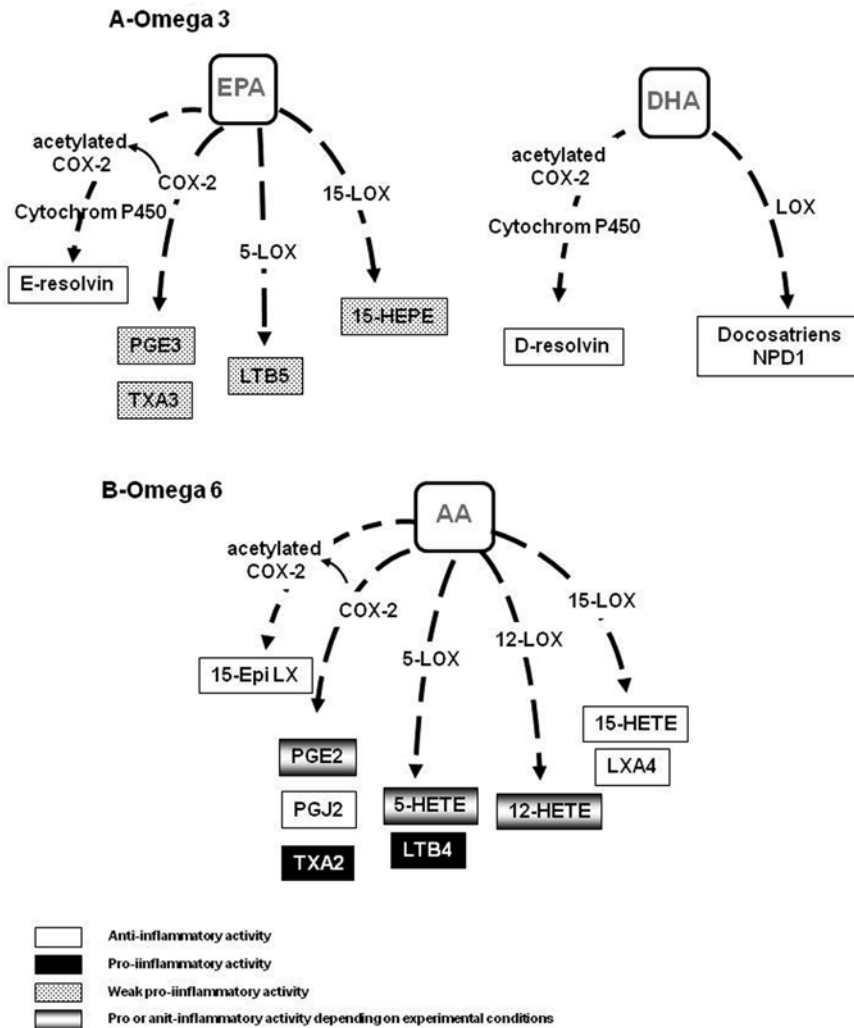
COX-1 and COX-2 are constitutively expressed in microglial cells and neurons, respectively. Under inflammatory conditions, their expression is induced in glial cells and endothelial cells of blood vessels in the brain. The eicosanoids produced by the inflammatory activity of COX-2 mainly yield PGE2, which is synthesized from AA. The actions of PGE2 in the brain lead to fever and an increase in vascular permeability, vasodilation, pain, and edema. However, a portion of the eicosanoids derived from AA metabolism is responsible for silencing the inflammatory response before it becomes detrimental to the organism. The lipoxins produced by the 15-LOX pathway, especially


Fig. 115.5 Metabolic derivatives of PUFAs. (**a**) Metabolic derivatives of docosahexaenoic acid (*DHA*) and eicosapentaenoic acid (*EPA*). (**b**) Metabolic derivatives of arachidonic acid (*AA*). *COX* cyclooxygenase, *HEPE* hydroxyeicosapentaenoic acid, *HETE* hydroxyeicosatetraenoic acid, *LOX* lipoxygenase, *LT* leukotriene, *LXA4* lipoxin A4, *PG* prostaglandin, *PGE2* prostaglandin E2, *TX* thromboxane, *NPD1* neuroprotectin D1

LXA4, are included among these mediators and, as such, have anti-inflammatory effects (reviewed in Serhan 2008). There exist other anti-inflammatory lipoxins, the 15-epi-lipoxins, which are produced not by the 5-LOX pathway but by the acetylation of COX-2 under the influence of aspirin. Certain series 2 prostaglandins, such as PGE2 and 15-deoxy-delta 12,14-prostaglandin J2 (15d-PGJ2), also display anti-inflammatory properties, blocking the synthesis of the LTs by the inhibition of 5-LOX, and inducing 15-LOX and the formation of lipoxins (reviewed in Serhan 2008). PGE2 and 15d-PGJ2 also inhibit the synthesis of the inflammatory cytokines IL-1β and TNFα (reviewed in Calder 2009). In vivo, these lipid derivatives of AA inhibit the inflammation associated with ischemia, colitis, arthritis, and fever (review in Scher and Pillinger 2005). The ω3 PUFAs reduce the synthesis of eicosanoids by inhibiting the activity of PLA2 and, as a consequence, the production of PGE2, TXA2, and LTB4 (reviewed in Calder 2009). The global impact on inflammation thus remains

complex. However, EPA is also metabolized by the COX and LOX enzymes, generating series 3 PGs and TXs, series 5 LTs and hydroxyeicosapentaenoic acids (HEPEs) with weak inflammatory or even anti-inflammatory effects in certain cases (Fig. 115.5). These examples clearly illustrate the complexity of the effects of the lipid derivatives of the PUFAs on inflammation. The recent discovery of resolvins and protectins, lipid derivatives of the ω3 PUFAs that play a key role in the termination phase of the inflammatory response, has clarified this situation. The synthesis of these derivatives from EPA and/or DHA depends on the acetylation of COX-2 by aspirin or by the cytochrome P450 pathway. The docosanoids derived from the metabolism of DHA (Fig. 115.5) include the docosatrienes generated by LOX. D series resolvins and the docosatrienes (or neuroprotectin D1) have been described in the blood and in glial cells in humans as well as in the mouse brain. In the brain, they have an anti-inflammatory and neuroprotective effect. In fact, resolvins inhibit the leukocytic infiltration that follows ischemia. These antiapoptotic compounds are synthesized by epithelial cells of the retina under conditions of oxidative stress, and in the brain of patients with Alzheimer's disease or after a stroke (reviewed in Serhan 2008). In addition, neuroprotectin D1 decreases the release of amyloid β peptide by neurons stimulated with IL-1β (Lukiw et al. 2005). While these results suggest that the resolvins and neuroprotectin D1 are powerful anti-inflammatory agents, their involvement in the protective effects of DHA with respect to neuroinflammation remains to be proven.

115.4.2 The Role of Nuclear Receptors in the Immunomodulatory Properties of the PUFAs

The PUFAs and some of their metabolites can regulate gene expression through the intermediary of members of the superfamily of nuclear receptors. This is true particularly with respect to the peroxisome proliferator-activated receptors (PPARs), the liver X receptors (LXRs), and the retinoid X receptors (RXRs), transcription factors that are mainly involved in the regulation of lipid metabolism and inflammation. The PPARs bind to DNA after forming a heterodimer with an RXR. Several ligands of PPARα and PPARγ inhibit the transcription of the genes for IL-1β, TNFα, IL-6, and COX-2, notably by attenuating the activation of the NFκB pathway. In addition, mice lacking the gene for PPARα display a prolonged inflammatory response, pointing to an anti-inflammatory effect of this receptor. DHA is one of the natural ligands of PPARα, and EPA can bind to all members of the PPAR family. The anti-inflammatory effects of the ω3 PUFAs and their effects on the regulation of lipid metabolism could thus bring these receptors into play. PPARγ is more involved in the anti-inflammatory activity of 15d-PGJ2, one of its natural agonists (review in Scher and Pillinger 2005). Nevertheless, in vivo, not much information is available regarding the role of these receptors in the modulation of neuroinflammation by the ω3 PUFAs.

115.4.3 The Role of Lipid Rafts in the Immunomodulatory Properties of the PUFAs

The ω3 PUFAs have an impact on the physiochemical properties of the cell membrane by virtue of their incorporation into membrane phospholipids. They can thus act directly on the activity of membrane proteins, especially through the modulation of lipid rafts. Lipid rafts are membrane microdomains with a high concentration of numerous receptors and proteins involved in signal transduction, thus

constituting veritable signaling platforms. The receptors of LPS, TLR4, and CD14, as well as TNFR1, gp130, and certain proteins involved in their signaling such as STAT3, are associated with lipid rafts (Triantafilou et al. 2002; Legler et al. 2003; Sehgal et al. 2002). The rafts are enriched in cholesterol and sphingolipids and poor in PUFAs, in contrast to the more fluid surrounding membrane, thus allowing them to float freely throughout the membrane. DHA is the PUFA with the highest conformational flexibility due to its six double bonds, which behave like joints around which the molecule undergoes tortional rotations. It has been shown that DHA and EPA modify the association of proteins with the lipid rafts, as well as the lipid composition of the rafts themselves, thus inhibiting the signal transduction associated with IL-2 in human T-lymphocytes (Jurkat cells) (reviewed in Chapkin et al. 2008). In mice, the consumption of fish oil leads to an increase in the ω3 PUFA content of raft and non-raft fractions of T-lymphocyte membranes, as well as to a reduction in the sphingolipid content of the rafts, along with a suppression of the activation of the IL-2 signaling pathway. Pretreatment with DHA strongly inhibits the production of IL-1β and of TNFα by microglial cells. This decrease is associated with a suppression of the cell surface expression of the proteins CD14 and TLR4 of the LPS receptor complex in microglia, without any modification in their subcellular localization, i.e. raft for CD14 and nonraft for TLR4 (De Smedt-Peyrusse et al. 2008). It remains to be determined if this is also the case for microglial cells in vivo.

115.5 Conclusion

There is growing evidence that the expression and action of proinflammatory cytokines in the brain are responsible not only for the development and maintenance of sickness behavior during the host response to infection, but also for the occurrence of nonspecific symptoms of sickness during chronic inflammatory disorders and aging. In addition, neuroinflammation can have detrimental consequences on neuronal viability, especially when maintained over long periods of time and transiently amplified by peripheral infectious episodes. All of this points to the interest of finding new ways of controlling inflammation in the brain. Because of their abundance in the brain and their modulatory effects on inflammation and cell functions, PUFAs definitely play a role in this process. However, this role needs to be better characterized by multidisciplinary studies aimed at assessing the effects of these molecules at different levels, from the molecular level to that of the organism as a whole.

Key Terms

Innate immune system: Comprises the cells and mechanisms that defend the host from infection by other organisms, in a nonspecific manner. Innate immune systems provide immediate defense against infection.

Cytokines: Immunomodulating agents secreted by certain cells of the immune system, which carry signals locally between cells; and thus have an effect on other cells. They are a category of signaling molecules.

PUFA: Depending on their degree of saturation, fatty acids are classified as either saturated fatty acids, monounsaturated fatty acids, or polyunsaturated fatty acids (PUFA). PUFA are found in dietary fats and oils, and are known as essential fats. Like vitamins, fatty acids are essential for life; they cannot be made in the body and must be obtained via the diet.

Lipid rafts: Cholesterol and sphingolipid-enriched microdomains floating freely in the cell membrane bilayers. They serve as organizing centers for the assembly of signaling molecules, influencing membrane fluidity and membrane protein trafficking.

Key Features

1. Microglial cells and astrocytes represent cerebral innate cells. They are activated by immunogenic stimuli to produce inflammatory cytokines.
2. During aging, the reactivity of microglial cells and astrocytes increase, leading to cerebral micro inflammation and consequently higher sensitivity of the neurons towards cytokines.
3. IL-1β, IL-6, and TNF-α and their receptors are expressed in the central nervous system, especially in glial cells throughout life.
4. Binding of IL-1β and TNF-α to their receptors is associated to the activation of NFκB and MAP kinases signaling pathways.
5. Binding of IL-6 to its receptor is associated to the activation of JAK/STAT signaling pathway.
6. Omega3 (ω3) and omega 6(ω6) represent two distinct PUFA families.
7. Linoleic acid (LA) is the precursor of ω6 PUFA family including arachidonic acid (AA).
8. α-Linolenic acid (ALA) is the precursor of ω3 PUFA family including docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA).
9. Ratio of ω6 to ω3 recommended in the diet is about 1:5, while in industrialized countries, ω6/ω3 reaches 1:20, leading to a significant deficiency in ω3 PUFAs.
10. PUFAs are essential and represent 35% of the lipids of the brain.
11. The brain PUFAs, mainly DHA and AA, are provided either directly from the diet or from their precursors ALA and LA via the liver.
12. Dietary ω3 PUFAs limit the central effects of inflammatory cytokines under conditions of innate immune system stimulation.
13. Aging goes with a decrease of brain ω3 PUFAs content.
14. Deficit of brain ω3 PUFAs content is a risk factor for age-related cognitive decline and or the development of inflammatory neurodegenerative diseases.
15. Dietary ω3 PUFAs affect the inflammatory status of elderly subjects and could modulate the associated cognitive deficits.
16. ω6 PUFAs and especially AA generate lipid derivatives with inflammatory activities while ω3 PUFAs (EPA and DHA) generate lipid derivatives with anti-inflammatory properties.
17. Dietary PUFAs modulate expression, production, and activation of signaling pathways of inflammatory cytokines.
18. PUFAs regulate gene expression via the nuclear receptors PPAR and RXR.
19. PUFAs modulate the expression of cytokine receptors and their signaling pathways via lipid rafts in the membranes.

Chapter 116
Dietary Supplementation of Omega-3 Polyunsaturated Fatty Acids in Autism

Pierluigi Politi, Hellas Cena, and Enzo Emanuele

Abbreviations

AA	Arachidonic acid
ABC	Aberrant behavior checklist
ABLLS	Assessment of basic language and learning skills
ADI-R	Autism diagnostic interview-revised
ALA	Alpha-linolenic acid
ASD	Autistic spectrum disorder
ASP	Asperger syndrome
CARS	Childhood autism rating scale
DHA	Docosahexaenoic acid
DSM-IV	Diagnostic and statistical manual of mental disorders
EPA	Eicosapentaenoic acid
GLA	Gamma-linolenic acid
PDD	Pervasive developmental disorders
PUFA	Polyunsaturated fatty acids

116.1 Introduction

Autism is a behaviorally defined neurodevelopmental disorder characterized by social and communication deficits, accompanied by repetitive and stereotyped behaviors, with onset before 3 years of age (Sigman et al. 2006). Leo Kanner of the Johns Hopkins Hospital first used the term autism in its modern sense when he introduced the label early infantile autism in a 1943 report of 11 children with striking behavioral similarities (Lyons and Fitzgerald 2007). In his words, "There is from the start an extreme autistic aloneness that, whenever possible, disregards, ignores, shuts out anything that comes to the child from the outside." It is this social impairment, along with impairments in communication, and the presence of restricted patterns of behaviors and interests that characterize autism (see Table 116.1).

The diagnostic indicators of autism are core behavioral symptoms rather than definitive neuropathologic markers. Autistic symptoms, however, can occur in a variety of combinations and present with

Table 116.1 Key features of autism

1. Autism is a complex developmental disability that causes problems with social interaction and communication.
2. Health care providers think of autism as a "spectrum" disorder, a group of disorders with similar features. One person may have mild symptoms, while another may have serious symptoms. But they both have an autism spectrum disorder.
3. People with autism may show unsuspected abilities.
4. Behavioral problems (aggressive and/or self-injurious behavior, tantrums) are frequently present.
5. Autism is generally diagnosed in the first 3 years of life.
6. Nevertheless, it is a lifelong condition.
7. Despite the clinical severity, people with autism can learn and function normally and show improvement with appropriate intervention, care, and education
8. Lifelong care is often a burden for families, but its costs can be strongly reduced with early diagnosis and intervention.

This table lists the key features of autism, including some basic epidemiology, clinical presentation, treatment and care

varying degrees of severity. The heterogeneity and clinical variability of autism has prompted the use of the term autistic spectrum disorders (ASDs) instead of autism. There are five ASDs described in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition-Text Revision of the American Psychiatric Association, i.e. (a) autistic disorder; (b) Asperger syndrome; (c) pervasive developmental disorder—not otherwise specified; (d) childhood disintegrative disorder; and (e) Rett syndrome. According to the ICD-10 categorization (code F84), there are nine different forms of ASDs comprising childhood autism, atypical autism, Rett syndrome, other childhood disintegrative disorder, overactive disorder associated with mental retardation and stereotyped movements, Asperger syndrome, other pervasive developmental disorders, and pervasive developmental disorder, unspecified. In any case, there is continued debate regarding the clinical boundaries of these disorders inasmuch as autistic-like traits and behaviors represent a continual spectrum rather than clinically defined diagnostic categories.

Although epidemiology data reported an incidence of 2–5 in 10,000 newborn babies before 1985, studies performed after the year 2000 converge upon rates of ASDs as high as 20–60 in 10,000 (Lintas and Persico 2009). This alarming rise in the prevalence of ASDs compelled researchers to explore why the number of children with ASDs seemed to be rising and sparked debate about a possible autistic "epidemic." There is uncertainty, however, regarding whether the increase in reported prevalence reflects a true increase in the incidence of ASD. In addressing the increased prevalence reports, experts frequently refer to the recent "broadening" phenotype of ASDs and the resulting inclusion of children with disorders that do not necessarily meet the criteria for true autism as a potential influence on the increased numbers (Kippes and Garrison 2006). Of note, the male: female sex ratio is 4:1, implying an involvement of X-linked genetic factors and/or imprinting mechanisms in the pathogenesis of this condition.

In general, it is believed that autism is a complex multifactorial disorder and has no single cause. Accordingly, growing evidence supports the idea that ASDs may be caused by several factors, including multigenic interactions and complex environmental contributions (Zecavati and Spence 2009). From a genetic standpoint separate genes seem to contribute to the social impairment, communicative impairment, and the rigid or repetitive behaviors, thus explaining the variation found along the spectrum of ASDs. Although most experts agree that there is a strong genetic component to autism, the more controversial discussions revolve around the possible environmental factors that may influence the phenotypic expression of ASDs. Most commonly cited environmental factors include immunizations (child and maternal immunization during pregnancy), environmental exposure (to infection, medications, or toxins), intolerance to food (primarily those containing casein and gluten), and specific perinatal events (e.g., fetal distress or anoxia, prematurity, low birth weight, uterine bleeding, or induced labor. Studies now under way are also investigating the relationship between factors such as atypical placental growth, abnormal gut tissue, inflamed tissue in the brain,

maternal/paternal age, and nutritional deficiencies. What was once considered a primary disorder of the brain is now being conceptualized as a multifactorial disorder, whereby the interaction between the genetic predisposition and environmental factors leads to a change in cerebral function.

116.2 Omega 3 Fatty Acids: A Clue for Orthomolecular Psychiatry?

In 1968, the two-time Nobel Prize winner and molecular biologist Linus Pauling published an article in *Science* entitled "Orthomolecular psychiatry" in which he described a biochemical model for investigating nutritional therapies for mental diseases (Pauling 1968). Reading (1979) defined orthomolecular psychiatric therapy as the study of the metabolic, endocrine, immunological, and toxic disturbances that are contributing to, perpetuating, exacerbating or even causing psychiatric symptomatology. In orthomolecular psychiatry, diseases are assumed to originate from multiple nonspecific causes, congenital and acquired. These causes give rise to biochemical aberrations, the accumulation of which results in symptoms and signs, from which the perception of a disease state follows. Orthomolecular psychiatry, therefore, pursues the treatment of mental disease by the provision of the optimum molecular environment for the brain, especially the optimum concentrations of substances normally present in the body. Successful treatment for psychiatric conditions according to orthomolecular psychiatry thus includes natural therapies such as nutrients and dietary changes. Modern advances in molecular biology generally support the concept of orthomolecular psychiatry as proposed 40 years ago. Accordingly, growing scientific evidence suggests that omega-3 polyunsaturated fatty acids (PUFA) may exert significant therapeutic effect as an orthomolecular psychiatry tool in a variety of different mental disorders, including schizophrenia, depression, and attention deficit hyperactivity disorder (Ross et al. 2007). This is both somewhat surprising, considering some of the fundamental differences between these conditions, but also promising, in particular in areas in which therapeutic options are limited.

   There is now good evidence indicating that PUFA accrued in rodent, primate, and human brain during active periods of perinatal cortical maturation, and that essential fatty acids play an important role in neuronal differentiation, synaptogenesis, and synaptic function (Green et al. 2006). PUFA are subdivided into the omega-3 (*n*-3) series (the first double bond is three carbons from the end (omega) carbon atom of the molecule) that are synthetically derived from linoleic acid (LA), and the omega-6 (*n*-6) series which are derived from alpha-linolenic acid (ALA), both 18 carbon atom containing fatty acids (see Table 116.2). LA and ALA are termed essential fatty acids because mammalian cells are unable to synthesize these fatty acids from simpler precursors. LA can be converted sequentially via a biosynthetic pathway into other omega-6 fatty acids, the 18 carbon gamma linolenic acid (GLA), and the 20 carbon arachidonic (AA) and dihomogammalinolenic acids (DGLA). Similarly, ALA is converted into longer chain omega-3 fatty acids such as 20 carbon eicosapentaeoic acid (EPA) and 22 carbon docosahexaenoic acid (DHA).

Table 116.2 Key features of omega-3 fatty acids

1. Omega-3 fatty acids are necessary for conception, growth, and fetal development.
2. Brain and nervous system development depends on omega-3 fatty acids.
3. Omega-3 fatty acids are found in human milk and their concentrations are higher in red blood cells of breast-fed infants than of bottle-fed infants.
4. Adequate omega-3 fatty acids are important for maintaining an adequate brain neurotransmitter function.
5. Omega-3 fatty acids have anti-inflammatory effects that may contribute to their neuroprotective properties.
6. Great progress has been made in the understanding of the role of omega-3 fatty acids in health and disease.
7. Promotion of adequate dietary recommendations on omega-3 intake is important in the prevention and management of neuropsychiatric disorders and mental wellness.

This table lists the key features of omega-3 fatty acids, with a special focus on their role in the central nervous system

Table 116.3 Omega-3 fatty acids and neuropsychiatric disorders

2. Attention deficit-hyperactivity disorder
3. Depression
4. Anxiety disorder
5. Bipolar disorder
6. Personality disorders
7. Schizophrenia
8. Eating disorders
9. Epilepsy
10. Alzheimer's disease
11. Sleep disorders

This table summarizes examples of clinical conditions with neuropsychiatric features for which the usefulness of omega-3 fatty acids has been suggested

Increasing evidence indicates, however, that although LA and ALA can be converted into their longer chain length metabolites, the rate of conversion in humans is very slow, resulting in an estimated 2–10% of ALA being converted to DHA or EPA. This suggests that a major source of the longer chain polyunsaturated fatty acid species such as EPA and DHA is likely to be dietary. Such a view is supported by data that supplementation with fish oils can markedly elevate the cellular levels of both these omega-3 PUFA (Gerster 1998).

Omega-3 PUFA are of particular interest from a nutritional standpoint in the field of orthomolecular psychiatry since the intake of these fatty acid is considered to be currently low in Western diets (see Table 116.3). Such a use is biologically plausible given that omega-3 fatty acids, in particular DHA, are abundant in the brain and are involved in, or modulate, the mechanism by which brain neurons communicate. Relative to brain maturation in humans, DHA accumulates in cerebral tissue at a rapid rate (14.5 mg/week) during the third trimester (gestational weeks 26–40) (McCann and Ames 2005). At term birth, DHA represents approximately 9% of total cortical fatty acid composition and increases by an additional 6% between birth and age 20 to compose 15% total cortical fatty acid composition. Of note, infants born preterm (<33 weeks of gestation) exhibit lower (−40%) cortical DHA concentrations relative to term infants (McNamara and Carlson 2006). These data indicate that the majority of DHA accumulation occurs in the human brain during the last trimester of normal gestation, and that DHA continues to accumulate throughout postnatal brain maturation. The linear increase in DHA accumulation in human frontal cortex between birth and 20 years of age corresponds with linear increases in frontal cortex white matter during this period, and additionally corresponds with the initial frontal gray matter expansion which continues until 12 years of age and then declines thereafter (Young et al. 1997). Interestingly, experimental studies in animals have shown that prenatal deficits in brain DHA accrual are associated with clear deficits in neuronal arborization, multiple indices of synaptic pathology, deficits in mesocorticolimbic dopamine neurotransmission, deficits in hippocampal serotonin and acetylcholine neurotransmission, neurocognitive deficits on hippocampus- and frontal cortex-dependent learning tasks, and elevated behavioral indices of aggression.

116.3 Evidence of Omega-3 Alterations in Autism

Previous studies linking reduced PUFA levels to autism represent the rationale for their use as a therapeutic means in this condition (see Table 116.4). Vancassel et al. (2001) were the first to compare essential fatty acid levels in the plasma of children with autism versus those with mental retardation.

Table 116.4 Studies examining the levels of omega-3 fatty acids in patients with autism compared with controls

Study	Participants	Target Analytes	Results
Meguid et al. (2008)	30 autistic children (18 males and 12 females) aged 3–11 years and 30 healthy children as control group	Linolenic acid Linoleic acid Arachidonic acid Docosahexaenoic acid	ASD children display reduced levels of linoleic acid (71%), DHA (65%) and arachidonic acid (45%) compared to apparently healthy subjects
Bu et al. (2006)	40 children with autism (20 with early onset autism and 20 with developmental regression) and age-matched, 20 typically developing controls and 20 subjects with nonautistic developmental disabilities	Fatty acids extracted from RBC	No major differences in essential fatty acids composition; however, increased levels of eicosenoic acid (20:1n9) and erucic acid (22:1n9) were found in autistic subjects with developmental regression compared with typically developing controls.
Sliwinski et al. (2006)	16 high-functioning male youngsters with autism (age 12–18) and 22 healthy volunteers	Plasma phospholipid omega-3 (3) and omega-6 (6) PUFA fractions and the 3/6 ratio	Patients with autism showed a significant increase in the fraction of C22:6–3 (docosahexaenoic acid, DHA) and an increase in the total 3/6 ratio
Hardy and Hardy (2002)	Subjects with pervasive developmental disorders	DHA/EPA in red blood cells membrane	90% of subjects with pervasive developmental disorders showed deficiencies of DHA/EPA in red blood cells membrane
Vancassel et al. (2001)	15 children with autism (4 girls, 11 boys) aged between 3 and 17 years (mean age 8 years 4 months), and 18 mentally retarded children (5 girls, 13 boys) aged between 1 and 19 years (mean age 8 years 8 months).	DHA, total PUFA	Significantly lower DHA and total PUFA concentrations in ASD children, omega-6 fatty acid levels were within the normal range

This table summarizes the studies in favor or against an altered omega-3 fatty acid status in autism

The authors reported significantly lower DHA and total PUFA concentrations in ASD children, whereas omega-6 fatty acid levels were within the normal range. In keeping with previous results, other authors (Bradstreet and Kartzinel 2001) detected omega-3 fatty acid deficiencies in nearly 100% of patients diagnosed with ASD. Another study has indicated that 90% of subjects with PDD have deficiencies of DHA/EPA in red blood cells membrane (Hardy and Hardy 2002). Reduced total omega-3 levels have been also reported in patients with regressive autism and Asperger syndrome (Bell et al. 2004). Recently, it has been suggested that ASD children display reduced levels of linoleic acid (71%), DHA (65%) and arachidonic acid (45%) compared to apparently healthy subjects (Meguid et al. 2008). Sliwinski et al. (2006) measured the levels of omega-3 and omega-6 polyunsaturated fatty acids in 16 high-functioning males with autism aged between 12 and 18 years. The authors reported a significant increase in DHA levels in autism that awaits independent replication. Although the great majority of published studies have suggested an unbalance of omega-3 levels in autism, one report (Bu et al. 2006) found no significant differences in essential fatty acids composition in 20 autistic patients compared with controls. However, different experimental designs, different number and characteristics of subjects recruited, ethnical differences, medical treatments, lack of standardization of methods for the determination of omega-3 levels and different ways in which serum or plasma samples were handled might at least partially explain the differences in the published data.

116.4 Omega-3 Fatty Acids as Treatments for Autism

The evidence that omega-3 fatty acid may be deficient in autism has prompted the idea that omega-3 supplementation might lead to an improvement in clinical symptoms and behavioral aberrations (Bent et al. 2009). Additionally, preliminary evidence mainly derived from clinical studies seems to suggest that specific nutraceutical interventions aiming to correct biochemical imbalances ASD may improve behavioral problems in this patient group (Chez et al. 2007; Dosman et al. 2007). This review considers the findings of the clinical trials and case reports that form the basis to support for the use of omega-3 PUFA as a treatment for autism. To accomplish this we utilized PubMed and PsycINFO to identify clinical trials and case reports of omega-3 fatty acids in patients with autism. The strategy employed was to search for articles which contained search terms "autism" and "omega-3, *n*-3 alpha linoleic, eicosapentaenoic, docosahexaenoic, EPA, DHA, ALA" limited by clinical trials and case reports.

A total of six studies were identified (see Table 116.5). Politi et al. (2008) conducted an open-label study in a single farm community center specifically designed for individuals with autism (Cascina Rossago, Ponte Nizza, Italy).

The trial involved 19 adults (15 males, 4 females) aged 18–40 years with severe autism (Childhood Autism Rating Scale [CARS] scores ≥40 in all subjects) during three different 6-week periods. Subjects were given 0.93 g of EPA and DHA. The frequency and severity of problematic behaviors was assessed before, during, and after treatment using the Rossago Behavioral Checklist, an ad hoc caregiver questionnaire focusing on behavioral problems.

The authors did not find any significant reduction of the severity and frequency of symptoms during the pretreatment and treatment periods. A slight improvement in behavioral alterations was evident during the post-treatment period, albeit not reaching the statistical significance threshold. However, this may due to random fluctuations in problematic behaviors due to seasonality and other factors (see Fig. 116.1). It is therefore concluded that variations in the behavioral scores found during the study could be due to caotic fluctuations in behavioral problems, and not to treatment effects. However, it should be kept in mind that this study involved a small sample size and was not carefully controlled.

Meguid et al. (2008) treated 30 autistic subjects (3–11 years) and 30 healthy controls with 130 mg of DHA, 35 mg of EPA, 10 mg of arachidonic acid. The treatment lasted for three months. Autistic behavior was evaluated with the CARS. Following the treatment schedule, 66% of patients showed an increase in plasma omega-3 concentrations as well as a significant improvement of autistic behavior.

Amminger et al. (2007) conducted a randomized, double-blind, placebo-controlled trial aiming at evaluating the efficacy of omega-3 fatty acids for the treatment of autism. The authors enrolled 13 children with autism (based on DSM-IV criteria and the ADI-R) and randomly assigned them to the daily use of 1.5 g of omega-3 fatty acids (0.84 g/day EPA, 0.7 g/day DHA) or a placebo for 6 weeks. They evaluated changes in the scores of the Aberrant Behavior Checklist (ABC) at 6 weeks. Although the authors observed a greater improvement in each subscales of the ABC (especially as regard hyperactivity and stereotypy), none of the reported changes reached the statistical significance threshold. Future studies should address the limitations of this randomized controlled trial by using a larger sample size with sufficient power to detect clinically important benefits, treating for a longer duration to examine the time course of treatment effects, including a biomarker to examine the mechanism of action of any benefits, including a broader array of outcome measures of potential areas of benefit in ASD, conducting careful assessments of side effects and safety, and assessing the adequacy of blinding.

Table 116.5 Studies examining the effects of omega-3 fatty acids supplementation in patients with autism

Study	Methods (type, length)	Participants	Interventions (daily dose)	Outcomes	Notes
Politi et al. (2008)	6-week open label, uncontrolled trial	Young adults with severe autism (n = 19)	0.93 g of DHA plus EPA. 5 mg of vitamin E	Rossago Behavioral Checklist (22-item list, each rated 0–4) No significant improvement from baseline scores	No mention about side effects
Meguid et al. (2008)	3-month uncontrolled trial	Autistic children aged 3–11 years (n = 30)	240 mg DHA plus 52 mg EPA and vitamin E 68 mg omega-6 fatty acids	CARS Significant improvement in CARS scores in 20 of 30 children	Vitamin E dose was not reported, no mention about side effects
Amminger et al. (2007)	6-week RCT	Children attending a specialized day care center for long-term treatment of autism (n = 13)	840 mg EPA plus 700 mg DHA and 7 mg vitamin E	ABC Nonsignificant advantage of omega-3 fatty acids compared with placebo for hyperactivity and stereotypy	One patient dropped out due to side effects
Patrick and Salik (2005)	3-month uncontrolled trial	Patients with autism and Asperger's syndromes (n = 22)	247 mg omega-3, plus 40 mg omega-6 and 27 IU vitamin E	ABLLS Significant increase in the 8 subscales	There was no control group, and 4 patients dropped out
Bell et al. (2004)	6-month uncontrolled trial	Two patients with Asperger syndrome and 7 with autism	860 mg EPA 300 mg DHA 2 IU vitamin E	Parents reported improvements in eye contact, social contact, irritability, aggression, hyperactivity	There was no control group and outcome measures were not standardized
Johnson and Hollander (2003)	Case report	1 male subject with autism, diagnosed at age 2.5	3 g/day (540 mg EPA/day)	Nonstandard clinician and parent reports Ease of anxiety and agitation	No mention about side effects

RCT randomized controlled trial, *ABC* aberrant behavior checklist, *CARS* childhood autism rating scale, *ABLLS* assessment of basic language and learning skills
Fig. 116.1 Periodic fluctuations of problematic behaviors according to seasonality in autistic patients at Cascina Rossago. The solid gray rectangle indicates the study period in the report by Politi and coworkers (2008)

Patrick and coworkers (Patrick and Salik 2005) enrolled 22 patients with autism or Asperger syndrome in an open-label study. During the study period (90 days) all patients were administered 247 mg of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) and 40 mg of gamma-linolenic acid (GLA). The subjects were evaluated at baseline, after 45 days and after 90 days of treatment using the Assessment of Basic Language and Learning Skills (ABLLS) test. The main finding of the trial was a statistically significant increase in the score of each subscale of ABLLS.

Bell and colleagues (Bell et al. 2004) ran a short (6-month) open-label trial in which 9 children with autism or Asperger syndrome were treated with two different form of omega-3 at different concentrations. No structured assessment was conducted but parents reported a significant improvement of their children behavior and general health.

A case report from Johnson and Hollander (2003) described an 11-year-old autistic boy with severe symptoms including tantrums, aggression, and compulsive rituals. After a gradual titrage (3 g/day) over 4 weeks, he was given 540 mg of EPA daily for 8 more weeks. Following the treatment, both parents and the physician observed an improvement of his behavior and quality of life. These improvements appeared after one week and continued throughout the entire study period.

Megson (2000) reported that administration of cod liver oil – which is rich in omega-3 and vitamins A and D – provided substantial benefits for persons with autism, suggesting that omega-3 or vitamins A and D could be potential complementary treatments for this condition.

116.5 Conclusions

EPA and DHA have been shown to positively influence a number of aspects of brain function and dysfunction; however, for many of these effects their mechanism of action remains to be fully elucidated. It is very likely that EPA and DHA operate through a number of different, potentially overlapping mechanisms, involving various cellular targets. Adequate dietary availability of DHA and EPA is clearly fundamental to brain function. DHA and EPA are important throughout adulthood, as well as during the brain growth spurts that characterize prenatal and postnatal development. Based on the available evidence, however, it is not possible to firmly recommend PUFA as a treatment for autism. As this condition is a notoriously complex disease, omega-3 supplementation may not prove to be an effective treatment for all autistic patients since the use of these compounds may benefit one patient but not be as successful with another; there appears to be no panacea. However, the large majority of the trials reported here had one conclusion in common – that omega-3 fatty acids had no serious side effects. Although the clinical trials varied in quality of design and tended to be small in terms of participants, further investigation of the use of omega-3 PUFA to treat at least some mental health problems is warranted. Further work is specifically required to determine if omega-3 supplementation might specifically benefit autistic patients showing abnormalities of omega-3 fatty acids in their sera. Other important issues for future studies of PUFA in autism concern the correct use and dosage of any fish oil product. Early studies into the effects of ALA, EPA and DHA have tended not to differentiate between these omega-3 PUFA, with the results broadly attributed to the omega-3 PUFA series as a whole. However, there is evidence to suggest that certain effects may be specific and unique for the different types of PUFA. It can no longer be assumed they have a mechanistic equivalence. In this regard, a recent review into the effects of omega-3 PUFA in mental illness has indicated that EPA may be more beneficial in mood disorders than DHA (Ross et al. 2007). Further an important, but as yet largely unexplored, issue is the most appropriate dosage of omega-3 PUFA to be used. Future studies will no doubt provide a more focused approach to the type and dose of omega-3 PUFA that is most appropriate for ASD.

116.6 Applications to Other Areas of Health and Disease

Although the effects of EPA for the brain development *in utero* are unclear, the presence of EPA and DHA in colostrum and breast milk suggests that these molecules may be involved in early development of CNS. Accordingly, due to their highly fluidizing properties, DHA and EPA can be found at the highest concentrations in the most dynamic membranes of the neural cells. The evidence presented here on omega-3 in ASD may prompt further research in other childhood neuropsychiatric disorders, including Tourette's syndrome, hyperkinetic disorder, and obsessive-compulsive disorder.

Summary Points

- People with autism can show remarkable alterations in omega-3 fatty acids concentration.
- Omega-3 fatty acids are essential for normal membrane function in neural cells.
- Controversy surrounds the issue of omega-3 fatty acids potential benefit on autism.
- These supplements may help some patients, not everyone; they cannot be considered panacea.
- Further evidence-based research is required to determine whether omega-3 supplementation might specifically benefit autistic patients showing serum abnormalities of omega-3 fatty acids.

Definitions and Explanations

Autism: A developmental disability marked by impairments in social interaction and communication and the presence of unusual, restrictive, and repetitive behaviors.

Omega-3: Important nutritionally-essential family of unsaturated fatty acids.

Randomized clinical trial: A clinical trial in which participants are assigned by chance to different treatments.

Uncontrolled study: A clinical trial in which participants are not assigned by chance to different treatments.

Nutraceutical: Any food or food ingredient that is considered to have a beneficial effect on health.

Chapter 117
Docosahexaenoic Acid and Cognitive Dysfunction

Michio Hashimoto, Hossain Md Shahdat, and Masanori Katakura

Abbreviations

Aβ	Amyloid β peptide
AD	Alzheimer's disease
ALA	α-linolenic acid
ATP	Adenosine triphosphate
CAT	Catalase
CNS	Central nervous system
DG	Dentate gyrus
DHA	Docosahexaenoic acid
EPA	Eicosapentaenoic acid
GPx	Glutathione peroxidase
GSH	Reduced glutathione
Hes1	Hairy and enhancer of split 1
LTP	Long-term potentiation
MCI	Mild cognitive impairment
MS	Multiple sclerosis
NMDA	N-methyl-D-aspartate
NSC	Neural stem cell
PPAR	Peroxisome proliferator-activated receptors
PUFA	Polyunsaturated fatty acid
ROS	Reactive oxygen species
RXR	Retinoid X receptor
SREBP	Sterol regulatory element-binding protein
ThT	Thioflavin T

117.1 Introduction

Docosahexaenoic acid (DHA, C22:6*n*-3), a dietary essential *n*-3 polyunsaturated fatty acid (*n*-3 PUFA) in highly-enriched fish oils, is synthesized through the elongation and desaturation of eicosapentaenoic acid (EPA, C20:5*n*-3) or the elongation of α-linolenic acid (ALA, C18:3*n*-3). Neural membranes of the cerebral cortex and the retina are very rich in DHA, which accounts for approximately 30–40% of the acyl group in glycerophospholipids (Lauritzen et al. 2001). The concentration of DHA is particularly high in gray matter of the cerebral cortex and in photoreceptor cells. DHA constitutes >17% by weight of total fatty acids in the brain of adult rats. It is recycled and used continuously for the biogenesis and maintenance of neuronal membranes. Neurons lack the ability to synthesize DHA from its precursor, ALA. DHA is obtained either directly from the diet or synthesized from ALA and/or EPA in the liver, and then transported to the brain through plasma lipoprotein (Scott and Bazan 1989). The cerebral endothelium and astrocytes have the ability to synthesize DHA from dietary precursors, suggesting that after its release from these tissues, DHA is taken into neurons from an extracellular medium. Nonetheless, this may be a minor pathway in quantitative terms as compared to DHA supplied to brain tissue from plasma (Rapoport et al. 2001).

During the growth spurt of the central nervous system (CNS) for 18 months after birth, accretion of DHA takes place rapidly (Bourre et al. 1989). DHA is an absolute prerequisite for the development of the human CNS and the continuous maintenance of brain cell function, which implies the essentiality of DHA for the human mental condition (Broadhurst et al. 1998) and intellectual evolution (Helland et al. 2003). DHA not only modulates physical properties of the lipid bilayer (Hashimoto et al. 2006a), but also provides second messengers for biological signaling (Phillis et al. 2006). In addition, DHA provides neural membranes with a physical environment for the activity of integral membrane proteins such as membrane-bound enzymes. It modulates ion channels and neurotransmitter receptors (Yehuda et al. 2002) and stabilizes neuronal membranes by suppressing voltage-gated Ca^{2+} currents and Na^+ channels (Young et al. 2000). Recent studies indicate that this fatty acid is implicated in cognitive development and learning ability and increases the plasticity of nerve membranes, the process of synaptogenesis, all of which are involved in synaptic transmission and the well-being of normal brain functions. Conversely, morphological and neurochemical consequences of DHA deficiency produce a decrease in neuronal cell bodies in several regions of the rat brain, a deficit in serotonin and dopamine neurotransmission, a decrease in glucose uptake, a reduction in cytochrome oxidase activity and a decrease in G-protein coupled signaling efficiency (Horrocks and Farooqui 2004) (Fig. 117.1). These neurochemical changes in brain tissue result in reduced learning and memory, and in elevated behavioral indices of anxiety, aggression, and depression (McNamara and Carlson 2006).

Alzheimer's disease (AD), a progressive neurodegenerative disorder characterized by progressive cognitive and memory decline, is the most common neurodegenerative disease that deprives millions of people worldwide of enjoying successful aging (Cummings and Cole 2002). Currently, there is no known treatment for AD. Epidemiological studies show that consumption of selected types of fats and antioxidants such as vitamin E and C lowers the risk of AD (Morris et al. 2003). In particular, growing evidence has shown that *n*-3 fatty acids from marine-life oils containing DHA and EPA may have therapeutic potential for the prevention and treatment of AD. AD is characterized by general loss of memory as well as a paucity of PUFAs, particularly of DHA (Horrobin 1998). Dietary DHA improves spatial learning ability associated with its accumulation in the hippocampus and cerebral cortex of young (Gamoh et al. 1999) and aged rats (Gamoh et al. 2001) and mice (Lim and Suzuki 2001), although the exact mechanism of the action of DHA in cognitive functions is not known. Furthermore, dietary DHA protects against (Hashimoto et al. 2002) and ameliorates (Hashimoto et al. 2005)
Fig. 117.1 Roles of docosahexaenoic acid in brain

memory deficits in the amyloid β (Aβ)-peptide-infused AD model rat and in the transgenic AD model mouse (Calon et al. 2004), suggesting a therapeutic effect of this fatty acid on AD. In the present review, we provide an overview of the literature regarding the role of DHA in AD and other neuronal dysfunctions involving cognitive deficits.

117.2 Characterization and Physiological Function of DHA

117.2.1 The Intrinsic Properties of DHA in Membrane-related Functions

DHA is one of the typical constituents of membrane phospholipids that are known as structural components of biomembranes. For the manifestation of signals to and from cells the signal ligands need to interact with plasma membranes and intracellular membranes. Therefore, DHA in the biomembranes is assumed to affect the functions of proteins, receptors, enzymes which get laid by DHA. In this context, membrane disorder (fluidity) is an important parameter that may affect the membrane-bound receptor and/or enzyme functions, suggesting that DHA in membranes plays both structural and functional roles. DHA increases the membrane fluidity of a variety of cells including platelet membranes (Hashimoto et al. 2006b), endothelial cells (Hashimoto et al. 1999), liver hepatocytes (Hashimoto et al. 2001), and synaptic plasma membranes (Shahdat et al. 2004). The effect of DHA on membrane fluidity and functions is controversial; however, Gordon et al. (1980) have reported that both membrane fluidity and membrane-bound enzyme activity increase in DHA-rich membranes. Many of the membrane-related functions require microaggregation, segregation, and dimerization in the bilayer environment. Thus, membrane fluidity plays a definite role in these membrane-related functions. In addition, the docking of synaptic vesicles or vesicles for exocytosis is assumed to be affected by the membrane microenvironment. The hydrophobic volume and the cross-sectional area of DHA are large. Also, DHA is believed to provide plasticity *in situ*. These inherent properties of DHA are believed to significantly affect overall bilayer physical properties and, subsequently, the functions of the proteins

laid by them. DHA remains highly concentrated in synaptic plasma membranes with an increase in the exocytosis of neurotransmitter-containing vesicles, suggesting that DHA-induced increase in membrane fluidity increases neurotransmission and related brain functions.

117.2.2 Antioxidative Effects of DHA

DHA is critical for cellular functioning and normal brain development in animals and humans (Calderon and Kim 2004; Wainwright et al. 1994). In aged animals, memory impairment occurs, in part, by reduced levels of cerebral DHA (Delion et al. 1996). Moreover, loss of brain DHA content in patients with AD is accompanied by loss of memory and learning ability (Horrobin 1998). The reduced DHA content may be due to enhanced free radical-mediated lipid peroxidation (Nourooz-Zadeh et al. 1999), decreased dietary intake, undefined impediments to the uptake and utilization of *n*-3 PUFAs, or impeded shuttling of DHA from the liver to the brain. A decrease in the level of serum DHA correlates with cognitive impairment (Suzuki et al. 1998), and epidemiological studies suggest neuroprotective consequences of diets enriched with *n*-3 PUFAs (Morris et al. 2003). DHA deficiency has been associated with the impairment of cognitive processes (Gamoh et al. 2001). Moriguchi et al. (2000) have shown longer escape latency in *n*-3 PUFA-deficient rats than in control rats, suggesting that an *n*-3 PUFA deficient diet affects the process of habituation, a simple form of learning. From these results, it is conceivable that the intake of DHA inhibits the accrual of oxidative stress and the decline in learning ability with aging.

How does DHA exert antioxidative effects while it is a highly PUFAs? The question could be considered very simple if the content of DHA in brain lipids is taken into account. The brain is very weak in antioxidative defense as compared with other organs of the body (Hossain et al. 1999). The brain consumes about one fifth of the total oxygen demand of the body to produce huge amounts of adenosine triphosphate (ATP) required for the 24-h opening and closing of neural ion channels for neurotransmission and for rapidly synthesizing synapatosomal plasma membranes of neuronal networks. Under these circumstances if DHA were an extra burden on the oxidative environment, the brain would degenerate very rapidly (Fig. 117.2). The reverse is known to be true, however, because brain functions benefit from an abundance of DHA, in other words, DHA increases, not impedes,
Fig. 117.2 Effects of oxidative stress on neurodegeneration

oxidative defense. Chronic administration of dietary DHA significantly decreases lipid peroxide levels by activating antioxidative enzymes including glutathione peroxidase (GPx), catalase, glutathione reductase, and antioxidant substrate-reduced glutathione (GSH) (Hossain et al. 1998, 1999). Infusion of DHA into amniotic fluid inhibits lipid peroxide levels in fetal brains (Green and Yavin 1995). In contrast, Arab et al. (2006) have reported that DHA increases the intracellular content of GSH with a concomitant increase in glutathione reductase and glutathione-S transferase (characteristics of antioxidative response) as confirmed by the increased mRNA levels of these enzymes. Bazan (2005) have reported that DHA is converted to docosahexatriene or the so-called neuroprotectin D1 which increases antioxidative defense or acts as an antioxidant. Therefore, whether DHA itself and/or DHA-derived docosanoid, or both, affect antioxidative defense remains to be clarified.

117.2.3 Modulation of Gene Expression by DHA

DHA supplementation produces overexpression, in animal brains, of many genes associated with signal transduction, synaptic plasticity, energy metabolism, and membrane trafficking (Kitajka et al. 2002). DHA is a ligand for the retinoid X receptor (RXR) that serves as a fatty acid sensor in the brain *in vivo* (Farooqui et al. 2004). In addition, DHA not only modulates gene expression, but also induces changes in the stability of the mRNA of lipogenic enzymes. DHA deficiency downregulates the expression of brain glucose transporters, resulting in a decrease of brain glucose utilization by the cerebral cortex in DHA-deficient rats (Pifferi et al. 2005). Changes in DHA-mediated gene expression are critical for adaptive responses for neural cell survival. Key transcription factors associated with these processes include peroxisome proliferator-activated receptors (PPAR) and sterol regulatory element-binding protein (SREBP) (Jump 2002). This evidence suggests that dietary DHA supplementation imparts numerous beneficial effects to the health of the human brain through the modulation of genes associated with synaptic plasticity, neuroinflammation, and energy metabolism (Horrocks and Farooqui 2004).

117.3 Cognitive Ability and DHA

DHA deficiency is associated with loss of discriminative learning ability (Neuringer et al. 1986; Yamamoto et al. 1987); thus, intake of DHA may restore lost learning ability (Gamoh et al. 1999). Long-term deficiency in ALA, a precursor of EPA and DHA, leads to decreases in the amount of DHA, in the density of synaptic vesicles, and in synaptic membrane fluidity in the brain (Calon et al. 2004). Moreover, *n*-3 PUFA deficiency causes a decline in learning ability in various tasks, such as light–dark discrimination (Yamamoto et al. 1987), shuttle avoidance (Hashimoto et al. 2002), and those posed by the radial-arm maze (Gamoh et al. 1999, 2001; Hashimoto et al. 2005) and the Morris water maze (de Wilde et al. 2002). It is thus plausible that the uptake of DHA into neural membranes, particularly in synaptic membranes, is related to the efficiency of learning ability. Based on these reports, DHA may play a principal role in memory formation, although the pertinent mechanisms are not clearly understood. Chronic administration of DHA increases DHA content in the hippocampus and the cerebral cortex and improves the performance of radial maze tasks by young and old rats (Gamoh et al. 1999, 2001), signifying the beneficial effect of DHA on learning ability. Enrichment with DHA promotes neuronal membrane synthesis and increases dendritic spine density in the hippocampus of adult gerbils (Sakamoto et al. 2007). A host of potential mechanisms of DHA action has been proposed: DHA may act by binding directly to the *N*-methyl-d-aspartate (NMDA) receptor

or by altering its lipid environment and thereby potentiating the NMDA response. It is also thought that DHA enhances the induction of long-term potentiation (LTP).

To the extent that *n*-3 PUFAs have trophic neural effects, higher consumption of these fatty acids is expected to correlate positively with the volume of gray matter in brain regions such as the amygdala, the hippocampus, and the anterior cingulated cortex. These regions are core components of a distributed corticolimbic circuitry that regulates emotional arousal in response to the regulation of affect in the service of adaptive behavioral responses. Higher consumption of long-chain omega-3 fatty acids is associated with a larger volume of gray matter in nodes of a corticolimbic circuitry supporting emotional arousal and regulation (Conklin et al. 2007). DHA promotes significant changes in neurotransmitter function, brain structure, and behavior. For example, animals fed DHA-deficient diets show reduced frontal cortex concentrations of monoamine neurotransmitters, dopamine, and serotonin (de la Presa Owens and Innis 1999). We have demonstrated that the number of Fos-positive neurons in the CA1 region of the hippocampus increase significantly in rats administered DHA for 15 weeks compared with controls, with a significant negative correlation of the number of Fos-positive neurons with reference memory errors measured by tasks in an eight-arm radial maze (Tanabe et al. 2004). The Fos protein, encoded by the immediately early gene c-fos, is known to be a transcription factor and a functional marker of neuronal activity. Thus, DHA intake could influence brain morphology through some or all of these mechanisms. Such associations may mediate previously observed effects of *n*-3 PUFAs on memory, mood and affect regulation.

117.4 Cognitive Dysfunction and DHA

117.4.1 Aging and DHA

The most notable risk factor of neurodegenerative disease in humans is old age. The onset of disease usually occurs from mid to late life, with progression depending on not only genetic but also environmental factors. DHA is retained in the brain during early development; however, generation of free radicals and reactive oxygen species (ROS) during the aging process causes a detrimental decline in DHA levels in neural membranes (Lauritzen et al. 2001). Also, a decline in the level of plasma DHA is associated with cognitive impairment with in aging (Conquer et al. 2000) and does not seem to be limited to AD patients (Yehuda et al. 2002). There are several possible reasons for this decline: a decrease in the ability of dietary fatty acids to cross the blood–brain barrier due to impaired transport function with aging, lipid peroxidation caused by accumulation of free radicals (Bjorkhem et al. 1998), a decrease in dietary intake, or impaired shuttling of DHA from the liver to the brain (Abad-Rodriguez et al. 2004). The deficiency affects mostly the cortex and hippocampus, areas which mediate learning and memory, and has been demonstrated in the Shimane Elderly Cohort Study of senior citizens older than 65 years of age, in which regression analysis reveals a positive correlation between EPA content in erythrocyte membranes and the scores of the revised Hasegawa dementia rating scale. Dietary administration of EPA increases not only EPA but also DHA in plasma and erythrocyte membrane levels in rats, leading to an increase of DHA levels in the hippocampus (Hashimoto et al. 2009). In a recent study, patients with blood DHA concentrations in the highest quartile have demonstrated a lower risk of developing dementia compared with the lowest three quartiles during a mean follow-up of 9 years (Schaefer et al. 2006). These results suggest that dietary supplementation with DHA alters the risk of cognitive impairment with aging and/or developing AD over the long term and that low concentrations of blood DHA account for a critical risk factor for cognitive dysfunction.
Fig. 117.3 Effect of aging on spatial-memory-related learning ability. Male Wistar rats at the age of 5 (○) and 100 (●) weeks fed a fish oil-deficient diet over two generations. The rats were subjected to the maze task using a partially (4/8) baited eight-arm radial maze. The learning ability is reflected in the number of reference memory errors, times of entry into unbaited arms. Values are means ± SEM in each block of six trials. Groups without a common letter for the main effects of groups are significantly different at $P < 0.05$. (Two-way ANOVA)

Aging is associated with not only a decrease in the content of DHA in the brain, but also loss of memory and learning ability. In aged animals, memory impairment occurs (Fig. 117.3), in part, by reduced levels of cerebral DHA (Delion et al. 1996). Reduced DHA levels and spatial cognitive learning ability with age can be restored by DHA supplementation (Gamoh et al. 2001). Glutamate receptor subunits GluR2 and NR2B in the rat forebrain, which decline with age and are related to memory function (Le Jeune et al. 1996), are up-regulated by DHA supplementation (Dyall et al. 2007). DHA administration reduces neuronal damage caused by ischemia (Okada et al. 1996). These data are consistent with our previous reports indicating that chronic administration of DHA reduces the levels of lipid peroxide by enhancing the cerebral activities of catalase and glutathione peroxidase in old rats (Hossain et al. 1998, 1999). Moreover, DHA supplementation not only restores the levels of DHA, but also increases membrane fluidity in synaptosomal plasma membranes of the rat cerebral cortex (Hashimoto et al. 2006a). Thus, the foregoing studies suggest that during aging DHA supplementation not only promotes normal membrane fluidity but also turns on the mechanism that maintains normal cognition and brain function.

117.4.2 Alzheimer's Disease and DHA

117.4.2.1 Human Studies

AD, a neurodegenerative disease that commonly affects the elderly, is characterized by loss of short-term memory and cognitive impairment. The cause of AD is unknown; however, the disease is associated with major pathological traits, such as overproduction and accumulation of Aβ produced by the proteolytic processing of amyloid precursor protein (APP) (Brunkan and Goate 2005), formation of neurofibrillary tangles caused by the aggregation of Tau protein within neurons (Mattson 2004), and

neuronal cell loss. Although treatment for AD is unknown, there is growing interest in the role of diet for its prevention and treatment. Numerous epidemiological studies have described an inverse association between AD risk and the status of *n*-3 PUFA intake. Studies among participants in the population-based prospective Rotterdam study have shown that consumption of fish, an important source of *n*-3 PUFAs, is inversely related to dementia, in particular to AD (Morris et al. 2003), in a prospective study of a human population on the progression of AD, have found that total intake of *n*-3 PUFAs is associated with reduced risk of AD, particularly the intake of DHA, but not of EPA. Moreover, cross-sectional analyses have linked low levels of plasma DHA with dementia and with AD in particular. Despite promising findings from epidemiological studies, no effect of EPA or DHA on AD has been observed in clinical studies (Freund-Levi et al. 2006; Kotani et al. 2006); nonetheless, analyses of subgroups suffering from mild AD or mild cognitive impairment (MCI) have shown benefit from DHA treatment (Freund-Levi et al. 2006; Kotani et al. 2006). The contrasting outcomes of those epidemiological and clinical studies suggest that *n*-3 PUFAs are effective only when consumed before the onset of the disease and when symptoms are mild.

117.4.2.2 Studies on AD Model Animals

Deposition of insoluble neuritic plaques and neurofibrillar tangles in the brain are the pathological hallmarks of AD, which is characterized by progressive neuronal loss with concomitant deterioration of memory and memory-related learning ability. Learning-related memory impairment is induced by the infusion of Aβ peptides into the cerebral ventricle of rats (Oka et al. 1999). AD model rats produced in our laboratory by the intraventricular infusion of A$\beta_{(1-40)}$ peptide solution have been used for the evaluation of the effects of dietary DHA administration on their learning-related ability. The results have demonstrated that the mean total number of avoidance responses, which was measured by the shuttle avoidance system, is higher in DHA preadministered AD model rats than in the AD model rats (Hashimoto et al. 2002), suggesting a protective effect of dietary DHA on the impairment of learning ability. Furthermore, DHA administration for 12 weeks reduces the increase in the number of memory errors, which was measured by the radial-arm maze, in AD model rats, suggesting an amelioration of impaired spatial cognition learning ability (Hashimoto et al. 2005). Intervention with DHA supplementation, even late in the life of the transgenic mouse model APPswe (Tg2576) of AD, has shown improvement in cognitive function as measured with the use of the Morris water maze (Calon et al. 2004). Thus, these results suggest that DHA is a possible therapeutic agent for protecting against and ameliorating learning deficiencies attributed to AD.

Dietary DHA administration inhibits *in vivo* levels of Aβ_{1-40} in AD model rats (Hashimoto et al. 2005). DHA has also been reported to lower the Aβ burden in the brains of transgenic mice (Lim et al. 2005), although the mechanisms remain unclear. Thus, it is assumed that DHA inhibits the extent of amyloid fibrillation *in situ*. DHA can inhibit *in vitro* fibrillation and help in the dissolution of pre-formed Aβ_{1-40} fibrils (Hashimoto et al. 2008). These results are thus in line with the notion that DHA is one of the essential brain nutrients that could reduce the prevalence of AD.

117.5 In vitro Amyloid Fibrillation and DHA

Amyloid plaques and neurofibrillar tangles are fibrillated Aβs. The molecular event of the α-helix to β-sheet transformation is not clearly understood, although numerous studies have been conducted on the topic. Figure 117.4 shows a schematic morphology from monomers to amyloid fibrillation: monomeric
Fig. 117.4 Schematic morphologies from monomers to amyloid fibrillation. The Aβ peptides remain in-membrane with their random coiled α-helical conformation. They are then misfolded into β-sheets and run orthogonally to form oligomers (protofilaments). The oligomers elongate by the addition of more β-sheet units and then mature to amyloid fibrils

α-helical units are transformed into β-sheets that through a lag phase run orthogonally to give rise to the so-called prefibrillar seeds or oligomers, which in turn elongate through the stacking of more β-sheet units to rod-like structures, then by further extension finally mature to fibrils. The driving force for these interactions involves both hydrophobic and electrostatic interactions (Khurana et al. 2003). Chronic administration of DHA significantly decreases Aβ levels in the detergent-insoluble membrane fractions prepared from the cortex of AD model rats (Hashimoto et al. 2005). Lim et al. (2005) have also reported that DHA decreases the amyloid burden in the mouse brain. In the light of these findings, it is assumed that DHA directly affects the process of fibrillation. In our studies, DHA was directly incubated with monomeric Aβ peptide, and the degree of fibrillation was evaluated through thioflavin (ThT) fluorescence intensity. ThT binds with the β sheet and emits fluorescence. In most of the visual fields of the confocal laser and electron micrographic grids, DHA-incubated samples had a smaller number of aggregates (Fig. 117.5b) than did the controls (Fig. 117.5a) or the fibers, indicating a clear-cut inhibitory effect by DHA on the extent of fibrillation.

The electron micrographs revealed that monomeric amyloids were transformed into a β-sheet and subsequently stacked orthogonally (polymerized) to form a ribbon-like fiber (Fig. 117.6). It is specu-lated that the hydrophilic side chains shield inside the fiber core while the hydrophobic structures normally remain buried in the interior of the native conformation. During this radical transformation, the amino acids of the Aβ peptide that take part in β-sheet constructs are not known; also, how DHA inhibits β-sheet elongation remains to be clarified. Since DHA is reported to stabilize the oligomers of Aβ (Johansson et al. 2007), we investigated whether DHA-induced inhibition of fibrillation occurs at the oligomeric stage. Accordingly, gel electrophoresis of samples incubated with DHA showed
Fig. 117.5 The effect of docosahexaenoic acid on Aβ fibrillar deposits. Aβ peptide$_{1-42}$ (**a**, **b**) was incubated with (20 μM) (**a**) or without (**b**) DHA for 24 h. A two-microliter sample from each was transferred to a glass slide, mixed with and equal volume of 5 μM ThT in 50 mM Tris-glycine buffer (pH 8.5) and visualized under a laser microscope. The number of pellets was lower in the DHA-incubated samples
Fig. 117.6 The effect of docosahexaenoic acid (DHA) on Aβ fibril formation. Aβ peptide$_{1-40}$ was incubated with (20 μM) (**b**) or without (**a**) DHA for 24 h. Two-microliter samples were subjected to 400-mesh grid, dried for 1 min, stained with 1% uranyl acetate, and visualized under an electron microscope. (**c**) and (**d**) are the insets of (**a**) and (**b**), respectively. The amplification is 66 K
Fig. 117.7 Effect of DHA on Aβ$_{1-40}$ oligomer species by gel electrophoresis. Aβ$_{1-40}$ was incubated with or without DHA at 37°C for 3 and 24 h; the mixture was then centrifuged at 13,800× *g*, and the supernatant containing the soluble oligomer fractions was subjected directly to 4–20% Tris-Tricine gradient gel analyses. The bands were stained with Coomassie brilliant blue. The amyloid species of molecular mass ~10 to 15 kDa oligomer (equivalent to tri-tetramers) were identified in the gels. DHA dose-dependently inhibited amyloid oligomer concentrations. The effect was prominent at 24 h

significantly decreased Aβ oligomeric species ranging from 10 to 14 kDa. The inhibitory effect was both time and concentration dependent, as indicated by the gradual decrease in the density of the oligomer band with higher DHA concentrations (Fig. 117.7). No high molecular weight oligomers were observed. The mechanism through which DHA inhibits the oligomerization of Aβ remains to be explored. DHA decreased the intensity of the intrinsic tyrosine fluorescence of Aβ fibrils (data not shown), indicating a perturbing effect during the α to β transformation and the subsequent stacking of β sheets during the elongation process. Nonetheless, further studies are needed to clarify the mechanisms of DHA in the inhibition of *in vitro* fibrillation. DHA not only inhibits the formation of amyloid fibers, but also significantly induces the defibrillation of preformed fibers (Hashimoto et al. 2008). These results are thus consistent with the results of *in vivo* studies demonstrating that DHA decreases the burden of amyloid fibers by inhibiting their fibrillation.

117.6 Neurogenesis and DHA

117.6.1 In Vitro and In Vivo Neurogenesis and DHA

Recent evidence strongly suggests that newborn neurons participate in the formation of learning and memory (Schinder and Gage 2004). Newly generated neurons are functionally integrated into hippocampal circuits, can survive for several months (Song et al. 2002), facilitate synaptic plasticity,

and enhance the LTP (Schinder and Gage 2004). Moreover, a significant relation has been demonstrated between the number of newborn neurons and cognitive learning performance of tasks in the Morris water maze (Kempermann et al. 1997). Based on this evidence, it is highly probable that endogenous neurogenesis modulates learning and memory functions. DHA is crucial for inducing LTP in the CA1 region of rat hippocampus slices and for enhancing the potassium chloride-evoked release of acetylcholine in the rat hippocampus (Fujita et al. 2001). Also, dietary administration of DHA increases the levels of DHA in the hippocampus and improves learning and memory performance tasks in the eight-arm radial maze (Gamoh et al. 1999, 2001). These data suggest that DHA increases newborn neurons and imparts beneficial properties to the function of learning and memory. We therefore hypothesized that DHA modulates both the generation of new functional neurons and the functions of the already existing neurons, as well as improves the hippocampal function of learning and behavior.

The effect of DHA on neuronal differentiation of neural stem cells (NSCs) *in vitro* and *in vivo* has been assessed in our laboratory (Kawakita et al. 2006): in the presence of DHA, neural stem cells obtained from 15.5-day-old rat embryos significantly increased the number of Tuj1 (a neural marker)-positive neurons compared with the control on four or seven culture days, and the newborn neurons in the DHA group were morphologically more mature than those in the control. In *in vivo* experiments, the proliferation of neurons in the hippocampus, estimated after chronic administration of DHA for 12 weeks, revealed that the number of 5-bromo-2′-deoxyuridine(+)/NeuN(+) newborn neurons increased significantly in the granule cell layer of the dentate gyrus (DG) in adult rats (Fig. 117.8). These results demonstrate that DHA effectively promotes neurogenesis both *in vitro* and *in vivo*, and suggest that DHA has the new property of modulating hippocampal function regulated by neurogenesis, neuronal growth, dendritic arborization and synapse formation, and thereby exhibits the cognition-enhancing ability.

Since NSCs in the adult hippocampus, including those in rats and humans, generate new neurons in adulthood (Schinder and Gage 2004), we administrated dietary DHA to adult rats and examined the effect on active hippocampal neurogenesis. Dietary administration of DHA significantly increased the number of newborn neurons (Fig. 117.8c), demonstrating that DHA promotes neurogenesis not only in cultured embryonic NSCs but also in the hippocampus of adult rats, and suggesting that DHA also modulates the generation of new neurons in the adult brain.
Fig. 117.8 Neuronal identity of newly divided cells in the adult dentate gyrus (DG). (**a, b**) Confocal images of DG in vehicle- (**a**) and DHA-treated (**b**) rats. BrdU (*red*), NeuN (*blue*). Scale bar = 50 µm. (**c**) Quantitative analysis of the number of newborn neurons in the entire granule cell layer of the DG in control and DHA groups. Data are shown as the means ± S.E.M. obtained from six hemispheres in three animals. $P < 0.005$

117.6.2 The Mechanisms of DHA-induced Neurogenesis

Activator-type bHLH transcription factors such as neurogenin, Mash1, and NeuroD enhance neuronal differentiation; on the other hand, repressor-type bHLH transcription factors such as hairy and enhancer of split 1 (Hes1) and Hes5 are essential for the maintenance and proliferation of NSCs (Kageyama et al. 2005). Crosstalk between these two types of bHLH transcription factors allows some NSCs to undergo differentiation and some to remain as NSCs. DHA decreases Hes1 mRNA and protein levels and increases NeuroD mRNA levels; furthermore, it increases MAP2, a target gene of Hes1 and NeuroD, mRNA and protein levels (Katakura et al. 2009), suggesting that it enhances neuronal differentiation of NSCs, in part, by controlling bHLH transcription factors. Hes1 directly controls cell proliferation through the transcriptional repression of CDK–cyclin complex inhibitor, $p27^{kip1}$ (Murata et al. 2005). Treatment of NSCs with DHA for 24 h significantly decreased the proportion of S-phase cells, whereas it significantly increased the proportion of G0/G1-phase cells, indicating that DHA promotes neuronal differentiation of NSCs, at least in part, through Hes1 repression and $p27^{kip1}$ induction (Fig. 117.9). At present, however, how DHA represses Hes1 gene expression is not clear. Further studies are needed to establish the mechanisms of Hes1 repression by DHA in NSCs. Using the assumed DHA characteristic of controlling cell fate might help in the restoration of injured neurons in neurodegenerative diseases including AD.

117.7 Multiple Sclerosis and DHA

An early Norwegian study has shown a lower incidence of multiple sclerosis (MS) in coastal communities with a high intake of fish, compared with inland rural communities where consumption of saturated fat is higher (Swank et al. 1952). Both mental and physical assessments tend to show improvement in MS patients ingesting fish oil with a very low-fat diet. Nonetheless, evidence regarding the progression

Table 117.1 Key features of docosahexaenoic acid

1. Docosahexaenoic acid (DHA, C22:6*n*-3) is an essential *n*-3 polyunsaturated fatty acids in the brain.
2. DHA remains highly concentrated in synaptic plasma membranes and increases neurotransmission and related brain functions.
3. DHA has strong antioxidative properties.
4. DHA supplementation imparts numerous beneficial effects to the health of the human brain through the modulation of genes associated with synaptic plasticity, neuroinflammation, and energy metabolism.
5. Chronic administration of DHA increases DHA content in the hippocampus and the cerebral cortex, and improves the memory related learning ability. Deficiency of DHA is linked to the impairment of neuronal development and cognitive learning ability related to a host of neurodegenerative diseases including AD.
6. DHA acts against amyloid fibrillation and decreases the amyloid burden in the brain.
7. DHA protects against and ameliorates the impairment of learning ability in the amyloid-infused AD model rats.

This table lists the key aspects of the DHA including its physical characteristics, the function at normal and pathological conditions

of MS is inconsistent and inconclusive, with no apparent significant association between *n*-3 PUFAs and the incidence of MS. A case-control study has demonstrated a reduced risk of MS attributed to fish consumption, but only among women (Marcheselli et al. 2003). The levels of *n*-3 and *n*-6 PUFAs in red blood cells and plasma of patients diagnosed with MS are low (Holman et al. 1989). MS is associated with an activated inflammatory response, and *n*-3 PUFAs can suppress interleukin and tumor necrosis factor-α production in MS subjects (Gallai et al. 1995). Moreover, a reduction in the amount of *n*-3 PUFA intake enhances several indices of immune response, including lymphocyte proliferation, natural-killer-cell activity, cytokine production, and delta-type hypersensitivity (Miles et al. 2004; Pischon et al. 2003). Fish oil supplementation given together with vitamins and dietary advice can improve clinical outcome in patients newly diagnosed with MS (Nordvik et al. 2000), presumably through the modulation of cytokines. Therefore, it seems reasonable to assume that treatment with *n*-3 PUFAs such as DHA may have a theoretical basis in the incidence of MS.

117.8 Applications to Other Areas of Health and Disease

Besides its beneficial role in neurodegeneration and memory loss (Table 117.1), DHA reduces the risk of depression and cardiovascular diseases such as atherosclerosis, coronary heart disease, inflammatory disease and platelet pathology. DHA supplementation promotes accretion of DHA in plasma, erythrocytes, the liver, visceral adipose tissue, spermatozoon, and brain segments (frontal cortex, hippocampus, and cerebellum) of adults as well as of fetuses and neonates; it helps in bone modeling of newborns, and both humoral and cellular immune functions are also ameliorated. Gestational diabetes, Type 2 diabetes mellitus, and insulin resistance is related to this fatty acid profile in red blood cells and skeletal muscle membranes. Moreover, DHA might help in the restoration of injured neurons in neurodegenerative Parkinson's disease, stroke, and brain ischemia. Thus, dietary intervention with DHA is suggested for the moderation of these complications.

Summary Points

- DHA remains highly concentrated in neuronal membranes.
- Deficiency of DHA is associated with generalized cognitive deficits and a host of neurodegenerative disorders, including Alzheimer's disease.

- DHA can easily pass through the blood–brain barrier. Thus supplementation with DHA would elevate brain DHA levels.
- Studies on the molecular mechanisms underlying the beneficial effects of DHA need to be carried out to reinforce the hypothetical concept that changing dietary habits or promoting dietary DHA could benefit human health, by the prevention or the slowing of cognitive impairment in mild cases of AD.
- DHA decreases the amyloid burden in the brain by inhibiting their fibrillation and deposition, suggesting that DHA is one of the essential brain nutrients that could reduce the prevalence of AD.
- DHA promotes neuronal differentiation of NSCs, at least in part, through Hes1 repression and p27^{kip1} induction.
- Further effort toward the accumulation of knowledge on the molecular mechanisms involved in this field of research is needed now in order to better clarify this concept.

Dictionary Terms

Docosahexaenoic acid: Docosahexaenoic acid (DHA; 22:6(*n*-3), all-*cis*-docosa-4,7,10,13,16,19-hexa-enoic acid) is an *n*-3 essential polyunsaturated fatty acid. Fish oils are rich in DHA. Most of the DHA originates in photosynthetic and heterotrophic microalgae, and is concentrated in organisms. Most animals make very little DHA, thus supplementation is encouraged.

Cognitive dysfunction: This is defined as unusually poor mental function associated with forgetfulness, confusion, and memory retention and attention deficit.

Alzheimer's disease: (AD) A neurodegenerative disorder, this is the most common cause of dementia, characterized clinically by progressive loss of memory and pathologically by neurofibrillar tangles and amyloid plaques in or out of neurons.

Amyloid beta: (Aβ) This is a peptide of 39–43 amino acids that appears to be the main constituent of amyloid plaques in the brains of Alzheimer's disease patients. Aβ is formed after sequential cleavage of an amyloid precursor protein, a transmembrane glycoprotein of undetermined function.

Amyloid fibrillation: The polymerization of amyloid beta sheets that are formed by vertical stacking along the long axis of fibers. Amyloid plaques and neurofibrillar tangles are the polymerized amyloid beta peptides.

Neurogenesis: This is the process by which neurons are created from neural stem cells. Adult neurogenesis is observed in predominantly two regions of the brain: the subventricular zone where the new cells migrate to the olfactory bulb, and the subgranular zone of the dentate gyrus of the hippocampus.

Neural stem cell: (NSCs) are the self-renewing, multipotent cells that generate the main phenotypes of the nervous system. NSCs differentiate into various tissues (neurons, glia, and oligodendrocytes).

Neurogenin: A transcription factor that enhances neuronal differentiation.

Multiple sclerosis: (MS) is an autoimmune disease in which the body's immune response attacks the central nervous system (brain and spine), leading to demyelination and often progresses to physical and cognitive disability. The onset of the disease usually occurs in young adults and is more common in females.

bHLH transcription factor: This factor's motif is characterized by two α-helices connected by a loop. The helix typically contains the DNA-binding regions and E-box; it binds to other proteins.

NOC	N-nitroso compounds
PBT	Pediatric brain tumors
SEER	Surveillance, Epidemiology and End Results
PNET	Primitive neuroectodermal tumor
CNS	Central nervous system
NOS	Not otherwise specified

118.1 Introduction

Central nervous system (CNS) tumors are the most common solid tumor of the pediatric age group in the United States with approximately 3,500 new cases diagnosed each year. Since brain neoplasms are also the second leading cause of death among children under the age of 15, they represent an important clinical and public health problem. Unfortunately, little is currently understood about their etiology. Although prior work suggests a role for certain genetic disorders in the development of pediatric brain tumors (PBT), e.g. neurofibromatosis type 1, ataxia telangiectasia, Li-Fraumeni syndrome, as well as cranial irradiation, such cases account for a small minority of all patients with this disease (Bunin 2000). The etiology of the vast majority of these tumors remains obscure.

Over the last 2 decades, the role of diet in cancer causation in general, and PBT in particular, has been a topic of increasing interest. Dietary N-nitroso compounds (NOCs) are suspected of playing a role in the development of childhood CNS tumors based on evidence of carcinogenicity in animal studies (Magee 1989). Of particular interest is the finding that the carcinogenic effects of these compounds may be age-dependent with the fetus being particularly susceptible. Various foods are sources of both preformed NOCs and NOC precursors that may form NOCs in vivo via the acidic environment of the stomach. Nitrosamides may be formed endogenously, along with other NOCs, from precursors such as nitrite derived from cured meats or other foods cured with sodium nitrite. All of the above contribute to the hypothesis that these compounds may play a role in the development of PBT.

An important feature of studying the potential etiological role of diet in human cancer is that it represents a potentially modifiable behavior. Determining whether maternal cured meat consumption impacts on disease development among this patient group may, therefore, represent an important disease prevention strategy. This article will examine the existing scientific evidence related to the hypothesis that maternal dietary intake of NOCs from cured meat during pregnancy influences PBT risk.

118.2 Epidemiology of Childhood Brain Tumors

Brain tumors are the most common solid tumor of childhood with an incidence of roughly 24–27 cases per million in the United States and Western Europe (Little 1999). They account for 20% of childhood neoplasms exceeded in frequency only by the leukemias. PBTs also represent the leading cause of cancer-related death in children with an overall mortality rate of 2.7 per 100,000 in the United States among children less than 15 years of age (Bleyer 1999). Currently PBTs account for approximately one-third of cancer-related deaths in this age group. Regarding specific age categories, PBTs are most common among children ages 2–5 and 5–10 years old, with 30% of such neoplasms occurring in each of these age ranges (Gilles et al. 1995).

The past several decades have witnessed an increased incidence of PBTs. For instance, based on data from the Surveillance, Epidemiology and End Results (SEER) program, the incidence of PBTs in 1973 was 2.4 cases per 100,000 children aged <15 years versus 3.5 cases per 100,000 in 1994 (Boyle et al. 1985) with a number of studies corroborating this increase (e.g. Bunin et al. 1996). Interestingly, the noted increase appears not to be linear over time but rather to have accelerated after 1985 (Smith et al. 1998). Although some investigators suggests that the wider availability of magnetic resonance imaging (MRI) post-1985, could account for the increased incidence secondary to improved diagnostic techniques, the fact that the higher incidence rates have persisted brings this theory into question.

Anatomically and histologically, PBTs represent a heterogeneous group of tumors with roughly 50% occurring supratentorially and 50% being infratentorial in origin. As seen in Table 118.1, astrocytomas represent the most common histology of the supratentorial tumors (roughly 25%), versus medulloblastoma among those arising infratentorially. Interestingly, about 20% of PBTs occur in infants and children less than 3 years of age. Compared with older children, intracranial neoplasms in the 0–3 year age group are more likely to be malignant, both histologically and in terms of malignant behavior, and are more commonly supratentorial in location (Cohen et al. 1993).

Table 118.1 Relative frequency of histological types of PBTs

Tumor histology	Relative frequency (%)
Supratentorial	
Astrocytoma	23
Craniopharyngioma	6
Embryonal tumors	6
Pineal region tumors	4
Ependymoma	4
Infratentorial	
Medulloblastoma	20
Astrocytoma	15
Brain stem glioma	10
Ependymoma	6

Overview of types of pediatric brain tumors categorized by histology

Astrocytoma is the most common CNS tumor in children constituting approximately half of all PBTs and about 9% of all neoplasms in the pediatric age group (Young et al. 1986). The second most common PBT is the cerebellar medulloblastoma, accounting for approximately 20% of PBTs. A histologically related tumor, primitive neuroectodermal tumor (PNET) occurs suprtentorially with medulloblastoma making up 80% of medulloblastoma/PNET combined. PNET is essentially an undifferentiated embryonal neoplasm distinct from the classic embryonal tumors. Medulloblastoma/PNET is characterized by a young age at onset, i.e. half of all cases are diagnosed prior to age 6, with approximately 30% occurring in children younger than 3 years of age.

Malignant gliomas are less common in children than adults and represent approximately 7–10% of PBTs. Histologically, 50–60% are anaplastic astrocytomas, 30–40% are the highly malignant glioblastoma multiforme with another 10–20% characterized as anaplastic oligodendrogliomas and malignant mixed gliomas (Dropcho et al. 1987). Most occur in the cerebral hemispheres with up to 25–35% diagnosed in children younger than 5 years. Brainstem gliomas are a devastating clinical entity and arise in the midbrain, pons or medulla in children between 3 and 9 years old. The majority are diffuse pontine tumors presenting as diffuse, expansile lesions. Although histological confirmation is often unavailable given their anatomic location, autopsy data shows that most of these lesions are malignant. Diffusely infiltrating pontine gliomas are highly aggressive with median survivals of 10–12 months. Focal pontine lesions, tumors with predominant cystic components and diffuse tumors arising outside the pons show markedly superior survivals with the dorsally exophytic or focal pontine lesions having 5-year survival rates of 90% or more.

As outlined above, PBTs represent a pathologically and clinically diverse group of neoplasms. It must be appreciated that this complicates epidemiological analyses of potential risk factors for this disease entity. Given the rarity of PBTs, many observational studies do not stratify analyses by histological subtype. Since evidence exists that pathological subtypes have distinct genetic and clinical characteristics, it is likely that risk factors may vary substantially across tumor histologies. Failure to consider histological subtype of PBTs in epidemiological studies may obscure potential underlying cause-effect relationships.

118.3 N-Nitroso Compounds as Human Carcinogens

Substantial evidence exists linking environmental factors and cancer risk in humans with Doll and Peto suggesting that as much as 60% of the human cancer burden may be attributable to the effects of diet (Doll and Peto 1981). Epidemiological evidence provides support for the central role played by dietary factors in cancer etiology. For instance, international incidence rates for colorectal cancer vary substantially with migrant studies documenting increasing incidence rates among groups moving from low-incidence to high-incidence areas (Boyle et al.1985). Similarly, prostate cancer incidence shows wide variation across populations with relatively high rates experienced among men in the United States and Western Europe and much lower incidence rates in Japan. As with colorectal cancer, migrant studies document that Japanese immigrant to the United States experience a substantial increase in risk versus their native counterparts (Haenzel and Kurihara 1968).

The NOCs constitute a large group of chemicals present in the environment and the human food supply. Concern over their possible risk to human health derives from initial observations of liver toxicity in sheep fed fish meal treated with sodium nitrite (Koppang 1964). Previously, Magee and Barnes reported on the carcinogenicity of nitrosodimethylamine (NMDA) which spawned substantial interest in this group of chemical carcinogens (Magee and Barnes 1956). Further evidence of concern regarding NOC developed from the work of Sander, demonstrating the formation of

carcinogenic nitrosamines from amine precursors and nitrite under conditions resembling those present in the mammalian stomach (Sander 1967). Since that time, animal studies with various NOCs unequivocally demonstrate multi-organ carcinogenicity in at least 40 different animal species, including higher primates (Bogovski and Bogovski 1981). Animal data also suggested that, unlike other carcinogens, there was probably no "non-susceptible" species (e.g. humans) (Lijinsky1999). Wide variation in susceptible target organ is seen among the animal experiments and appears dependent on the chemical structure of the carcinogen. Interestingly, dose, frequency of exposure, and route of administration appear to influence/change the observed target organ (Lijinsky and Kovatch 1989). Overall, data exist documenting the carcinogenicity of over 300 NOCs in one or more animal species.

118.3.1 SubGroups of NOCs

Based on chemical structure, NOCs can be divided into two distinct groups, i.e. N-nitrosamines and N-nitrosamides. Both are formed by the chemical reaction of a nitrite compound with amines or amides. N-nitrosamines have been the subject of substantial scientific investigation and are known to induce tumors of the liver, lung, esophagus, bladder, and pancreas, among others, in numerous animal species (Hecht 1997). The toxic effects of N-nitrosamines appear species-specific and independent of route of administration ; they require metabolic activation by cytochrome P450's to act as carcinogens (Hecht 1997). Interestingly, although capable of inducing a variety of neoplasms, N-nitrosamines do not appear associated with tumors of the brain or spinal cord.

N-nitrosamides are direct alkylating compounds and are carcinogenic in various animal models and mostly induce tumors of the CNS. Ivankovic et al. studied the effects of these compounds on prenatal rats, administering ethylurea together with a nitrite during pregnancy, resulting in CNS tumors in the offspring (Ivankovic 1979). These experiments showed that ethylnitrosourea forms in vivo in animals and results in CNS malignancies.

N-nitrosamides can also be formed endogenously in the stomach as shown by Sen et al., among others (Sen et al. 2001). This is supported also by animal experimentation, for instance, via the work of Mirvish et al. showing N-nitrosalkylurea formation in rats by adding nitrite and the N-nitroso-precursor methyl- and dimethylurea to food and drinking water (Mirvish and Chu 1973). The majority of the experimental animals developed CNS tumors, suggesting that N-nitrosamides formed in the stomach can cross the blood–brain–barrier to reach their target organ. This latter finding has obvious implications with regard to potential CNS cancer risk associated with these compounds in humans.

118.4 NOCs in Foods

A variety of food items may contain preformed NOCs secondary to food processing, such as nitrite-cured and smoked meat, fish, cheese, and beer (Dietrich et al. 2005). During the curing process of meats, nitrosation of amines/amides can occur. For instance, salt containing sodium nitrite used in the curing process can nitrosate amines or amides and result in the formation of NOCs. Smoking or drying of meat that involves exposure to higher concentrations of nitrogen than in ambient air can also act as a potential nitrosating agent (Dietrich et al. 2005). Nitrites present in foods can form N-nitrosamides in the presence of nitrosable precursors such as amides and amide-like compounds, including ureas and gaunidines, e.g. meat derived creatine and creatinine (Shepard et al. 1987). Vegetables are the main

dietary source of nitrates, which are converted to nitrite in saliva. In fact, vegetables contribute approximately 75% of the total daily intake of nitrate. High levels are found in lettuce, spinach, celery and turnip greens among others. N-nitrosamides are unstable compounds and pre-formed N-nitrosamides are unlikely to be present in large quantities in foods, in contrast to the N-nitrosamines.

It is interesting to note that with the identification of the carcinogenicity of NOCs, subsequent efforts were directed at decreasing the amounts of nitrite used for curing meats. Since the early 1970s, the amount of nitrite added to meat has been substantially reduced with vitamin C added as a nitrosation inhibitor (Dietrich et al. 2005). Surveys of sodium nitrite levels in cured meat products between 1970 and 1990 documented decreased levels in all products investigated with the exception of hot dogs. The reduction in nitrite and elimination of nitrate has taken place by both voluntary efforts by manufacturers as well as via government regulation in some countries. These controls have led to the reduction of the nitrosamine content of many cured meats and reduced exposure to nitrite which is involved in the endogenous formation of NOCs. Nonetheless, the impact of these compounds on human health secondary to presence in the food supply is complex for many reasons. Nitrate, nitrite and NOC concentrations in food products can vary widely for the same food item from different sources. Epidemiological studies are complicated by accurate recall of food intake and the use of proxy measures of exposure. In addition, the endogenous formation of NOC and its precursors may represent an even more important source of exposure than exogenous intake. All of these factors, and others, contribute to uncertainty in accurately evaluating the risk posed to human health.

118.5 NOCs and Brain Tumor Risk in Children: Epidemiological Data

As outlined above, experimental studies show that certain NOCs, particularly nitrosamides (in particular, nitrosureas) can induce brain tumors in the offspring of pregnant rodents and monkeys, illustrating that these compounds represent transplacental carcinogens. Experimental evidence also suggests that methylureas can be produced from meats secondary to reactions with creatinine in the presence of nitrite in an acidic environment. This latter finding provides a biologically plausible mechanism for the endogenous formation of these compounds in the acidic milieu of the stomach. These laboratory findings prompted the first report of epidemiological evidence that consumption of cured meats by pregnant mothers could increase the risk of brain tumors in their offspring (Preston-Martin et al. 1982).

Preston-Martin et al. conducted a case-control study in Los Angeles County, enrolling 209 young brain tumor patients (less than 25 years of age) and 209 controls. Patients were identified via the Los Angeles County Cancer Surveillance Program. Dietary intake data were obtained via a questionnaire administered by a single interviewer. Dietary information pertained to food items ingested during pregnancy.

The distribution of tumor histologies of included patients is given in Table 118.2.

As seen in Table 118.3, information on dietary intake of multiple varieties of cured meats was obtained, including fried bacon, ham, sausage, hot dogs, and salami among others. Using the highest reported intake of each item as the exposure of interest showed statistically significant effects for dietary intake of ham and "all cured meats combined". Lunch meats and fried bacon showed no effect while the other included dietary items were borderline, non-statistically significant. The authors hypothesized that brain tumors in study subjects were related to in utero exposure to NOCs and their precursors.

Some of the limitations of this report include the fact that the study population was not truly "pediatric" in that subjects up to age 25 were included in the analysis. Also, it was not possible to adjust for

Table 118.2 Distribution of tumor types (Preston-Martin et al. 1982)

Tumor histology	# patients
Astrocytoma	93
Medulloblastoma	31
Glioblastoma	19
Ependymoma	12
Glioma NOS	17
Meningiomas	13
Neuromas	9
Gangliogliomas	3

Types of pediatric brain tumors included in case–control study published by Preston-Martin in 1982

NOS not otherwise specified, # number, 11 additional tumors were of other or unknown histology

Table 118.3 Odds ratios for specific dietary factors during pregnancy and brain tumor risk

Food item	Odds ratio for highest intake level	One sided p-value
Fried bacon	1.1	0.39
Ham	1.9	0.008
Sausage	1.4	0.07
Hot dogs	1.7	0.06
salami	1.3	0.09
Other lunch meats	1.1	0.38
All cured meats combined	2.3	0.008

This table shows the risk of developing pediatric brain tumors associated with the dietary intake of specific cured meat by study subjects' mothers during pregnancy

the intake of vitamins such as vitamin C and E which block nitrosation reactions and could modify effects seen in observational studies. The report also included a wide variety of tumor histologies which may confound epidemiological analyses if the biology and etiology of tumor types differ.

In a 1989 epidemiological study, Howe et al. reported on cured meat intake and brain tumor risk among patients aged 19 years or younger treated at two Canadian Hospitals (Howe 1989). No other maternal dietary factors were examined. As in the above noted study by Preston-Martin et al., the Howe et al. case-control analysis included a very wide range of tumor histologies with approximately 60% of cases having either an astrocytoma (not otherwise specified) or medulloblastoma. Cured meat consumption by pregnant mothers stratified as less than or greater than once per week showed an odds ratio of 1.13 (0.551–2.31), a non-statistically significant result. Important caveats are that the wide variety of tumor histologies included and an imprecise measure of exposure which could both contribute to attenuation of an overall effect for cured meat on the outcome of interest.

118.5.1 Relevant Data from the 1990s

Kuijten et al. published a case-control study examining a number of gestational factors and the risk of childhood astrocytoma, the most common pediatric brain tumor (Kuijten et al. 1990). The report included data on 163 cases, aged under 15 years, derived from hospital-based registries in Pennsylvania, Delaware, and New Jersey, along with population-based controls. Relevant exposure data were obtained via telephone interview. The only dietary factors explored were consumption of

alcohol and cured meats. The latter showed an odds ratio of 1.9 (0.9–4.2) although this association was seen only among women with more than a high school education.

The relationship between maternal diet and risk of primitive neuroectodermal brain tumors (PNET) was studied by Bunin et al. and reported in the New England Journal of Medicine in 1993 (Bunin et al. 1993). Again, using a case-control design, data on 166 patients diagnosed prior to age 6 were obtained from the Children's Cancer Group. Population-based controls were selected by random-digit dialing and were matched by area code and the next five digits of the telephone number, date of birth, and race. Dietary data were obtained via interview with the mother by trained interviewers.

Odds ratios related to the risk of PNET secondary to maternal intake of a number of cured meats were calculated (Table 118.4). Only bacon intake showed a significantly increased risk of disease with a 71% greater risk associated with maternal intake of this food item. None of the other cured meats studies were found to increase brain tumor risk.

Interestingly, green salad, sweet potatoes, oranges and grapefruit showed protective effects of a greater than 50% reduction in risk. Overall, the authors felt the resultant data provided little support for the hypothesis that NOCs are potential risk factors for PNET in young children.

Paris was the setting for a French case-control study of 109 pediatric brain tumor patients collected from 13 hospitals in the city over a 2-year period (1985–1987) (Cordier et al. 1994). Almost half of the patients carried a diagnosis of astrocytoma (45%) with 17% diagnosed with medulloblastoma. Ependymoma (14%), neuroblastoma (2%), other gliomas (8%), and tumors classified as "other" composed 15% of the patients group. Patients were aged 0–15 years, and 73% of the group had biopsy-confirmed tumors. One hundred and thirty population controls, frequency matched by year of birth, were included in the study. Risk factor data were obtained via interview by a single interviewer.

A variety of data on maternal intake of cured meats during pregnancy were collected with exposures classified as "all cured meats", "ham", and "cured meats other than ham", with the latter including bacon, sausage, and salami, among others. Adjusting outcomes for child's age and sex, maternal age, and number of years of schooling of the mother, no increased risk of PBT was seen with maternal ingestion of any of the above noted food items, with odds ratios ranging from 0.7 to 0.9 with non-statistically significant 95% confidence intervals. Several foods were shown to be protective, including carrots, leeks, green peppers and fresh or frozen fish.

An addition epidemiological study from 1994 originated from Australia (McCredie et al. 1994). As with the studies previously reviewed, the sample size for the McCredie report was small, i.e. 82 cases and 164 population-based controls. Study subjects ranged in age from 0–14 years and were diagnosed during the period of 1985–1989. Cases were identified using the New South Wales Cancer Registry. Although the authors state that 72% of subjects were diagnosed with malignant gliomas, tumor histology was not otherwise characterized. The vast majority of tumors, i.e. 96%, were histologically verified. Dietary information of maternal diet during pregnancy was obtained via a structured questionnaire and personal interview. The exposure category of interest, i.e. "cured meats" included, ham, bacon, hot dogs, salami, devon, corned beef, spam and sausage.

Table 118.4 Odds ratios and 95% confidence intervals of cured meat intake and PNET risk (Bunin et al. 1993)

Cured meat type	Odds ratio	95% confidence interval
Bacon	1.71	(1.02–2.89)
Sausage	1.44	(0.81–2.56)
Hot dogs	1.00	(0.59–1.70)
Ham	0.77	(0.41–1.14)
Lunch meat	0.92	(0.55–1.53)

This table shows the risk of development of pediatric brain tumors associated with maternal intake during pregnancy of specific cured meat types

Comparing the highest quartile of intake with the lowest, and adjusting for age, sex, mother's education and mother's body mass index, yielded an odds ratio of 2.5(1.2–5.7) indicating a more than doubling of the risk of PBT associated with antenatal maternal intake of cured meats. As opposed to a number of the prior studies noted previously, McCredie et al. found no protective effect associated with intake of fruits or vegetables. Although, as the authors point out, the study results are based on a small sample size, they conclude that the analysis provides limited support for a PBT risk secondary to maternal intake of cured meats.

Bunin et al., in a study performed simultaneously with their previously referenced article on PNET, examined the role of maternal diet and the risk of astrocytoma in children under the age of 6 years (Bunin et al. 1994). The tumor types included in this analysis were astrocytoma, anaplastic astrocytoma, glioblastoma multiforme, mixed glioma with astrocytic elements, or glioma not otherwise specified (NOS). Spinal cord and optic nerve malignancies were specifically excluded. Eighty-nine percent of the 155 tumors included in the analysis were biopsy-proven with 60% confirmed as astrocytoma, and 19% as glioblastoma or anaplastic astrocytoma. Of the 27 gliomas NOS, 25 occurred in the brain stem. Controls were selected via a previously published random digit dialing procedure with controls pair-matched to cases on telephone area code and next five digits of the telephone number, date of birth of the subject and race. Relevant data were collected by trained interviewers via telephone. The types of cured meat considered in the analysis were bacon, sausage, hot dogs, ham and lunch meat.

The statistical analysis reported on "cured meats" only as a single variable and showed no effect on PBT risk, i.e. OR = 1.7 (0.8–3.4) comparing the highest to lowest quartile. If subjects were stratified by family income, a significant effect for bacon was seen, i.e. OR = 2.5(1.2–5.3) for those with a family income less than $25,000 versus income greater than $25,000 (i.e. OR = 0.7 [0.3–1.3]). Income stratification showed no effect on PBT risk in either the lower or higher income category for "cured meat" intake. Weekly consumption of hot dogs was associated with an almost doubling of PBT risk although the 95% confidence interval for this exposure included the null value. Overall, the study results do not provide support for the hypothesis that cured meats increase the risk of childhood astrocytomas.

Sarasua and Savitz (1994) examined cured and broiled meats in relation to childhood cancer, including 45 with brain tumors. It appears that all tumor types were included in the analysis without restriction to malignant versus benign tumors or by histology (Sarasua and Savitz 1994). Subjects were children aged 0–14 years diagnosed with any form of cancer between January of 1976 and December 31st, 1983 while residents of the 1970 Denver, Colorada standard metropolitan statistical area. Controls were chosen by random digit dialing and matched to cases on age, gender, and telephone exchange area.

The meat groups studied included ham, bacon, sausage, hot dogs, and lunch meats. Exposure categories were stratified, in general, into two groups, i.e. intake of less than one time per week and 1+ times per week. A number of variables in the analysis were considered as potential confounders, including child's age, maternal smoking, maternal vitamin use, per capita income, father's education, and year of diagnosis. Information on diet was obtained during an in-home interview with a parent, in most cases, the patient's mother.

Table 118.5 provides an overview of the relevant study results. Of the cured meats examined, only ingestion of hot dogs appeared associated with an increased risk of PBT, i.e. OR = 2.3 (1.0–5.4), although the 95% confidence interval included the null value. Lunch meats and the exposure classified as "ham, bacon and sausage" both showed no positive effect. Surprisingly, the data on lunch meats showed a small protective effect. Table 118.6 shows the effect of stratification of the data based on whether the study subjects took vitamins. Clearly, vitamin intake resulted in profound changes in the resultant odds ratios with substantial attenuation of effect secondary to vitamin intake. These finding suggest and important role for these nutrients in modifying PBT risk secondary to cured meats and highlights the need to take vitamin intake into account in any observational study of the cured meat/PBT association.

Table 118.5 Association between maternal cured meat consumption and PBTs (Sarasua and Savitz 1994)

Exposure	Odds ratio	95% confidence interval
Ham, bacon, sasauge 1+/week	1.0	(0.5–2.1)
Hot dogs >0/week	2.3	(1.0–5.4)
Lunch meats 1+/week	0.4	(0.2–0.8)

The table shows the strength of the association between maternal intake of specific cured meats and the risk of pediatric brain tumors in the case-control study by Sarasua et al

Table 118.6 Effects of vitamin intake on the association of cured meats and PBTs (Sarasua and Savitz 1994)

Exposure	Odds ratio	95% confidence interval
Without vitamin intake		
Ham,bacon,sasauge 1+/week	4.8	(1.5–13.7)
Hot dogs >0/week	6.8	(2.5–18.5)
Lunch meats 1+/week	3.2	(1.0–9.8)
With vitamin intake		
Ham, bacon, sausage 1+/week	1.3	(0.6–3.0)
Hot dogs >0/week	1.8	(0.8–3.9)
Lunch meats 1+/week	1.0	(0.5–2.1)

The data in this table compliment those shown in Table 118.5. The data in Table 118.6 show the effects of maternal dietary intake of vitamins on pediatric brain tumor risk associated with intake of specific cured meats

In 2007, Pagoda et al. published an update of their prior study from 1996 examining maternal cured meat consumption and PBT risk. The updated report attempted to use "more valid" measures of exposure using a database of published nitrite levels of various food items. They then determined predicted nitrite levels of various cured meat types and used these values to assign nitrite exposure levels to their study subjects.

The study subjects were obtained via the West Coast Childhood Brain Tumor Study and included 540 cases and 801 population-based controls aged 0–19 years from 19 counties in three West Coast regions. Frequency of consumption and portion size for cured meat items were obtained from the mothers of cases and converted to average daily grams of consumption. "Cured meats" included bacon, sausage, hot dogs, ham and "other cured meats". Tumor types included were "astroglial tumors", "medulloblastoma/ PNET" and "other", with astroglial tumors making up 57% of the study population.

Nitrite levels were found to have decreased in all of the cured meat items considered with the exception of hot dogs. PBT risk among pregnant women ingesting the highest level of dietary nitrite, i.e. >3.0 mg/day, showed a tripling of PBT risk among their offspring with an odds ratio of 3.0 (1.2–7.9). This nitrite intake is roughly equivalent to eating three hot dogs per day throughout pregnancy. Lower intakes were also associated with somewhat lower cancer risk. The authors concluded

that "A substantial risk of pediatric brain tumors appears to be associated with relatively high levels of maternal cured meat consumption during pregnancy".

118.5.2 Recent Data

Several additional recent epidemiological studies address the question of maternal cured meat intake and PBT risk. These include an analysis by Lubin et al. (2000). In this case-control study all cases of brain tumor among subjects less than 18 years old diagnosed between 1984 and 1993 in Israel constituted the study group. A total of 300 cases were matched two-to-one with control subjects obtained via the Population Registry and matched by sex, country and year of birth. Approximately 47% of patients suffered from "astroglial" tumors with medulloblastoma accounting for an additional 25.3% (Lubin et al. 2000). As seen in a number of previously viewed studies, dietary data were collected via personal interview with the study subject's mother using a semi-quantitative food questionnaire. Monthly and weekly reported food consumption was converted into average daily amounts.

The only relevant "cured meat" related food category analyzed by the authors was "preserved meat and sausages". Comparing the highest tertile of intake with lowest yielded an odds ratio of 1.13 (0.8–1.6), which does not support a role for this food item in PBT risk. Interestingly, neither vitamin C nor E intake during pregnancy showed any protective effect.

In a 2005 study, Bunin et al. readdress the issue of maternal diet and the risk of medulloblastoma/ PNET among children aged less than 6 years (Bunin et al. 2005). The study used methods similar to their previous paper on this topic (Bunin et al. 1993) as well as the same database as the source of patients. "Cured meat" consisted of separate categories for ham, lunch meat, hot dogs and lunch sausage. The authors also presented data for an exposure category termed "cured meat and fish". None of the cured meat categories showed any effect of intake during pregnancy and PBT risk with ORs ranging from 0.8 to 1.1 comparing highest to lowest weekly intake. All associations showed non-statistically significant 95% confidence intervals. A 2006 study by the same group of authors did not present any new data on the cured meat/PBT relationship (Bunin et al. 2005).

118.6 Meta-Analysis of Observational Data

As detailed above, the biological plausibility of an association between NOCs and PBT's and the initial epidemiological evidence provided by Preston-Martin et al. (1982) prompted additional exploration of this topic by others. A major limitation of the existing literature is the relatively small number of patients enrolled in any individual study. This is understandable given the rarity of PBTs. Nonetheless, small sample size limits the statistical power to detect an effect, if, in fact, one exists. Meta-analysis provides an avenue for a more critical appraisal of a body of knowledge plagued by such shortcoming by allowing the pooling of data and thereby increasing sample size. Such methods also allow examination of the study design issues that may influence study outcome and interpretation. The strength of meta-analysis is its dependence on a prospectively defined protocol, explicit study inclusion criteria, comprehensive literature search, and use of accepted statistical methodologies to evaluate the validity of the observed outcome based on various assumptions in study design and statistical analyses.

In 2004, Huncharek et al. published a meta-analysis examining the cured meat/PBT association. Using methods described by Greenland, the author conducted a Medical Literature Analysis and Retrieval System (MEDLARS) literature search covering the years 1966–2001. This electronic

search was supplemented by searches of the CancerLit and Excerpta Medica databases as well as the CD-ROM version of "Current Contents". Electronic searches were supplemented by manual literature searches of study bibliographies, review articles, textbooks, etc.

The literature search yielded seven observational studies available for statistical pooling (i.e. Bunin et al. 1993, 1994; Cordier et al. 1994; Kuijten et al. 1990; McCredie et al. 1994; Preston-Marin 1996; Sarasua and Savitz 1994). A total of 1,226 cases and 1,768 controls were enrolled in the seven reports. Only McCredie et al. (1994) and Prestin-Martin et al. (1996) showed statistically significant increased risk with maternal cured meat intake during pregnancy. The summary relative risk derived by pooling individual study odds ratios and 95% confidence intervals was 1.68 (1.30–2.17), consistent with a 68% increase risk of PBT among children of mothers ingesting "high" levels of dietary cured meats during pregnancy compared with "low" intake as defined in the individual reports.

Four of the studies included in the meta-analysis stratified cured meat by type, e.g. bacon, hot dogs etc. (Bunin et al. 1993; Cordier et al. 1994; Preston-Martin 1996; Sarasua and Savitz 1994). Pooling data using hot dogs as the exposure of interest showed a summary relative risk of 1.33 (1.08–1.66) while "high" versus "low" intake of sausage yielded a result consistent with a 44% increased risk of PBT associated with this intake, i.e. summary relative risk of 1.44 (1.01–2.06). Maternal consumption of ham during pregnancy was not associated with an increased risk of PBT with a summary relative risk of 0.96 (0.75–1.23).

Although the data from this meta-analysis are intriguing with a total sample size greater than 1,000 subjects, numerous limitations characterize the available database. The number of published studies examining the PBT/dietary cured meat relationship is small. In addition, inadequate information exists for a detailed appraisal of a dose-response relationship. Demonstration of a dose-response between exposure and outcome is an important criterion for drawing causal inferences. Almost all of the existing studies stratified cured meat intake categorically, e.g. by tertile or quartile, without quantitatively defining the stratified intakes. It is therefore impossible to directly compare intake categories without such information and precludes a rigorous meta-analytic evaluation of dose response, such as that described by Berlin et al. (1993). A dichotomous classification of "high" versus "low" is not fully informative and may provide a spurious result depending on the absolute nutrient intake across studies. Further work needs to incorporate such information. In addition, the small numbers of studies available for statistical pooling does not allow for an analysis of the effects of maternal intake of cured meat and PBT of specific histologies. The striking differences seen among brain tumor types in terms of natural history and biological behavior/genetic characteristics may, at least partly, reflect distinct etiologies. Lack of stratification based on tumor type could confound pooled analyses.

118.7 Conclusions

Malignant brain tumors remain an important cause of morbidity and mortality among the pediatric age group. Other than rare genetic syndromes associated with increased PBT risk, the etiology of this group of devastating tumors is largely unknown. In this context, numerous epidemiological studies have implicated environmental exposures in brain tumor development These include maternal/paternal smoking during pregnancy (Gold 1994), insecticides (Gold et al. 1979) and dietary factors (Preston-Martin et al. 1982).

Prior work suggests that various NOCs are neural carcinogens in a variety of animal models. This finding is of epidemiological interest since both preformed NOCs and precursors occur in the human diet from various sources. Animal feeding studies suggest that in vivo nitrosation may be an important source of carcinogenic compounds from NOC precursors. Tannenbaum and Mergens demonstrated that feeding pregnant rate nitrites along with amines or amides resulted in offspring at high

risk for brain tumors (Tannenbaum and Mergens 1980). Interestingly, this effect was attenuated by the administration of vitamins E and C.

As discussed above, Preston-Martin et al. published data in 1983 suggesting that maternal cured meat consumption during pregnancy increases brain tumor risk in offspring (Preston-Martin 1983). This question was examined in the context of the "NOC hypothesis" with the authors pointing out that cured meat contains nitrosamines and that high levels may also be released in cooking fumes. The biological plausibility of the association between NOCs and pediatric CNS tumors and the initial epidemiological evidence provided by Preston-Martin et al. prompted addition studies by others. Nonetheless, numerous limitations of the existing scientific database preclude definitive conclusions regarding the validity of this suspected association. As discussed throughout this review, these limitations include, among others; (1) the small size of the available epidemiological database, (2) lack of stratification of available data by tumor histology, (3) lack of data on the effects of adjustment for vitamin intake, (4) use of crude, non-quantitative exposure classifications in most observational studies, (5) inability to quantify possible endogenous formation of NOCs in human epidemiological analyses and (6) lack of a clear dose-response between exposure and outcome of interest. Cleary, overcoming many of the above study design limitations would contribute to a clearer understanding of the true association between maternal intake of NOCs and PBT risk. At present, the validity of the "NOC hypothesis" remains uncertain.

118.8 Applications to Other Areas of Health and Disease

Work related to understanding the biology of NOCs, their ability to induce cancer in animals and humans and elucidating the epidemiological characteristics of these cancers is an important area of research. Prior work, as outlined above, suggests that diet is a major determinant of cancer in human populations. Sufficient epidemiological evidence exists highlighting the role of dietary factors in the development of cancer in humans with migrant studies providing important substantiating evidence. Nonetheless, the proposed association between maternal NOC intake during pregnancy and PBT remains uncertain. The problems that limit interpretation of the existing database regarding this association are similar to those encountered in other diet/disease contexts. Therefore, the NOC/PBT relationship serves as an important paradigm for nutritional cancer epidemiology in general.

Additional research with regard to NOC/PBT may include more detailed characterization of the correlation, or lack thereof, between intake of total cured meats and specific meat types and rates of childhood brain tumors, as well as other cancers, across multiple populations. Due to problems with case-control studies in terms of recall or selection bias, cohort studies may be particularly relevant. Although childhood brain tumors are rare, additional work using adult cohorts could provide important relevant information, since extrapolations from adults to children would support a potential causal association. Clearly, methodological refinements could lead to improved insight into this suggested cause/effect relationship.

Additional work aimed at further elucidation of the biological plausibility of the association would also contribute to more clearly establishing a causal connection. Determining more precise estimates of human intake, including endogenous production of NOCs, could bolster the human observational data. Developments in the area of biomarkers may represent a potential avenue for improved "molecular epidemiology" in this field.

Clearly, an important aspect of establishing a possible causal connection between NOCs and PBT risk is the potential for development of cancer prevention strategies based upon this information. Dietary factors are potentially modifiable and therefore represent a method for direct intervention in a causal pathway leading to a devastating disease in humans. Community-based initiatives or other

public health intervention programs could represent an important research field to develop from the more fundamental laboratory and epidemiological work currently being done in this area.

118.9 Methodological Consideration

An important caveat regarding the human epidemiological data reviewed above centers on the possible confounding of a NOC/PBT relationship by other dietary factors, specifically, intake of fruits and vegetables. Prior work shows that, in general, there is an inverse relationship between dietary intake of cured meats and ingestion of fruit and vegetable. Some of the available observational studies show that PBT risk was lower among those subjects with "high" fruit/vegetable consumption.

This raises the possibility that the observed association between NOC intake and PBT could be due to a protective effect of fruits and vegetables with the cured meat association due to meat's negative correlation with fruits and vegetables. Other epidemiological studies show a protective effect between increasing fruit/vegetable intake and decreased risk of a number of human cancers and such a relationship may also exists with regard to PBTs. This issue has received inadequate consideration in the relevant literature and represents an important avenue for further research.

Summary Points

- CNS tumors are the most common solid tumor of the pediatric age group in the United States with approximately 3,500 new cases diagnosed each year.
- Since brain neoplasms are also the second leading cause of death among children under the age of 15, they represent an important clinical and public health problem.
- Dietary NOCs are suspected of playing a role in the development of childhood CNS tumors based on evidence of carcinogenicity in animal studies.
- Astrocytoma is the most common CNS tumor in children constituting approximately half of all PBTs and about 9% of all neoplasms in the pediatric age group.
- Malignant gliomas are less common in children than adults and represent approximately 7–10% of PBTs. Histologically, 50–60% are anaplastic astrocytomas, 30–40% are the highly malignant glioblastoma multiforme with another 10–20% characterized as anaplastic oligodendrogliomas and malignant mixed gliomas.
- The NOCs constitute a large group of chemicals present in the environment and the human food supply. Concern over their possible risk to human health derives from initial observations of liver toxicity in sheep fed fish meal treated with sodium nitrite.
- Evidence of concern regarding NOC developed from the work of Sander demonstrating the formation of carcinogenic nitrosamines from amine precursors and nitrite under conditions resembling those present in the mammalian stomach (Sander 1967).
- The toxic effects of N-nitrosamines appear species specific and independent of route of administration and require metabolic activation by cytochrome P450's to act as carcinogens.
- N-nitrosamides are direct alkylating compounds and are carcinogenic in various animal models and mostly induce tumors of the CNS.
- In 2004, Huncharek et al. published a meta-analysis examining the cured meat/PBT association. Pooling data using hot dogs as the exposure of interest showed a summary relative risk of 1.33 (1.08–1.66) while "high" versus "low" intake of sausage yielded a result consistent with a 44% increased risk of PBT associated with this intake, i.e. summary relative risk of 1.44 (1.01–2.06).
- At present, the validity of the "NOC hypothesis" remains uncertain.

Definitions and Explanations

PBT: Pediatric brain tumor.

NOC: N-nitroso compound. This group of chemicals represents a large group of carcinogens that occur in the environment and can be formed in the body by nitrosation of secondary or tertiary amines. Total human exposure includes both exogenous and endogenous components.

Meta-analysis: A group of statistical procedures for pooling data from multiple clinical trials or observational studies to obtain a summary measure of effect.

Summary relative risk: A summary outcome measure used in meta-analyses designed to pool data from observations studies using individual study outcomes (either odds ratios or relative risks) and 95% confidence intervals.

Pons: Is a structure located on the brain stem. It is cranial to the medulla oblongata, caudal to the midbrain, and ventral to the cerebellum. In humans and other bipeds this means it is above the medulla, below the midbrain, and anterior to the cerebellum.

Key features of N-nitroso compounds

Characteristic	N-nitrosamines	N-nitrosamides
Formation	Reaction of a nitrite compound with amines or amides	Same as N-nitrosamines
Formation inhibitor	Redox compounds	Redox compounds
carcinogenicity	-Require activation via cytochrome P450	Do not require activation via cytochrome P450
	Induce tumors at multiple sites including, liver, lung, esophagus, bladder, pancreas, kidney, trachea, nasal cavity	Induce tumors of central nervous system, lymphatic system, stomach, gastrointestinal system, bone
neuro-carcinogen in animals?	No	Yes

This table compares and contrasts some key features of nitrosamides and nitrosamines

Chapter 119
Behavioral Aspects of Nonalcoholic Fatty Liver Disease: Diet, Causes, and Treatment

Giulio Marchesini, Chiara Nuccitelli, Elena Centis, Silvia Di Domizio, Alessandro Suppini, Rebecca Marzocchi, and Riccardo Dalle Grave

Abbreviations

ALT	Alanine aminotransferase
BMI	Body mass index
HDL	High density lipoprotein
HOMA	Homeostasis model assessment
CBT	Cognitive-behavioral treatment
NAFLD	Nonalcoholic fatty liver disease
NAS	NAFLD activity score
NASH	Nonalcoholic steatohepatitis

119.1 Introduction

Nonalcoholic fatty liver disease (NAFLD) is a clinical/biochemical condition characterized by fatty liver with/without necroinflammation and fibrosis, and is considered the hepatic expression of the metabolic syndrome (Marchesini et al. 2003). The disease has long been considered a benign condition, but there is now evidence that fatty liver may progress to nonalcoholic steatohepatitis (NASH), to fibrosis, cirrhosis, and ultimately to terminal liver failure or hepatocellular carcinoma (Caldwell and Crespo 2004). The hepatic involvement has obesity and diabetes as pivotal expressions and insulin resistance as the underlying metabolic defect (Sanyal 2002), also in normal-weight subjects without diabetes (Bugianesi et al. 2005). Low insulin sensitivity, either genetically determined or obesity associated (acquired), favors the accumulation of free fatty acids and triglycerides within the liver cells, resulting in hepatocellular damage, which may be self-maintaining and progressive (Table 119.1).

From an epidemiological point of view, the increasing prevalence of NAFLD parallels the worldwide epidemics of diabetes and obesity in Western countries. Despite increased awareness of the multiple diseases associated with being overweight and obese, the prevalence of obesity and metabolic syndrome has increased dramatically in recent years, and NAFLD incidence in adults and children is rapidly rising as well (Charlton 2004; Fraser et al. 2007).

Table 119.1 Key facts of nonalcoholic fatty liver disease (NAFLD)

1. Nonalcoholic fatty liver disease (NAFLD) encompasses a spectrum of liver involvement in subjects without significant alcohol intake (<20 g/day), characterized by accumulation of triglycerides in the hepatocytes (steatosis). NAFLD is largely caused by unhealthy lifestyles (excess calorie intake, low physical activity), favoring obesity and diabetes mediated by insulin resistance
2. Steatosis (>5% of hepatocytes) is present in 30% or more of the adult population in Western countries. Steatosis may be accompanied by necroinflammation and fibrosis, leading to disease progression
3. Subjects with NAFLD are at risk of developing advanced liver disease (cirrhosis, terminal liver failure, hepatocellular carcinoma) of metabolic origin. Reduced calorie intake and increased physical activity are the key issues in disease prevention and in treatment strategies

This table lists the key facts of NAFLD, including the diagnosis of disease, the factors associated with disease progression, the possible outcome of disease and prevention and treatment strategies

The various features of the metabolic syndrome appear in chronological order in NAFLD patients (Suzuki et al. 2005a). Weight gain and low High density lipoprotein (HDL) cholesterol generally precede raised liver enzymes and the other insulin resistance-related features. Raised aminotransferase levels (namely alanine aminotransferase – ALT), hypertriglyceridemia, and hypertension appear nearly simultaneously, and precede glucose intolerance. However, NAFLD may also exist in the presence of normal ALT, and the use of raised liver enzymes as a surrogate marker of NAFLD leads to underestimation of the prevalence of the disease to an extent variable according to gender and age.

As the disease stems from excess calorie intake and lack of physical activity, the correction of unhealthy lifestyles forms the background approach to any prevention and treatment strategy (Bellentani et al. 2008), even when pharmacological agents (mainly insulin-sensitizing agents) are tested. As it is the case of obesity, drug therapy remains a second line treatment, to be added to behavior therapy if and when lifestyle modifications are not achieved or have not produced the expected liver improvement in patients at risk of progressive disease.

119.2 Overweight/Obesity and Weight Loss

NAFLD patients are typically overweight or obese and insulin resistant, and compared to individuals without hepatic steatosis, they show a significantly higher energy intake.

Weight loss may rapidly reverse fatty liver, even in subjects with diabetes, by decreasing the overflow of fatty acids responsible for hepatic and peripheral insulin resistance and the levels of proinflammatory and profibrotic adipokines (Petersen et al. 2005). Even a 2-week calorie restriction, independently of exercise (Tamura et al. 2005), causes a 27% reduction in intrahepatic fat content despite a minimal change in total body fat in type 2 diabetic patients. The change in hepatic triglyceride content is also associated with significant changes in hepatic glucose production and whole-body insulin sensitivity (Petersen et al. 2005).

A weight loss of at least 10% of initial body weight in obese patients undergoing dietary treatment is frequently associated with reversal of abnormal liver function tests. More recently, even a moderate weight loss (approximately 6%) improved insulin resistance and reduced the intrahepatic fat content (Sato et al. 2007). In 15 biopsy-proven NASH patients, a 1-year intense nutritional counseling and a moderately restricted diet producing a mean weight loss of 2.9 kg (3% of body weight) led to a histological improvement in 60% of cases, who had experienced an average weight loss of only 7% (Huang et al. 2005). Even a 4–4.5% Body mass index (BMI) loss may be sufficient to achieve a 50% reduction in ALT levels (Sreenivasa Baba et al. 2006). Similarly, in 48 patients undergoing dietary restrictions resulting in a moderate weight loss (mean 3.7 kg at 24-month followup) liver

Table 119.2 Potential components of fast-food diet accounting for hepatotoxicity

- High-fructose corn syrup
  - Makes food more palatable
  - Reduces central satiety (lower effect on ghrelin)
- High glycemic index
- Higher consumption of saturated and *trans*-fats
- Caramel coloring rich in advanced glycated end-products
- Increased consumption of red meat
- High calorie intake

The detrimental effects of fast-food diet have been largely reproduced in experimental animals fed high-fructose corn syrup and *trans*-fatty acids (Tetri et al. 2008)

function tests improved in 96% of cases and 50% had a complete reversal of previously elevated ALT (Knobler et al. 1999). A few studies have also tested the effects of moderately energy-restricted diets, supplemented with vitamins or polyunsaturated fatty acids, without any significant deterioration in inflammation and fibrosis (Okita et al. 2001). More rapid weight loss (1.6 kg/week achieved by very low calorie diets) may be harmful, and should not be suggested (Andersen et al. 1991), even if very recent studies did not confirm the deleterious effects of massive weight loss induced by bariatric surgery on the liver.

Beside total energy intake, there is evidence that also dietary fat composition may have an independent effect on insulin sensitivity. Musso et al. showed that the nutritional habits of NASH patients are characterized by a different quality of fat and vitamins compared with controls, independently of calorie intake (Musso et al. 2003). Other studies reported significant differences in total fat and saturated fat and low fiber contents (Cortez-Pinto et al. 2006) or increased amounts of refined carbohydrates (Solga et al. 2004), which may easily activate lipogenesis. This could partly explain why even lean and nondiabetic subjects may develop NAFLD (Kim et al. 2004).

In general, the detrimental effect of fast-food (or cafeteria) diets on liver enzymes is well documented in several studies in experimental animals, as well as in humans, through mechanisms which may add to each other to a variable extent (Table 119.2) (Marchesini et al. 2008). For the majority of them, the final effect is excess calorie intake, leading to obesity, but specific negative effects of individual components of fast-food diet on the liver and on insulin sensitivity may also be suggested.

In a pilot experiment carried out in 18 young healthy subjects who doubled their caloric intake by means of a fast food-based diet for 4 weeks and limited physical activity, body weight increased dramatically (+6.4 kg, 10% weight gain), and serum ALT increased on average from 22 U/L to 68 (+220%, much more in males), accompanied by a remarkable accumulation of triglycerides in the liver, measured by magnetic resonance spectroscopy (+155%) (Kechagias et al. 2008). These results are supported by data in experimental animals, where combining risk factors for the metabolic syndrome, by feeding mice trans-fats and high fructose corn syrup, induced histological changes resembling NASH and produced a metabolic profile similar to that observed in NASH patients (Tetri et al. 2008).

119.3 Sedentary Lifestyle and Physical Activity

Beside calorie restriction and gradual weight reduction, physical activity represents a pivotal factor of healthy lifestyle with a protective and therapeutic role in NAFLD (Zelber-Sagi et al. 2008). Moderate-intensity aerobic exercise has beneficial effect on adiponectin, insulin resistance, resistin, and nutritional factors, and alters substrate use in skeletal muscle (Perseghin et al. 1996). A variety

of adipocytokines have been implicated in the development of hepatic steatosis, as well as in disease progression to inflammation and fibrosis (Marra et al. 2008), and they all are sensitive to physical exercise. Also in the absence of weight loss, physical activity enhances insulin sensitivity and glucose homeostasis through an insulin receptor upregulation in muscle tissue and increased delivery of glucose and insulin to the muscles. Exercise also reduces the accumulation of hepatic triglycerides by stimulating lipid oxidation and inhibiting lipid synthesis in liver, and higher levels of physical activity were associated with lower intrahepatic fat content in individuals with or without fatty liver (Perseghin et al. 2007). Liver enzyme levels were independently associated with physical activity in a large sample of British women (Lawlor et al. 2005) and an inverse association was demonstrated between physical fitness and the prevalence of NAFLD (Church et al. 2006).

As exercise is helpful in redistributing fat stores and reducing visceral obesity, in increasing HDL cholesterol levels and reducing the risk of type 2 diabetes mellitus, the beneficial effect of exercise on NAFLD might also be mediated by changes in risk factors for steatosis.

Epidemiological trials reported an inverse association between the metabolic syndrome and the participation in intense physical activity, high muscle strength and high cardio-respiratory fitness (measured by peak oxygen uptake by the working muscles) (Farrell et al. 2004; Jurca et al. 2004; Lakka et al. 2003). In keeping with these data, Krassnoff et al. reported suboptimal health-related fitness (cardio-respiratory fitness, body composition, muscle strength) and physical activity in patients with NAFLD, in relation to the different histological severity (Krasnoff et al. 2008). In particular, low cardio-respiratory fitness was associated with increasing disease severity, graded according to NAFLD activity score (NAS) criteria (Kleiner et al. 2005). More recently, only resistance (vs. aerobic) physical activity was associated with a lower prevalence of NAFLD, lower concentrations of leptin and lower rates of abdominal obesity (Zelber-Sagi et al. 2008).

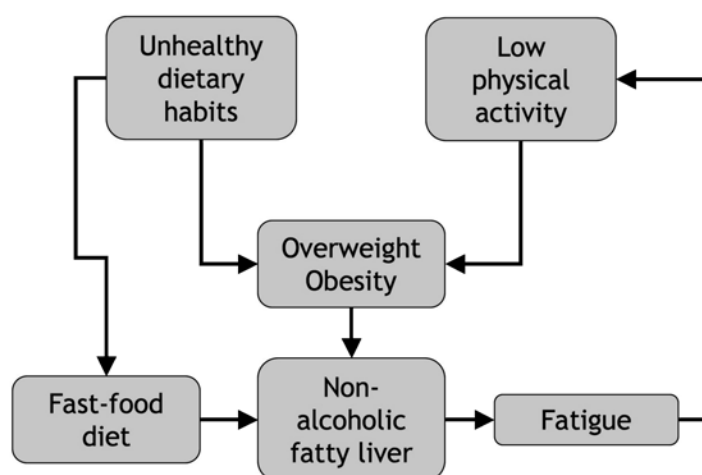
Any attempt to stimulate physical activity in NAFLD is limited by the demonstration that fatigue is a significant problem in NAFLD, associated with impairment in physical function (Newton et al. 2008). Although fatigue appears to be unrelated to either severity of underlying liver disease or insulin resistance, it may increase sedentary habits, creating a vicious circle where adherence to exercise programs may be limited (Fig. 119.1).


Fig. 119.1 Vicious circle linking diet/nutrition and physical activity to nonalcoholic fatty liver via fast-food diet and fatigue. Dietary habits and physical activity contribute to overweight and obesity. Excessive dietary intake is frequently associated with fast-food diet, which adds to overweight/obesity in the pathogenesis of nonalcoholic fatty liver disease. Hepatic steatosis is characterized by fatigue, which may contribute to low physical activity creating a vicious circle

Very few studies have been carried out on the therapeutic effectiveness of physical activity, usually in combination with diet and weight reduction (Hickman et al. 2004; Ueno et al. 1997). In the Ueno study (1997), the amount of physical activity was so strenuous (walking from 3,000 to 10,000 steps at 500-step increase every 3rd day, then jogging, 20 min twice a day) that it can hardly be proposed outside controlled clinical studies. More recently, Sreenivasa Baba (Sreenivasa Baba et al. 2006) demonstrated a significant reduction in ALT levels in patients with NASH who adhered to a moderate intensity aerobic exercise (45 min/day, for at least 5 days/week), regardless of weight loss. However, resistance training can also improve insulin sensitivity, metabolic profile, and decrease visceral fat, regardless of weight loss (Ibanez et al. 2005; Tsuzuku et al. 2007).

Exercise intervention is usually represented by regular aerobic exercise, such as brisk walking, jogging, stationary and outside biking, and stepping, and plays a fundamental role in preventing lean body mass wasting during weight loss. Resistance training may result in even larger favorable effects in lean body mass. Given the extensive evidence of the benefits of aerobic exercise training on the modulation of cardiovascular risk factors, the 2007 update of the American Heart association concludes that resistance training should be viewed as a complement to, rather than a replacement for, aerobic exercise (Williams et al. 2007).

Considering that both nutritional therapy and physical intervention are effective in NAFLD, their combination is more effective than physical activity alone, at least in the short-term (10 weeks) (Chen et al. 2008). However, in NAFLD patients without overweight/obesity, physical activity may represent the single first line approach to improve insulin resistance.

119.4 Behavior Therapy

Given the general consensus on the synergistic action between calorie restriction and exercise on NAFLD, behavior therapy addressing both changes is the mainstay of treatment, but achieving and maintaining long-term lifestyle modification is not free from difficulties.

Prescriptive diets have a limited long-term efficacy on weight loss; the prescriptive approach does not help patients change nutritional habits in their daily life by cognitive restraint, but merely imposes restrictions. After the prescriptive period, most patients resume their old habits and regain weight. Making patients increase their physical activity is even more difficult. Sedentary people do not easily understand the importance of physical exercise for psychological and physical health and how much exercise is needed to improve cardiovascular and metabolic diseases. Besides, barriers to physical exercise are extremely strong, mainly on the side of logistics (time constraints, job and family duties, etc.). Patients with higher BMI and older age are less compliant to exercise, and they might have poor motivation to make lifestyle modifications (Sreenivasa Baba et al. 2006). Only a few obese patients are able to adopt and sustain modifications of their habits, and to implement lifestyle changes is both complex and costly. In particular, most patients attending obesity and diabetes clinics are well aware of the need to reduce calorie intake, but do not perceive increased physical activity as a mandatory target of treatment. In a recent study integrating the activity of general practitioner and specialist centers in the care of subjects with the metabolic syndrome, we showed that most patients belonged to the very early stages of change (i.e., the willingness and ability to modify specific lifestyle habits) when asked their willingness to be engaged in physical exercise, whereas most of them considered a restricted diet a necessary component of weight loss (Fig. 119.2) (Melchionda et al. 2006). Nearly half of our male population and 80% of females reported a completely sedentary lifestyle, and 29% of cases had raised ALT levels.

Only behavioral treatment can give patients the practical instruments to achieve their eating and exercise goals, incorporate them into lifestyle, and maintain the results for a long period, possibly
Fig. 119.2 Stage of change in 503 patients with the metabolic syndrome enrolled in a study involving general practitioners and a specialist unit (Melchionda et al. 2006). Note the much higher prevalence of subjects in the precontemplation and contemplation stage for engaging in physical activity (PA – from 40% to 50%, both in males and females) than for engaging in dietary restraint (Diet – 25% or less)

Table 119.3 Principles of behavior therapy in the NAFLD area

- Communicate with empathy
- Discuss the long-term risks associated with NAFLD
- Discuss pros and cons of proposed changes to lifestyle
- Explore reasons for perpetual poor dietary choices and limited exercise
- Explain treatment and its benefits
- Encourage self-efficacy
- Design individualized programs of healthy eating and stimulate physical activity, according to individual preferences

Note that the principles are perfectly similar to those used in obesity. A liver biopsy is needed for a precise diagnosis of grade and stage, and may help stimulate adherence to the behavior program

indefinitely. During the behavior program patients are given a set of principles and techniques for modifying their diet and exercise, such as keeping a record of their daily food intake and physical activity, counting food calories and duration of exercise or steps with pedometers, and exercising during routine daily life without disrupting their habits.

Behavioral change strategies are designed to develop and maintain desirable lifestyles and/or to reduce undesirable habits; in the area of weight loss this means to develop "food intake control" and "regular physical activity", and to decrease "uncontrolled food intake" and "sedentary habits", as well as to acquire relapse-prevention strategies that may guarantee long-term durability of change (Table 119.3).

The behavioral approach to weight loss has been shown to produce an average 0.5–1 kg weekly weight loss, or an approximate 8–10% total weight loss, with drop-out rates less than 20%. In the last 30 years, the average weight loss which may be achieved by the behavioral approach has doubled, but treatment length has tripled (Wadden et al. 2007), carrying out a progressively larger risk of dropout in the "real world" of obesity clinics.

Table 119.4 Suggested amount of calorie restriction and physical activity in the treatment of nonalcoholic fatty liver

Calorie restriction

- Daily intake of 25 kcal/kg ideal body weight
- Daily calorie defect of 500 kcal of pre-treatment calorie intake
- Daily calorie defect equal to 20% of pre-treatment calorie intake

Physical activity

- Brisk walking – 30 min/day or 10.000 steps (5–7 sessions/week)
- Bike or stationary bike – 30 min (5–7 sessions/week)
- Swimming – 1 h (3–4 sessions/week)
- Other aerobic exercise – 1 h (3–4 sessions/week)

Nontrained patients should progressively increase their physical activity from 15 min during the first week to 20 min during the second week and then to 30 min from the third week

Behavior therapy is usually delivered in groups of 10–20 participants, with weekly sessions for a period of 3–12 months. The approach is based on several strategies aimed at enhancing patients' compliance to lifestyle modification (Vuppalanchi and Chalasani 2009). Clinical practice also suggests the importance of making patients aware of their disease, i.e., of giving patients appropriate information about the causes, the risk factors, the mechanism(s) of progression, the prognosis, and the appropriate therapy of liver disease, as well as of giving them appropriate targets (Table 119.4).

Only a few studies have explored the effect of behavioral approach in NAFLD patients. A recent review (Bellentani et al. 2008) pointed out that, among the ten studies in which behavioral approach had been used to promote lifestyle change in NAFLD, only two were controlled (Kugelmas et al. 2003; Zelber-Sagi et al. 2008). In the first study, lifestyle modifications were compared with life style modification plus vitamin E administration, and in both arms the only beneficial effect was attributable to behavioral intervention, without any additional effect of vitamin E supplementation. The second study considered the effects of a lifestyle approach with or without orlistat therapy. In this case, the lifestyle approach was beneficial, but orlistat treatment showed the expected additive effect in favoring weight loss.

Although the methodology of lifestyle intervention is different from adults, several data suggest that behavioral therapy is also effective in children with NASH. In a randomized controlled trial, a lifestyle intervention consisting of a diet, tailored to individual requirements, and increased physical activity significantly improved liver histology and laboratory abnormalities, without any additional effects of vitamin E plus ascorbic acid (Nobili et al. 2008). In a very recent study, a multidisciplinary lifestyle intervention (physical activity, nutrition education and behavior therapy) was effective in improving ALT and reducing the prevalence of NAFLD in obese children with a diagnosis of fatty liver at ultrasounds (Reinehr et al. 2009).

We recently reanalyzed the approach based on lifestyle changes in our first 120 NAFLD cases treated either by a standard nutritional counseling and prescriptive diet or a more intense behavior therapy. The study was part of a protocol used in our Unit in the treatment of metabolic diseases (namely obesity and diabetes) and consisted of 12 weekly group sessions, chaired by physicians, dieticians, psychologists, and exercise experts for 3 months (Forlani et al. 2009). Fifty-three cases accepted the intensive treatment (cognitive-behavior treatment – CBT group). Compared with subjects entering the prescriptive diet protocol (diet group), the CBT group was characterized by higher BMI ($36.2 \pm$ SD 4.9 kg/m^2 vs. 30.9 ± 4.9; $P < 0.001$), higher insulin (21.7 ± 9.4 μU/mL vs. 16.9 ± 9.2; $P = 0.011$), without differences in fasting glucose (109 ± 24 mg/dL vs. 106 ± 27; $P = 0.665$) and in ALT (moderately lower in CBT; 61 ± 28 mU/mL vs. 74 ± 43; $P = 0.055$). After adjustment for sex, age, the parameters of the metabolic syndrome, and the pre-treatment levels of ALT, the probability to normalize ALT during a 2-year followup was higher in the CBT group (odds ratio, 3.34; 95% confidence interval, $1.19 – 9.35$; $P = 0.022$). Also the time course of ALT was different, and was

Fig. 119.3 Time-course
of body mass index
(BMI – *upper panel*) and
alanine aminotransferase
(ALT – *lower panel*) in
NAFLD patients treated by
prescriptive diet (Diet) or
cognitive-behavior treatment
(CBT). Data are presented as
mean ± SD. Note that the
time x treatment, repeated
measures ANOVA shows a
statistically significant
advantage of CBT on Diet in
both BMI ($P < 0.001$) and
ALT levels ($P = 0.043$)
characterized by a more rapid reduction of enzyme levels in response to behavior therapy ($P = 0.043$), whereas the changes in insulin resistance (measured by the homeostasis model assessment – HOMA technique), although larger in CBT, did not reach statistical significance (Fig. 119.3).

On a population base, the effects of behavior therapy aimed at improving life-style modifications were tested in a Japanese cohort of NAFLD subjects (Suzuki et al. 2005b). Subjects with raised liver enzymes received detailed health care instructions through customized brochures on diet (total calorie and fat restriction and simplified calorie calculations), exercise (increase daily activity and fitness exercise for 20–30 min/day, at least three times per week), and giving up alcohol if necessary. Lifestyle modifications were assessed by questionnaires and by physicians' interviews during annual followup visits. After 1 year, 5% or greater weight reduction was associated with ALT improvement and a 3.6-fold increased odds of ALT normalization. Furthermore, maintaining weight loss (<5% weight regain) was associated with a 4.6-fold increased odds of maintaining normal ALT in a 2-year followup.

When health instructions are administered in a tailored and specific way, the efficacy of behavioral treatment can also be operator-independent and not related to the frequency of followup visits.

119.5 Conclusions

Given that NAFLD is increasing worldwide and that the efficacy of dieting and increased physical exercise strengthen each other, behavioral approach should be encouraged for preventing and treating fatty liver, both in adults and in children. Prevention should start from young age with programs addressed to increase population awareness about metabolic diseases. Changing lifestyle habits is easier if prevention programs start from early childhood, when unhealthy habits are not definitely established.

In a previous paper we brought to the attention of the scientific community a superficial attitude in the definition of programs aimed at lifestyle modifications (Marchesini et al. 2005). In general, the programs referred to as "nutritional counseling" are not structured according to the principles of behavioral treatment, and the interventions are frequently limited to diet prescription. In this area, adequate long-term trials having histology as outcome measure are urgently needed to show the potential effectiveness of structured behavior programs to avoid progression to NASH, liver cirrhosis and eventually hepatocellular carcinoma.

The role of physicians and other health professionals in lifestyle modifications needs to be re-evaluated and a "team approach" should be tested. Unfortunately, competence in behavior therapy is rarely present in Liver Units, and time constraints limit the possibility of undertaking lifestyle programs (Bellentani et al. 2008). Hepatologists treating NAFLD patients, as well as general practitioners providing baseline care, should either receive adequate training in behavioral therapy or limit their intervention to engaging patients and referring them to trained lifestyle therapists who operate in the area of metabolic diseases (dietitians, psychologists, physical activity supervisors, case managers). They should be given full responsibility for their intervention, working closely with the liver specialists who should periodically monitor the clinical course of liver disease and the associated pharmacological treatment.

This strategy might be successful, but other strategies need to be adopted at the population level for prevention. Only a synergistic approach involving all the nodes of a treatment network and a global societal response might be effective in reducing the burden of advanced liver disease and premature death due to NAFLD/NASH.

119.6 Applications to Other Areas of Health and Disease

The dissemination of the knowledge about the relationship between behavior and NAFLD also extends to all the other diseases that are part of the metabolic syndrome, as well as to other conditions significantly associated with insulin resistance, in particular:

- Atherosclerosis
- Diabetes
- Dyslipidemia
- Hypertension
- Overweight/Obesity
- Renal failure
- Polycystic ovary syndrome

Summary Points

- The association of unhealthy lifestyles (high calorie intake, low physical activity) with insulin resistance and the presence of liver fat (NAFLD) is well established.
- Reduced calorie intake and physical exercise exert a synergistic effect on insulin sensitivity and favor the removal of triglycerides and free fatty acids from the hepatocytes.
- The adherence to lifestyle changes and the maintenance of long-term weight loss can only be achieved by a behavioral approach.
- Very few studies have so far tested the effectiveness of lifestyle approach in the prevention of fatty liver progression to advanced fibrosis and cirrhosis, assessed by liver histology.

- Due to time constraints in busy liver units, hepatologists might limit their activity to engaging patients and refer them to teams operating in the area of diabetes and obesity, including dietitians, psychologists, and exercise experts.
- Prevention programs should address the problem of nonalcoholic fatty liver in childhood.

Definitions and Explanations

Aerobic and resistance exercise: Aerobic exercise is any exercise that involves or improves oxygen consumption. Examples of aerobic exercise are brisk walking, bike and stationary bike, running, and jogging. Aerobic exercise and fitness are frequently compared with anaerobic exercise, of which strength training and weight training are the most salient examples. The two types of exercise differ in the duration and intensity of muscular contractions involved.

Insulin resistance: A condition where lower-than-normal insulin effects are produced by normal insulin concentrations or where higher-than-normal insulin concentrations are needed to produce normal insulin effects.

Lifestyle: Lifestyle is the behavior characteristic of each person, i.e., the way he/she lives. The behaviors and practices within lifestyles are a mixture of habits, conventional ways of doing things, and reasoned actions.

Nonalcoholic fatty liver: A liver disease of metabolic origin developing in individuals with negligible alcohol intake (<20 g/day), linked to insulin resistance, histologically similar to the liver disease occurring in persons who consume alcohol in amounts at risk of alcoholic liver disease.

Physical fitness: The capacity to perform physical exercise, measured by the maximal amount of oxygen consumption.

Prescriptive diet: A rigid scheme of daily diet, with reference to amounts (in grams) or portions. The use of substitutions is allowed only within the same group of nutrients.

Chapter 120
Interactions Between Diet, Immune System and Brain Function in the Symptom Profile of Chronic Fatigue Syndrome

Yvonne Christley, Tim Duffy, and Colin R. Martin

Abbreviations

CFS	Chronic fatigue syndrome
EFA	Essential fatty acid
CDC	Centre for Disease Control and Prevention
5-HT	5-hydroxytryptamine
EPA	Eicosapentaenoic acid
LA	Linoleic acid
Th1	T helper cell type 1
Th 2	T helper cell type 2
T cell	Lymphocyte
NK	Natural killer
RBC	Red blood cell
AA	Arachidonic acid
SFA	Saturated fatty acid

120.1 Introduction

Chronic fatigue syndrome (CFS) has been identified as being a severe, systemic, acquired illness which is accompanied by debilitating fatigue. Little or no improvement in fatigue follows periods of rest. It is recognised that CFS may be aggravated by physical or mental activity that lasts more than 6 months. As well as incapacitating fatigue, CFS is also characterised by a wide range of other symptoms (see Fig. 120.1) including cognitive dysfunction, sleep disturbance, myalgia, arthralgia, headache, gastrointestinal upset, sore throat, painful lymph nodes and mood disturbance (Jason et al. 1997).

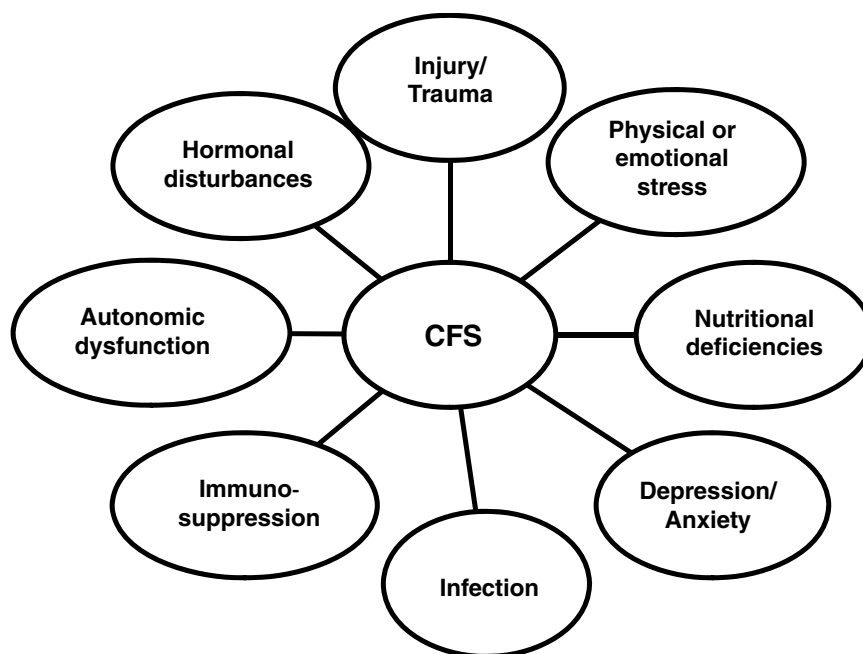

Fig. 120.1 The most frequently suggested causes of chronic fatigue syndrome are summarised below. The diagram provides a summary of the most frequently suggested and investigated causes of chronic fatigue syndrome. However, despite more than two decades of intensive research the precise cause of chronic fatigue syndrome remains unknown

Until now, researchers have been unable to identify a specific cause of CFS. Consequently, no agreed diagnostic test for CFS exists. The impact of these limitations is that diagnosis of CFS is currently one of exclusion often made on the basis of subjective clinical interpretation and of patient self report.

Despite tremendous investment of time and energy, the study of CFS has been weighed down by the absence of clear standardised diagnostic criteria and definitions. In an effort to address these problems, the Centre for Disease Control and Prevention (CDC) introduced a case definition in 1988, and subsequently revised it in 1994 (Fukuda et al. 1994) (see Table 120.1). Within the revised definition, complications were removed concerning the inadvertent inclusion by the definition of patients whose fatigue had a psychiatric basis, the inclusion of which had negative effects on the analysis of epidemiological and treatment effectiveness research in CFS (Buchwald et al. 1996).

In the absence of effective treatment strategies to alleviate the debilitating symptoms of CFS, many patients are forced to explore alternative differing therapy options. The popular dietary and nutritional literature demonstrates an abundance of alleged miracle cures. Grant et al. (1996) in an analysis of the dietary and nutritional supplement habits amongst CFS patients found that many CFS sufferers advocate the use of dietary supplements, (especially vitamins and minerals), as a method of alleviating the symptoms of their illness.

Nutritional deficiencies in CFS have been afforded considerable attention in the scientific literature, with numerous studies exploring potential links between nutritional deficits as a means of unraveling the underlying pathophysiology of CFS. Indeed some investigations have established reduced levels of magnesium (Cox et al. 1991), B vitamins (Heap et al. 1999), essential fatty acid levels (Horrobin 2002), l-carnitine (Plioplys and Plioplys 1995) and tryptophan in some CFS patients. However, these findings have been widely disputed and challenged due to methodological limitations and inconsistent results.

Much less contentious is the association between CFS and oxidative stress. A significant body of evidence has emerged from the CFS literature to support the view that oxidative stress is a core feature

Table 120.1 Centre for Disease Control and Prevention revised definitional criteria for the diagnosis of chronic fatigue syndrome

1. Clinically assessed unexplained, persistent or relapsing chronic fatigue that is of new or definitive onset. The fatigue must not be the result of ongoing exertion or relieved by rest and should results in significant reductions in occupational, educational, social or personal activities.
2. The simultaneous occurrence of *four* or *more* of the following symptoms is also required and must be present for 6 or more consecutive months of infirmity and should not have predated the fatigue.
• Short-term memory impairment or concentration
• Sore throat
• Tender cervical or auxiliary lymph nodes
• Muscle pain
• Headaches of a new type, pattern or severity
• Unrefreshing sleep
• Post-exertional malaise lasting more than 24 h
• Diffuse joint pain without swelling or tenderness

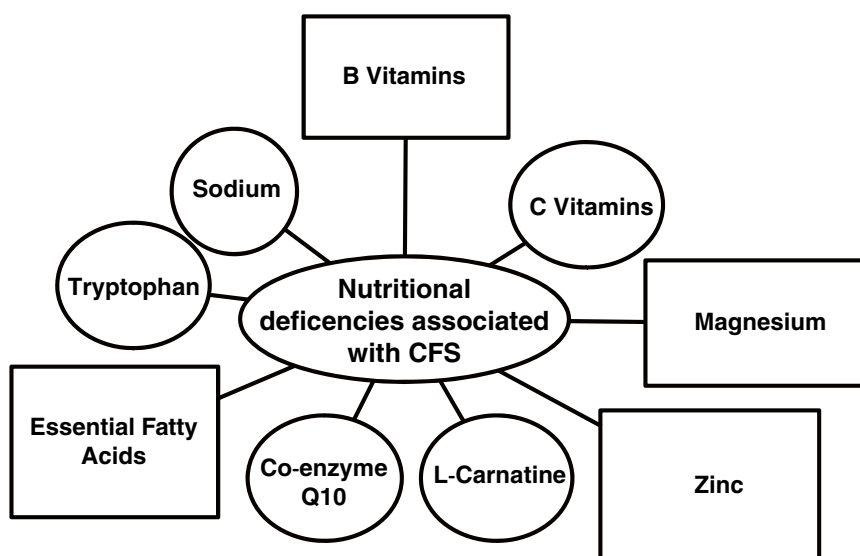
This table summarises the key symptoms and duration required to meet the Centre for Disease Control and Prevention's revised definitional criteria for the diagnosis of Chronic Fatigue Syndrome. This definition is the most commonly used definitional criteria for determining the presence or absence of chronic fatigue syndrome


Fig. 120.2 Nutritional deficiencies associated with chronic fatigue syndrome (*CFS*). The figure illustrates the nutritional deficiency thought to be associated with the symptom profile of CFS. The research literature has found some evidence of B vitamin, essential fatty acid, magnesium and zinc deficiencies in CFS. Less consistent associations have also been made between sodium, tryptophan, C vitamins, L-carantine and coenzyme Q 10 deficiencies in CFS. *CFS* chronic fatigue syndrome

of this illness and manifests as profound fatigue due to cellular damage (Lane et al. 1998). This suggest that antioxidant supplementation in CFS might merit closer examination. As such considerable effort has been invested in exploring the impact of dietary supplements on the symptom profile of CFS. Figure 120.2 illustrates the nutritional deficiencies thought to play a causative role in CFS.

These studies however have been seriously hampered in their ability to produce reliable and valid transferable findings. The reason for this is that the vast majorities of studies have examined nutritional status in CFS by investigating individual vitamin or minerals and as such have produced very wide-ranging and inconsistent results. Because of the nature of these difficulties the actual usefulness

of nutrition supplements in CFS remains indefinite. In an effort to address these problems, Brouwers et al. (2002) investigated the therapeutic impacts of multivitamins in CFS; however, they found no evidence to support the use of a multivitamins in the treatment of CFS. Despite these inconsistencies, considerable body evidence has emerged in the literature that illustrates potential associations between deficiencies of essential fatty acids (EFA), B vitamins, magnesium and oxidative stress in CFS. In light of this evidence, this chapter will analyze and discuss EFA, B vitamin, magnesium deficiency and oxidative stress in CFS.

120.2 Essential Fatty Acids, Immunity and CFS

EFA have a number of important biological functions (see Fig. 120.3) and contribute to health and well-being throughout the lifespan. EFAs cannot be manufactured by the body and are obtained through the diet. EFAs and, in particular, omega 3 have been associated with the development of a number of diseases especially depression (Horrobin 2002). There exists substantial biochemical evidence to indicate that omega 3 EFAs have considerable impact on the neural structure and function of the brain and central nervous system.

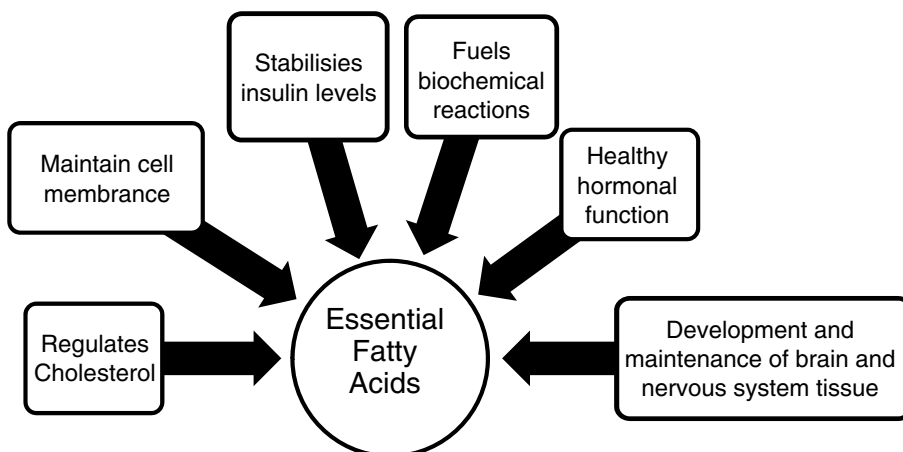
Omega 3 EFAs have been found in elevated concentrations in both the brain and central nervous system and play an important role in neurotransmitter synthesis, degradation, release, reuptake and binding (Delion et al. 1996). Furthermore, low concentrations of omega 3 have been linked to reduced levels of the neurotransmitter dopamine, greater serotonin activity and amplified concentrations of 5-HT (5-hydroxytryptamine) receptors in the frontal cortex (Delion et al. 1996). Hibbeln (1998) further shows a strong negative association between poor oily fish consumption (known to be rich in omega 3) and depression in a study across 13 countries. A Finnish corroborated these findings, identifying an increased occurrence of depressive symptoms in persons who rarely ate oily fish compared to those who ate fish regularly (Tanskanen et al. 2001).


Fig. 120.3 Most important functions of Essential Fatty Acids. The six most important functions of essential fatty acids is to regulate cholesterol, maintain cell membranes, stabilise insulin levels, fuel biochemical reactions, maintain healthy hormonal function and the develop and maintain brain and nervous tissue

120.3 The Relationship Between Omega 3 Essential Fatty Acids and Depression

More clinically orientated studies have identified a relationship between omega 3 EFA consumption and depressive symptoms in patients with major depression. Low levels of omega 3 have been found in patients with major depression than in normal controls (Peat et al. 1998). In addition, Maes et al. (1999) found that depression severity is directly related to a subtle balance between plasma and erythrocyte phospholipid levels of omega 3 and omega 6.

As depression is closely associated with the symptom profile of CFS a number of studies have investigated the potential connections between the symptoms of CFS and EFA. Behan et al. (1990) in a double-blind, placebo-controlled trial found that EFAs had a therapeutic effect in patients with post viral fatigue syndrome (referred to in contemporary terms as CFS). This important study found that the CFS patients had reduced levels of EFAs and raised levels of saturated fatty acids (SFA) compared to normal controls. Eighty five percent of the CFS patients reported significant improvements in symptoms of fatigue, myalgia, dizziness, concentration and depression following a 3 month trial of high dose omega 3 and omega 6. Warren et al. (1999) attempted to replicate the Behan et al. (1990) study. However, they were unable to demonstrate any therapeutic effects of Efamol Marine (a supplement containing omega 3 and 6) in CFS patients.

Maes et al. (2006a) have argued that these seemingly paradoxical findings may be attributed to the elevated amount of omega 6 found in Efamol Marine. They contend that there is a very precise balance between decreases in eicosapentaenoic acid (EPA) (an omega 3 fatty acid) and decreases in arachidonic acid (AA) (an omega 6 fatty acid) and increases in linoleic acid (LA) an omega 6 fatty acid in CFS. In light of this they argue that EFA supplementation in CFS might be best addressed by the use of omega 3 EFAs only.

120.4 Essential Fatty Acids Zinc and the Symptoms of CFS

Puri (2004) adds further support to the use of omega 3 only, finding an improvement in CFS patient symptoms after 8–12 weeks of a high dose of omega 3. In addition to this, Maes et al. (1999) have described the important synergy between the proportions of omega 3, omega 6 and serum zinc in CFS patients. Interestingly, these findings are consistent with similar studies in major depression, which demonstrate a link between omega 3, omega 6 and zinc. Reductions in serum zinc are key features of the inflammatory process in both depression and CFS (Maes et al. 1999).

Furthermore, the symptoms associated with zinc deficiency overlap with those of CFS, especially fatigue, depression and cognitive difficulties. Low serum zinc can result in the increased creation of pro-inflammatory cytokines and may cause damage to cell-mediated and humoral immunity, thus potentially contributing to the immunological symptoms in both CFS and major depression (Bremner and Beattie 1995).

Adequate levels of EFA and zinc are of supreme importance in CFS (Puri 2004) and are central to attempts at articulating its pathophysiology (see Fig. 120.4). A number of studies have investigated immune dysfunction and its relationship to EFAs in CFS. To date immune dysfunction is thought to relate to the suppression of natural killer cells and Th1 (T helper cell type 1) cell activity, alongside elevated Th2 (T helper cell type 2) and cytotoxic T cell (lymphocyte) activity in CFS patients (Skowera et al. 2004). Immune dysfunction as described is thought to be associated with the presence of well-established and long-standing viral infections (Puri 2004).
Fig. 120.4 Potential mechanism by which essential fatty acids might be associated with the symptoms of CFS. A persistent viral infection might be acting to inhibit the biosynthesis of Omega 3 and zinc (both of which have powerful antiviral properties) thus producing some of the symptoms of CFS

Here again, EFAs figure prominently in CFS. Viral infections and particularly enduring ones are thought to decrease the host's ability to utilize EFAs. The virus inhibits the use of EFA in order to nullify its potent antiviral properties (Horrobin 1999). Consequently, the virus in inhibiting the utility of EFAs causes a reduction EFA substrate. This not only disrupts the effectiveness of interferons in the administration of their antiviral role, but also considerably restrains their activity. Liu et al. (2003) in an investigation of the levels of fatty acids in CFS found that CFS patients showed signs of significantly reduced EFA compared to normal controls. The study made links between CFS and oxidative stress, produced by excessive oxidation thus resulting in the depletion of EFA in CFS patients.

In a similar study, Gray and Martinovic (1994) established that the amounts of EFA in CFS patients were comparable to the amounts detected in people who had experienced excessive and prolonged levels of stress. Such extreme deviations from normal EFA metabolism could explain some of the diverse immune, endocrine, sympathetic and nervous system symptoms that have come to typify CFS (Gray and Martinovic 1994).

120.4.1 B Vitamins

The B vitamins, especially B6, B12 and folic acid, are commonly used by CFS patients to alleviate symptoms. A tentative association between the symptoms of CFS and B vitamin deficiencies has been established in a number of studies (see Fig. 120.5). Serious questions remain, however, as to the accuracy and comparability of these results, particularly in relation to how B vitamin deficiencies should be detected and measured.

Heap et al. (1999) evaluated the B group vitamins in CFS and found consistent pyridoxine, riboflavin and thiamine deficiencies in CFS patients compared to controls. The most significant of the deficiencies being pyridoxine. This is interesting as low pyridoxine in the central nervous system can manifest as depression. Heap et al. (1999) also concluded that these deficiencies were probably not a result of poor dietary intake of B vitamins or poor absorption, but came about as a result of subnormal vitamin activity at a cellular level.

Furthermore, Jacobson et al. (1993) in a study of serum folate in CFS found that 50% of the CFS patients sampled had serious folic acid deficiencies, with a further 13% being borderline. Fatigue and depression are common symptoms in CFS and are also closely related to folate deficiency. In fact, folate deficiency is known to depress the immune system, and as CFS presents with evidence of immune activation, the contribution of a borderline folate deficiency might contribute to a better understanding of the immunological picture in CFS. The effectiveness of folate supplementation in CFS has been investigated. For example, Kaslow et al. (1989) found therapeutic benefits from the daily, intra-muscular injections of 800 mcgs of folate in CFS patients. This study was, however, severely limited in that the dose was quite small as was the time frame for measuring treatment effect.

Fig. 120.5 Association
between CFS symptoms and
Vitamin B deficiencies. The
figure illustrates the tentative
associations that have been
made between the symptom
profile of CFS and the
symptoms of vitamin B
deficiencies
Fig. 120.6 The neurological symptoms associated with vitamin B12 deficiency. The figure illustrates the numerous neurological symptoms that are produced in consequence to Vitamin B12 deficiency

Vitamin B12 deficiency also presents with a myriad of neurological manifestations similar to CFS. Pall (2001) has investigated the biochemical abnormalities in CFS and the mechanisms by which B12 might alleviate them. Links have been found between elevated levels of nitric oxide and its oxidant by-products peroxynitrite and CFS. These substances may be directly responsible for many of the symptoms of CFS and are released in response to oxidative stress. As B12 is a powerful scavenger of nitric oxide it has considerable potential to alleviate CFS symptoms irrespective of its pathogenesis. The effects of nitric oxide on the brain and central nervous system are well established, particularly in relation to brain function and pain sensitivity. Lindenbaum et al. (1988) investigated B12 levels in serum methylmalonic acid and homocysteine, both before and after B12 therapy in patients with neuropsychiatric symptoms. The study uncovered that subclinical B12 deficiency had caused parasthesia, ataxia, muscle weakness, hallucinations, personality and mood changes, fatigue, sore tongue and diarrhoea (see Fig. 120.6).

Furthermore, Regland et al. (1997) found high levels of homocyestine in the cerebrospinal fluid of CFS patients that was positively related to low levels of B12. As B12 deficiency causes a deficient remethylation of homocyestine, the study concluded that the low B12 was contributing to the increased homocysteine levels and consequently increased fatigue.

120.4.2 Magnesium

Like CFS, magnesium deficiency has been implicated in the development of depression, myalgia, fatigue and memory problems and has been found to have some therapeutic effect in the treatment of a number of neuropsychiatric complaints. Seelig (1998) has highlighted significant covariance between key aspects of cellular and humoral immunity in magnesium deficiency and CFS. Both CFS and magnesium deficiency cause a reduction in the numbers and activity of Natural Killer (NK) cells and as observed by Levine and Chester (1994), CFS patients do tend to have an increased sensitivity to lymphoid and immune-associated malignancies.

Many of the symptoms of CFS are profoundly similar to those found in magnesium deficiency (Seelig 1998). As such, a number of studies have examined the role of magnesium in CFS. Cox et al. (1991), in a 6-week controlled study of 32 CFS patients, compared the effect of intramuscular injections of magnesium sulphate (50%) versus placebo (water). Significant improvements were demonstrated in pain and mood in the patients who received the magnesium sulphate injections compared to controls.

Jenkins and Rayman (2005) also found reduced levels of RBC (Red Blood Cell) magnesium in CFS patients. Keoney et al. (2000) studied the effects of magnesium supplementation in CFS and found that CFS patients with moderate magnesium deficiency had reduced antioxidant capacity, which was not related to poor intake of dietary magnesium. In addition Keoney et al. (2001) investigated the antioxidant status of lipoprotein peroxidation in CFS. In this study, it was found that alongside reduced omega 6 essential fatty acid, oxidative stress and more specifically lipid peroxidation might play a role in the pathogenesis of CFS.

Additionally, Cheney (1994) asserts that has the efficacy of magnesium in the treatment of CFS might be enhanced by the addition of an antioxidant. He argues that since magnesium deficiency is associated with free radical production, (as well as having direct effects on immunologic mechanisms) the effectiveness of magnesium supplementation might be improved by the addition of an antioxidant (Seelig 1998).

120.5 Application to Other Areas of Health and Disease

Some of the nutritional deficiencies found in CFS are also applicable and relevant to other areas of disease. In particular, the symptoms of CFS overlap significantly with a number of illnesses of unknown aetiological cause, especially fibromyalgia, which shares a number of significant symptoms with CFS. Fibromyalgia is a rheumatic condition characterized by widespread musculoskeletal pain, morning stiffness, muscle fatigue, nonrestorative sleep, depressive-anxious mood, headache, irritable bowel, tiredness and weakness (Wolfe et al. 1990). Fibromyalgia is one of the most frequently diagnosed conditions in rheumatology and has a population incidence of between 0.5% and 5.8% (Gran 2003).

Despite considerable investment in understanding fibromyalgia, its aetiology and pathogenesis remain elusive. Furthermore, between 21% and 58% of fibromyalgia patients also meet the diagnostic criteria for CFS (White et al. 2000).

120.6 Chronic Fatigue Syndrome, Fibromyalgia and the Role of Oxidative Stress

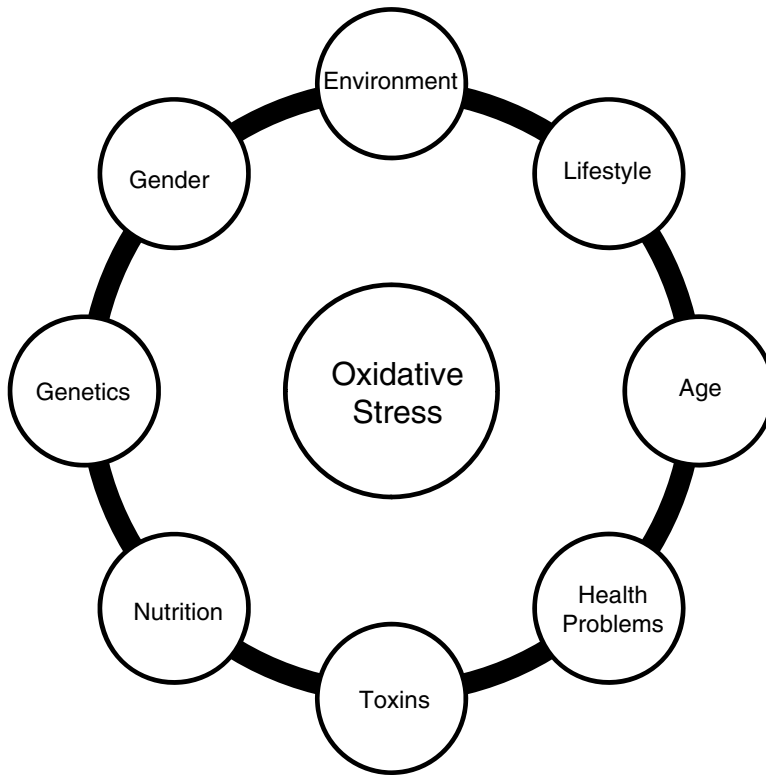
A key feature of fibromyalgia is the presence of diffuse musculoskeletal pain and as such an extensive amount of research has been conducted into the aetiological role of pain in fibromyalgia. In contrast, very little research has been conducted into the nature of pain in CFS. In light of the


Fig. 120.7 The key factors that contribute to oxidative stress. The figure illustrates the most commonly identified factors that are thought to contribute to the development of oxidative stress. The adverse health effects of oxidative stress may occur in response to an accumulation of damage caused by multiple factors acting together

significant overlap between CFS and fibromyalgia, this is surprising as some similarities between the pain mechanism in fibromyalgia and CFS have been noted. Of particular interest the role of oxidative stress and its contribution to pain perception. Oxidative stress is known to contribute to fibromyalgia pain. A small number of studies have investigated the associations between oxidative stress and pain in CFS. Meeus and Nijs (2006) found that pain in CFS could be attributed to high levels of nitric oxide produced as a result of oxidative stress. Furthermore, significant and positive correlations between levels of oxidative stress and severity of CFS symptoms have been found and are related specifically to pain, muscular tension and fatigue (Maes et al. 2006b).

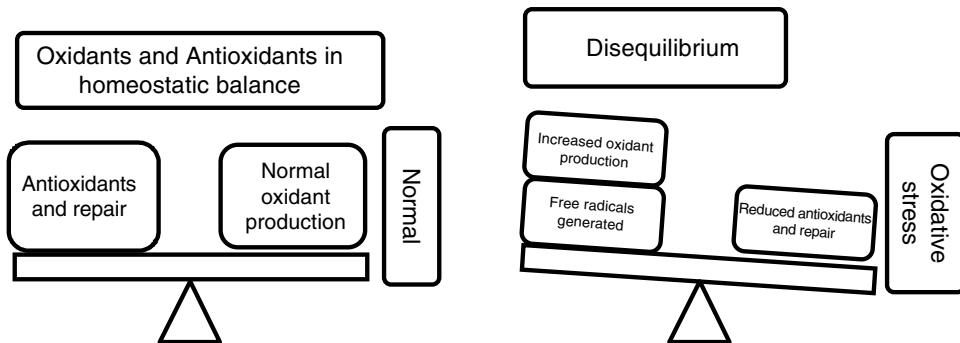
Oxidative stress leads to premature cell death and is associated with many diseases and illnesses, particularly of the central nervous system. Figure 120.7 illustrates the many factors that contribute to the development of oxidative stress. The mechanism by which this occurs is due to an increase in free radicals generated by oxidative stress, thus disrupting the delicate homeostatic balance between products of oxidation and antioxidant defences, see Fig. 120.8. These free radicals cause lipid peroxidation ultimately resulting in tissue damage (Simonian and Coyle 1996). This has a major therapeutic implication in CFS and fibromyalgia as increased lipid peroxidation, reinforces the possibility that dietary supplementation with essential fatty acids may be helpful.


Fig. 120.8 The homeostatic balance between oxidants and antioxidants in normal individuals and individuals in a state of oxidative stress. In normal conditions, there is a homeostatic balance between the production of oxidants and antioxidants. Antioxidants play a very important role in maintaining the body's ability to repair the cellular damage caused by oxidative stress. In oxidative stress, there is disequilibrium between the production of oxidants and antioxidants. The increased levels of oxidants generate free radicals and reduce the levels of antioxidants and their consequent ability to minimise cellular damage

120.6.1 The Health Enhancing Properties of Essential Fatty Acids

An extensive body of scientific evidence already exists to illustrate the health enhancing properties of essential fatty acids in cardiovascular disease (Harris et al. 2007), diabetes mellitus (Kabir et al. 2007), Rheumatoid Arthritis (Galarraga et al.2008), Alzheimer's (Schaefer et al. 2006) and renal disease (Hogg et al. 2006) to name but a few. These studies support the need for further research into the nature of oxidative stress and nitric oxide in CFS and the associated potential that antioxidant treatments such as omega 3 and 6 fatty acids, vitamins and others might offer.

Furthermore, if oxidative stress is thought to contribute to CFS then the role of diet in the treatment of CFS may be important. Vegetarian diets that are rich in free radical scavengers have been found to have a profound effect on joint stiffness, pain and general health in fibromyalgia, these symptom improvements were attributed to increased antioxidant levels. Vegetarian diets are of considerable interest as many studies have found evidence to indicate a positive association between vegetarian diet and decreased risk for chronic illnesses such as obesity, coronary artery disease, hypertension, diabetes and some types of cancer (Fraser 2009). This is an important area for future research as very little is known about the effectiveness of different diets on the symptoms of CFS.

120.7 Conclusion

A number of nutritional and dietary deficiencies have been investigated in the study of CFS. In almost every study reviewed for this chapter, researchers have identified at the very least borderline nutritional deficiencies in essential fatty acids, B vitamins and magnesium. These important deficiencies are thought to manifest as a result of the disease process in CFS as these patients do not demonstrate evidence of poor dietary intake. Investigations into the potential role EFAs play in CFS have produced some very interesting findings. Of particular importance is the association between reduced levels of omega 3 EFAs, low zinc and oxidative stress in CFS and the consequent complex inflammatory relationship this produces.

Furthermore, B vitamins are of central importance in eliminating the toxic by-products of oxidative stress and have been found to be deficient in some CFS patients. As B vitamin deficiencies present as a myriad of neurological symptoms these deficiencies might explain some of the symptoms of CFS. In addition to this, magnesium deficiencies have also been observed in CFS and are linked with free radical production thus contributing to oxidative stress, suggesting that nutritional deficiencies of this nature might benefit from antioxidant supplementation. Thus it is evident from the literature that a better understanding of the relationship between EFA, B vitamin and magnesium deficiencies and oxidative stress in CFS is of primary importance in attempts to unravel the pathophysiology of CFS.

Summary Points

- Nutritional deficiencies in essential fatty acids (EFA), B vitamins and magnesium, have been identified in CFS. These deficiencies do not appear to be associated with reduced dietary intake and are thought to relate to oxidative stress and the illness process.
- Some CFS patients have reduced levels of essential fatty acids, in particular omega 3 and zinc which result in symptoms of depression and may account for mood related symptoms in CFS. EFA supplementation has been found in some studies to improve CFS symptoms.
- Deficiencies of B6, B12 and folic acid have been found in CFS patients. Folate deficiency is known to depress the immune system, and as CFS presents with evidence of immune activation, the contribution of a borderline folate deficiency might contribute to a better understanding of the immunological picture in CFS.
- The symptoms of CFS are associated with raised levels of nitric oxide and its oxidant by product peroxynitrite, which is released in response to oxidative stress. B12 is a powerful scavenger of nitric oxide thus providing potential mechanisms for relieving CFS symptoms regardless of the pathogenesis.
- Magnesium deficiency is associated with symptoms of depression, myalgia, fatigue and memory problems and has been found to have some therapeutic effect in the treatment of a number of neuropsychiatric complaints. Some evidence suggests magnesium supplementation in CFS improves pain and mood.
- Magnesium deficiency in CFS might be associated with reduced antioxidant capacity associated with free radical production and oxidative stress. Thus the effectiveness of magnesium supplementation might be improved by the addition of an antioxidant.

Definitions

Oxidative stress: It is a discrepancy in a cell's ability to produce oxidants (e.g. free radicals) from either intrinsic or extrinsic sources, and its ability to reduce them with endogenous scavengers. Excess oxidants injure the cell's lipids, proteins and nucleic acids, which result in cumulative damage that can initiate adverse health events or diseases.

Essential fatty acids (EFA): They are unsaturated fatty acids that are essential to health; they cannot be manufactured by the body and therefore must be obtained from the diet. There are two families of EFAs omega 3 and omega 6. It is Important to maintain a balance between omega 3 and omega 6 fatty acids in the diet as omega 3 fatty acids help reduce inflammation while most omega-6 fatty acids tend to promote inflammation. An inappropriate balance of these essential fatty acids contributes to the development of disease, where a good balance helps maintain and even improve health.

Peroxynitrite: It is a powerful oxidant formed as a result of a reaction between superoxide and nitric oxide. Peroxynitrite plays a key role in cell dysfunction and death and is associated with disease states such as diabetes and atherosclerosis.

Lipoprotein peroxidation: It is the process whereby free radicals steal electrons from the lipids in cell membranes, the result of which is cell injury and the increased development of free radicals.

Free radicals: They are a group of exceedingly reactive molecules which cause indiscriminate damage to structural proteins, enzymes, macromolecules, DNA, thus playing a significant role in tissue damage and inflammation.

Key points

Symptoms of chronic fatigue syndrome key points

- Chronic fatigue syndrome (CFS) is a debilitating and complex disorder
- It is typified by the presence of overwhelming fatigue that is not improved by rest and is present for more than 6 months
- In addition to fatigue patients also complain of numerous nonspecific symptoms, including weakness, muscle pain, impaired memory, cognitive difficulties, insomnia and post-exertional fatigue

Chronic fatigue syndrome and oxidative stress key points

- Evidence reviewed in this chapter identifies a number of nutritional deficiencies that may contribute to the wide and varied symptoms of CFS.
- Oxidative stress and its negative influence on magnesium, b vitamins and essential fatty acid metabolism may play an important role in the clinical manifestation of CFS
- Further research is required to better understand the role of Oxidative stress in chronic fatigue syndrome

Magnesium, B vitamins, essential fatty acids and chronic fatigue syndrome key points

- The aetiology and pathogenesis of chronic fatigue syndrome remains unknown
- Magnesium, b vitamins and essential fatty acids play important roles in regulating the immune, nervous and vascular as well as cellular communication functions
- Further research is required to enable a more comprehensive understanding of these mechanisms and how these might be inhibited in chronic fatigue syndrome

Chapter 121
The Relationship Between Nutrition and Neurocognitive Function in Schizophrenia

Mick P. Fleming and Colin R. Martin

Abbreviations

CHD	Coronary heart disease
CLDN5	Claudin 5
DNA	Deoxyribonucleic acid
DQB1	DQ beta1
EFA	Essential fatty acids
EPA	Eicosapentaeconoic acid
IgA	Immunoglobulin A
MTHFR	Methylenetetrahydrofolate reductase
PANSS	Positive and negative syndrome scale
PUFA	Polyunsaturated fatty acids
SNP	Single nucleotide polymorphism
TGM2	Tissue transglutaminase 2

121.1 Introduction

The physical health of people who have schizophrenia is poorer compared with the general population (McCreadie 2003). The report from the House of Commons Select Committee on Health Inequalities found that those with schizophrenia are more likely to have higher rates of coronary heart disease (CHD), diabetes, stroke or respiratory disease, obesity, and on average are likely to die 10 years younger than people who do not have schizophrenia (House of Commons 2009). This confirmed findings from earlier studies which found a two- to fourfold relative risk of premature death for people with schizophrenia (Connolly and Kelly 2005). Evidence suggests that the diet of people with schizophrenia indicates poor dietary choices and poor dietary intake which is a significant contributory risk factor for the illnesses noted before (Peet 2004a).

A recognized side effect of the treatment of schizophrenia with atypical antipsychotic medication is that of increased appetite and weight gain and this contributes to the overall health profile of

e-mail: colin.martin@uws.ac.uk

people with schizophrenia. Poor health outcomes for people with schizophrenia are also associated with sedentary lifestyles caused by sedation, lack of exercise, smoking, and other social and lifestyle factors (Peet 2004a).

Relationships have been found between diet and the maintenance of schizophrenia symptoms. Evidence dating back to 1965 has found that having a gluten intolerance also known as celiac disease is a risk factor for developing schizophrenia and that a gluten-free diet contributes to a reduction in schizophrenia symptoms (Dohan 1966, Dohan et al. 1969; Singh and Kay 1976; Potkin et al. 1981; Kalaydjian et al. 2006). Researchers have concluded that a genetic predisposition to gluten intolerance and schizophrenia is activated environmentally through diet (Eaton et al. 2004). Possible mechanisms are the influence of diet on DNA methylation which in turn encourages or discourages gene expression (Singh et al. 2003) and the blood plasma levels of certain essential fatty acids and their metabolites (Joy et al. 2003).

121.2 Schizophrenia

The conceptual framework for the syndrome of schizophrenia is characterized by severe thought disorder and disturbances to perception. A diagnosis of schizophrenia is based on the criteria within diagnostic manuals ICD10/DSMIV (Table 121.1) (WHO 1992; APA 1994). It relies on the presence of at least two symptoms which persist for a time period of at least 1–6 months. The symptoms that characterize schizophrenia are positive symptoms, those behaviors and experiences that would preferably be absent such as hallucinations in any of the five modalities (auditory, visual, olfactory, touch, taste), delusions, disorders of stream and content of thought and negative symptoms or deficits/absence of behaviors, and experiences that are desirable such as motivation, energy, volition, affective flattening, and a normal range of emotions. There are a number of long-term debilitating and distressing effects on personality. These result in negative psychological and social effects which can lead to severe impairments in physical, social, emotional, and general life functioning (Martin and Fleming 2009). The average annual incidence of schizophrenia is 15 per 100,000 persons, the average figures for prevalence are approximately 4.5 per 1,000 persons and the risk of developing the illness over a person's lifetime is 0.7% (Tandon et al. 2008).

Table 121.1 Key features of schizophrenia diagnosis

1. The conceptual framework for the syndrome of schizophrenia is characterized by severe thought disorder and disturbances to perception.
2. A diagnosis of schizophrenia is based on the criteria within diagnostic manuals ICD10/DSMIV (WHO 1992; APA 1994).
3. It relies on the presence of at least two symptoms which persist for a time period of at least 1–6 months.
4. Positive symptoms are those behaviors and experiences that would preferably be absent such as hallucinations in any of the five modalities (auditory, visual, olfactory, touch, taste), delusions, disorders of stream, and content of thought. Negative symptoms or deficits/absence of behaviors and experiences that are desirable such as motivation, energy, volition, affective flattening, and a normal range of emotions.
5. The long-term debilitating and distressing effects on personality. These result in negative psychological and social effects which can lead to severe impairments in physical, social, emotional, and general life functioning (Martin and Fleming 2009).
6. The average annual incidence of schizophrenia is 15 per 100,000 persons; the average figures for prevalence are approximately 4.5 per 1,000 persons and the risk of developing the illness over a person's lifetime is 0.7% (Tandon et al. 2008).

This table lists the key facts of schizophrenia and its diagnosis including the differences between the positive and negative symptoms of schizophrenia and figures confirming the levels of the disorder in the general population

121.2.1 Schizophrenia and Physical Health Outcomes

A literature search strategy using MEDline, PsycInfo, and CINAHL was completed; the search was conducted using the following search terms:

1. "diet" AND "schizophrenia"
   The search strategy was expanded to include:
2. search terms as keywords featured in the title, abstract, full text, or caption text;
3. an additional search term of "psychosis" was also used.

Ten sources were identified from the literature search. All these sources were relevant and so abstracts of these ten papers were collected and reviewed.

A further four relevant papers relating to diet, gluten intolerance, and schizophrenia and three relevant papers relating to diet, genetics, and schizophrenia were found by cross-referencing sources from the ten sources identified in the initial electronic search. In all 17 papers were reviewed.

Comparatively people with schizophrenia have poorer physical health than the general population. Studies have found consistent trends which show higher rates of cardiovascular disease, type 2 diabetes, and respiratory disease in people with schizophrenia (Fig. 121.1) (Brown et al. 2000; Mortensen and Juel 1993; Schizophrenia and Diabetes Expert Group 2004). Where people with schizophrenia had received a diagnosis of CHD 31% had received the diagnosis prior to age 55, compared with 18% of other people with CHD; 22% of those people with schizophrenia died within 5 years of receiving the heart disease diagnosis, compared with 8% of other people with heart disease (Fig. 121.2) (Nocon and Sayce 2008). The age of dying is also lower, people with schizophrenia are twice as likely to die early (Mortensen and Juel 1993) and this could be as many as 10 years earlier (House of Commons 2009). Physical inactivity as a result of sedative treatment or as a consequence of the deficits caused by negative symptoms contributes to these physical health outcomes. Obesity and smoking also contribute and people with schizophrenia are over-represented in both these categories.
Fig. 121.1 Comparison of the numbers of people with a diagnosis of CHD aged 55 years in England and Wales (Nocon and Sayce 2008) This figure compares two groups of people, those with schizophrenia and those in the general population who have received a diagnosis of CHD by the time they have reached 55 years of age in England and Wales; the figures are in percentages
Fig. 121.2 Comparison of those people dying within 5 years of receiving diagnosis of CHD in England and Wales (Nocon and Sayce 2008) This figure compares two groups of people, those with schizophrenia and those in the general population who have died within 5 years of receiving a diagnosis of CHD in England and Wales; the figures are in percentages

McCreadie et al. (1998) found that in their sample of community dwelling people with schizophrenia that most were overweight or obese. In a sample of 226 people on long-term depot antipsychotic medication were four times more likely to be clinically obese than those in the general population (Silverstone et al. 1988). In a later report 86% of females and 70% of males using the body mass index in the sample of 102 were found to be obese or overweight (McCreadie 2003). Other studies suggest that 33% of people with schizophrenia are obese compared with 21% in the remaining population (Nocon and Sayce 2008). Obesity does increase the risks of morbidity from CHD, type 2 diabetes, hypertension, and respiratory problems (Connolly and Kelly 2005). People with schizophrenia are also more likely to smoke compared with the general population (Martin et al. 2008). Between 61% and 80% of people with schizophrenia or serious mental illness are smokers compared with 33% of the remaining population (Nocon and Sayce 2008; Rethink 2009). Diabetes has been associated with schizophrenia itself as well being a consequence of treatment either as side effect of antipsychotic medication or as an artifact of obesity caused by increased appetite and weight gain. Peet (2004a) notes that insulin resistance has been found in people with schizophrenia prior to discovery of antipsychotic medication and in drug naïve people (Fig. 121.3).

121.2.2 The Contribution of Diet to Health Outcomes

Diet plays a large part in contributing to these poor health outcomes for people with schizophrenia. McCreadie (2003) compared the dietary habits of community-dwelling people with schizophrenia to the general population, using the Scottish Health Survey. He found that the consumption of fresh fruit, vegetables, skimmed or semi-skimmed milk, potatoes, pasta or rice, and pulses by males reached less acceptable levels than by males in the general population. However, males with schizophrenia consumed breakfast cereal more frequently than their counterparts. Females with schizophrenia consumed less acceptable levels of skimmed or semi-skimmed milk, potatoes, pasta, or rice than females in the general population. The Scottish dietary targets for the period of the study was for 400 g of fruit per day or 35 portions per week. The mean number for the schizophrenia group was 16 portions of fruits and vegetables per week. These comparisons were made with people within the
Fig. 121.3 Comparison of those people who smoke in England and Wales (Nocon and Sayce 2008). This figure compares two groups of people, those with schizophrenia and those in the general population who smoke in England and Wales; figures are in percentages

general population that were unemployed and on state benefits and in social class V. In his review of dietary studies, Peet (2004a) found that people with schizophrenia consumed less dietary fiber and antioxidant vitamins, than control groups and consumed more saturated fats and sugars. The McCreadie study involved participants who were making choices about their diet and they chose less healthy food options. Where antipsychotic medication increases appetite and where people make choices of less healthy options then they are likely to choose less healthy foods in greater amount when they have an increased appetite.

Diet is partly determined by social and political factors such as social class; however, lifestyle and dietary habits can be modified and so the effects of poor diet can be preventable. This has been borne out by studies reporting the results of diet and physical activity programs with people who have schizophrenia. Twenty-eight people with schizophrenia, rated as obese as measured by scoring 27 or above on the body mass index, were placed on a calorie-controlled diet (1,300–1,500 calories for women and 1,600–1,800 calories for men) and a 6-month regime of physical activity (60 min level walking and walking on stairs three times per week). Results showed a significant decrease in body weight, body mass index (5.4%), and waist circumference (3.3 cm; Wu et al. 2007). These results do show that dietary habits can be modified; however, all the people in the trial were in-patients and very little detail is given about the methods used to maintain compliance to the program and the amount of independent dietary choice that was given to those in the trial. As the majority of people with schizophrenia live in the community it is important to know how to support and maintain these dietary changes outside of the hospital and its influence. Weight loss of 6.19 kg compared with 1.6 kg weight gain in the control group was found after a 3-month structured diet program in 32 people with schizophrenia who were out-patients (Nese 2008). Group delivered educational interventions can reduce weight gain in comparison with a control group but the weight loss is less than for other more structured interventions (Littrell et al. 2003). McCreadie et al. (2005) randomly allocated 102 people with schizophrenia to groups which received free fruits and vegetables for 6 months and instruction in meal planning and food preparation, free fruits and vegetables or as normal diet. Those in the group receiving free fruits, vegetables, and instructions were consuming significantly more fruits and vegetables than those on the diet as usual. This change was not sustained after the intervention was withdrawn (Fig. 121.4) (McCreadie et al. 2005).

Percentage comparison of those people who are obese
Fig. 121.4 Comparison of those people who are obese in England, Scotland, and Wales as measured by the body mass index (McCreadie 2003; Nocon and Sayce 2008). This figure compares two groups of people, those with schizophrenia and those in the general population who are considered to be obese as measured by the body mass index in England, Scotland, and Wales; figures are in percentages

121.2.3 Nutrition, Diet, and the Outcomes for Schizophrenia

121.2.3.1 Celiac Disease/Gluten Intolerance and Schizophrenia

Autoimmune diseases have been linked to schizophrenia. A history of autoimmune disease was found to be associated with a 45% increase in the risk for schizophrenia in subjects and their parents when compared with people who did not have schizophrenia (Eaton et al. 2006). In this study using subjects where the autoimmune disease had occurred prior to the onset of schizophrenia five autoimmune disorders were more prevalent than others. Celiac disease or gluten intolerance was one the diseases identified in the study (Table 121.2). An association between celiac disease and schizophrenia had already been investigated prior to 2006. Celiac disease is one that causes inflammation and damage to the villi in the small intestine. Gluten is a protein found in wheat, barley, rye, and oats. It is made up of two other proteins gliadin and glutenin. When gluten is ingested the body's immune system activates antibodies that attack the villi. These are finger-like structures and when damaged by the antibodies are unable to absorb water, vitamins, and other essential nutrients. As well as intestinal signs such as diarrhea and irritable bowel a number of neurological signs such as cerebral ataxia, peripheral neuropathy, dermatitis herpetiformis, and myopathy have commonly been linked to celiac disease (Reichelt et al. 1990). It has been noted that celiac disease can be asymptomatic which may mean that the disease may go undiagnosed in the general population and may be as high as 16% in people with undiagnosed neurological problems (Bradford et al. 2008). Testing for the presence of IgA antiendomysial and anti-tissue transglutaminase antibodies is considered to be a specific and sensitive test for the disease (Volta et al. 1991). Earlier anthropological studies had found a correlation between the scarcity and lower consumption of wheat grains during World War II and a reduction in the admissions for schizophrenia. Conversely in countries where there was an increase in wheat consumption admissions for schizophrenia increased. This relationship was further confirmed when countries that had initially had lower wheat consumption increased their wheat consumption there was an equivalent increase in the prevalence of schizophrenia (Reichelt et al. 1990). In an epidemiological study of 7,997 Danish people with a first admission for schizophrenia

Table 121.2   Key features of celiac disease

1. Celiac disease is caused by an intolerance or sensitivity to gluten.
2. Gluten is a protein found in wheat, barley, rye, and oats. It is made up of two other proteins gliadin and glutenin.
3. Villi are finger-like structures that emanate from the wall of the intestine; their function is to slow down the passage of food through the intestine so that the villi can absorb the nutrients from the food.
4. When gluten is ingested the body's immune system activates antibodies that attack the villi.
5. When damaged by the antibodies the villi are unable to absorb water, vitamins, and other essential nutrients.
6. As well as intestinal signs such as diarrhea and irritable bowel a number of neurological signs such as cerebral ataxia, peripheral neuropathy, dermatitis herpetiformis, and myopathy have commonly been linked to celiac disease (Reichelt et al. 1990).
   Celiac disease affects between 0.3% and 1% of the European population. The prevalence of celiac disease is 1:200 in the European population and 1:100 in the USA (Kalaydjian et al. 2006). Exact figures are difficult to calculate because there may be many undiagnosed cases due to the different ranges of presenting symptoms and that people do not always experience obvious symptoms.

This table defines celiac disease, the mechanisms of the intestinal structures called villi, and the effects of gluten intolerance on those structures. The table further provides a list of the main signs of celiac disease and an approximation of the prevalence

with a known maternal identity four people, five mothers, and three fathers were receiving treatments for celiac disease (1.5 per 1,000). Each subject in the study was matched by gender and year of birth with 25 controls. The authors calculated that the relative risk for schizophrenia from celiac disease was 3.2 ($P < 0.0001$; Eaton et al. 2004). Although the risk appears high because of the rarity of both disorders this risk can only account for a small number of cases of either disorder. Critics point out that the inclusion of the data from parents in the study is potentially misleading and if this data was excluded form the study then the prevalence of celiac disease in people with new onset schizophrenia would have been 0.5 per 100 which is the same as the control group (Campbell and Foley 2004). Previous studies had also found comorbid celiac disease and schizophrenia (Dohan 1983). The prevalence of known celiac disease is rare; it is 0.3–1% or lower and figures for the prevalence of schizophrenia in the general population is 4.5 per 1,000 or 0.45–1% (Kalaydjian et al. 2006; Tandon et al. 2008). This would make the finding of comorbidity unusual and significant. In their literature review, Kalaydjian et al. (2006) found that the proportion of people with celiac disease who also received a diagnosis of schizophrenia ranged between 1% and 4.2% in the studies reviewed. Gliadin antibodies have been found to be more prevalent in people with schizophrenia than in control groups (Kinnell et al. 1982). It has been stated that 30% of schizophrenia sufferers have high levels of antibodies against wheat gluten in their body (Dr. Jun Wei, BBC Website April 21, 2009). Toxic responses to gluten have been found where cats and rats have been given wheat gliadin and gluten. Responses have included changes in behavior and central nervous system monoamines and decreases in dopamine beta hydroxylase activity (Reichelt et al. 1990). Dopamine is a neurotransmitter that has been implicated in the causation of schizophrenia. This hypothesis is based on the premise that the symptoms of schizophrenia are due to overactive dopamine signal transduction (Seeman and Kapur 2000). Two key observations support this hypothesis: first antipsychotic medication particularly the phenothiazines have an antagonistic effect and have the action of promoting binding and hence blocking dopamine receptors. This results in the reduction of activity in dopaminergic tracts and alleviates the symptoms of schizophrenia (Van Rossum 1967). It has been found that phenothiazines have a specific affinity for the dopamine receptor D2. Secondly, observations show that amphetamine administration induces behaviors and symptoms similar to those of schizophrenia. Dopamine theories of schizophrenia postulate that as the use of amphetamines influence the levels of the neurotransmitter dopamine in the brain then schizophrenia is also caused by increased dopamine or the overactivity of dopamine receptors.

121.2.4 Clinical Evidence

Evidence suggests that a gluten- and casein-free diet can significantly influence the course of relapse and recovery of schizophrenia symptoms (Table 121.3). Studies have experimented by removing and then blindly reintroducing gluten and casein to the diet of people with schizophrenia who were hospitalized. Those on gluten-free diets for 10 days were discharged twice as quickly as those on the higher gluten diet (77 days vs 139 days; Dohan 1966). In a later study 47 men with schizophrenia were randomly assigned to a gluten-/casein-free diet on admission to a locked ward and compared with 55 men who were given a high cereal diet. Sixty-two percent of men on the gluten-/casein-free diet were released to an open ward quicker than those on a high cereal diet. In a replicated study that provided the same results gluten was blindly reintroduced and the observed benefits were reversed (Dohan et al. 1969). A similar study design found that the reintroduction of gluten and casein after a period of gluten- and casein-free diet showed an interruption of therapeutic improvement as measured by psychopathology, affect, and participation ratings in people with schizophrenia and continued improvement was shown when the gluten and casein were removed from their diet (Singh and Kay 1976). These findings were unrelated to changes in antipsychotic treatment. Two later studies using the same study design did not find the same pattern of results. Eight people with chronic schizophrenia were placed on a gluten-, cereal-, and milk-free diet, when gluten was reintroduced to their diet there was no consequent deterioration in schizophrenia symptoms as measured by the Brief Psychiatric Rating Scale. There was also no evidence of an inflammatory response (Potkin et al. 1981). No differences were found in a group of four people with schizophrenia after a 36-week period of gluten-free diet (Osborne et al. 1982). Studies with small numbers are likely to miss the small subset of people who have both celiac disease and schizophrenia (Kalaydjian et al. 2006).

Table 121.3 Details of the trials and results of gluten-/casein-free diets with people who have schizophrenia

Study	Study Design	Sample	Intervention	Outcome
Dohan (1966)	Blind comparison.		Gluten-free diet for 10 days.	Average length of stay: 77 days, gluten-free diet, 139 days, gluten-containing diet.
Dohan et al. (1969)	Blind randomized trial.	102	47 gluten-/casein-free diet, 55 high cereal diet.	62% on gluten-/casein-free diet versus 36% discharged to nonlocked wards after 7 days,
Singh and Kay (1976)	Blind control trial.	14	Gluten-/casein-free diet for 6 weeks followed by reintroduction of gluten/casein.	Improvement in psychopathology and social avoidance and exacerbation of psychopathology/ interruption of therapeutic progress during reintroduction of gluten/casein.
Potkin et al. (1981)	Double blind trial.	8	Gluten-/cereal grains-/ milk-free diet, gluten challenge reintroduction of 30 g of gluten for 5 weeks versus placebo for 8 weeks.	Serum alpha-1 acid glycoprotein measures no evidence of inflammatory response to gluten challenge and no deterioration in clinical status.
Vlissides et al. (1986)	Double-blind control trial.	24	Gluten-free diet vs gluten-containing diet for 14 weeks.	Improvements in behavioral dimensions as measured by psychotic in-patient profile; two relapsed during gluten challenge.

This table provides summary details of the authors, study design, numbers of participants, types of dietary intervention, and results of the studies of gluten-/casein-free diet trials with people who have schizophrenia

Beneficial changes were found in a group of 24 hospitalized people with schizophrenia/psychotic disorders as rated by the Psychotic in Patient Profile when they were given a gluten-free diet. However, there was no deterioration when gluten was reintroduced into their diet (Vlissides et al. 1986).

121.2.5 Explanatory Theories

A number of theories have been hypothesized to explain the relationship between gluten intolerance and schizophrenia. Although there is no definite evidence to point to a causal relationship between the two phenomena gluten-induced inflammatory processes may provide clues as to the development of schizophrenia. Initially, explanations were that the psychoactive ingredients in casein and gluten may be pathogenic for people who are genetically vulnerable to having schizophrenia (Dohan et al. 1969). Investigations of the common immunological responses between people with schizophrenia and those with celiac disease have found a decrease of IgA titers in people with schizophrenia and a similar deficiency in 2–3% of people with celiac disease. Raised levels of immunomodulating agents have been found in both groups and have been associated with duration of schizophrenia symptoms (Kalaydjian et al. 2006).

One category of immunomodulating agent cytokines are made up of peptides; an excess of urinary peptides were found in people with schizophrenia (Reichelt et al. 1990). This finding could be evidence of an immunomodulating process that influences the course of schizophrenia. The peptides themselves could influence brain functioning. The peptides found in the Reichelt et al. (1990) study were opioid peptides formed during digestion of the gluten and which if taken up across the blood–brain barrier can have active effects on brain functioning and neurotransmitter levels (Kalaydjian et al. 2006).

Genetic/environmental interactions have tended to dominate explanations. Explanation points to a shared genetic vulnerability to both celiac disease and schizophrenia in a small number of people and that gluten is the environmental trigger. Studies have sought to investigate the proximity of genes that have been implicated in the development of both celiac disease and schizophrenia. Tandon et al. (2008) identify three types of study design used in schizophrenia genetic research:

1. Linkage studies are used to identify specific genetic markers and chromosomes where deviant genes are situated on the human genome. These studies observe variations and abnormalities within chromosomes. Chromosome 11q23–25 and 2q11–13 have been linked to celiac disease which overlaps with chromosome 11q22.3–24.1 which has been linked to schizophrenia. The CLDN5 gene in chromosome 22 and the DQBI gene 6p21.3 are linked to the vulnerability of both celiac disease and schizophrenia (Ye et al. 2005).
2. Association studies seek to identify which gene variations modify the risk for schizophrenia. They provide evidence about the genetic markers for schizophrenia. The most common design of studies is to compare clinical (schizophrenia) and nonclinical (no schizophrenia) gene variant samples to identify those specific gene variants and the frequency of those variations that could provide a vulnerability to schizophrenia. The genetic marker for celiac disease 6p23–P22.3 is situated adjacent to the disbindin locus which has been linked to schizophrenia. Tissue transglutaminase 2 (TGM2) is involved in the production of gliadin antibodies. Single nucleotide polymorphisms (SNPs) are variants within genes that are expressed during the process of new cell development. In a sample of 131 family trios each with an offspring who has schizophrenia eight SNPs present in the TGM2 gene were found to be excessively transmitted to effected offsprings and could be implicated in the development of schizophrenia (Bradford et al. 2008). Methylation

is the reversible biochemical modification of DNA. Faulty DNA methylation may affect the expression of genes by silencing a gene which can affect the stability of chromosomes which then contributes to the development of complex multifactorial conditions such as schizophrenia. Diet is a source of methyl and can contribute to DNA methylation (Singh et al. 2003). Folic acid and other vitamins contribute significantly as a source of methyl. There are three important issues: first, the generic malabsorption as an effect of celiac disease will mean a deficiency of folic acid and an influence on DNA hypomethylation. Secondly, polymorphisms C677 > T and C1298A in the methylenetetrahydrofolate reductase (MTHFR) gene has been linked to problems with the production of DNA methylation. Thirdly, polymorphisms in the MTHFR gene have also been implicated in the development of schizophrenia. Two polymorphisms of the MTHFR gene, 677C > T and A 1298C was found in 44 people with schizophrenia compared with 35 controls; 66.7% of the schizophrenia group compared with 34.3% in the control group had the T allele of the 677C > T polymorphism. Measurement of the positive, negative, and general symptoms of schizophrenia showed a greater intensity of symptoms in those people with the 677C > T allele (Mavros et al. 2008).

121.2.6 Diet, Neurotrophins, Polyunsaturated Fatty Acids and Schizophrenia

Brain-derived neurotrophins are proteins within the central nervous system that provide nutrients for neurons and support for changes in the connection between neurons (synaptic plasticity). Deficient levels of brain-derived neurotrophins have been associated with more severe schizophrenic illness (Tan et al. 2005). A hypocalorific diet was found to increase the levels of serum brain-derived neutrophins (Guimaraes et al. 2008). A low tryptophan diet was associated on improved performance on the Stroop Color and Word Test indicating no abnormalities in frontal lobe functioning and improvements in psychotic symptomatology in a group of 11 people with schizophrenia (Rosse et al. 1992).

Data published by the Agriculture Organization of the United Nations an ecological study found a correlation between a higher national dietary intake of refined sugar, saturated fat, and dairy products and a worse 2-year outcome for schizophrenia (Peet 2004b). High sugar and high fat diet leads to reduced brain expression of brain-derived neurotrophic factor which is important for the outgrowth of dendrites (Peet 2004b). Polyunsaturated fatty acids (PUFA) make up 15–30% of the dry weight of the brain. Reduced levels of the two main types of PUFAs n6 and n3 have been found in the cell membrane of people with schizophrenia (Peet 2002). Neuronal membrane structure and metabolism is dependent on blood plasma levels of certain fatty acids (Joy et al. 2003). Inefficient fatty acid metabolism may increase the risk for schizophrenia and functional deficiencies of omega-3 fatty acids that are essential to brain development and may contribute to abnormalities of behavior, learning, and mood (Richardson 2003). Early trials of supplements enriched with PUFAs such as eicosapentaenoic acid (EPA) given in addition to antipsychotic medication showed positive results in terms of a reduction in both positive and negative schizophrenia symptoms (Peet 2002) (Table 121.4). Omega-3 fatty acids were found to correct positive and negative schizophrenia symptoms, cerebral atrophy, and an abnormal ratio of fatty acids in the cell membranes of a drug naive person with schizophrenia (Puri et al. 2000). A systematic review of the antipsychotic effects of omega-3 EPA analyzed the resul ts from five studies (*n* = 313) and found mixed results (Joy et al. 2003). Omega-3 EPA may have some antipsychotic properties when compared with placebo even if not given as supplement to antipsychotic medication. Where people were already taking antipsychotic medication they were found to have greater improvement in mental health compared to those receiving placebo supplement. Although there was less than 25% improvement in scores on PANSS

Table 121.4 Details of the trials of PUFAs for people with schizophrenia

Study	Study design	Sample	Intervention	Outcome
Holman and Bell (1983)	Double-blind crossover trial	13	Evening primrose oil with supplements.	No beneficial effects found but there is a possibility that evening primrose oil potentiates the epileptogenic properties of antipsychotics.
Wolkin et al. (1986)	Double-blind therapeutic trial	16	Prostaglandin precursor essential fatty acids	No beneficial effects on tardive dyskinesia
Fenton et al. (2001)	Blind placebo randomized control trial	87	3 g of ethyl eicosapentaenoate or placebo was given for 16 weeks as supplements to antipsychotic medications.	No difference was found between groups in terms of positive or negative symptoms, mood, cognition, or global impression ratings.
Peet and Horrobin (2002)	Blind placebo multicenter trial	115	Placebo or 1, 2, or 4 g of ethyl eicosapentaenoate was given for 12 weeks addition to typical and atypical antipsychotic medications.	In those given 2 g/day improvements were found in the PANSS and its subscales. There was a large placebo effect in those on typical and new atypical antipsychotic medications. There was a significant effect of ethyl eicosapentaenoate on all rating scales.

This table provides summary details of the authors, study design, numbers of participants, type and dosage of PUFAs used in the trial, and results of the studies of PUFA trials with people who have schizophrenia

the mental state of both medicated and unmedicated people was better if they received omega-3 EPA supplements (Joy et al. 2003). The authors recommended that large well-designed trials are required and needed.

121.3 Conclusions

There are physical health risks associated with having schizophrenia. These risks are associated with lifestyle, treatment effects, and smoking and result in obesity and premature death. Despite the political will to improve the health for this vulnerable client group clinicians need to develop healthy lifestyle initiatives. The service user group "RETHINK" has considered the factors that may have contributed to this situation and recommend antistigma training for GPs and the staff that work in their practices. They also recommend easier access and availability of smoking cessation courses in areas where people with mental health problems can attend. Health services have a responsibility to provide support with education regarding healthy eating choices, healthy options, food preparation, healthy lifestyle choices, activity and freely available fresh fruit and vegetables. Interventions should be designed for long-term delivery for people both in hospital and those living in the community.

Evidence suggests that there are a small number of people with celiac disease and also have a shared vulnerability to schizophrenia. This relationship has been confirmed in both anthropological and small clinical studies. The clinical studies have used only small numbers in their sample. Bearing in mind the small number of people with this shared vulnerability, studies require larger samples to determine the true effect of gluten-/casein-free diets on schizophrenia symptoms. Gene/environment interactions have been hypothesized as the mechanism for this shared vulnerability. However, genetic studies have failed to consistently identify a specific gene that is responsible for the shared vulnerability.

Studies have lacked precision and there is limited evidence of genetic variations being linked to specific symptoms. There appears to be a lack of consistency across the findings of the studies which inhibit the research community from drawing firm conclusions about the specific range of genes implicated in the development of schizophrenia, celiac disease, and the range of effects each of these genes have on the development of specific symptoms of schizophrenia. It is impossible to say which genetic variations lead to the development of auditory hallucinations or paranoid ideas.

Emerging ecological and clinical evidence suggest there is a link between high intake of saturated fats, refined sugar, and poorer outcomes for people with schizophrenia. Supplements of polyunsaturated fatty acids have also been linked to improvements in schizophrenia symptoms. The results from these clinical studies are promising but results from larger randomized controlled trials are needed.

121.4 Application to Other Areas of Health and Disease

There are implications for people with other serious mental health problems. Treatment for the manic phase of bi-polar disorder includes treatment with typical and atypical antipsychotic medications. The side effect of this treatment is weight gain and the tranquilizing effect may lead to a more sedentary lifestyle. Although the treatment with antipsychotic medication may be of shorter duration it may contribute to poorer physical health outcomes for people with this disorder. Health providers need to be aware of the types of physical health interventions being recommended by RETHINK.

There is some evidence to suggest that a small percentage of people have a shared vulnerability to both schizophrenia and immunological responses such as celiac disease. This knowledge has implications for health researchers. Shared vulnerability gives clues as to the etiology of schizophrenia. Already research has focused on the immunological pathway to elicit further clues. Shared genetic pathways should continue to be explored in order to develop replication, consistency, and more precision in findings.

One suggestion has been that untreated celiac disease in young people may lead to schizophrenia. Whilst there is limited evidence to support this hypothesis health practitioners need to be aware of the signs of celiac disease for early identification and treatment of the disease to avoid any future complications and potential links to mental health conditions.

PUFAs have been associated with improvements in not only schizophrenia symptoms but in depression. Health researchers need to explore the mechanisms by which these improvements are derived. Trials of PUFA's with other mental health conditions are required to increase our understanding of their wider effect. It would be of particular interest in those conditions that have a recognised pattern of neuronal deterioration such as dementia.

Summary Points

- People with schizophrenia are likely to die 10 years younger than other people because of their physical health.
- People with schizophrenia are more likely than other people to major health problems such as cardiac disease, stroke, hypertension, and diabetes.
- These higher risks have been calculated at two to four times higher for the rate of cardiovascular diseases and respiratory diseases and five times the rate for diabetes.
- Diet, lifestyle, psychiatric treatment, and diagnostic overshadowing contribute significantly to these risks.

- Both celiac disease (gluten intolerance) and schizophrenia affect 0.3–1% of the population. Anthropological studies have found a relationship between wheat consumption and hospitalization for schizophrenia.
- Biological studies have found gluten and gliadin antibodies to be more prevalent in people with schizophrenia than their relatives. Where people have been found to have both conditions a gluten-free/reduced diet has been found to provide beneficial outcomes in terms of a reduction in the positive symptoms of schizophrenia and reduced risks of hospitalization.
- Diet has been proposed as one of the environmental factors that influence the production of neutrophins or contribute to the expression or not of genes that have been implicated in the etiology of schizophrenia.
- Poorer outcomes in schizophrenia have been associated with a high ratio of saturated fatty acids to polyunsaturated fatty acids in the national diet and the consumption of refined sugar and dairy products. Reviews of trials of polyunsaturated fatty acid supplements for people with schizophrenia shows positive changes to schizophrenia symptom outcome when given along with or without antipsychotic medication.

Definition of Key Terms

Anthropological studies: Studies exploring the factors that contribute to the development of humankind, society, and civilization.

Antispsychotic medication: A term used to describe several categories of drugs that act on the functioning of the central nervous system in order to control behavior, emotion, and the distressing symptoms of schizophrenia and other psychoses. Their main effect is that of tranquilization and they have a wide range of troublesome movement, hormonal, and psychic side effects.

Gliadin: It is a protein combined with a carbohydrate, known as a glycoprotein and along with glutenin form gluten.

Gluten: A protein formed from the proteins gliadin and glutenin and is a constituent of wheat flour, barley, rye, and oats.

Lifestyle: Patterns of social relationships, culture, and consumption of material goods.

Polyunsaturated fatty acids: A group of unsaturated fatty acids where the carbon chain has two or more double or triple valence bonds per molecule. These include omega 3 and omega 6 and occur as linolenic acid and arachidonic acid. These acids are found in vegetable, fish, and seed oils.

Saturated fatty acids: A group of fatty acids that do not have the double or triple valence bond. Derived from animal fats or by the hydrogenation of unsaturated fatty acids.

Schizophrenia: A psychiatric syndrome characterized by severe thought disorder, disorders of perception, speech, and emotions, and behavioral and movement disturbances.

Chapter 122
Neuronal Circuits and Neuroendocrine Responses Involved in Dehydration Induced by Water Restriction/Deprivation

Zheng-Hua Zhu, Bai-Ren Wang, James S. McTaggart, and Li-Ze Xiong

Abbreviations

ACTH	Adrenocorticotropic hormone
AngII	Angiotensin II
AP	Area postrema
AQP4	Aquaporin-4
AV3V	Anteroventral third ventricle area
AVP	Arginine vasopressin
avPVN	Anteroventral part of PVN
BNST	Bed nuclei of the stria terminalis
CeA	Central amygdaloid nucleus
CNS	Central nervous system
CRH	Corticotropin releasing hormone
CVOs	Circumventricular organs
E	Estrogen
ECF	Extracellular fluid
ER	Estrogen receptor
Fos-LIR	Fos-like immunoreactivity
GABA	γ-aminobutyric acid
GFAP	Glial fibrillary acidic protein
HNS	Hypothalamo-neurohypophyseal system
ICF	Intracellular fluid
LPB	Lateral parabrachial nucleus
LSV	Ventrolateral septum
MCNs	Magnocellular neurosecretory cells
MeA	Medial amygdaloid nucleus
MnPO	Median preoptic nucleus
NE	Norepinephrine
NIL	Neurointermediate lobe
NO	Nitric oxide

NTS   Nucleus tractus solitarius
OT   Oxytocin
OVLT   Organum vasculosum of the lamina terminalis
PVN   Hypothalamic paraventricular nucleus
SFO   Subfornical organ
SON   Supraoptic nucleus

122.1 Introduction

Homeostasis in the face of physical or psychological stressors (such as dehydration, hemorrhage, restraint) is essential for an individual's health and survival. In these circumstances the stable state is maintained by a series of coordinated responses including neuroendocrine, immune and behavioral changes. A typical stress response consists of three parts: (1) sensory input, detected by specific receptors, (2) central processing systems, which integrate these signals, and (3) motor output, including the executive effectors. The hypothalamo–pituitary–adrenocortical (HPA) axis is involved in the reaction to a variety of stressors, but accumulating data show that additional, specialized central networks are involved in the responses to specific stressors (Van de Kar and Blair 1999; Watts 2001; Pacak and Palkovits 2001; Herman et al. 2003). Although adaptive stress responses are beneficial to health and survival, their persistent inappropriate activation may lead to disease and even mortality.

Body fluid homeostasis involves the maintenance of body fluid volume and osmolarity within an appropriate range. Dehydration by water restriction/deprivation causes changes in intracellular fluid (ICF) volume, extracellular fluid (ECF) volume, and sodium concentrations in plasma. These changes are detected by osmoreceptors and baroreceptors in the periphery and the brain, which activate or suppress behavioral and physiological responses such as water-seeking, water intake, and salt appetite. These responses counteract changes in the volume and osmolarity of fluids (a negative feedback response), maintaining homeostasis. Over the past 2 decades, several key components of the neuronal and neuroendocrine mechanisms underlying water/salt balance have been revealed, but in many cases the details are still not well understood (Johnson and Thunhorst 1997; Watts 2001; Antunes-Rodrigues et al. 2004). In this chapter we present a brief introduction to the changes in neuronal circuits, neuroendocrine, gene and glia responses, following dehydration.

122.2 Body Fluids

Body fluids consist of water containing a variety of dissolved substances, such as electrolytes and proteins, as well as cells, such as blood cells. In adults, body fluids constitute approximately 55% of female and 60% of male total body weight.

Body fluids are divided into three main compartments – ICF, interstitial fluid, and plasma – by the plasma membranes and the membrane of the vascular endothelial cells. ICF makes up two-thirds of total body fluids. ECF makes up the remaining one-third, comprising plasma and all other interstitial body fluids, such as lymph, cerebrospinal, pleural, pericardial, and peritoneal fluids. About 80% of ECF is interstitial fluid and about 20% of ECF is plasma. Na^+ is the major ion in ECF; therefore, the maintenance of its concentration is crucial for homeostasis of osmotic pressure.

The contents of the fluids are in constant motion, and exchange by filtration, reabsorption, diffusion, and osmosis between the three compartments, which maintains fluid volume at a fairly constant level and also correctly proportioned in each compartment at any given time. This dynamic equilibrium is crucial for the maintenance of an effective circulating volume, osmotic gradients, acid–base balance, normal action potentials in neurons and muscle cells, and secondary active transport.

122.3   Water Balance

Water is the main component of all body fluids and by far the largest single component of the body itself, accounting for 45–75% of total body weight. The percentage of water in a given person depends on a variety of factors, such as the amount of fat tissue, age, body size, and gender. Fat tissue contains approximately 20% water, while muscle mass contains about 65%, therefore lean people have a greater percentage of water than overweight people, since fat tissue contains much less water. The percentage is highest in infancy and decreases with age, and males have a higher percentage of body water than females since the latter have a greater percentage of subcutaneous fat.

The body can gain water (2,500 mL/day) by the ingestion of liquids (1,600 mL/day) and moist foods (700 mL/day), and also by the metabolic synthesis of water by various chemical reactions (200 mL/day). Water can be lost from the body via urine (1,500 mL/day), skin evaporation (500 mL/day), lung exhalation (300 mL/day), and elimination by the gastrointestinal tract (200 mL/day). Normally, the daily water gain is approximately equal to the water that is lost – water balance.

When water loss is greater than water gain, such as in conditions of water restriction/deprivation, there is an inevitable loss of ICF or ECF accompanied by an increase of the sodium concentration, leading to water translocation between different body fluid compartments and a decrease of cell and/or plasma volume, which in turn increases osmolarity. The ratio of intracellular to extracellular water largely reflects an osmotic equilibrium achieved by the relative concentrations of impermeable ions found in the two compartments. The concentration of extracellular sodium is the primary ionic factor determining this osmotic equilibrium. Thus, any net change in water or sodium alters not only fluid balance but also osmotic equilibrium, resulting in altered fluid distribution between the three compartments.

Therefore, it is difficult to absolutely separate water balance from sodium balance; hence when the term "fluid balance" is used, it typically means water and sodium balance. Consequently, regulation of fluid balance may be investigated experimentally by restriction or deprivation of water, but also by injection of hypertonic saline as both approaches deplete the ICF and/or ECF compartments.

Mammals counteract electrolyte and water imbalance via a variety of neural and endocrine mechanisms and signals – e.g. thirst, anti-diuretic hormone (ADH), aldosterone, atrial natriuretic peptide (ANP), and the sympathetic nervous system (the autonomic nervous system and renin–angiotensin system). ADH, also known as arginine vasopressin (AVP), is secreted by neurons in the central nervous system (CNS) and acts in the kidney to increase the permeability of the distal tubules and collecting ducts to water, which causes increased facultative reabsorption of water. Aldosterone and angiotensin II (AngII) increase Na^+ resorption by the renal tubules, leading to increased obligatory reabsorption of water. ANP decreases Na^+ resorption, leading to both decreased obligatory reabsorption and increased water loss in urine. Thirst is stimulated along with decreased saliva production, increase of the blood osmotic pressure, and decrease of blood volume and blood pressure, which

Table 122.1 Key features of water balance and dehydration

1. Water accounts for 45–75% of the total body weight
2. The ratio of water in a given person depends on such factors as the amount of fat tissue, age, body size, and gender
3. Normally, the daily water gain is approximately equal to the water lost, e.g. 2,500 mL/day in average
4. Dehydration happens when water loss is greater than water gain, which leads to an inevitable loss of intracellular or extracellular fluid and an increase of the plasma sodium concentration accompanied by thirst, anorexia, thermoregulation, even psychological behavior
5. To maintain water balance during dehydration, a variety of neural and endocrine mechanisms are activated, such as antidiuretic hormone (ADH), aldosterone, atrial natriuretic peptide (ANP), and the autonomic nervous system/ renin–angiotensin system.

result in stimulations of the hypothalamic thirst center through the activation of tactile receptors in the mucosa of dry mouth and throat, hypothalamic osmoreceptors, and the renin–angiotensin system, respectively. All these changes lead to the desire to drink, restoring normal fluid volume (see reviews: Johnson and Thunhorst 1997; Antunes-Rodrigues et al. 2004) (Table 122.1).

122.4 Central Osmoreceptors and the Hypothalamo-Neurohypophyseal System

Central osmoreceptors are located in the circumventricular organs (CVOs), which are specialized brain structures named for their proximity to the ventricles of the brain. The CVOs include the subfornical organ (SFO), organum vasculosum of the lamina terminalis (OVLT), median eminence (ME), neurohypophysis, and area postrema (AP). In addition to their periventricular midline location in the brain, they share certain common features such as an extensive vasculature lacking a blood–brain barrier (BBB). Therefore these cells are in direct contact with both plasma and cerebrospinal fluid and ideally placed to sense any change in ECF composition. CVOs also comprise of a dense population of a variety of peptidergic factor receptors, such as the AngII receptor, ANP receptor, estrogen receptor (ER), and atypical ependymal cells. Of the CVOs listed, only three (SFO, OVLT, and AP) contain neuronal cell bodies with efferent fibers extending to other brain regions and are referred to as the "sensory CVOs." Because their neurons are directly exposed to the chemical environment of the circulation, the sensory CVOs are thought to be responsible for sensing various kinds of circulating information, including the Na^+ concentration and osmotic pressure of the body fluids (Fig. 122.1a; see reviews: McKinley et al. 1994; Bourque and Oliet 1997; Zhang and Bourque 2003).

In addition to CVOs, an increase in plasma osmolarity is also detected by intrinsic osmoreceptors of magnocellular neurosecretory neurons (MCNs) in the hypothalamo-neurohypophyseal system (HNS; Bourque and Oliet 1997; Zhang and Bourque 2003). HNS is an important integrative system that mediates neuroendocrine responses. It consists of many MCNs located in the hypothalamic paraventricular nucleus (PVN) and supraoptic nucleus (SON). These neurons synthesize the neurohormones AVP and oxytocin (OT), and release them into the blood circulation via axonal projections from the SON and PVN to the posterior pituitary to modulate the balance of body fluids and osmolarity after dehydration (Fig. 122.1b; Van de Kar and Blair 1999; Pacak and Palkovits 2001; Herman et al. 2003; Antunes-Rodrigues et al. 2004).

Regulation of ECF volume and osmolarity depends on the coordinated action of multiple mechanisms that change intake and excretion of water and sodium. The involvement of central osmoreceptors and HNS in body fluid balance has been revealed over the previous 2 decades; however, many details still need to be investigated further.
Fig. 122.1 Brain nuclei and circuits involved in dehydration. (**a**) The central osmoreceptor complex and HNS. Cell bodies of magnocellular neurons in the SON and PVN project their axon to the posterior lobe of the pituitary where they release OT and AVP into the general blood circulation. They receive afferent inputs from central osmosensitive neurons located in the OVLT, SFO, MnPO, and AP. OVLT and SFO neurons also project to the MnPO. Indirect sensory input from peripheral osmoreceptors, coming via relays in the NTS, is also represented (Reprinted from Hussy et al. (2000). With permission) (**b**) Hypothalamic neuropeptidergic circuit that regulates body fluid and mineralocorticoid homeostasis. (1) Humoral inputs to the SFO; (2) humoral inputs through the AP; (3) viscerosensory neuronal inputs to the NTS; (4) ascending projections from the NTS to the perifornical and the paraventricular nuclei, as well as to AV3V; (5) AngII-containing neurons in the SFO with their projections to the medial preoptic area; (6) ANP-containing neurons in the OVLT and the medial preoptic area with supraoptic and paraventricular projections; (7) supraoptic and paraventricular vasopressinergic projections to the PP; (8) AngII-containing projections from the PF to the SFO; (9) ascending noradrenergic fibers from the ventrolateral medulla and PB to preoptic and magnocellular hypothalamic nuclei. *AC* Anterior commissure, *AP* area postrema, *AV3V* anteroventral third ventricle area, *F* fornix, *HNS* hypothalamo-neurohypophyseal system, *ME* median eminence, *MnPO* median preoptic nucleus, *NTS* nucleus of the solitary tract, *OC* optic chasm, *OVLT* organum vasculosum of the laminae terminalis, *PB* parabrachial nucleus, *PF* perifornical nucleus, *PP* posterior pituitary lobe, *PVN* hypothalamic paraventricular nucleus, *SFO* subfornical organ, *SON* supraoptic nucleus (Reprinted from Pacak and Palkovits (2001). 122.5 Responses in CNS to Dehydration

122.5.1 Brain Regions and Neuronal Circuits Involved in Dehydration

Many different techniques, such as electrolytic lesion, electrical and chemical stimulation, as well as immunohistochemistry, have been used to identify the brain areas, neural circuits, and neurotransmitters that regulate intake and excretion of water and sodium.

Recent studies have demonstrated that immediate early genes, such as *c-fos*, are expressed transiently in the CNS in response to neuronal activation, and these expression patterns correlate with findings from other methods, such as electrophysiological studies. Therefore, immunohistochemical staining of the Fos protein has been used extensively as a marker for cellular activation in the neuroendocrine system to reveal the neural circuits of body fluid homeostasis (Mckinley et al. 1994; Rawland 1998).

To map the brain areas that respond to dehydration, *c*-Fos protein expression (Fos-like immunoreactivity, Fos-LIR) was examined following chronic water restriction in Wistar rats (Zhu et al. 2006). After 1 week to allow for environmental adaptation and another week for water intake training (twice per day at fixed time points), animals were subjected to either normal drinking (drinking as in the training period, TW group), restricted drinking (once per day and nothing at the other drinking time, WR group), or restricted drinking plus empty water bottle stimulus (drinking once per day and an empty water bottle at other drinking time, EB group) for 3, 7, and 14 days, respectively. Physical responses to the dehydration included weight loss, increases of hematocrit (HCT), serum Na^+ concentration and corticosterone levels; behavioral responses included increased attacking and exploratory behavior. In the EB and WR groups these changes were associated with a significant increase of Fos-LIR expression in SFO, median preoptic nucleus (MnPO), AP, PVN, and SON. However, the time course of Fos expression in these two groups was different. In the EB group, the increase of Fos-positive cell number occurred earlier, often starting on day 3, and peaking on day 7. In the WR group, Fos expression in these nuclei increased more slowly, often starting on day 7, and peaking on day 14 (Figs. 122.2, 122.3, and 122.4). These results indicate that the response pattern in the brain differs depending on the duration and intensity of dehydration.

Ueta et al. studied the effects of 24 and 48 h water deprivation on the expression of *c*-Fos protein in the brain of inbred polydipsic mice, which exhibit extreme polydipsia without a lack of AVP, and compared the results with nonpolydipsic mice. In both groups of mice, water deprivation induced a significant increase in Fos-LIR in the PVN, SON, MnPO, OVLT, and SFO, while a far greater increase was seen in the MnPO, SFO, and AP in the polydipsic mice compared with the nonpolydipsic control mice, indicating that neurons in the CVOs are strongly activated by water deprivation in mice, especially polydipsic mice (Ueta et al. 1995).

Chae et al. examined Fos-LIR in the SON and PVN induced by 6–18 h water deprivation in the day and night cycle with an outbred laboratory population of white-footed mice, *Peromyscus leucopus*. In this study, 6 h of water deprivation produced a near-maximal increase in the number of cells positive for Fos-LIR in the SON and PVN during the dark period, when mice are active, whereas it only slightly affected the Fos-LIR during the light period, when mice are inactive and do not drink. During the day, as much as 12 h of water deprivation was required to increase the Fos-LIR to levels
Fig. 122.2 Behavioral responses after water restriction in experimental rats. Grooming is the main behavioral response in the normal drinking animals (Control, Con) as well as drinking twice-per-day animals (TW group). Actions of attacking and exploring are significantly increased in empty bottle stimulus rats (EB group), but only exploring in water restriction rats (WR group). Results are expressed as mean ± SEM, *n* = 6, *$P < 0.01$ vs. Con group (Reprinted from Zhu et al. (2006). With permission)
Fig. 122.3 Fos expression in rat brain at different time points following dehydration. The numbers of Fos-immunoreactive cells are increased in various areas/nuclei of the rat brain, such as SFO, MnPO, AP, PVN, SON, MeA, and LSV, after receiving water restriction stimulus (drinking twice-per-day, TW group; empty bottle stimulus, EB group; water restriction, WR group; normal drinking, Con group). Results are expressed as mean ± SEM, $n = 6$, $*P < 0.05$, $**P < 0.01$ vs. Con group. *AP* area postrema, *CeA* central amygdaloid nucleus, *LSV* ventrolateral septum, *MeA* medial amygdaloid nucleus, *MnPO* median preoptic nucleus, *NTS* nucleus of solitary tract, *PVN* hypothalamic paraventricular nucleus, *SFO* subfornical organ, *SON* supraoptic nucleus (Reprinted from Zhu et al. (2006). With permission)

comparable with those achieved at night. The circadian dependence of the changes in *c*-Fos expression in PVN and SON in response to water deprivation correlates with the circadian changes in behavioral and physical characteristics such as plasma osmolarity, weight loss, and water intake, demonstrating the activation of PVN and SON during dehydration (Chae et al. 1998).

Morien et al. examined the pattern of Fos-LIR in CVOs following 0–48 h water deprivation in rats under normal light–dark conditions (nLD) and reverse light–dark conditions (rLD). The number of Fos-positive cells increased with the duration of water deprivation in the SON, PVN, OVLT, MnPO, and SFO in both the nLD and rLD conditions. Furthermore, compared with the nLD groups, the rLD groups had significantly more Fos-LIR in SON and PVN after 5 or 24 h water deprivation, in the MnPO after 5 h, and in the SFO after 24 h water deprivation (Morien et al. 1999). Therefore, this study also demonstrates the activation of both the CVOs and HNS by water deprivation.

All these studies indicate that the activation of CVOs and HNS play an important role in the regulation of water balance during dehydration. The same phenomenon was also reported in many other investigations (see review: Rawland 1998). Moreover, certain other nuclei, such as ventrolateral
Fig. 122.4 Microphotographs showing the Fos expressions in PVN and SON after dehydration. c-Fos expression increased in a different pattern in PVN and SON depending on the duration and intensity of dehydration following 3, 7, and 14 days dehydration by drinking twice-per-day (TW), empty bottle stimulus (EB) and water restriction (WR), respectively. *PVN* hypothalamic paraventricular nucleus, *SON* supraoptic nucleus. Bar = 100 μm (Reprinted from Zhu et al. (2006). With permission)

septum (LSV), the medial part of the amygdaloid nucleus (MeA), the central part of the amygdaloid nucleus (CeA), NTS, the bed nuclei of the stria terminalis (BNST), and the lateral parabrachial nucleus (LPB), were also shown to be involved in dehydration (see review: Johnson and Thunhorst 1997; Rawland 1998; Pacak and Palkovits 2001). These data are consistent with our investigations, as Fos expression in the MeA, CeA, and LSV was also significantly increased in both the EB and WR groups, although the time course was slightly different between the two groups.

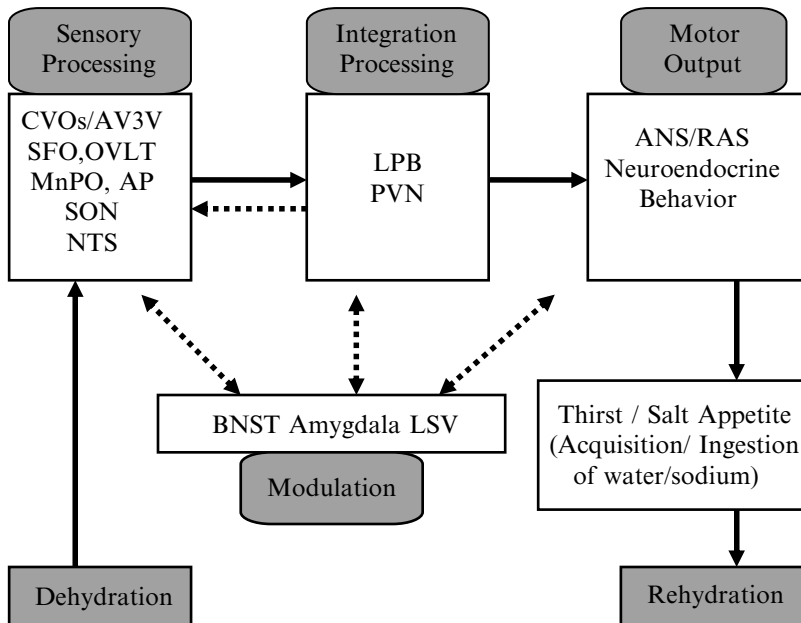
These immunohistochemical experiments suggest that numerous neuronal nuclei and circuits are activated during dehydration, and constitute a body fluid-related neural network (Honda et al. 1990;


Fig. 122.5 A schematic representation of central circuits modulating dehydration. There are three parts in the response process. (1) Sensing. The CVOs, including SFO, MnPO, OVLT, and AP (i.e., the sensory complex containing abundant osmoreceptors) are activated to sense changes in body fluid volume and osmolarity. All signals from these nuclei are directly or indirectly sent to SON and PVN. The NTS might act as a relay of peripheral signals. (2) Integration. The PVN and LPB integrate the information from the HNS and send output signals to change motor behavior. (3) Motor part. Neurons in SON and PVN, which receive signals from CVOs and intrinsic osmoreceptors, secrete OT and AVP into the general circulation to provoke drinking behavior through modulation on the ANS/RAS activity, neuroendocrine response, and behavior. Some other forebrain structures (such as BNST, LSV, amygdala) are considered to play important roles in the modulation of all these responses. *ANS* autonomic nervous system, *AP* area postrema, *AV3V* anteroventral third ventricle area, *BNST* bed nuclei of the stria terminalis, *LPB* lateral parabrachial nucleus, *LSV* ventrolateral septum, *MnPO* median preoptic nucleus, *NTS* nucleus of solitary tract, *PVN* hypothalamic paraventricular nucleus, *RAS* renin–angiotensin system, *SFO* subfornical organ, *SON* supraoptic nucleus, *OVLT* organum vasculosum of the lamina terminalis

Hussy et al. 2000; Watts 2001), as described in Fig. 122.5. Further studies are needed to elucidate the connectivity of these nuclei and how these connections are employed to regulate the response to dehydration.

122.5.2   Neuropeptides and Neurotransmitters in the CNS Involved in Dehydration

There is substantial data suggesting that the HNS mediates the neuroendocrine responses to dehydration. Axons of magnocellular neurosecretory cells (MCNs) projecting from the SON and PVN MCNs to the posterior pituitary release AVP and OT. The release of AVP and OT is determined largely by the rate and pattern of MCN firing, which is modulated by osmolarity. However, it is becoming apparent that the MCNs also receive signals from a wealth of afferents containing many classic neurotransmitters and other neuropeptides co-localize with AVP and OT in MCNs. These data suggest that the secretion of AVP and OT is modulated by a complicated neuropeptide/neurotransmitter response system.

122.5.2.1 AVP and OT

AVP and OT are involved in a wide spectrum of physiological functions, including the regulation of fluid homeostasis, cardiovascular regulation, emotion, social recognition, and reproduction, but are mainly known as the principle neuropeptides for the regulation of body fluid. AVP and OT are synthesized and stored in the cell bodies of SON and PVN MCNs. When a rise in plasma osmolarity is detected by intrinsic MCN osmoreceptors, or specialized osmoreceptive neurons in the CVOs that project to the MCNs, AVP and OT are released by the activated MCNs into the circulation from terminals in the posterior pituitary gland. They then travel through the blood stream to specific receptor targets in the CNS or peripheral tissue to modulate the autonomic system, renin–angiotensin system, and the kidney, leading to increased permeability of the collecting ducts and reducing the renal excretion of water, thereby promoting water conservation, anti-diuresis, and natriuresis.

Dehydration due to water deprivation or salt loading causes axonal transport and release of AVP and OT into the blood, which decreases the content of AVP and OT in the MCNs. This, of course, causes a significant increase in plasma AVP and OT concentrations, as well as increased electrical activity of vasopressinergic and oxytocinergic neurons of magnocellular hypothalamic nuclei (also seen as increased Fos protein expression in these neurons). AVP and OT mRNA levels in the MCNs are also increased. The magnitude of these changes is correlated with the duration of the dehydration and is also dependent on the time of day the dehydration started, paralleling to the rise of the blood plasma osmolality as well as the decrease of blood volume during dehydration. All these changes almost recover to the normal level after rehydration (Xiong and Hatton 1996; Johnson and Thunhorst 1997; Rawland 1998; Pacak and Palkovits 2001; Arnhold et al. 2007).

122.5.2.2 Classic "Local" Neurotransmitters Interacted with MCNs

MCNs receive a wealth of afferents including glutamatergic, GABAergic, catercholaminergic, cholinergic, serotonergic, and histaminergic axon terminals with the corresponding receptors located in the postsynapse and/or presynapse from the CVOs as well as other forebrain, midbrain, and hindbrain structures. Administration of agonists and antagonists of the receptors for these various neurotransmitters induces different neurohypophyseal hormone responses to dehydration. Therefore, these classic neurotransmitters are likely to be involved in the regulation of AVP and OT release (Johnson and Thunhorst 1997; Van de Kar and Blair 1999). For example, Di et al. showed that dehydration leads to an increase in glutamate and GABA release in the supraoptic MCNs, and there was a marked enhancement of norepinephrine (NE)-facilitated glutamate release and NE-inhibited GABA release (Di and Tasker 2004).

Recent studies have shown that nitric oxide (NO) in the brain may also play an important role in fluid balance by modulating AVP and OT secretion from the HNS. For example, NO synthase levels increase throughout the entire HNS during acute and chronic osmotic stimulation or water deprivation as shown by immunohistochemistry, in situ hybridization, and microdialysis studies. The drinking induced by water deprivation and AngII is inhibited by intracerebroventricular (i.c.v) injection of l-arginine (see review: Kadekaro 2004). The NO signaling cascade may regulate the release of AVP and OT by enhancing the expression of Ca^{2+}-activated K^+ channels (BK channels), which are colocalized in the supraoptic nuclei and neural lobe of rats (Kadekaro et al. 2006), or in part by facilitating the local release of glutamate/aspartate following water deprivation or osmotic challenge (Gillard et al. 2007).

122.5.2.3 Peptides Co-localized with AVP or OT in MCNs

Double-immunohistochemical staining techniques have shown that many neuropeptides colocalize with AVP and/or OT in MCNs. Some of these substances are involved in osmotic function such as AngII, corticotropin-releasing hormone (CRH), apelin (APL), galanin (GAL), and neuropeptide Y (NPY).

AngII: AngII-containing fibers and angiotensin receptor I are located in CVOs. AngII-containing cell bodies are found in several brain areas, including the SON and magnocellular parts of the PVN, where AngII is colocalized with AVP. Studies of lesions on anteroventral third ventricle area (AV3V) and i.c.v. injection of AngII indicate that AngII plays a critical role in dehydration-induced thirst, water intake, and salt appetite. This occurs through effects on the angiotensin receptor I (AT-I) or interaction with other hormones such as ANP and NO in regulating the release of AVP and OT (Johnson and Thunhorst 1997; Antunes-Rodrigues et al. 2004; Bundzikova et al. 2008).

CRH: CRH is expressed in several regions of the adult rat brain, but most prominently in PVN parvocellular neurons. CRH is known to mediate endocrine, autonomic, behavioral, and immune responses to stress. During osmotic stimulation, an increase of CRH-immunoreactivity was observed in oxytocinergic magnocellular neurons in the PVN and SON, and expression of CRH receptor-1 mRNA, which was undetectable in the SON and PVN in control rats, was also significantly increased, indicating direct regulation of AVP and OT neurons (Arima and Aguilera 2000). A study by Lauand et al. (2007) showed that a significant increase in plasma ANP, OT, AVP, and corticosterone levels was observed after i.c.v. microinjections of hypertonic NaCl, AngII, or carbachol. Pretreatment with dexamethasone decreased the plasma corticosterone and OT levels, with no changes in AVP secretion. Furthermore, significant increase in Fos-immunoreactive neurons was observed in MnPO, PVN, and SON after i.c.v. stimulation. These results indicate that central osmotic, cholinergic, and angiotensinergic stimuli activate MnPO, PVN, and SON, with subsequent OT, AVP, and ANP release. The responses are also modulated by glucocorticoids, the endpoint effector of the HPA axis, implying that CRH can also indirectly regulate the secretion of AVP and OT.

Apelin: APL, a neuropeptide recently identified as the endogenous ligand for the G-protein-coupled receptor APJ, is widely expressed in the CNS, especially highly concentrated and colocalized with both AVP and OT in the MCNs of the SON and PVN. APL is involved in several physiological processes, including the regulation of the cardiovascular system and immune response. Recently, it was shown that APL influences water regulation through AVP modulation. A study by Reaux et al. found that i.c.v. administration of APL significantly reduced water intake in the initial 30 min after re-exposure to drinking water, and lowered circulating levels of AVP in mice deprived of water (Reaux et al. 2001). Reaux-Le Goazigo et al. found that APL-immunoreactive neurons in the SON and PVN also contained AVP, but the two peptides were segregated to distinct subcellular compartments. Both the number and labeling intensity of magnocellular APL-immunoreactive cells increased significantly after 24 or 48 h dehydration, whereas the number and labeling density of AVP-immunoreactive neurons were significantly decreased. The dehydration-induced increase in APL immunoreactivity was markedly diminished by central injection of a selective AVP-1 receptor antagonist, providing additional evidence that the neuropeptide APL is involved in body fluid homeostasis regulation via cross-regulation of AVP release (Reaux-Le Goazigo et al. 2004). Another study also showed that AVP and APL are conversely regulated in the facilitation of systemic AVP release and the suppression of diuresis (Llorens-Cortes and Moos 2008).

Galanin: GAL, a 29/30-amino acid peptide originally isolated from the porcine intestine, is widely distributed in the rat CNS. It is involved in numerous physiological actions, including wake–sleep regulation, reproduction, nociception, cognition, as well as energetic and osmotic homeostasis. In the hypothalamus, GAL is particularly present in the preoptic area, PVN and SON, and the arcuate nucleus/median eminence. GAL mRNA and GAL immunoreactivity have been observed in the

MCNs of the SON and PVN, and are mainly colocalized with AVP, but also to a lesser extent with OT. During dehydration or salt loading, GAL mRNA levels increase in MCNs, while GAL protein immunoreactivity markedly decreases in PVN, SON, and posterior pituitary, with increase of expression of GAL-R1 receptors. In normally hydrated rats, i.c.v. injections of GAL did not affect the hypothalamic and neurohypophysial OT content, but distinctly increased the plasma OT concentration. GAL diminished the hypothalamic AVP content, but had no effect on neurohypophyseal AVP storage. In contrast, GAL administered i.c.v. to rats deprived of water, significantly inhibited AVP and OT release from the HNS, leading to a significant decrease of plasma AVP and OT levels. These results suggest that the modulatory effect of GAL on AVP and OT release is dependent upon the hydration of the animal. GAL acts as an inhibitory neuromodulator of AVP and OT secretion under conditions of dehydration, but stimulates this process in the state of equilibrated water metabolism (Ciosek and Cisowska 2003; Kozoriz et al. 2006; Lang et al. 2007).

Neuropeptide Y: NPY co-exists with AVP or OT in the magnocellular neurons of the PVN and SON. It influences cardiovascular function, feeding, anxiety, depression, epilepsy, neuroprotection, neurogenesis, and the regulation of water homeostasis. Under basal condition, the expression of NPY immunoreactivity is primarily within fibers of the PVN and SON, but a few NPY-immunoreactive cells have also been observed in the MCNs. Subjecting animals to osmotic stressors, either water deprivation or replacing the drinking water with hypertonic saline, significantly increases NPY and Y1R mRNA and protein expression in the PVN and SON. This indicates that the overall effect of increased NPY, with regard to water balance, is similar to that of AVP and OT (Larsen et al. 1993; Urban et al. 2006).

122.5.2.4 Other Substances Involved in Dehydration

Estrogens: Previous reports suggested that the estrogens (Es) influence body fluid balance, but the precise mechanism and site of their action, which allow them to carry out this role, were only recently revealed. The demonstration of ER in neural tissues that bear no direct relation to reproduction led to the hypothesis that the expression of ER in brain nuclei is critical for the maintenance of fluid osmolarity. In the rat brain, ERβ is prominently expressed in the AVP-expressing MCNs of the hypothalamus, whereas ERα is densely expressed in neurons of the sensory circumventricular organ in the basal forebrain. During resting conditions, ERβ is densely expressed on VP-expressing MNCs. During hyperosmolarity challenge, the expression of ERβ is significantly reduced both at the mRNA and protein levels – an effect that reverses when these neurons return to their osmotic set-point. In contrast, increased expression of the ERβ transcript was observed following experimental hyponatremia, a condition in which VP release is strongly inhibited. Thus, in the MCNs, ERβ expression varies inversely with VP release, and consequently, to changes in plasma osmotic pressure. In addition to the proposed roles of ERα in mediating fluid intake through the CVOs, it is also likely to regulate the activity of the magnocellular neurons through a regulation of the output signal sent to MCNs from the forebrain osmoreceptive in the basal lamina terminalis region so as to influence magnocellular neuron ERβ expression (see the review: Sladek and Somponpun 2008).

Orexin: Rodents display increased locomotor exploration when dehydrated as shown in Fig. 122.2, a behavior that improves the likelihood of locating new sources of water while simultaneously placing additional demand on the already compromised water levels. However, the mechanisms underlying this increased exploration are unclear. Recently, Tsunematsu et al. (2008) shed new light on the matter. They found the AVP-induced activation of orexin-expressing neurons might be involved in this response. In this study, AVP and OT directly induced depolarization and an inward current in orexin neurons. AVP-induced activation of orexin neurons was inhibited by a V1a receptor (V1aR) selective antagonist, but was not observed in V1aR knock-out mice. Furthermore, i.c.v.

administration of AVP or water deprivation increased locomotor activity in wild-type mice, but not in transgenic mice lacking orexin neurons and V1aR knock-out mice were less active than wild-type controls. These results suggest that the activation of orexin neurons by AVP has an important role in the regulation of spontaneous locomotor activity in mice, which increases the likelihood of locating water when dehydrated.

Obestatin: Recently, Samson et al. showed that dehydration-induced AVP secretion was inhibited by obestatin in a dose-dependent manner without affecting the plasma OT levels. Central administration of antiobestatin antibodies resulted in an exaggerated basal AVP release and an increased AVP response to overnight water deprivation. Antiserum treatment also resulted in significantly increased *ad libitum* water drinking, as well as drinking in response to dehydration. These data indicate that obestatin may be an important contributor to the maintenance of fluid and electrolyte homeostasis by the regulation of drinking and AVP release (Samson et al. 2007, 2008).

Other proteins: Gouraud et al. used two-dimensional fluorescence difference gel electrophoresis to investigate the dehydration-induced changes of proteomes in SON and pituitary neurointermediate lobe (NIL). Seventy proteins were altered by dehydration including 45 in NIL and 25 in SON. Using matrix-assisted laser desorption/ionization mass spectrometry, some of these proteins was identified. Six proteins in NIL were identified (two upregulated, four downregulated) and nine proteins in the SON (four upregulated, five downregulated). The important of five of these proteins – heat shock protein 1alpha (Hsp1alpha), neuronal axonal membrane protein 22 (NAP22), 58 kDa glucose-regulated protein (GRP58), calretinin, and proprotein convertase subtilisin/kexin type 1 inhibitor (ProSAAS) – has been confirmed using other methods such as semiquantitative western blotting, two-dimensional western blotting, enzyme-linked immunoassay, and immunohistochemistry. Thus, these proteins may also play roles in both regulating and effecting HNS remodeling during dehydration (Gouraud et al. 2007).

Taken together, these studies indicate that the HNS undergoes a dramatic, function-related plasticity during dehydration. In addition to the direct activation by water and/or salt imbalance, the release of AVP and OT are also modulated by many other factors, such as glutamatergic, GABAergic, noradrenergic synapses and AngII, CRH, APL, GAL, NO, obestatin, orexin, and E.

122.5.3 Glial Cells in CVOs and the HNS in Response to Dehydration

122.5.3.1 New Insights into the Function of Glia in the CNS

The brain is composed of two major cell types, neurons and glia. Glial cells are divided into two major classes: microglia, which regulate the inflammatory response of neural tissue to injury or infection, and macroglia, which are composed of ependymal cells, oligodendrocytes, Schwann cells, and astrocytes. Astrocyte, the most numerous glial cell type accounting for one-third of the brain mass, has irregularly shaped cell bodies and is characterized by the expression of glial fibrillary acidic protein (GFAP) and an abundance of leaflet-like processes that maintain contact with blood vessels, neurons, and other glial cell types. Astrocytic processes rarely extend beyond a 50-μm radius, indicating that they exert largely local control. However, the propagation of Ca^{2+} waves through networks of astrocytes may affect the activity of distant neurons integrated into different neuronal circuits (Garcia-Segura and McCarthy 2004).

Though glial cells significantly outnumber neurons, they have been considered to be supportive – the "glue" that provides structural support to neurons – rather than functional. However, recent studies have revealed an important role for glia in homeostatic and neuronal modulatory functions,

including maintenance of the BBB, regulation of water and ion homeostasis and amino acid neurotransmitter metabolism, as well as energy and nutrient supply to neurons.

There is only limited evidence that glial cells contain vesicles and release transmitters in a similar way to neurons. However, it has become clear that these cells are functional components of the CNS, as they express receptors for most neuroactive compounds, including neurotransmitters and hormones, and show excitability based on intracellular Ca^{2+} alterations. Glial cells integrate signals from neurons and other glial cells, including hormonal inputs.

122.5.3.2 Role of Glia in Neuroendocrine Function

Glial cells express many of the same hormone receptors as found on neurons, such as the receptors for melatonin, thyroid, and steroid hormones, AVP, OT, leptin, CRH, and insulin. Hormones are also a critical component of neuronal/glial cross talk, leading to neuromodulatory and neurotrophic actions under physiological and pathological conditions (Newman and Volterra 2004). For a recent review of the participation of glial cells in the regulation of hormonal secretion by hypothalamic neurons, see Garcia-Segura and McCarthy (2004).

122.5.3.3 Role of Glia in the Regulation of Water and Salt Imbalance Induced by Dehydration

Astrocytes are highly complex cells that respond to a variety of external stimuli. The housekeeping role of astrocytes requires that they both sense and respond to many signals, including changes in energy supply, neuronal activity, extracellular ion concentrations, and osmolarity. Maintenance of a stable internal osmotic environment is essential for normal cerebral activity. Recently, an abundance of data has shown that astrocytes play an important role in maintaining tight control of water and ionic homeostasis via sodium-level-sensitive sodium channels (Nax), aquaporin-4 (AQP4) water channels, and taurine in CVOs and/or HNS and pituitary (Hussy et al. 2000; Simard et al. 2004).

Glial Morphological Change in the HNS and Pituitary During Dehydration

Dehydration induces profound alterations in HNS activity, a process known as function-related plasticity. Such plasticity may occur through glial-mediated alteration of neuropeptides/neuromodulators, as discussed before, but also by morphological change in the HNS and pituitary. These morphological changes may be grouped into three distinct varieties (Theodosis et al. 1998; Miyata et al. 2001; Virard et al. 2008).

The first is reversible "glial retraction" in the MCNs, which is thought to be mediated by reorganization of the astrocytic cytoskeleton, astrocytic reorientation, and astrocytes reentering the cell cycle. Under normal conditions, MCN somata are separated from their neighbors by fine astrocytic processes and/or neuropil. Following dehydration, the astrocytic covering of the MCN somata and dendrites is significantly reduced and becomes thin, such that the neuronal surfaces are extensively juxtaposed.

The second is pituicyte stellation. In the posterior pituitary, neurohypophyseal astrocytes (pituicytes) proliferate in response to local factors present during neurosecretory activity. Pituicytes also exhibit dynamic and reversible interactions with axon terminals and blood vessels, suggesting a role in the control of hormone release. In euhydrated conditions, when demand for hormone is low, pituicytes

engulf secretory endings and are interposed between the terminals and the basal lamina. In order to enter the fenestrated capillaries, hormone molecules must pass through the basal lamina into the perivascular space. Pituicyte interposition is thus a barrier to hormone entry into the circulation. During dehydration, pituicyte processes retract, enhancing neurovascular contacts by rearrangement of terminal-astrocyte and terminal-vessel contacts, rather than enlargement or sprouting of magnocellular terminals themselves, allowing increased occupation of the pericapillary basal lamina by nerve terminals and direct access to the perivascular space.

The third is reduction of the GFAP levels. Glial morphology is determined by cytoskeletal elements such as microfilaments, intermediate filaments, and microtubules. GFAP is the major constituent of the astrocytic cytoskeleton and is widely used as functional marker of glial cells. A significant reduction in GFAP-like immunoreactivity is observed in the SON as a result of dehydration, reflecting a possible role in the mediation of changes in cell shape (Hawrylak et al. 1998).

Glia and Nax in CVOs

Sodium is the major ionic component of ECF, and sodium homeostasis is inseparably linked with body fluid control. Thus, the dynamic regulation of Na^+ and water intake is essential to life. When an animal is dehydrated, the Na^+ concentration in body fluids increases, and therefore the plasma osmolarity increases by 5–10%. Although the CVOs are thought to be responsible for body-fluid homeostasis through the osmoreceptors, AngII/AngII receptors or ANP/ANP receptors, the system for sensing Na^+ levels within the brain, remains to be elucidated. Recently, studies have identified a putative Na^+ sensor – the Nax channel – located on glial cells in the CVOs within the brain and distinct from the osmosensor. These channels are able to detect an increase of Na^+ in body fluids and are involved in regulation of water/salt balance.

The Nax channel, formerly called NaG/SCL11 (in rats), Nav2.3 (in mice), and Nav2.1 (in humans), has been classified as a subfamily of voltage-gated sodium channels (Fig. 122.6a). The gene encoding Nax is designated as SCN7A. The primary structure of Nax, however, markedly differs from that of other voltage-gated sodium channel family members even in the key regions for voltage-sensing and inactivation. Noda and his colleagues have elucidated the role of these Nax channels in body fluid balance by generating a transgenic mouse with the *lacZ* reporter gene inserted in the reading frame of the Nax gene, resulting in a null phenotype (*Nax*$^{-/-}$).

lacZ expression in the brains of *Nax*$^{+/-}$ and *Nax*$^{-/-}$ mice was found in specific loci in the CNS, including the CVOs (SFO, OVLT, ME, and NHP) and several other minor nuclei (Fig. 122.6b). In *c*-Fos immunohistochemistry experiments, Fos-LIR-positive cells were not detected in any region of the CVOs of these mice when water was available; however, at 12, 24, and 48 h after water deprivation, there was significant Fos-LIR in the CVOs in both mice. The increase of FOS-LIR was particularly notable in the SFO and OVLT, where approximately twice as many Fos-positive nuclei were observed in *Nax*$^{-/-}$ mice as compared with *Nax*$^{+/+}$ mice. These results suggest that *Nax*$^{-/-}$ mice show increased neural activity in the SFO and OVLT after water deprivation compared with wild-type (*Nax*$^{+/+}$) controls (Watanabe et al. 2000).

Double-immunostaining and immuno-electron microscopic analyses have revealed that Nax are exclusively localized to perineuronal lamellate processes extending from ependymal cells and astrocytes in SFO and OVLT, and no significant immunopositive signals are detected in neuronal cell bodies and their processes, including synapses. Furthermore, in SFO cells from *Nax*$^{+/+}$ mice, all the sodium-sensitive cells are Nax immunopositive, whereas no sodium-sensitive cells were observed in SFO cells derived from *Nax*$^{-/-}$ mice, indicating that sodium-sensing cells in the SFO are almost exclusively glial cells. Further studies with *GAD-GFP* knock-in mice suggest that glial lamellate processes
Fig. 122.6 Specialized sodium channel Nax for sodium-level sensing (**a**) phylogenetic tree of mammalian voltage-gated sodium channel subunits; (**b**) expression loci of Nax in the adult CNS. The Nax-positive circumventricular organs (CVOs) in the mid-sagittal section are schematically represented. Of note is that the AP was negative for *lacZ* expression. *AP* area postrema, *SFO* subfornical organ, *OVLT* organum vasculosum laminae terminalis, *ME* median eminence, *NHP* neurohypophysis (Reprinted from Noda (2007). expressing Nax channels contact various neurochemical circuitries in the SFO and OVLT, encompassing GABAergic interneurons in the SFO (Watanabe et al. 2006).

Infusion of a hypertonic Na$^+$ solution into the cerebral ventricle caused increased water intake and aversion to saline in wild-type animals, but not in *Nax$^{-/-}$* mice. Importantly, the aversion to salt was not induced by the infusion of a hyperosmotic mannitol solution with a physiological Na$^+$ concentration in the *Nax$^{-/-}$* or *Nax$^{+/+}$* mice. When Nax cDNA was introduced into the brain of the knock-out mice with an adenoviral expression vector, only animals that received a transduction of the Nax gene into the SFO among the CVOs recovered salt-avoiding behavior under dehydrated conditions. These results clearly show that the SFO is the center of the control of salt-intake behavior in the brain, where the Na$^+$-level-sensitive Nax channel is involved in sensing the physiological increase in the Na$^+$ level of body fluids (Watanabe et al. 2000; Hiyama et al. 2002, 2004; Noda and Hiyama 2005; Noda 2007).

The studies discussed before indicate that glia bearing the Nax channel in CVOs, especially SFO, play an important role in the regulation of water/salt balance.

Taurine in HNS (see reviews: Hussy et al. 2000; Albrecht and Schousboe 2005)

Taurine is an abundant sulfur-containing β-amino acid and the second most abundant amino acid in the brain (after glutamate). It is widely distributed in the brain, and is especially concentrated inside cells where the concentration can reach tens of millimoles. The highest levels of taurine are found in cerebral cortex, hippocampus, caudate putamen, cerebellum, and certain hypothalamic structures, including the SON. The cellular localization of taurine is quite heterogeneous. It is found predominantly in cerebellar Purkinje neurons, and in neurons of the cerebral cortex, putamen, and hippocampus, but a prominent localization in glia in the thalamus, hypothalamus, and brain stem nuclei.

Taurine is released by hypoosmotically induced swelling of both neurons and glial cells – in culture, brain slices and in vivo – and it has been proposed as a major factor of volume regulation of brain cells. The taurine release induced by hypoosmotic stimulation is strictly dependent upon cell swelling, and not upon changes in ionic concentration (such as Ca^{2+} and Na$^+$), and is inhibited by Cl$^-$ channel blockers. Taurine release is proportional to the magnitude of the hypotonic stimulation, changes in osmolarity as little as 2.5% significantly enhance the release. Therefore, taurine is an

amino acid involved in cell volume regulation and is one of the major inorganic osmolytes used by cells to compensate for changes in extracellular osmolarity.

In the HNS, taurine is found prominently in glial cell bodies in the ventral glial lamina, as well as in the glial processes that surround the MCNs. In the posterior pituitary, which contains the axon terminals of SON and PVN MCNs, taurine is found essentially in the pituicytes – the specialized glial cells in the neurohypophysis that engulf the axonal processes and terminals. This highly specialized localization of taurine in the hypothalamo-neurohypophysial system raises the question of the specific role of this organic compound in neuroendocrine function. Because the movements of taurine in and out of the cells depend so closely on the osmotic pressure of the ECF, conceivably it could be implicated in the osmoregulation of the activity of SON neurons, thus participating in the regulation of whole body water balance.

In the SON, taurine is highly concentrated in astrocytes and released in an osmodependent manner through volume-sensitive anion channels. As taurine is an agonist of neuronal glycine receptors, it is likely to contribute to the inhibition of neuronal activity induced by hypotonic stimuli. This inhibitory influence would complement the intrinsic osmosensitivity of SON neurons, mediated by excitatory mechanoreceptors activated under hypertonic conditions; under isoosmotic conditions, the excitability of SON neurons would be partly determined by integration of the basal activity of two opposite systems: on one hand excitatory neuronal mechanoreceptors are responsible for a depolarizing cationic conductance, and on the other hand, neuronal glycine receptors are activated by taurine released from glial cells, inducing a sustained hyperpolarizing anionic current. Hyperosmotic stimuli reinforce mechanoreceptor activity and inhibit taurine release; hypoosmotic stimuli shut the mechanoreceptor channels and greatly enhance the release of taurine, resulting in activation of glycine receptors. These two complementary processes make this structure much more sensitive to the prevailing osmolarity, which is especially important to detect small alterations of salt concentration in the ECF.

The inhibitory influence of glial taurine on neuroendocrine SON neurons may not be limited to the neuronal soma and dendrites, as a similar mechanism may also be present in the neurohypophysis, where the axons of MCNs end. Indeed, preliminary results indicate the presence of glycine receptors on nerve terminals in the neurohypophysis. This could indicate additional osmotic control of AVP and OT release at the level of MCN terminals. This mechanism may also contribute to osmodetection in other hypothalamic osmosensitive structures, such as OVLT, SFO, and MnPO, because neurons in these regions also express cationic stretch-inactivated mechanoreceptor channels and are activated by glycine and/or taurine through strychnine-sensitive glycine receptors.

These recent results imply that the role of taurine is not limited to regulation of cell volume, but that is also important for whole-body fluid balance, which is achieved by its modulation of neuronal activity. The influence of glial on neurosecretion in response to changes in plasma osmolarity may complement the effects of central and peripheral osmoreceptors, resulting in osmoregulation.

Aquaporin-4 in the CVOs and HNS

AQP4 is a water-selective transporter originally cloned from lung tissue that is also expressed strongly in the brain. In situ hybridization and immunoperoxidase staining studies in adult rat brain revealed AQP4 expression in cells lining the ventricular system, the pial surface, SON, PVN, SFO, AP, median eminence, hippocampus, spinal cord, and cerebellum. Furthermore, in all these locations, the distribution of AQP4 is non-neuronal, being restricted to astrocytes or ependymal cells. Postembedding immunogold labeling for AQP4 in glial cells reveals a heterogeneous, subcellular localization, with the protein being particularly abundant in membranes of perivascular processes, suggesting a polarized expression. However, a nonpolarized distribution of AQP4 was shown in

astrocytes of the CVOs and HNS, where AQP4 is present in the plasma membranes facing both capillaries and magnocellular neurons.

Recently, analysis of transgenic mice lacking AQP4 has provided compelling evidence for the involvement of AQP4 in cerebral water balance, astrocyte migration, and neural signal transduction. In particular, AQP4-null mice have reduced brain swelling and improved neurological outcome in models of cytotoxic cerebral edema, including water intoxication, focal cerebral ischemia, and bacterial meningitis. However, in models of vasogenic (fluid leak) edema, including cortical freeze-injury, brain tumor, brain abscess, and hydrocephalus these mice experienced worse brain swelling and clinical outcome. Most importantly, the specificity and intensity of AQP4 staining within the CVOs and HNS strongly suggest that water channels allow variations of plasma osmotic pressure to be transferred from blood to osmosensitive neurons, though it is unclear whether AQP4-bearing glial lamellae act as transducers in the osmosensory response across the plasma membrane (Nielsen et al. 1997; Wells 1998; Tait et al. 2008).

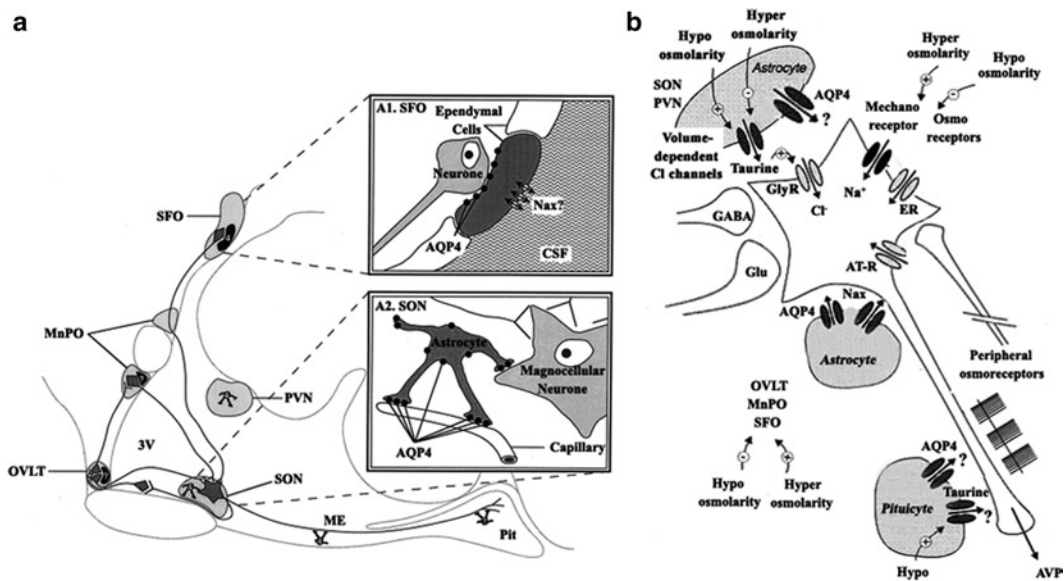
In summary, glial cells regulate neuroendocrine and hormonal signaling in the HNS, contributing to the regulation of body fluid balance. the precise mechanisms that allow them to carry out this role are still poorly understood, but the striking morphological alteration observed in the SON and PVN glia, as well as pituicytes, during dehydration suggest that Nax, taurine, AQP4 all have an important role in the regulation of body fluid homeostasis (Fig. 122.7). There may, of course, be other unidentified factors.


Fig. 122.7 Interaction between glia and neuron in circumventricular organs (CVOs) and hypothalamo-neurohypophyseal system (HNS) following dehydration. OT and AVP from HNS are released after receiving signals from osmoreceptor or mechanoreceptor in CVOs and HNS. This process is also modulated by other neuropeptides through receptors such as ER and AT-R. Astrocytes may also play an important role in the regulation of body fluid balance through Nax, AQP4, and taurine-related mechanisms. (**a**) Schematic representation of the interaction between AQP4-positive cells and the neuronal elements of the "osmoreceptor complex." 122.5.4 Gene/Transcriptor Changes Involved in the Modulation of the HNS During Dehydration

HNS, as an important integrative system, plays an important role in mediating neuroendocrine responses to dehydration through the axonal projections from SON and PVN MCNs to the posterior pituitary. These responses are accompanied by function-related plasticity and remodeling of the HNS, including a wealth of activity-dependent changes in cell morphology, electrical properties, biosynthetic, and secretory activity which ultimately facilitates hormone production and delivery and, hence, the survival of the organism. This plasticity appears to be governed by a complex and dynamic interplay between the intrinsic properties of the MCNs, interactions between MCN neurons, interactions with glia, and the influence of extrinsic synaptic inputs. Although the molecular mechanisms of these processes are not well understood, the levels of many genes/transcriptors change during dehydration.

da Silveira et al. examined the time-course of changes in c-Fos, AVP, and OT mRNA in rat PVN and SON following acute and chronic water deprivation (6, 24, 48, and 72 h, nondehydrated as control). Besides the hematocrit, osmolarity, plasma sodium, and weight loss were increased after water deprivation, as expected, a significant increase in both AVP and OT mRNA expression was observed 6 h after dehydration, reaching a peak at 24 h and returning to basal levels at 72 h in the SON; in contrast, in the PVN, AVP and OT mRNA upregulation occurred 24 h after dehydration, but levels had decreased 72 h after dehydration (though were still higher than control animals). Additionally, c-Fos mRNA expression in both the PVN and SON was increased 6 h after water deprivation, though it progressively decreased at 24, 48, and 72 h after dehydration (da Silveira et al. 2007). These results suggest that dehydration increases not only the release of OT and AVP from MCNs, but also increases OT- and AVP-mRNA expression.

A recent microarray study identified genes and transcripts that were upregulated or downregulated in the SON, PVN, and the NIL of the pituitary gland after water deprivation. In one experiment, 459 differentially expressed transcripts were identified and many of them were novel expressed sequence tags (ESTs). In situ hybridization (ISH) revealed that four transcripts (three of which are novel: d255, d873, d1011) were significantly upregulated or downregulated in the SON after dehydration. In another experiment, downregulation of 10 and upregulation of 28 transcription factor transcripts was observed. Five of the upregulated mRNAs, namely gonadotropin inducible ovarian transcription factor 1 (Giot1), Giot2, cAMP-responsive element-binding protein 3-like 1, CCAAT/enhancer-binding protein, and activating transcription factor 4 were also probed by in situ hybridization, which revealed a significant increase in their expression in SON and PVN MCNs after 3 days of water deprivation and, in some cases, upregulation in parvocellular PVN neurons as well (Sharman et al. 2004; Ghorbel et al. 2006; Hindmarch et al. 2006).

Some of the genes/transcripts identified in these studies (Table 122.2) may be novel effectors or regulators of HNS neuronal plasticity and physiological remodeling during dehydration, although the exact roles of these novel genes within this network remain to be determined.

In summary, a complicated network in CNS is activated to keep the balance of body fluids during dehydration as described in Table 122.3, providing a normal external and internal condition for body cells to maintain survival.

122.6 Applications

Body fluid imbalances are among the most commonly encountered problems in clinical medicine. This is in large part because many different disease states can disrupt the finely balanced mechanisms that control intake and output of water and solutes. Because body water is the primary determinant of

Some novel genes identified in HNS during dehydration are listed, although their role in dehydration is yet unknown. Other upregulated or downregulated known genes occurred during dehydration are unlisted

Table 122.3 Brain response to dehydration

Nuclei/regions/circuits

CVOs: SFO, OVLT, MnPO, AP, sensing changes of osmolarity through osmolarity receptors

NTS: Relaying peripheral signals to thirst center

HNS: Modulating neuroendocrine or behavior response through releasing AVP and OT

LPB, BNST, LSV, and amygdala: Modulating the afferent or efferent signals to or from HNS

Neuroendocrine

AVP and OT are released into circulation to regulate water balance directly, many other neuropeptide/neurotransmitters including glutamate, GABA, NE, NO, angiotension II, CRF, apelin, galanin, orexin, Es, and obestatin, act as modulators in this process

Glia

Glia involved in dehydration through interaction with neurons by Nax channel, APQ4 channel and secretion of taurine in CVOs and HNS

Genes

During dehydration, some novel genes are identified as listed in Table 122.2; other known genes are upregulated or downregulated, indicating alteration and modulation in gene level are involved in dehydration

Brain responses to dehydration are summarized in this table, including involved central nuclei, neuroendocrine responses, gene, and glia

the osmolarity of ECF, disorders of body water homeostasis can be divided into hypoosmolar disorders, in which there is an excess of body water relative to body solute, and hyperosmolar disorders, in which there is a deficiency of body water relative to body solute. Hyperosmolarity is encountered in the clinic due to hemorrhage, hypotension, and diabetes insipidus but may also be encountered due to other "natural" circumstances, such as excessive heat (e.g., in desert environments) or a lack of access to water due to trappage (e.g., after a natural disaster). Serious dehydration without intervention is deleterious to individual health and can threaten survival. Dehydration induced by water restriction/deprivation, or injection of hypertonic sodium solution, has been widely used to explore the mechanisms that regulate water/salt balance in laboratory animals. If better, novel therapies are to be developed (and the correct existing therapies to be employed), it is crucial to better understand the neural circuitry and endocrine responses that regulate water/salt imbalance.

Summary Points

1. Water restriction induces loss of ICF and ECF, leading to imbalance of water and salt, which increases thirst and salt appetite. Behavioral changes accompany these motivational changes, such as water seeking and intake and ingestion of salt content food/fluid increases. Together, these responses work to recover fluid balance.
2. The main response nuclei and neurocircuits activated by dehydration are present in the CVOs and nucleus tractus solitarius (NTS; the sensors), SON and PVN (the effectors), and PVN and LPB (the information integrators).
3. Oxytocin and AVP from neurons in the SON and PVN are released into the general circulation to regulate water retention and natriuresis through peripheral mechanisms. This process is modulated by many other neuropeptide/neurotransmitters such as glutamate, GABA, NE, NO, angiotension II, CRH, apelin, galanin, orexin, Es, and obestatin.
4. In addition to some known genes including OT and AVP mRNA upregulated or downregulated, other novel genes and transcripts are identified during water deprivation. These may be involved in the functional plasticity and remolding of the neural circuits responsible for body fluid homeostasis.
5. Glia may play an important role in water and salt balance via modulation of Nax channels, AQP4 water channels, and secretion of taurine in CVOs and/or HNS.

Definition of Key Terms

CVOs: Are specialized brain structures proximal to the ventricles of the brain including SFO, OVLT, ME, NHP, and AP. They are thought to be the organs that sense various kinds of circulating information including Na^+ concentrations and osmotic pressure in the body fluid.

HNS: Is known as the integrative structure playing an important role in mediating neuroendocrine responses during stress challenge.

Osmoreceptor complex: Consists of both neurons and glias in CVOs and HNS sensitive to osmolality.

HNS remodeling: Refers to a series of changes including morphological, electrical, protein expression, and transcriptional alterations in neurons or glial cells in HNS during stress challenge.

Nax channel: Classified as a subfamily of voltage-gated sodium channels, is expressed in perineuronal processes of astrocytes and ependymal cells which envelope particular neural populations in the CVOs. They are considered to be sodium-level sensor involved in water/salt intake regulation in the brain.

Taurine: Is the second most abundant amino acid in the brain. It is widely distributed in the CNS and is most concentrated in glia. It has multiple functions in the brain, e.g., as a trophic factor, an osmolyte, a neuromodulator, and an inhibitory neurotransmitter.

AQP4: Originally cloned from lung tissue, is one of the aquaporin water channel family. It is expressed strongly in astrocytes throughout the CNS, particularly in the ventricular system, hypothalamus, and cerebellum. It plays an important role in the normal and pathological brain, including regulation of cerebral water balance, astrocyte migration, and neural signal transduction.

Chapter 123
Feminine Norms and Disordered Eating

Melinda A. Green, David Kugler, Ashley Stillman, Christopher Davids,
Katherine Read, Kelly Siglin, and Amanda Jepson

Abbreviations

CFNI   Conformity to feminine norms inventory
ED   Eating disorder
MMPI   Minnesota multiphasic personality inventory
PAQ   Personal attribute questionnaire
BSRI   Bem sex-role inventory
GRAS   Groninger androgyny scale
DEBQ   Dutch eating behavior questionnaire
FIDS   Feminist identity development scale
EDI   Eating disorder inventory
PDQ   Personal description questionnaire
EDE-Q   Eating disorder examination-questionnaire
EAT   Eating attitudes test

123.1 Introduction

The etiology of eating disorders (EDs) is characterized by a complex interplay of psychological, biological, and sociocultural factors. Significantly higher prevalence rates of ED diagnoses among women have led researchers to consider the relationship between sociocultural feminine norms and disordered eating behaviors. Hyperfemininity is a gender-related construct frequently linked to heightened ED risk (see Paxton and Sculthorpe 1991). Hyperfemininity is a psychological state characterized by an extreme endorsement of traditional sociocultural feminine norms (Boskind-Lodahl 1976). The purpose of this chapter is to explore the relationship between hyperfemininity and ED symptomatology.

123.2 Femininity Theory of EDs

The *femininity theory of EDs* suggests disordered eating results from an oversubscription to traditional feminine gender norms. Traditional feminine norms include fragility, passivity, submissiveness, dependence, approval seeking, and an intense focus on appearance characterized by the relentless pursuit of extreme thinness (Boskind-Lodahl 1976). Femininity theory conceptualizes EDs as maladaptive attempts to achieve social approval and acceptance via conformity to feminine norms. The theory proposes hyperfeminine women are at an increased risk for EDs because they are overly reliant upon sociocultural feminine norms in self-definition and personal evaluations of self-worth. As a result, hyperfeminine women overemphasize appearance, weight, shape, passivity, and dependence in personal judgments of self-worth in the same way the surrounding culture overemphasizes these characteristics in appraisals of feminine worth. According to femininity theory, the tendency to internalize such cultural values places hyperfeminine women at-risk for EDs. Figure 123.1 outlines the main tenets of femininity theory.

A significant body of research supports femininity theory. Table 123.1 provides an overview of the methodologies and findings of the relevant research. Hatsukami and colleagues (1982) surveyed masculine and feminine characteristics via the Masculinity-Femininity Scale (Scale 5) of the Minnesota Multiphasic Personality Inventory (MMPI: Hathaway and McKinley 1942) among 52 bulimic females and 120 female polysubstance abusers. Results indicate bulimic participants were significantly more likely to endorse feminine characteristics. Similarly, Norman and Herzog (1983) report restricting anorexics, normal-weight bulimics, and bulimic anorexics display hyperfeminine MMPI profiles. Williamson and colleagues (1985) indicate bulimic participants endorse the highest amount of feminine behavior on the MF Scale, obese participants an intermediate amount, and normal

Heilbrun and Mulqueen (1987)	174 college women Androgynous Feminine Masculine	Femininity: sex role questionnaire ED symptoms: Eating disorder inventory	Feminine group increased ED symptoms
Pettinate (1987)	37 inpatient ED Females 12 inpatient depressed females 34 high school and college women	Femininity: Bem sex role inventory	Higher femininity scores in ED inpatients
Van Strien (1988)	540 women	Femininity: Groginger Androgyny scale ED symptoms: Dutch eating behavior scale	Higher femininity scores linked to overeating
Brown et al. (1990)	340 college women	Femininity: Attitudes toward women scale ED symptoms: BULIT Bulimia test	Higher femininity predicts ED behaviors

ED eating disorders, *MMPI* Minnesota multiphasic personality inventory

controls the lowest amount. Orleans and Barnett (1984) report a significant positive correlation between feminine behaviors as assessed by the Masculinity-Femininity Scale and ED symptomatology.

The relationship between hyperfemininity and heightened ED symptoms has been established via other instruments as well. Squires and Kagan (1985) found restrictive dieters, as indicated by the DIET scale (Kagan and Squires 1984), endorse high levels of feminine traits on the Personal Attributes Questionnaire (PAQ; Spence et al. 1974). Heilbrun and Mulqueen (1987) assessed anorexic and bulimic symptomatology according to the Eating Disorder Inventory (EDI; Garner et al. 1983) among androgynous, feminine, and masculine women. Findings indicate the highest level of ED symptomatology among feminine women. Similarly, Pettinati and colleagues (1987) found ED patients scored significantly higher on the femininity scale of the Bem Sex-Role Inventory (BSRI; Bem 1974) compared with depressed patients or normal high school and college student controls. Van Strien and Bergers (1988) also report a direct correlation between femininity as assessed by the Groninger Androgyny Scale (GRAS; De Graaf 1984) and emotional and external eating as measured by the Dutch Eating Behavior Questionnaire (DEBQ; Van Strien et al. 1986).

More recent findings indicate additional support for an association between femininity and EDs. Synder and Hasbrouck (1996) report women who demonstrate high conformity to traditional feminine norms, as indicated by high scores on Stage 1 of the Feminist Identity Development Scale

(FIDS; Bargad and Hyde 1991), are more likely to endorse body dissatisfaction and drive for thinness on the EDI (Garner et al. 1983). Similarly, meta-analytic results of 22 studies indicate a small, statistically significant relationship between hyperfeminine characteristics and ED symptomatology (Murnen and Smolak 1997). The small effect size indicates that many other biological, psychological, and sociocultural contributors are important factors in the onset and maintenance of disordered eating, but hyperfemininity does play a role.

123.3 Hyperfeminine Subtypes

Despite a robust research literature linking hyperfemininity to heightened ED symptomatology, it is unlikely all aspects of femininity are equally predictive of ED risk status. Therefore, it is important to investigate the relationship between hyperfeminine subtypes and ED symptoms. Endorsement of some feminine norms may predict heightened ED status, while other norms may show a minimal or inverse relationship to ED symptomatology. This possibility is highlighted by discrepant research findings which either (1) fail to indicate a relationship between hyperfemininity and increased ED symptomatology (e.g., Srikameswaran et al. 1984; Timko et al. 1987; Brown et al. 1990) or (2) indicate an inverse relationship (Lewis and Johnson 1985). An examination of the relationship between ED behaviors and feminine subtypes is needed in order to more fully understand how this relationship may vary as a function of norm subtype. This association has been investigated in many studies.

Paxton and Schulthorpe (1991) used the Personal Description Questionnaire (PDQ; Antill et al. 1981) to divide gender-related norms into subtypes to investigate the relationship between feminine subtypes and ED symptoms. The PDQ contains four 10-item subscales indicative of positive feminine, negative feminine, positive masculine, and negative masculine characteristics. The authors used Pearson product-moment correlation coefficients to examine the relationship between gender subtypes, as assessed by the PDQ, and ED symptomatology as assessed by the Eating Attitudes Test (EAT; Garner and Garfinkel 1979) and the Drive for Thinness, Body Dissatisfied, and Bulimia subscales of the EDI (Garner et al. 1983).

Results indicate small, statistically significant positive correlations between feminine negative characteristics and the EAT, Drive for Thinness, and Bulimia subscales (Paxton and Schulthorpe 1991). Negative feminine characteristics, as defined by the PDQ, include a predisposition to be approval seeking, worrying, nervous, timid, dependent, shy, weak, bashful, anxious, and self-critical. More recent studies have made additional efforts to identify which particular feminine norms predispose to heightened ED risk.

Mahalik and colleagues (2005) developed the Conformity to Feminine Norms Inventory (CFNI; Mahalik et al. 2005) to provide a multidimensional assessment of femininity and subsequently used the inventory to examine the relationship between conformity to feminine norms and EDs. The CFNI is an 84-item self-report instrument designed to assess attitudes, thoughts, and behaviors which reflect conformity to, and nonconformity to, eight traditional feminine norms. Norms assessed by the CFNI include niceness in relationships, involvement with children, thinness, sexual fidelity, modesty, involvement in romantic relationships, domestic behaviors, and investment in appearance. Participants respond to questions on a four-point Likert scale ranging from "strongly disagree" to "strongly agree." Higher scores indicate higher conformity to the gender norm assessed by the relevant subscale (Mahalik et al. 2005).

Mahalik and colleagues (2005) evaluated the relationship between feminine characteristics as assessed by the CFNI and ED symptoms as assessed by the EDI-2 (Garner 1991). A series of 72 Pearson product-moment correlation coefficients were calculated to evaluate relationships between

the seven EDI-2 subscales, the EDI total score, the eight CFNI subscales, and the CFNI total score. Results indicate statistically significant positive correlations between several EDI-2 subscales and the Thinness, Modesty, Romantic Relationship, and Invest in Appearance subscales of the CFNI (see Mahalik et al. 2005 for a comprehensive overview). Results further indicate statistically significant inverse relationships between the Ineffectiveness and Interpersonal Distrust subscales of the EDI-2 and the Nice in Relationships and Care for Children subscales of the CFNI. Results imply that thinness, modesty, appearance focus, and investment in romantic relationships are feminine norms which serve as sociocultural risk factors for EDs, while niceness in interpersonal relationships and caring for children are protective factors.

Mahalik and colleagues (2005) advanced understanding of the subtypes of feminine traits associated with ED risks. However, the calculation of 72 correlation coefficients as the sole analysis strategy is problematic for several reasons. First, there is an increased likelihood of Type I error because multiple analyses were conducted without a Bonferroni adjustment. Second, the analysis strategy did not account for overlapping variance between CFNI subscales. Green and colleagues (2008) attempted replication with a statistical analysis plan which controlled for overlapping variance and inflated Type I error. Table 123.2 provides an overview of statistically significant findings from both studies.

Table 123.2 Relationship between CFNI Feminine norm subtypes and ED behaviors

Green and colleagues (2008) assessed feminine characteristics via the CFNI and ED symptomatology via the Eating Disorder Examination-Questionnaire (EDE-Q; Fairburn and Beglin 1994). A multiple regression analysis was performed to evaluate the eight CFNI subscales as predictors of EDE-Q global scores. Partial regression coefficients indicate the Thinness CFNI subscale was the only statistically significant predictor of ED symptoms. Results suggest conformity to a feminine norm which equates thinness with ideal feminine appearance represents a significant risk factor for body dissatisfaction and disordered eating behaviors. To more fully understand this risk factor, it is important to gain insight into the impact of the thin-ideal. It is critical to examine how this sociocultural norm for feminine appearance exerts its impact on the eating behavior and body satisfaction of girls and women.

123.4 Impact of the Thin-Ideal

Western cultures pervasively promote and habitually reinforce thinness in girls and women (Garner et al. 1980; Morris et al. 1989; Wiseman et al. 1992). This sociocultural predilection is readily apparent across multiple contexts (Rodin et al. 1984). The feminine thin-ideal is especially prevalent in Western media (Silverstein et al. 1986). Media messages consistently equate thinness with feminine beauty, social value, and success across multiple domains including interpersonal, educational, health, and vocational (Rodin et al. 1984). The impact of such messages is significant.

Media messages exert a powerful impact upon human attitudes, thoughts, and behaviors. Media exposure is pervasive and media messages are highly accessible. Feminine appearance ideals portrayed by the mass media are inherently restrictive. The overwhelming majority of images depict thin objectified women (Fredrickson and Roberts 1997). Objectified media images devalue internal characteristics of female icons and emphasize external characteristics, such as body shape and appearance, as a source of sexual pleasure. The media inundation of thin objectified images of women creates a culture where feminine worth is largely defined by narrow standards for external appearance. Subsequently, the internal characteristics of girls and women are devalued across multiple sociocultural contexts (American Psychological Association, Task Force on the Sexualization of Girls 2007).

Saturation of thin objectified media images leads to an overly restrictive feminine appearance norm within the broader culture. The thin objectified feminine appearance norm leads to preoccupation with physical appearance and widespread body dissatisfaction among large groups of girls and women who exist in this toxic cultural milieu (Rodin et al. 1984; Fredrickson and Roberts 1997). Research indicates this sociocultural factor exacts a robust influence on the development of disturbed body image which serves as a strong predictor of subsequent eating disturbance (Hienberg and Thompson 1995). Numerous empirical studies provide evidence of the many negative psychological outcomes following exposure to the media thin-ideal.

Becker (2004) investigated reactions to the introduction of Western media among 30 Fijian girls 3 years following the introduction of television into the culture. Narrative data from semi-structured interviews shows increased body dissatisfaction and bulimic symptomatology following media exposure. Cited motives for engaging in bulimic behaviors include a desire to emulate thin female media characters. According to participants' interview responses, bulimic symptoms reflected a desire to attain social worth via appearance-based competition with success defined as achievement of the media-portrayed thin-ideal. This shift was especially notable within the Fijian culture, where a robust female body was widely celebrated prior to the introduction of Westernized television.

Additional research further highlights the detrimental psychological impact of the media feminine thin-ideal. Stice and Shaw (1994) explored exposure to media images of ultra-thin models, average-sized models, or control images among 157 female undergraduates. Results indicate women exposed to thin-ideal images showed increased depression, stress, shame, insecurity, guilt, and body

dissatisfaction. Further analyses showed thin-ideal endorsement, negative affect, and body dissatisfaction predicted bulimic symptoms following exposure. Similarly, Ogden and Mundray (1996) investigated psychological reactions following acute exposure to thin versus overweight media images among 20 men and 20 women. Results indicate enhanced body satisfaction following exposure to overweight pictures and decreased body satisfaction following exposure to thin pictures. This effect was more pronounced for women.

Hawkins and colleagues (2004) exposed 145 college women to thin-ideal or control images. Results indicate heightened negative mood, body dissatisfaction, and ED symptoms and decreased self-esteem following exposure to thin-ideal versus neutral images. Hausenblas and colleagues (2002) investigated responses to the media thin-ideal among 35 male and 30 female undergraduate students. Participants were exposed to the slides of media thin-ideal images and slides of themselves. Results show women report significantly less pleasure while viewing self-slides compared with their male counterparts. Tiggemann and Slater (2003) report increased body dissatisfaction in a sample of 84 women following exposure to a thin-ideal music video versus a neutral music video. Meta-analytic findings from 25 studies confirm exposure to the media thin-ideal is associated with increased body dissatisfaction (Groesz et al. 2002).

123.5 Differential Impact of the Thin-Ideal: Psychological Risk Factors

It is decisively clear from the thus mentioned research findings that many girls and women experience untoward psychological consequences as a direct result of exposure to the objectified media thin-ideal. However, many exposed women never develop a diagnosable ED or significant eating disturbance as a result of exposure. Therefore, risk and protective factors must play a role in differential reactions to exposure. One identified protective factor is an enhanced ability to be critical of sociocultural feminine norms which equate thinness, feminine beauty, and feminine worth (Murray et al. 1996; Green et al. 2008). Research indicates several additional psychological and sociocultural risk factors moderate the relationship between thin-ideal exposure and ED symptoms. The relevant literature on moderating factors is outlined next.

Heinberg and Thompson (1995) confirm women high in sociocultural awareness/internalization of sociocultural norms are more likely to experience depression following thin-ideal exposure. Additional findings indicate women high in initial body dissatisfaction are more likely to experience distress following exposure (Heinberg and Thompson 1995; Posavac et al. 1998). Dieters, restrained eaters, and persons high in social comparison are also more likely to react negatively to thin-ideal media exposure (Mills et al. 2002; Tiggemann and Slater 2003).

These psychological risk factors provide some insight as to why certain women and girls are more susceptible to develop ED symptoms and body dissatisfaction in response to sociocultural norms for feminine appearance. Additional research indicates that another impactful gender-related risk factor for eating disturbance includes perceived deficits in desirable masculine qualities.

123.6 The Desire for Masculine Qualities and Gender Discrepancy Theory

The gender discrepancy theory of EDs specifies women and girls are trapped by competing gender-related sociocultural messages which simultaneously encourage hyperfemininity in some domains while rewarding masculinity and devaluing femininity in others (Dunn and Ondercin 1981; Steiner-Adair 1986). The theory specifies females at-risk for eating disturbance internalize conflicted sociocultural messages.

As a result, these at-risk women try to reassert femininity via the painstaking creation of an external appearance which conforms to the thin-ideal while simultaneously striving to conform to traditional masculine attitudes and behaviors in nonappearance domains.

Gender discrepancy theorists postulate normative feminine qualities, such as cooperativeness, nurturance, relationship building, caregiving, and postpubescent weight gain, are devalued by the broader culture. Since women and girls high in ED symptomatology are more likely to display these devalued hyperfeminine traits, they are more likely to feel ostracized due to gender. Therefore, as the broader culture devalues traditional feminine characteristics, at-risk women may be likely to internalize this devaluation and instead prioritize socially rewarded external feminine traits, such as the thin-ideal. They may simultaneously embrace socially rewarded internal masculine traits, such as achievement orientation, autonomy, self-assurance, and competitiveness.

The desire to attain these socially rewarded goals is problematic because many of the goals are incompatible with hyperfeminine characteristics. According to gender discrepancy theory, this incompatible state leads at-risk girls and women to question self-identity and strive to achieve social status via conformity to highly rewarded goals (i.e., the thin-ideal, competitive behavior, autonomy) even if those goals deviate from their own natural inclinations. Steiner-Adair (1986) refers to this state as the "Super Woman" ideal of femininity. This ideal is characterized by a socially dictated, relentless desire for independence, thinness, beauty, perfection across multiple life domains including autonomous career achievement, and a devaluation of caregiving, nurturing, and interpersonal support. Women adhering to this ideal are likely to see other women as competitors and strive to defeat the competition across multiple venues, including the appearance and thinness domains. This tendency undermines cooperativeness and harmonious personal relationships and contributes directly to ED symptoms via a thinness focus. Figure 123.2 outlines the main tenets of gender discrepancy theory.

Much empirical support exists for discrepancy theory. Dunn and Ondercin (1981) indicate compulsive eaters desire higher levels of masculine traits compared with asymptomatic controls. Steiner-Adair (1986) reports significantly higher levels of ED symptoms among female adolescents endorsing the cultural "Super Woman" ideal compared with asymptomatic counterparts. Asymptomatic counterparts were significantly more likely to minimize the importance of competition and beauty and instead prioritize the maintenance of interpersonal relationships. Similarly, Hubert Lacey and colleagues (1986) demonstrate a relationship between bulimic symptomatology and autonomous achievement orientation, disconnected interpersonal relationships, and concerns regarding femininity.
Fig. 123.2 Gender discrepancy theory of eating disorders (Dunn and Ondercin 1981; Steiner-Adair 1986)

According to gender discrepancy theory, ED risk is centered upon gender discrepancy and the desire to achieve a different balance of masculine and feminine traits rather than an association between ED risk and actual levels of masculine and feminine traits. Therefore, gender discrepancy theorists encourage the assessment of actual versus desired traits when examining the relationship between ED symptoms and gender-related traits. Empirical evidence reinforces this notion. For example, possessing actual levels of higher traditional masculine traits is correlated with decreased ED symptomatology across multiple studies (see Murnen and Smolak 1997) while a discrepancy between actual and desired masculine traits is associated with increased ED risk. In order to more fully understand why certain women devalue personal feminine characteristics, strive for masculine characteristics, compete with other women, and develop ED symptoms, it is important to understand the many sociocultural rewards and punishments contingent upon weight. Research indicates sociocultural forces confer significant weight-related rewards and punishers for women and girls.

123.7 Reinforcement for Thin-Ideal Conformity as a Function of Gender

Rodin, Silberstein, and Striegel-Moore (1984) state thinness in girls and women is equated with social worth across multiple contexts. Empirical evidence from a variety of domains supports this notion. Findings from the vocational realm indicate obese women are more likely to face unwanted career-related outcomes compared with either obese men or normal weight female counterparts. Averett and Korenman (1995) report obese women experience lower income compared with normal weight women. This effect was weak and inconsistent for obese men. Several additional studies also find obese women are more likely to experience employment discrimination compared with normal weight counterparts or obese men (Bellizzi et al. 1989; Pingitore et al. 1994).

Maranto and Fraedrich Stenoien (2000) indicate the wage penalty for obese women far exceeds that of obese men and occurs at a significantly lower level of obesity. Findings suggest mildly obese women (defined as 20% above normal weight) endure wage decrements which exceed those of morbidly obese African American men (defined as 100% above normal weight). Findings further indicate men as a group are protected from wage penalties until their level of obesity exceeds normal weight standards by at least 100 lb. Taken together, results suggest the punitive economic consequences of weight gain are markedly greater for women and occur at significantly lower levels of obesity. Adverse vocational effects for obesity as a function of gender are reviewed in Table 123.3.

Rewards for conformity to the feminine sociocultural thin-ideal are also readily apparent across several interpersonal domains. Cann (2001) reports judgments of high social competence are significantly more likely to be based on lower weights for women compared with higher weights for men. Regan (1996) investigated perceptions of obese and normal weight male and female targets among 96 college undergraduates. Results indicate obese women were viewed to be significantly less competent, sexually attractive, warm, and responsive compared with obese men. Obese women were also viewed to be significantly less attractive, warm, responsive, and skilled compared with average weight peers. Finally, obese women were considered to have significantly lower sexual desire compared with normal weight female counterparts. Perhaps such gender-related sociocultural stereotypes partially explain why obese women are significantly more likely to experience stigma in dating practices and sexual relationships compared with obese men (Chen and Brown 2005).

Table 123.3 Adverse vocational effects of obesity and overweight as a function of gender

Study	Population	Construct	Results
Averett and Korenman (1995)	5,090 women 4,951 men	Family income	Obese women: lower family income than normal weight women; minimal effect for men
Maranto and Fraedrich Stenoien (2000)	3,208 women 3,393 men	Weight-based wage penalties	Women experience weight-based wage penalties at much lower levels of obesity than men
Sargent and Blanchflower (1994)	12,537	Hourly earnings	Women: inverse relationship between weight and earnings Men: no relationship
Sarlio-Lahteenkorva and Lahelma (1999)	6,016	Unemployment Individual income Household disposable income	Overweight women: higher unemployment, lower income, lower disposable income; no effect for overweight men
Sarlio-Lahteenkorva et al. (2004)	2,068 women 2,314 men	Individual income	Obese women: significantly lower income in higher education positions or white-collar positions; no

Additional research from the dating realm indicates men are significantly less likely to choose overweight female romantic partners than women are to choose overweight male romantic partners (Stake and Lauer 1987; Sobal et al. 1995). Other research from the interpersonal realm suggests weight-related teasing by peers and family members occurs more often to overweight girls compared with overweight boys (Neumark-Sztainer et al. 2002). A recent research review of 17 studies indicates overweight girls undergo a significantly higher level of social stigmatization compared with overweight boys. Overweight girls are significantly more likely to experience physical, relational, and verbal bullying (Tang-Peronard and Heitmann 2008).

123.8 Implications for Prevention and Treatment

It is obviously apparent from the aforegiven findings that violation of the sociocultural feminine thin-ideal carries ample negative consequences for women and girls. It is also blatantly clear that extreme adherence to this ideal is a significant risk factor for eating disturbance. Therefore, women and girls experience a double-bind with regard to this norm where both adherence and dismissal can contribute to unwanted negative consequences. Women and girls less likely to experience ED symptoms in this maladaptive cultural context are those who demonstrate high awareness and skepticism of the sociocultural dictates for ideal feminine beauty. Therefore, media literacy programs should be incorporated into ED prevention and treatment programs in order to encourage healthy skepticism of the thin, objectified media thin-ideal. Such programs should effectively highlight the negative impact of this ideal on the psyches of girls and women. Researchers should critically evaluate the short- and long-term impact of media literacy interventions in treatment and prevention efforts via prospective research designs.

The intervention recommended thus is designed to reduce ED risk at the level of the individual. However, a more cost-effective and efficient long-term strategy would be to reduce the overall prevalence of sociocultural messages which narrowly define traditional feminine beauty in terms of

Table 123.4 Interventions to reduce adherence to sociocultural feminine norms linked to ED risk

Develop media literacy programs to encourage healthy skepticism of the feminine thin-ideal at the level of the individual.

Outline the negative impact of the media thin-ideal across multiple forums, both personal and political.

Introduce a wider range of feminine body types into media depictions.

Dissuade sociocultural messages which equate feminine worth with external feminine appearance.

Promote sociocultural messages which equate feminine worth with internal feminine characteristics.

Decrease the frequency of cultural practices which denigrate women and dismiss the importance of traditional feminine qualities.

Decrease the cultural objectification of women. Using feminine appearance and sexual appeal to sell products leads to a societal preoccupation with feminine external attractiveness which promotes body dissatisfaction and obsession with thinness.

Develop ED prevention programs designed to foster appreciation of positive internal feminine characteristics and decrease appearance focus in appraisals of personal self-worth.

Cultural objectification of women: Reduce the social value of women to physical appearance with a particular emphasis on viewing the female body as an object for sexual pleasure

ED eating disorder

extreme thinness. The systematic introduction of a range of feminine body types into media depictions of successful, attractive women would present alternate role models. This reform would significantly reduce sociocultural pressures to conform to an emaciated thin-ideal which is unrealistic and unhealthy for a large percentage of girls and women.

Another important intervention strategy is to dissuade adherence to sociocultural messages which equate feminine appearance with feminine worth. Primary, secondary, and tertiary programs should focus on fostering awareness of the many noteworthy internal characteristics of female participants while simultaneously discouraging an overreliance upon external appearance in self-definition. Key aspects of this intervention are to increase self-esteem via a positive focus on stable internal qualities and to decrease the need for social comparison and social competition based on appearance-related attributes. Table 123.4 provides a summary of interventions designed to reduce adherence to the traditional feminine norms and hyperfeminine behaviors linked to ED symptoms.

123.9 Application to Other Areas of Health and Disease

Sociocultural messages which equate feminine beauty, thinness, and feminine worth foster ED symptoms in women and girls who endorse such messages. This represents an important women's public health issue because EDs are accompanied by substantive decreases in physical and mental health. Anorexia nervosa has the highest mortality rate of any psychiatric diagnosis due to the detrimental impact of self-imposed starvation on multiple organ systems (American Psychiatric Association 2000). Bulimia nervosa is also accompanied by a myriad of negative physical and mental health consequences. Changing sociocultural messages surrounding feminine appearance and the thin-ideal will inevitably impact the overall prevalence of ED symptoms, exerting positive effects on the physical and mental health of women and girls. In conclusion, the many gender-related sociocultural risk factors outlined before represent important areas for future ED interventions. A summary of key points is presented in Table 123.5.

Table 123.5 Summary of gender-related sociocultural contributors to ED symptoms among women

Gender-related construct	ED risk
Increased thin-ideal internalization	Heightened
Increased self-objectification	Heightened
Increased societal objectification	Heightened
Sociocultural devaluation of postpubescent feminine weight gain	Heightened
Overt discrimination against overweight and obese women	Heightened
Exposure to objectified media thin-ideal	Heightened
Sociocultural definitions of feminine worth centered upon appearance	Heightened
Increased social competition among women on the basis of appearance	Heightened

Thin-ideal internalization: High endorsement of the media thin-ideal in personal expectations for physical appearance; Self-objectification: Tendency to view one's body as an object for sexual pleasure; Societal objectification: Tendency to view feminine worth in terms of physical appearance – female bodies are constructed as sexual objects in this cultural context

Summary Points

- Gender-related sociocultural messages contribute to heightened ED symptoms among girls and women.
- Girls and women who endorse higher levels of traditional feminine norms are at an increased risk for disordered eating.
- Adherence to a feminine norm which equates personal self-worth with thinness most notably predicts ED risk.
- Westernized media widely markets objectified images of thin women and habitually equates thin images with success and optimal femininity beauty.
- Exposure to thin, objectified media images predicts a host of negative psychological outcomes among girls and women.
- Devaluation of traditional feminine characteristics and idealization of traditional masculine characteristics creates a discrepant gender identity in women and girls at-risk for eating disturbance. Femininity is reasserted via the pursuit of extreme thinness.
- Thinness in girls and women is rewarded in Western cultures.
- Obese and overweight women experience significant discrimination in vocational, educational, and interpersonal realms.
- ED prevention and intervention efforts should provide education about the detrimental impact of sociocultural messages which equate thinness, beauty, and feminine worth.
- Alternate models of feminine worth, beauty, and success should be widely incorporated into Westernized media content.

Summary Table

Key features of feminine norms in eating disorders

- Hyperfeminine behavior increases risk for EDs.
- Increased endorsement of the cultural feminine thin-ideal is a significant risk factor for EDs.
- Sociocultural ideals reinforce the thin-ideal feminine thin-ideal.
- Punitive discriminatory practices against overweight and obese women further promote adherence to the feminine thin-ideal.
- The societal objectification of women equates feminine worth with thinness and sexual appeal, increasing risk of body dissatisfaction and EDs.

Definitions

Hyperfemininity: A psychological state characterized by an extreme endorsement of traditional sociocultural feminine norms.

Traditional sociocultural feminine norms: Cultural expectations for feminine behavior which emphasize appearance, passivity, timidity, nurturance, cooperativeness, caregiving, a relational focus, and thinness.

Femininity theory of eating disorders: Theory states eating disorders are the result of an oversubscription to traditional feminine norms.

Feminine negative characteristics: A subtype of feminine traits which serve as risk factors for eating disturbance including a predisposition to be approval seeking, worrying, nervous, timid, dependent, shy, weak, bashful, anxious, and self-critical.

Feminine thin-ideal: Prototype of ideal feminine beauty which specifies a slender body type.

Objectified media thin-ideal: Westernized media images of optimal feminine beauty which highlight a scantily clad, slender body type viewed as an object for sexual pleasure.

Gender discrepancy theory of eating disorders: Theory states competing gender-related sociocultural messages lead women to assert femininity via thinness while simultaneously asserting masculinity in other domains.

"Super Woman" feminine ideal: Feminine identity characterized by a socially dictated, relentless desire for independence, thinness, beauty, and perfection across multiple life domains including autono career achievement, serves as a risk factor for eating disturbance.

Chapter 124
The Dietary Antioxidants Alpha-Tocopherol and Alpha-Lipoic Acid and Their Synergy in Brain Disorders

Oscar Gonzalez-Perez

Abbreviations

HNE	4-Hydroxy-2-nonenal
5-HT	5-Hydroxytryptamine
ATPase	Adenosine triphosphatase
ALA	Alpha-lipoic acid
DNA	Deoxyribonucleic acid
GABA	Gamma-amino butyric acid
GPX	Glutathione peroxidase
GAP43	Growth-associated protein 43
NAD+	Nicotinamide adenine dinucleotide oxidized
NADP+	Nicotinamide adenine dinucleotide phosphate oxidized
NADHP	Nicotinamide adenine dinucleotide phosphate reduced
NADH	Nicotinamide adenine dinucleotide reduced
ROS	Reactive oxygen species
RNA	Ribonucleic acid
SOD	Superoxide dismutase
VE	Vitamin E

124.1 Introduction

The consumption of edible plants, fruits, and vegetables has shown to prevent the occurrence of a number of diseases and, under certain circumstances, to reduce the oxidative damage in humans. Vegetables, fruits, and seeds are rich sources of antioxidants, for instance lipoic acid, vitamins A, C, and E, flavonoids, polyphenols, lycopenes, proanthocyanidins, astaxanthins, and others. These compounds might protect the organism against free-radical-induced injuries and diseases. The utilization

of antioxidants may be potentially useful for preventing lesion enlargement, and for treating pathological conditions that have an oxidative process as a major source of neurological damage, for instance brain ischemia, diabetic neuropathy, Parkinson's disease, multiple sclerosis, Huntington's disease, amyotrophic lateral sclerosis, or Alzheimer's disease. Despite dramatic advances in our understanding of these neurological diseases, at present there is no satisfactory treatment to reduce death and disability in patients. Antioxidant agents have been investigated as therapeutic alternatives to diminish cerebral damage, with varying results. In this chapter, we will discuss the role of oxidative stress in brain injury and the effects of two important antioxidants (vitamin E (VE) and lipoic acid) on the preservation of neural integrity after oxidative damage.

124.2 Reactive Oxygen Species and Oxidative Stress

Reactive oxygen species (ROS) play an important role in neuronal signaling and physiology; however, at higher levels, they can lead to neuronal dysfunction and cell death. There are two types of ROS: oxygen free radicals and nonradical oxygen derivatives (see Table 124.1).

ROS can arise from numerous sources including redox metal ion–catalyzed reactions, mitochondrial-resident electron transport chain function, glycation end products, and enzymatic reactions. Under physiological circumstances, ROS play important roles in body homeostasis by modulating and mediating vital processes, such as, glucose metabolism, cellular respiration, cerebral perfusion, vascular permeability, inflammation, immune response, physiological aging, and others. However, high levels of free radicals participate in tissue injury and disease progression in a number of pathologies: diabetes neuropathy, cancer, cardiac and brain ischemia, Alzheimer's disease, and others (Paravicini et al. 2004; Poon et al. 2004; Heo et al. 2005; Blomgren and Hagberg 2006; Butterfield 2006; Chrissobolis and Faraci 2008; Gonzalez-Perez et al. 2008).

Oxidative stress is manifested by excessive production of free radicals that, depending on the nature of the substrate attacked, produces different reactions including lipid peroxidation, protein oxidation, or deoxyribonucleic acid/ribonucleic acid (DNA/RNA) oxidation. These pathological processes have characteristic markers used to identify the targeted cell structure, for example:

1. Protein oxidation is characterized by overproduction of protein carbonyls, 3-nitrotyrosine or protein glutathionylation.
2. Lipid peroxidation is associated with production of free and protein-bound reactive alkenals as 2-propen-1-al (acrolein) and 4-hydroxy-2-nonenal (HNE); thiobarbituric acid reactive substances; and isoprostanes and neuroprostanes derived from peroxidation of arachidonic acid and docosohexanoic acid, respectively.

Table 124.1 Reactive oxygen species

Oxygen free radicals		Nonradical oxygen derivatives	
Name	Formula	Name	Formula
Hydroxyl radical	$^{\bullet}OH$	Hydrogen peroxide	H_2O_2
Hypochlorite ion	$ClO^{\bullet}$	Singlet oxygen	$^1O_2$
Superoxide anion	$^{\bullet}O_2{}^-$	Ozone or trioxygen	O_3
Hydroperoxyl	$HO_2{}^{\bullet}$	Peroxynitrite or peroxonitrite	$ONOO-$
Alkoxyl	$RO^{\bullet}$	Hypochlorous acid	$HOCl$
Peroxyl	$ROO^{\bullet}$		

Condensed formulas and chemical names of the two types of reactive oxygen species: oxygen free radicals and nonradical oxygen derivatives

3. DNA oxidation can be identified by quantifying the levels of 8-hydroxy-2-deoxyguanosine and advanced glycation end products (reaction products of reducing sugars with amines).

Regardless of the targeted cell structure, the oxidation of proteins, lipids, or DNA leads to structural changes, biochemical dysfunction, and cell death.

124.3 Brain Injury and Oxidative Stress

The brain consumes about one-third of the inspired oxygen, has the second highest concentration of fatty acids (exceeded only by adipose tissue), and has a high abundance of redox-capable transition metal ions coupled. In addition, this organ has very little glycogen deposits and a relatively low abundance of antioxidant defense systems. These characteristics make the brain the most vulnerable organ to *lipid peroxidation*. Recently, reactive nitrogen species are considered novel sources of oxidative stress in brain, which has been associated with protein deposits in several neurodegenerative disorders. This pathological process is called *nitrosative stress* and is also considered critical in brain dysfunction. The elevated production of reactive oxygen or nitrogen species, their production in inappropriate relative amounts, or deficiencies in antioxidant defenses may result in pathological stress to neurons and cerebral tissue. In summary, if oxidative or nitrosative stress is excessive or if defense and repair responses are inadequate, neuronal injury is caused. Therefore, antioxidant therapies appear to be a feasible approach to reduce brain damage and disease progression.

124.4 Dietary Antioxidants Against Oxidative Stress

There is considerable evidence for a role of antioxidant nutrients in the maintenance of health in contributing to the decreased incidence of free radical-induced diseases. Specifically, alpha-lipoic acid (ALA) and VE have been broadly studied under experimental and clinical conditions because of their unique chemical and nutritional properties. Moreover, these antioxidants are present in the normal human diet, their side effects are infrequent and the combinations of both substances appear to have synergistic effects for reducing cellular damage in oxidation-related pathological events. Therefore, this chapter will be focused on discussing the role of ALA and VE to neutralize oxidative processes in the brain.

124.4.1 Alpha-Lipoic Acid (ALA)

ALA, also known as lipoate, was discovered in 1951 as a molecule essential for aerobic life, participates in various transfer reactions within the pryruvate dehydrogenase complex by assisting in acyl-group transfer and as a coenzyme in the Krebs cycle. ALA helps preserve the homeostasis of cellular and mitochondrial membranes by modifying the metabolism of ketoacids and modulating mitochondrial ratios of nicotinamide adenine dinucleotide reduced/nicotinamide adenine dinucleotide oxidized (NADH/NAD+) and nicotinamide adenine dinucleotide phosphate reduced/nicotinamide adenine dinucleotide phosphate oxidized (NADHP/NADP+) (Packer et al. 1995, 1997). Lipoic acid is synthesized in the body in very small amounts and is covalently bound to the E2 enzyme subunit
Fig. 124.1 Chemical structure of alpha-lipoic acid (ALA). Structural formulas of ALA (**a**) and dihydrolipoic acid (the reduced form of lipoate) (**b**)

of the four different alpha-keto acid dehydrogenase complexes in mitochondria. Under physiological conditions, the normal serum level of lipoate is 0.1 mg/mL, but this level can be rapidly modified by variety of foods where ALA is abundantly found, such as liver, heart, kidney, and red meat, as well as wheat germ, spinach, broccoli, potatoes, and beer yeast.

After dietary intake, lipoate is absorbed into the circulation from the intestine and within cells is reduced and exported to interstitial space as dihydrolipoate (Fig. 124.1). Due to its amphiphilic properties, the ALA neutralizes free radicals in both the fatty and watery regions of cells (Packer, et al. 1995, 1997). These antioxidant properties are mainly located in its thiol group, which reacts directly with ROS and provides strong chelating activity on transition metals. Lipoate also contributes in other antioxidant systems by enhancing the effects of superoxide dismutase (SOD) (Seaton et al. 1996), coenzyme Q10, and glutathione (Murphy et al. 1992; Roy et al. 1997), and by regenerating other antioxidants such as ascorbate (vitamin C) and alpha-tocopherol (Packer et al. 1995, 1997). Lipoic acid is thought to function as a neuroprotective agent and an anti-inflammatory compound, providing effective treatment for Alzheimer's disease, Parkinson's disease, and multiple sclerosis. Additionally, lipoic acid has been tested to treat mercury intoxication. The administration of ALA at dose of 600–1,200 mg/day is sufficient to reach therapeutic serum levels of 4–8 mg/mL at 3rd to 5th day. Taken together, this evidence indicates that ALA is an important antioxidant that may be clinically useful to control neurological conditions related to the overproduction of oxidant radicals (Packer et al. 1995).

124.4.2 Vitamin E (VE)

Alpha-tocopherol is the most abundant natural isoform of VE (Fig. 124.2) and the one with the highest bioavailability. For this reason, the term alpha-tocopherol is frequently referred as synonymous of VE. VE is abundant in wheat germ, almonds, hazelnuts, peanuts, spinaches, broccoli, kiwi, and mango, and in several oils including soybean, sunflower, corn, and safflower. In humans, the normal serum levels of VE oscillate between 11.6 and 46.4 mmol/L. The antioxidant capacity of VE is independent of enzymatic reactions and resides in transferring a phenolic H^+ to oxidant radicals derived from oxidized
Fig. 124.2 Chemical structures of the eight isoforms of vitamin E (VE). Structural formulas of the eight isoforms of VE. The most abundant isoform in the nature is the alpha-tocopherol, which also has the highest physiological activity

polyunsaturated fatty acids. VE increases in intracellular concentrations of the antioxidant enzymes SOD and glutathione peroxidase (GPX) (Conti et al. 1993; Monget et al. 1996). In addition, VE reduces important cellular sources of oxidant radicals by diminishing malonaldehyde concentrations and mitochondrial activity (Villalobos et al. 1994). Therefore, VE is one of the first line of defense against DNA oxidative damage and lipid peroxidation of unsaturated fatty acids in the cell membrane.

124.4.3   Lipoic Acid and Vitamin E in Brain Disorders

Several studies have evaluated the therapeutic or prophylactic potential of VE or ALA in neurological diseases. Deprivation of dietary VE is associated with larger cerebral infarcts in rats (van der Worp et al. 1998). Intraperitoneal administration of alpha-tocopherol diminishes the effects of oxidative damage caused by alteration of the antioxidant defense system in rats (Naziroglu et al. 1999). VE may partially inhibit activated chaperone-mediated autophagy in status epileptic (Cao et al. 2009). Dietary supplementation of VE increases apolipoprotein E levels that, in turn, reduces amyloid-beta and age-related neurodegeneration (Chan and Shea 2009). Alpha-tocopherol improves performance on a spatial working memory task and attenuates cholinergic neuron pathology in the basal forebrain in a Down's syndrome mouse model (Lockrow et al. 2009).

Regarding the efficacy of ALA for reducing cerebral oxidative damage, several reports suggest a neuroprotective effect in models of focal and global cerebral ischemia (Cao and Phillis 1995; Muller

and Krieglstein 1995), *x*-irradiation-induced oxidative stress (Manda et al. 2007), mitochondrial aging, and peripheral neuropathy (Roy et al. 1997). ALA prevents the development of clinical signs and preserves the integrity of brain–blood barrier in acute experimental allergic encephalomyelitis, a rodent model for multiple sclerosis (Schreibelt et al. 2006) and in human patients (Yadav et al. 2005). Lipoate has important anti-inflammatory effects as shown by reducing glial reactivity and by modulating the levels of nuclear factor kappa B p65 in brain (NFkappaB) (Jesudason et al. 2008). When administered to pregnant rats, ALA decreases DNA damage and oxidative stress induced by alcohol in the developing hippocampus and cerebellum (Shirpoor et al. 2008). Dietary supplementation of ALA delays the progression of age-related cognitive decline (Arivazhagan et al. 2002; Suchy et al. 2009) and reduces ischemic cerebral damage when complicated with diabetes (Piotrowski et al. 2001). ALA is also effective in protecting neural cells against glutamate-induced cytotoxicity. This protective effect of ALA plus appears to be independent of its stereochemistry and is synergistically enhanced by selenium (Tirosh et al. 1999).

However, ALA and VE are not always effective in diminishing oxidative damage in the brain, especially when these compounds are used alone or without combination of antioxidants. For instance, alpha-tocopherol does not reduce post-traumatic cerebral edema induced by cold injury (Stoffel et al. 1997) and has limited clinical benefits in Parkinson's disease, amyotrophic lateral sclerosis, and Alzheimer's disease (Parkinson 1993; Sano et al. 1997; Gaedicke et al. 2009). Other reports indicate that ALA does not have clinical relevance to treat trigeminal trophic syndrome (Fruhauf et al. 2008) and does not have a significant neuroprotective effect in brain ischemia after intraperitoneal or intracranial administration (Wolz and Krieglstein 1996). Therefore, researchers are now interested in establishing whether beneficial effects of antioxidants become more evident when these substances are administered together. On this regard, recent evidence indicates that antioxidant combinations are more effective than the use of a single antioxidant. One of the combinations with reproducible and promising results is the combination of ALA plus VE. ALA markedly modifies in situ concentrations of VE (Packer et al. 1995, 1997). This process is mediated by ascorbate recycling, glutathione disulfide reduction, and involves ubiquinone and dehydroascorbate radicals (Fig. 124.3). The combination of VE and vitamin C has been studied, but the pro-oxidant activity of ascorbate is important and its benefits are not quite evident. In addition, ALA is also capable of reducing thioredoxin; thus the antioxidant properties of ALA are more complete than that of vitamin C (Packer et al. 1997).

124.4.4 Synergism Between Lipoate and Tocopherol

During the past 2 decades, an increasing number of reports regarding the therapeutic applications of the combination of VE plus ALA have been published (see Table 124.2). These investigations indicate that the combination of both antioxidants is effective in reducing oxidative damage in several pathological conditions, such as diabetic neuropathy, Alzheimer's disease, rheumatic arthritis, cardiac and cerebral ischemia, cataract degeneration, and in the aging process (Haramaki et al. 1993, 1995; Maitra et al. 1995; Stoyanovsky et al. 1995; Coombes et al. 2000a, b, 2001; Gonzalez-Perez and Gonzalez-Castaneda 2006). One of the first studies that revealed the synergistic effect between alpha-tocopherol and lipoate was done in microsomal fractions obtained from normal and VE-deficient animals (Scholich et al. 1989). In that study, the controls showed a prolonged lag phase before the onset of low-level chemiluminiscence in microsomes that were not found in the VE-deficient fractions. Oral supplementation of ALA–VE significantly reduces lymphocyte apoptosis in a global cerebral ischemia model. Favorable effects of an ALA–VE mixture were found in
Fig. 124.3 Biochemical recycling of VE. Vitamin E is recycled via intracellular alpha-lipoic acid. In this complex mechanism, the main metabolic intermediaries are vitamin C (ascorbate) and ubiquinol. R–OO•: Oxidant radical; R–OOH: Neutralized radical

a thromboembolic stroke model; this study analyzed the efficacy of the prophylactic administration of ALA plus VE upon ischemia. ALA–VE mixtures efficiently reduced glial scar, improved the recovery after brain ischemia, and increased the tissue levels of synaptophysin and growth-associated protein 43 (GAP43), a couple of synaptic remodeling proteins (Gonzalez-Perez et al. 2002). This prophylactic treatment also reduces infarct volume and lipid peroxidation after cerebral ischemia (Garcia-Estrada et al. 2003). Additional findings indicated that the ALA–VE combination decreases the age-associated Na(+),K(+)-adenosine triphosphatase (ATPase) activity. Because of the critical importance of Na(+),K(+)-ATPase in neuronal functions, the results of this study may have important implications in controlling age-related functional deficits of the brain (Bagh et al. 2008). In a model of acute intoxication with lindane, ALA and VE were neuroprotective as shown by preservation of the neurotransmitters gamma-amino butyric acid (GABA) and serotonin (5-hydroxytryptamine, or 5-HT) in olfactory lobe, cerebrum, hippocampus–hypothalamus, cerebellum, and pons-medulla (Bist and Bhatt 2009). Interestingly, a treatment with a triple combination of VE, LA, and vitamin C protects the arachidonic acid level in the brains of diabetic and nondiabetic rats (Ozkan et al. 2005). Arachidonic acid is crucial to the optimal development of the brain and eyes and to preserve cognitive abilities.

Other findings indicate that the combination of ALA and VE increases endothelial levels of the antiapoptotic protein Bcl-2 without significant changes in the levels of the proapoptotic protein Bax (Marsh et al. 2005). In parallel, the ALA/VE mixture has been combined with other dietary antioxidants, such as vitamin C, beta-carotene, and selenium, and then evaluated under several conditions of exercise, experimental diabetes, cold, age, and cancer, and promising results have also been obtained (Bailey and Davies 2001; Sharman and Bondy 2001; Mosca et al. 2002; Schmidt et al. 2002; Mantovani et al. 2003; Ozkan, et al. 2005). Taken together, this evidence strongly suggests that the combination of ALA and VE is better than the antioxidant monotherapy.

Table 124.2 Key facts of the synergy alpha-tocopherol/alpha-lipoic acid

Findings	Antioxidant isoforms (dose)	Model (specie)	Reference
Reduction in the lipid peroxidation induced by UV-light on microsomal fractions	α-Tocopherol (62.7 mg/kg diet)/dihydrolipoic acid (50 μM)	In vitro (rat)	Scholich et al. (1989)
Less retinal degeneration induced by UV light	α-Tocopherol (50–100 μM)/dihydrolipoic acid (25–100 μM)	In vitro (rat)	Stoyanovsky et al. (1995)
Restoration of the activities of glutathione peroxidase, catalase, and ascorbate free-radical reductase in lenses that prevents cataract formation	α-Tocopherol (62.7 mg/kg diet)/lipoic acid (25 mg/kg body weight)	In vivo (rat)	Maitra et al. (1995)
Improvement of cardiac recovery, less arrhythmias incidence and lipid peroxide levels, and strong myocardiac contractility during postischemic reperfusion and posthypoxic reoxygenation of heart	α-Tocopherol (100 μM)/ dihydrolipoic acid (50 μM) (Haramaki et al. 1993, 1995)α-Tocopherol (1,000 IU VE/kg diet)/lipoic acid (1.65 g/kg diet) (Coombes et al. 2000a, b, 2001; Ko and Yiu 2001)	In vitro e in vivo (rat)	Haramaki et al. (1993, 1995); Combes et al. (2000a, b; Ko et al. (2001)
Reduction in maximal twitch tension and tetanic force production in unfatigued skeletal muscle	α-Tocopherol (1,000 IU VE/kg diet)/lipoic acid (1.65 g/kg diet)	In vivo (rat)	Coombes et al. (2001)
Attenuation of acute mountain sickness and improvement of the physiological profile of mountaineers at high altitude	α-Tocopherol (100 UI/day)/lipoic acid (150 mg/day)	In vivo (human)	Bailey and Davies (2001)
Modulation of apoptosis in CD4 and CD8 lymphocytes	α-Tocopherol (10 mg/day)/lipoic acid (100 mg/day)	In vivo (human)	Mosca et al. (2002)
Increase in remodeling proteins (GAP43 and synaptophysin) in the ischemic penumbra area and smaller brain infarction volume	α-Tocopherol (50 mg/kg body weight)/lipoic acid (20 mg/kg body weight)	In vivo (rat)	Gonzalez-Perez et al. (2002); Garcia-Estrada et al. (2003)
Reduction in serum levels of IL–6 and TNFα	α-Tocopherol (70 mg/day)/lipoic acid (200 mg/day)	In vivo (human)	Mantovani et al. (2003)
Apoptosis protection by increasing the levels of endothelial cell Bcl-2	α-Tocopherol (50 μM)/lipoic acid (1 mM)	In vitro (bovine)	Marsh et al. (2005)
Attenuation of the cyclosporine-induced decrease in erythrocyte superoxide dismutase activity and cyclosporine-induced vascular dysfunction	α-Tocopherol (1,000 IU VE/kg diet)/lipoic acid (1.6 g/kg diet)	In vivo (rat)	Lexis et al. (2006)
Less antioxidant enzyme activity of GPX and catalase under exercise training conditions	α-tocopherol (1,000 UI/kg diet)/lipoic acid (1.6 g/kg diet)	In vivo (rat)	Marsh et al. (2006)
Less accumulation of high-molecular-weight amyloid beta-proteins	α-Tocopherol (50 μM)/lipoic acid (1 mM)	In vitro (human)	Woltjer et al. (2007)
Reduction in the age-associated Na(+),K(+)-ATPase neuronal activity	α-Tocopherol (1.5 mg/100 g body weight)/lipoic acid (3 mg/100 g body weight) and N-acetylcysteine (500 mg/kg body weight)	In vivo (rat)	Bagh et al. (2008)
Neuroprotection in GABA and 5-HT levels in the brain of mice acutely intoxicated with lindane	α-Tocopherol (50 mg/kg body weight)/lipoic acid (20 mg/kg body weight)	In vivo (mouse)	Bist and Bhatt (2009)

This table summarizes the experimental and clinical evidence regarding on the synergy between ALA and VE analyzed under different oxidative processes

The mechanism by which ALA and VE have synergic effects are not well understood; as mentioned above it has been proposed that alpha-tocopherol is regenerated via lipoate (Maitra et al. 1995; Stoyanovsky et al. 1995; Ko and Yiu 2001). Yet, the VE recycling alone requires at least two metabolic intermediate steps and cannot explain the magnitude of findings described above. Therefore, it is possible that other processes are involved in this synergism. Other possible mechanisms include:

1. The increase of SOD levels, specifically the manganese SOD form (MnSOD) (Coombes et al. 2000b).
2. The increase of activity levels of GPX mediated by selenium (Scott et al. 1976; Conti et al. 1993; Haramaki et al. 1993; Coombes et al. 2000a, b).
3. The modulation of the balance between the anti- and proapoptotic proteins Bcl-2/Bax (Marsh et al. 2005).

In summary, the synergistic mechanism of ALA–VE combination is not entirely understood, but it is clear that potent antioxidant effects are achieved when both ALA and VE are administered simultaneously. Because both antioxidants are essential components in our diet and the oral supplementation is well tolerated, inexpensive, and very safe, the combination of ALA and VE can be a feasible prophylactic/therapeutic alternative for oxidative processes in the brain. Therefore, diets or commercial supplements enriched with these two specific antioxidants are a promising alternative for people suffering from neurological conditions associated with overproduction of oxygen free radicals.

124.5 Aplications to Other Areas of Health and Disease

Oxidative stress is involved in the pathogenesis of a wide spectrum of systemic conditions. Therefore, the ALA–VE combination might be useful for preventing initiation and progression of damage of many pathological conditions that have an oxidative process as the major source of injury, such as cancer, rheumatoid arthritis, chemotherapy, exercise, cataracts, heart failure, myocardial infarction, diabetic neuropathy, atherosclerosis, chronic fatigue syndrome, aging process, and others. In consequence, strategies directed at counteracting oxidative processes will certainly be important in clinical medicine. However, further experimental studies and clinical trials are needed to establish the therapeutic potential of the ALA–VE combination in humans.

Summary Points

- The central nervous system consumes about one-third of the inspired oxygen and has the second highest concentration of fatty acids. Therefore is the most vulnerable tissue to oxidative damage.
- The main mechanism of cerebral injury is called lipid peroxidation, which occurs when unsaturated fatty acids are oxidized by oxygen free radicals.
- Overproduction of oxidant radicals and/or a deficit in antioxidant defenses can give rise to a pathological condition or contribute to disease progression in the brain.
- VE and lipoic acid are dietary antioxidants that cross the brain–blood barrier and react rapidly with ROS and neutralize oxidative damage, but when they are administered as monotherapy their benefits are limited. Hence, the combination of antioxidants appears to be more effective to control oxidative brain damage.
- Besides its antioxidant capabilities, the ALA plays an important role in VE recycling. As consequence, the combination of tocopherol/lipoate has potent synergistic effects to efficiently reduce the magnitude of cerebral damage.

Definitions

Reactive oxygen species (ROS): Family of highly reactive ions or molecules that have at least one unpaired electron at their last orbital.

Oxidative stress: Biochemical process that arises when the production of free radicals is not equivalently balanced by their scavenging or conversion to non-free-radical products.

Lipid peroxidation: Mechanism of oxidative damage that occurs when a unsaturated fatty acid is oxidized by oxygen free radicals and a hydroperoxide is generated in the brain.

Antioxidant: Substances that react with ROS and inhibit initiation and propagation of oxidative damage by radical scavenging, sequestrating transition metals, and reducing peroxides by enzymatic hydrolysis of ester bonds. The efficiency of antioxidants is determined by their ability of rapidly reacting with oxidant radicals to form new radicals less reactive.

Alpha-lipoic acid ($C_8H_{14}O_2S_2$): Organic sulfur-containing fatty acid that consists of a cyclic disulfide and a carboxylic acid with a molar mass of 206.33 g/mol. It is also known as lipoate, thioctic acid, or 6,8-dithiooctanoic acid.

Vitamin E ($C_{29}H_{50}O_2$): It is the collective name for a set of eight fat-soluble vitamins (molar mass is 430.69 g/mol): α-, β-, γ-, and δ- tocopherols, and α-, β-, γ-, and δ- tocotrienols.

Chapter 125
Obsessive Eating

Naoko Narita, Mami Tazoe, and Masaaki Narita

Abbreviations

DSM-IV	Diagnostic and statistical manual of mental disorders
5-HT	5-Hydroxytryptamine, serotonin
GH	Growth hormone
IGF-1	Insulin-like growth factor-1, somatomedin-C
ACTH	Adrenocorticotropic hormone
TSH	Thyroid-stimulating hormone
TEG	Tokyo University egogram
STAI	State-trait anxiety inventory
BMI	Body mass index

125.1 Introduction

Obsessive eating is a term that is not used as a clinical diagnosis, but refers to a pathological habit of eating accompanied by neuropsychological disorders. The characteristic clinical feature that is common in obsessive eating is an obsessive and continuous ingestion of a restricted number of food items or other substances regardless of their nutritional value, which often results in nutritional and/or hormonal imbalance, and may result in serious health problems including psychological state alteration.

Eating disorders, which are subcategorized in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) as anorexia nervosa, bulimia nervosa, and eating disorder not otherwise specified, are characterized by unusual eating habits caused by an intense fear of becoming fat (American Psychiatric Association 1994). Although the precise etiology of eating disorders is unclear, abnormalities of biogenic amine neurotransmitters such as serotonin (5-hydroxytryptamine, 5-HT) and dopamine are found in some patients (Brewerton and Jimerson 1996; Kaye et al. 1999; Wolfe et al. 2000), suggesting the relevance of these factors to eating habits. Since abnormal eating habit is the essential phenotype of eating disorders (Behrman et al. 2000), the occurrence of obsessive eating habits in patients with eating disorders is not surprising (Kaye 2008).

The other representative disorder that may accompany obsessive eating habits is autism spectrum disorder (autism spectrum disorder). Autism spectrum disorder is a congenital neurological disorder characterized by impairment of socialization, abnormalities of communication, and limited activity and curiosity (Charman and Baird 2002; Filipek et al. 1999). The serotonergic system appears to be developmentally dysregulated in autism. Early studies showed high levels of 5-HT in the blood platelets of autistic patients (Anderson et al. 1987; Betancur et al. 2002; Cook Jr et al. 1993). More recently, PET imaging with radiolabeled L-tryptophan has demonstrated asymmetries in 5-HT synthesis in the dentatothalamocortical pathway of autistic boys (Chugani et al. 1997). 5-HT synthesis was decreased in the left frontal cortex and thalamus, but was elevated in the right dentate nucleus. Feeding problems, typically called "selective eating behavior," often coexist with the diagnosis of autism (Kodak 2008). Autism spectrum disorder patients tend to refuse food items other than the very limited number they select, which may also result in inadequate nutritional intake.

Although these disorders are clinically distinct, the obsessive–compulsive features due to their high anxiety levels, which may be caused by the 5-HT abnormalities, explain the common symptoms relating to eating. Therefore, psychobiological commonalities may exist in the preonset phase of obsessive eating. Moreover, the nutritional imbalance may modify postonset neurobiological functioning and behavior owing to the ingredients of the target food items the patients are obsessed with.

125.2 Obsessive Eating in Eating Disorders

125.2.1 Overall Etiology of Anorexia Nervosa/Bulimia Nervosa

Anorexia nervosa is characterized by self-imposed weight loss and amenorrhea. A distorted psychopathological attitude toward eating and body weight is pathognomonic of anorexia nervosa. (Behrman et al. 2000). DSM-IV (American Psychiatric Association 1994) classifies anorexia nervosa into a restricting type and binge-eating/purging type based on the presence of binge-eating/purging (rapid consumption of large amounts of food, followed by induced vomiting or misuse of laxatives). In DSM-IV, bulimia nervosa is distinguished from anorexia nervosa based on the clinical manifestations, although the psychological background including excessive concern about body shape and weight is common to both. In contrast to the emaciation generally observed in anorexia Nervosa patients, bulimia nervosa patients hardly manifest noticeable under- or overweight. The DSM-IV criteria define bulimia nervosa as follows: the binge-eating/purging episodes are observed at intervals of less than 2 h, and the patient has a minimum average of two episodes per week for at least 3 months.

Anorexia nervosa and bulimia nervosa patients share particular eating habits including binge eating, restricted food selection, and obsessive eating. Dysfunction of serotonergic or dopaminergic neuronal systems is the most likely pathophysiological process in these disorders (Bosanac et al. 2005). The serotonergic neuronal system originates from the midbrain raphe nucleus, and its projection regulates diverse physiological functions, including sleep, appetite, pain, motor function, cognition, sexual activity, and emotions such as mood and anxiety. Decreased activity of the serotonergic neuronal system is often observed in patients with eating disorders (Fumeron et al. 2001; Sorbi et al. 1998). On the other hand, the dopaminergic neuronal system has a role in cognition, locomotor activity, exploration, motivation, feeding, and sexual behavior. Activation of the dopaminergic neuronal system in restricting anorexia nervosa patients has been suspected based on their clinical manifestations and the increase of dopamine metabolites observed in their cerebrospinal fluid (Devesa et al. 1988; Kaye et al. 1999). However, no conclusive evidence is available to date.

It is conceivable that the frequent comorbidity of anorexia nervosa/bulimia nervosa with other psychiatric disorders is quite relevant to abnormalities of serotonergic/dopaminergic systems. For instance, it is fairly common to observe food- and weight-related obsessive–compulsive symptoms during the course of anorexia nervosa. Patients with anorexia nervosa often are obsessed with calculating calories, searching for low-calorie food, or performing obviously excessive amounts of exercise. All of these features can be interpreted as phenotypes of obsessive–compulsive disorder (obsessive–compulsive disorder) or obsessive–compulsive personality disorder (obsessive–compulsive personality disorder). Recent neurobiological, genetic, and psychological investigations have accumulated evidence of an overlapping spectrum between anorexia nervosa, bulimia nervosa, and Binge Eating Disorder (originally classified in the eating disorders-NOS in DSM-IV) and obsessive–compulsive disorder or obsessive–compulsive personality disorder (Lazaro et al. 2005; Serpell et al. 2002).

Prevalence rates for obsessive–compulsive disorder or obsessive–compulsive features in eating disorders are relatively high, ranging between 25% and 69% in anorexia nervosa, and 3–40% in bulimia nervosa (Lawson et al. 2007). Abnormal eating habits such as restriction and binge eating themselves can be explained by compulsive behavior to achieve affect regulation (e.g., reducing anxiety). Therefore, there is a keen debate about the pertinence of separating eating disorders and obsessive–compulsive disorder as different diagnostic categories, because they are presently assigned to separate categories in DSM-IV (Grilo 2004; Wu 2008). Moreover, mood disorders, anxiety disorders, and personality disorders are more commonly present with bulimia nervosa than anorexia nervosa, suggesting that the etiologies of anorexia nervosa and bulimia nervosa are quite similar but not identical (Carlos et al. 2009; Kaye 2008). However, it is noteworthy that such disorders, which are possibly comorbid with anorexia nervosa/bulimia nervosa, are also known to be caused at least partially by serotonergic neuronal dysregulation.

Obsessive eating in patients with bulimia nervosa/Binge Eating Disorder is more likely to involve obsession with the cycle of overeating and purging rather than with the food itself. This behavior can be understood to be similar to an addiction to drugs or other substances. Usually the patients experience regret and anguish after the binge eating episode, followed by inadequate compensatory behavior such as vomiting, laxative abuse, diuretic abuse, or overexercise, but are unable to escape from the addiction by themselves. Anxiety, depression, and low self-esteem frequently coexist in these patients, often becoming their dominant thought and subsequently increasing the likelihood of comorbidities like mood disorder and anxiety disorder (Carlos et al. 2009). In contrast to patients with bulimia nervosa/Binge Eating Disorder, those with restricting anorexia nervosa present obsessive eating habits less frequently (Emily et al. 2008). They rather develop malnutrition, hormonal imbalances, and a variety of electrocardiographic abnormalities due to reduced total calorie intake and dehydration, which are the most lethal manifestations, and thus are important in the treatment of the patients.

Recently, we encountered a remarkable and uncommon case of an adolescent with restricting anorexia nervosa who presented with obsessive and restricted banana ingestion for more than 2 years (Tazoe et al. 2007). As a result, the patient developed extreme hyperkalemia, hyperdopaminemia, pseudoaldosteronism, and dysthymia, which could not be explained by the pathology of restricting anorexia nervosa alone. Moreover, the patient had presented with obvious aggression and inner-impulse paralleling an increase in whole blood dopamine, suggesting that the brain dopamine concentration was also affected by the obsessive and restricted banana ingestion. Since bananas are known to be rich sources of both dopamine and potassium (Kanazawa and Sakakibara 2000; Kasuga and Katano 2008), the clinical condition of this patient was thought to be dramatically altered by the massive ingestion of bananas. Details of the case are presented in the following subsections.

125.2.2 Case

At the age of 15, the female patient visited a pediatric clinic for emaciation, amenorrhea, and appetite loss, which had been noted by her school teacher. The patient had been on a strict diet intentionally for the past half year, and had lost 6.2 kg of weight (decreasing from 46.9 to 40.7 kg; BMI = 15.7). She was born at term, her psychomotor development was normal, and had no past history of Attention Deficit/Hyperactivity Disorder or other behavioral problems. Her pulse rate and blood pressure were within the normal range, and the electrocardiogram and cardiac ultrasound showed no abnormality. Although no abnormality was found in the regular blood analysis data, obvious hormonal imbalances were noted as follows: GH 1.47 ng/mL ($\downarrow$), IGF-1 88 ng/mL ($\rightarrow$), ACTH 14 pg/mL ($\rightarrow$), Free T4 0.81 ng/dL ($\downarrow$), Free T3 1.65 pg/mL ($\downarrow$), TSH 1.740 μU/L ($\rightarrow$), and estradiol < 10 pg/mL ($\downarrow$). Minor elements such as Cu, Zn, vitamins B_1 and B_2, lactate, and pyruvate were all within normal ranges. She had pigmentation of the skin and was obviously hyperactive.

125.2.3 Obsessive Banana Ingestion Directly Affects the Blood Dopamine Concentration and Electrolytes

Figure 125.1 shows the course of illness observed in the patient. She was hospitalized two times over a 60-month observation period, and the lowest body weight reported was 27.0 kg (BMI = 10.3). An increase in extraordinarily obsessive behavior began to be observed during her first hospitalization period (from the 8th month of the observed period). She denied ingesting any food item other than bananas (5–20 pieces a day) and hard mineral water (up to 500 mL a day), and was obsessed by the need to engage in excessive daily exercise. Following this obsessive eating behavior, blood analysis showed a gradual increase of serum potassium and whole blood dopamine. The second hospitalization period was required when her body weight dropped as low as 27.0 kg at the 16th month of the observation period. Intravenous hyperalimentation along with cognitive–behavioral therapy was performed during each hospitalization period.

After the 24th month of the observation period, the patient's whole blood dopamine concentration jumped to 180 ng/mL. At the same time her serum potassium was as high as 6.1 mEq/L, although no abnormality was observed in electrocardiogram and blood pressure examination. Later, in the 38th month of the observed period, her dopamine concentration increased to as high as 210 ng/mL. At the 40th month of the observation period, her weight decreased again to 32 kg. Her serum potassium level was 5.7 mEq/L, aldosterone was 708.8 ng/dL, and renin was 130 pg/mL, all of which are relatively higher than the normal range in the Japanese population. Although the patient kept normal blood pressure throughout the course of the illness, the increases in renin and aldosterone suggested that she fell into a state of pseudoaldosteronism during this time period. Serum catecholamine analysis showed an extreme increase of free dopamine (0.47 ng/mL, normal range < 0.03); however, no increase in epinephrine (<0.01 ng/mL) or norepinephrine (0.39 ng/mL) was observed.

In response to treatment with cognitive–behavioral therapy, she began to ingest food items other than banana after 26 months of this restrictive eating pattern. Over the next 12 months, economic reasons prevented her from returning to the clinic; however, the most recent examination at the 56th month of the observation period showed distinct improvement in her blood values, including serum potassium of 5.6 mEq/L and whole-blood dopamine of 56 ng/mL. In addition, her weight had increased to 36 kg. She seemed at that time to have "calmed down" and her skin was obviously depigmented.

125.2.4 Obsessive Banana Ingestion May Have Modified the Psychobiological State in the Patient

The patient's psychological state had been continuously assessed by our team clinical psychologist (MT) regularly during the course of her illness, using three types of psychological tests: the tree drawing test (Koch 1952; Kosaka 2008), the Japanese version of the state-trait anxiety inventory (STAI) (Iwata et al. 1998), and the Tokyo University egogram (TEG), which evaluates ego states (Oshima et al. 1996).

The whole clinical course was classified to six stages according to the degree of emaciation, treatment, and blood analyses as follows (see also Fig. 125.1).

Stage I. Prior to the first hospitalization: She did not cooperate with the psychological therapy or with oral ingestion of nutrient drinks. She walked more than 10 km daily, and exercised her abdominal muscles intensively to build her "ideal body." One drawing (Fig. 125.2) was obtained during this stage.

Stage II. First admission: Within 6 months after the first visit, she had reduced her weight to 32.1 kg (BMI = 12.2). She underwent forced admission to the pediatric ward, where she was treated by intravenous hyperalimentation infusion, along with behavior restriction therapy. She gained 4 kg during the 30-day admission, and was discharged from the hospital afterward. Two drawings (Fig. 125.3a and b) were obtained during this period.

Stage III. Between the first and second hospitalizations: The patient was obsessed by the idea that all processed foodstuffs are contaminated by additives and pesticides. Eventually, she stopped eating
Fig. 125.1 The course of illness in the patient with obsessive banana ingestion. The illness course of the patient is schematically presented. Changes in body weight, whole blood dopamine, serum potassium, and habit of food ingestion are shown. Two intravenous hyperalimentation treatments during hospitalization (IVH [1] and IVH [2]) and continuous cognitive–behavioral therapy were performed. The stages indicated in the figure correspond to the descriptions in the text
Fig. 125.2 Tree drawing test drawing of the patient at Stage I. Tree drawing test drawing of the patient at Stage I is shown. Note that the branches are cut off in the middle. This feature is consistently observed in the rest of her drawings. The rigid crown shape and the solid and strong lines are also characteristic

except for a maximum of 20 pieces of banana and 500 mL of mineral water per day. She stuck to one type of banana (an organic product from Ecuador) and one brand of hard mineral water. During this period, two drawings (Fig. 125.4a and b) were obtained from the patient.

Stage IV. Second hospitalization: Her weight dropped to 27.0 kg (BMI = 10.3) at this time, which again became an indication for intravenous hyperalimentation treatment and admission. This time she gained over 13 kg and was discharged. However, there was no change in her eating and exercise habit. Two drawings (Fig. 125.5a and b) were obtained during this period.

Stage V. Increase in blood dopamine level due to excessive consumption of bananas: Against the counsel of physicians, psychologists, and her family members, the patient continued her strict avoidance of food items other than bananas and hard mineral water. Blood analysis revealed increased levels of serum potassium, whole blood dopamine, aldosterone, renin, and angiotensin, which suggested a state of pseudoaldosteronism and hyperdopaminemia. At this stage, she also began to show obvious impulsiveness and irritability, which are not frequently observed in anorexia nervosa patients. One drawing (Fig. 125.6) was obtained during this period.

Stage VI. Remission from the obsessive banana ingestion with recovery of all of the blood values: Her impulsiveness and irritability had almost disappeared and she was eating many kinds of food, although the amount was still small. One drawing (Fig. 125.7) was obtained during this period.
Fig. 125.3 **a** and **b** Tree drawing test drawings of the patient at Stage II. Tree drawing test drawings at Stage II, on admission (**a**) and on discharge (**b**) following the patient's first hospitalization period, are shown. Note that the defective crown size and form seen on admission have improved by discharge

125.2.4.1   The Tree Drawing Test

See Table 125.1 for key features of the tree drawing test.

Figure 125.2 shows the patient's drawing at Stage I. The form of her drawing was interpreted as defensive to stimuli from the outer world (outlining of the crown is rigidly shut) and emotionally shut off from relationships with others (the branches are all cut off in the middle), which are both considered to represent a pathologically low energy state. The lines of drawing were consistently solid and high in strength during all stages, which was thought to represent the inherent individuality of her obsessive tendency.

Figures 125.3a and b were both obtained during Stage II, the first hospitalization period. On admission (Fig. 125.3a), the crown was drawn with discontinuous lines in the tree drawing test, suggesting her susceptibility to the outer world. The branches were still the same, having the cut-off-in-the-middle shape, suggesting her emotionally shut-off state. In addition, the crown was shaded, which was thought to represent her depressive state. The size of the crown was reduced and a branch grew beneath the crown, which was considered representative of her psychological regression. On discharge after approximately a month of hospitalization, her drawing (Fig. 125.3b) still showed signs of defensiveness and emotional shutting off. However, the crown was enlarged and was no longer painted, and no branches were seen beneath the crown. These observations suggested that her
Fig. 125.4 **a** and **b** Tree drawing test drawings of the patient at Stage III. Tree drawing test drawings earlier (**a**) and later (**b**) in Stage III are shown. The patient was obsessed with banana ingestion, and her condition gradually deteriorated during this period. Note that the outline of the crown was drawn differently, and later, the crown protruded from the paper

psychological regression had ended. Instead, the drawing showed flowers and butterflies with a trunk of wide width, which was thought to represent her self-display and magnified self. The lines of the drawing are solid and very strong, similar to those of previous drawings.

During Stage III, the period when the patient's obsessive banana ingestion began and continued, tree drawing test was performed twice and an obvious change in the crown form was observed. The outline of the crown was drawn fluffy with repeated lines in the earlier drawing of Stage III (Fig. 125.4a), which was deformed into more sharp-pointed and discontinuous form in the later drawing (Fig. 125.4b). These observations were interpreted to mean that her susceptibility to outer stimuli grew and she needed to pile up the lines to be more defensive. Later on, she became irresistibly hypersensitive and more aggressive. This time, the crown protruded out from the paper, representing her acting-out state.

During Stage IV, the second period of hospitalization that occurred when her critical emaciation had progressed as a result of her obsessive banana ingestion, tree drawing test was performed twice (Fig. 125.5a and b). In Fig. 125.5a, the tree drawing test performed on admission, the patient's drawing showed a wide trunk, branches beneath the crown (regression), and a discontinuous outline of the crown. It seemed she no longer had the energy to shut the crown through repeated drawing; the single discontinuous line can easily let the outer stimuli invade into her inner-self. On discharge after the second hospitalization period, the form of the tree drawing test (Fig. 125.5b) showed slight improvement, with a wide trunk and fruits that represent self-display and magnified self.
Fig. 125.5 **a** and **b** Tree drawing test drawings of the patient at Stage IV. Tree drawing test drawings at Stage IV, on admission (**a**) and on discharge (**b**) following the second hospitalization period, are shown. Note that on admission, the form of the drawing seems collapsed and the crown has a discontinuous outline, showing loss of energy

Generally speaking, to this point, her psychological energy had been decreasing in tandem with the stage progression. However, at Stage V, when her obsessive eating was at a maximum and her blood dopamine concentration was elevated as high as 180 ng/mL, her drawing showed drastic changes. Figure 125.6 shows her drawing at this stage. The form of the crown was completely changed, with lines rising one by one from the inner area of the tree, as if showing the effort of the patient's resistance to her bursting inner-impulse. For the first time, a horizon appeared in her drawing as a notched line, representing a decrease in her anxiety and an apparent stabilization (in her subjective sense, although she was not healthy). The lines were drawn smoothly with no disconnection, showing her full of energy without anxiety or depression. These changes were totally inexplicable and unexpected based on her physical state, which was characterized by body weight as low as 30 kg, indicating that she was critically ill with anorexia nervosa.

At Stage VI, the bizarre observations seen in the drawing at Stage V had completely disappeared, namely, the drawing showed the pattern that had originally been observed in the patient (Fig. 125.7). The form of the crown was smooth, with a continuous outline with no rigidness, indicating that her defensiveness and susceptibility to the outer stimuli were decreased in her current psychic state. The extremely wide trunk (especially at the bottom) and fruits/butterfly showed that her self-display and magnified self-tendency still exist, suggesting that she was not completely healthy but was seemingly back to her original psychic state as a result of stopping banana ingestion and the consequent decrease in her blood dopamine concentration.

Fig. 125.6 Tree drawing test drawing of the patient at Stage V. Tree drawing test drawing at Stage V is shown. Note the formation of the crown with lines rising one by one from the inner side of the tree, as if showing the patient's effort to resist her bursting inner-impulse
125.2.4.2 The STAI

The STAIs were performed at Stages III, IV, and V. The STAI-state anxiety score was 55, 68, and 46, and the STAI-trait anxiety score was 47, 58, and 49, respectively at each stage. At Stage V, the patient's anxiety levels, which had been rising along with her illness condition suddenly decreased, apparently showing that the patient "did not feel" anxious anymore during this period. These finding were similar to the results of the tree drawing test.

125.2.4.3 The Ego State

The patient's ego states were examined at Stage I and Stage V. At Stage I, low energy was observed in the egogram, and low CP (Critical Parent) and FC (Free Child) were observed along with high AC (Adopted Child). These results were interpreted to indicate low ego state, low self-assertion, and emotional repression with high law-abiding tendency. This observation was consistent with her tree drawing test and the diagnosis of restricting anorexia nervosa. In contrast, at Stage V, high energy was observed in the egogram. Her ego state showed a result that was the complete inverse of that in Stage I, with high-rising CP and FC, and an obvious decrease in AC. At this stage, the patient "feels" high ego energy, high self-assertion, and emotional elevation with low law-abiding tendency, and is seemingly full of vigor. Again, this observation did not contradict the results of the tree drawing test and STAI at this stage, suggesting transitory and unexpected psychological alteration had occurred at Stage V.

Fig. 125.7 Tree drawing test drawing of the patient at Stage VI. Tree drawing test drawing at Stage VI is shown. After remission of the obsessive banana ingestion, the bizarre observations seen in the Tree drawing test drawing at Stage V have completely disappeared and the drawing now resembles Figs. 125.3b and 125.5b, from the earlier post-treatment periods
Table 125.1 Key features of the tree drawing test

1. Tree drawing test is also known as Baum test ("baum" means "tree" in German), first developed and distributed in Germany by Koch in 1950s (Koch 1952)
2. Using a size of 210 × 297 mm drawing paper, a 4B pencil, and an eraser, the subject is instructed to draw a tree which bears fruits of any kind, in any way he/she likes
3. The size and location of the tree on the sheet are considered to represent the self-cognition and relative relationship between the subject and surrounding environments
4. The shape and the size of the crown are considered to represent the subjective inner mental state, in relation with the outer world
5. The trunk and the elements drawn along with the tree (fruits, flowers, butterflies, birds, etc) are thought to represent the "self" state and desire of the subject
6. The strength, solidness, energy, continuity, and repetition of the drawing lines are examined closely to observe the subject's inherent individuality and pathological characteristics

This table lists the key features of the tree drawing test including the history, the procedure, and the tips for interpretation

125.3 The Impact of Obsessive Eating of Banana on Neurobiology and Behavior

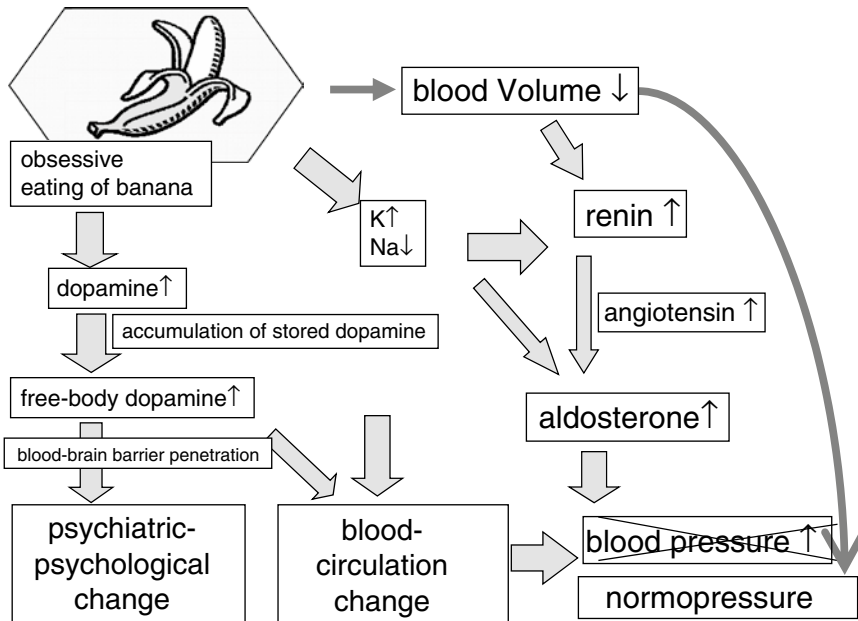
The patient followed an unusual course of restricting anorexia nervosa, which was considered to be related to her long period of obsessive and restricted banana ingestion. The summary points of the case are shown in Fig. 125.8. Bananas are known to be a dopamine-rich food. Approximately 0.72 mg


Fig. 125.8 The summarized feature of the case. The summarized feature of the case with obsessive eating of banana is shown. The increase of blood potassium and dopamine induced by unusual consumption of banana was considered to be responsible for the pseudoaldosteronism and the psychiatric-psychological change in the patient

of dopamine is contained within 100 g (approximate weight of the edible portion of one banana) of ripe banana fruit, and 100 g of unripe banana fruit contains as much as 10 mg of dopamine. Moreover, 100 g of ripe banana skin and thread contain 235 mg of dopamine and 100 g of unripe banana skin and thread contain approximately 1,940 mg of dopamine (Kanazawa and Sakakibara 2000). Dopamine is absorbed in a sulfate-conjugated form from the digestive tract, and normally the free dopamine level is not affected by the dose of ingested dopamine (Davidson et al. 1981; Dunne et al. 1983).

The patient showed some level of hyperdopaminemia from the beginning of her illness course, which is consistent with previous reports of dopaminergic neuronal hyperactivity in anorexia nervosa (Devesa et al. 1988; Kaye et al. 1999). However, the dramatic increase in her whole-blood dopamine concentration, which was observed immediately after she began excessive ingestion of bananas, cannot be explained simply based on the pathogenesis of anorexia nervosa. Rather, considering the fact that the patient preferred unripe bananas to ripe ones and often ate the skin and thread of the banana as well, her daily ingestion of dopamine must have increased significantly. That increase may eventually have led to an increase in free dopamine (0.47 ng/mL, compared with the normal range in the Japanese population of <0.03 ng/mL), without a corresponding increase in epinephrine or norepinephrine, most likely because banana contains particularly large amounts of dopamine, but relatively smaller amounts of epinephrine and norepinephrine. We suspect that in the case of this patient, sulfate-binding dopamine became oversaturated by daily ingestion of large amounts of banana, which led to the resulting increase in free dopamine.

In addition to hyperdopaminemia, the patient demonstrated hyperkalemia and pseudoaldosteronism. Bananas are also known to be rich in potassium, containing 330–400 mg of potassium in 100 g of the edible portion of the fruit (Kasuga and Katano 2008). Hyperkalemia, along with hyperdopaminemia, is considered to be the leading cause of pseudoaldosteronism. An obvious increase in

blood renin and angiotensin was observed, but her blood pressure remained normal throughout the course of her illness, probably because of her absolute hypovolemia.

In the initial tree drawing test and egogram performed prior to the onset of obsessive eating, the patient showed low energy and ego states, with defensiveness, low self-assertion, and a strong protective tendency, which were all reasonably explained by the psychopathology of anorexia nervosa and essential obsessive personality of the patient (Mizuta et al. 2002). However, in tree drawing test, egogram, and STAI performed after 2 years of obsessive ingestion of only banana, the opposite results were observed; high energy and ego states, with an extreme internal impulsiveness and low anxiety and high self-assertion. Given that this alteration in psychological state occurred with simultaneous hyperdopaminemia and disappeared along with remission of the obsessive banana ingestion, it is possible that the extreme increase in her blood dopamine level resulting from obsessive banana ingestion was responsible for saturating binding proteins and increasing free dopamine, which affected her psychological state.

Her obvious aggression and inner-impulse, in accord with the increase in whole-blood dopamine, suggest that the brain dopamine concentration was also affected by the obsessive and restricted ingestion of banana. Dopamine is well known to have poor blood–brain barrier penetration because of physiological blockade caused by its high polarity. However, a recent study revealed that blood–brain barrier penetration of dopamine could be increased in a dose- and time-dependent manner by continuous arterial infusion of dopamine (Martel et al. 1996). Thus, it seems reasonable to assume that blood–brain barrier penetration by dopamine was modified in the patient, who experienced hyper-free dopaminemia, as a result of lengthy and excessive ingestion of banana.

Nutrient imbalance resulting from deficiency of vitamins and minerals such as calcium, iron, zinc, phosphate, and magnesium may be observed in eating disorders, and this imbalance may cause skin disease, endocrinological disorder, or osteopenia (Seidenfeld et al. 2004). Zinc is an important brain nutrient, acting as a neuromodulator/neurotransmitter mainly in the cortex in relation to glutaminergic neurons (Harrison and Gibbons 1994; Takeda et al. 2000). Deficiency of zinc may be related to cognitive disorder or depression (Meunier et al. 2005). However, no clear link to eating disorders has yet been proven, and no sign of zinc deficiency was observed in the present case.

The case of our patient is noteworthy as an extreme example of how ingested food directly affects the biochemical and psychic state. The patient showed strong and irrational obsessive behavior with food and exercise compared to patients with regular anorexia nervosa. Since abnormal eating habits are common in patients with anorexia nervosa, it is necessary to identify detailed eating habits of anorexia nervosa patients to avoid the cumulative effects of a particular food on their physical and psychic state.

125.4 Applications to Other Areas of Health and Disease

As mentioned above, obsessive eating is a pathological eating habit, rather than a clinical diagnosis. Thus, any neuropsychological disorder associated with obsessive behavior caused by anxiety has the potential to provoke obsessive eating habits, regardless of its etiology. From this perspective, not only eating disorders, which are defined based on the eating habit, but obsessive–compulsive disorder, obsessive–compulsive personality disorder, autism spectrum disorder, and any other congenital chromosomal defect can show obsessive eating as one of their clinical symptoms.

Obsessive eating can accompany any type of eating disorders, especially when binge eating symptoms coexist. Recently, new concepts of night eating syndrome and sleep-related eating disorder have been proposed as atypical categories of eating disorders. They are characterized by unusual amount of food consumption during the night time, and the behavior can often be obsessive (O'Reardon et al. 2005).

Another pathological condition related to obsessive eating that should be mentioned here is pica. Pica is usually seen in infancy and early childhood and is characterized by repeated or chronic ingestion of non-nutritional substances, such as plaster, charcoal, clay, wool, ashes, paint, and earth. It is known that pica is frequently associated with neuropsychological disorders, including autism spectrum disorder, schizophrenia, and mental retardation (Herguner et al. 2008; Lockner et al. 2008; Behrman et al. 2000), and patients often fulfill the criteria of obsessive–compulsive disorder as well (Bhatia and Gupta 2007).

Interestingly, eating disorders, obsessive–compulsive disorder, autism spectrum disorder, and other psychological disorders that are potentially related to obsessive eating are comorbid among each other to some degree (Grilo 2004; Hambrook et al. 2008; Wu 2008). Moreover, pharmacological treatments, including SSRIs and topiramate, are effective to some extent in all of these disorders (Arnone 2005; Niederhofer 2008; Rosenblum and Forman 2003), suggesting that neurocognitive pathophysiology, including serotonergic and glutaminergic neuronal systems, may be involved in the etiology of these disorders, as well as in obsessive eating habit.

Summary Points

- Obsessive eating is a term not used as a clinical diagnosis, but refers to a pathological habit of eating accompanied by neuropsychological disorders.
- Obsessive eating habit can be associated with eating disorders, autism spectrum disorder, obsessive–compulsive disorder, and other neuropsychological disorders that are considered to be related to serotonergic dysfunction.
- We have reported a case of restricting anorexia nervosa in a female adolescent who was obsessed by an extremely restricted eating habit.
- As a result of eating only bananas and mineral water over more than 2 years, she exhibited biochemical and metabolic disorders as well as a psychological disorder.
- She developed hyperkalemia, hyperdopaminemia, and pseudoaldosteronism possibly as a result of an imbalance of nutritive intake. However, hypertension was not observed, most likely because of absolute hypovolemia.
- The psychological tests performed over the course of her illness showed changes in her psychic state, such as increased anxiety levels, and decreased psychological energy and ego energy.
- In her most extreme phase of hyperdopaminemia, she revealed the conflict associated with resisting her inner-impulse in her Tree drawing test drawing, which differed completely from the drawings made during other stages of the illness.
- The accumulation of free dopamine due to obsessive banana ingestion was considered to affect the patient's psychic state.

Definitions and Explanations of Key Terms or Words

Obsessive eating: A term that is not used as a clinical diagnosis, but rather refers to a pathological habit of eating accompanied by neuropsychological disorders.
Eating disorders: Unusual eating habits resulting from an intense fear of becoming fat as defined in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV).
Anorexia nervosa: A subcategory of eating disorders characterized by self-imposed weight loss and amenorrhea. A distorted psychopathological attitude toward eating and weight gain is pathognomonic of anorexia nervosa.

Bulimia nervosa: Another subcategory of eating disorders characterized by recurrent binge eating, followed by compensatory behavior such as vomiting or misuse of laxatives.

Obsessive–compulsive disorder: A subcategory of anxiety disorders in DSM-IV characterized by involuntary intrusive thoughts and compulsive behavior.

Autism spectrum disorder: A spectrum of congenital neurological disorders characterized by impairment of socialization, abnormalities of communication, and limited activity and curiosity.

Serotonin (5-hydroxytryptamine, 5-HT): A biogenic amine neurotransmitter synthesized from L-tryptophan. 5-HT modulates diverse effects of the neuronal system, including sleep, appetite, pain, motor function, cognition, sexual activity, as well as emotions such as mood and anxiety.

Dopamine: A biogenic amine neurotransmitter synthesized from l-tyrosine. Dopamine also regulates diverse functions of neuronal system, including cognition, locomotor activity, exploration, motivation, feeding, and sexual behavior.

Chapter 126
Eating Disorders and Suicide

Antonio Preti, Maria Valeria Camboni, and Paola Miotto

Abbreviations

AN	Anorexia nervosa
AN-BP	Anorexia nervosa, binge-eating/purging type
AN-R	Anorexia nervosa, restricting type
BD	Bipolar disorder
BED	Binge eating disorder
BMI	Body mass index
BN	Bulimia nervosa
BN-NP	Bulimia nervosa, nonpurging type
BN-P	Bulimia nervosa, purging type
CI	Confidence interval
CRF	Cortical releasing factor
CSF	Cerebrospinal fluid
DSH	Deliberate self-harm
DSM-IV-TR	*Diagnostic and Statistical Manual*, IV edition, Transitory Revision; the diagnostic manual of the American Psychiatric Association
EDNOS	Eating disorder not otherwise specified
EDs	Eating disorders
ESEMeD	European Study of the Epidemiology of Mental Disorders
5-HIAA	5-Hydroxyindolacetic acid, the major metabolite of serotonin
5-HT	5-Hydroxy-tryptophan, or serotonin
HPA	Hypothalamic pituitary adrenal axis
MDD	Major depressive disorder
NA	Noradrenalin
NCS-R	National Comorbidity Survey Replication
PD	Personality disorder
SIB	Self-injury behavior
SSRIs	Selective serotonin reuptake inhibitors
SUD	Substance use disorder

126.1 Introduction

Worldwide, suicide is one of the top five causes of death among 15–25 year-old people, the age group that is exposed the most to the risk of developing an eating disorder. Indeed, suicide was reported as one of the main causes of death in people with eating disorders (EDs) (Sullivan 1995), and suicidal behavior is reported as highly prevalent in patients with EDs (Franko and Keel 2006; Signorini et al. 2007).

At present, the definition of EDs is conferred to a set of behavioral disorders characterized by disordered eating and body dissatisfaction, a high level of psychological distress related to eating behavior, and high comorbidity with other mental disorders, principally anxiety, mood, and substance use disorders (SUDs).

Current classifications identify two main syndromes of EDs: anorexia nervosa (AN) and bulimia nervosa (BN), and a wide range of subclinical conditions called "eating disorders not otherwise specified" (EDNOS). Among the EDNOS, binge eating disorder (BED) recently acquired a more precise clinical and epidemiological validity and is now considered worthy of clinical and diagnostic autonomy (Hudson et al. 2007).

This chapter reviews the evidence on suicidality in EDs to provide some clues on prevention and treatment that might also be relevant for other areas of health and disease.

126.2 Eating Disorders: General Characteristics

Typically, the self-esteem of individuals with EDs is highly dependent on their body shape and weight: low self-esteem is reported as an antecedent of the development of EDs (Jacobi et al. 2004).

Severe disturbances in eating behavior are the main feature of EDs: in AN there prevails the refusal to maintain a minimally normal body weight, while BN is characterized by repeated episodes of binge eating followed by inappropriate compensatory behaviors as self-induced vomiting, misuse of laxatives, diuretics, or other medications, fasting, or excessive exercise. Episodes of binge eating and inappropriate compensatory behaviors can occur in AN too, while binge eating without compensatory techniques is the main feature of BED. Often, obesity follows as a consequence of uncompensated recurrent episodes of binge eating.

Binge is defined as eating in a discrete period of time (usually less than 2 h) an amount of food that is definitely larger than most individuals would eat under similar circumstances. It may include sweet, high calorie foods as ice cream or cake, and it comes with a sense of lack of control. People are often ashamed of their eating problems and try to conceal their symptoms, so the episodes of binge eating usually occur in secrecy. Typical triggers are dysphoric mood states, interpersonal stressors, or intense hunger following dietary restraint. Binge eating may reduce dysphoria, but generally distressing self-criticism and depressed mood follow.

The most common compensatory technique after binge eating is the induction of vomiting: it produces relief from physical discomfort and also decreases the fear of gaining weight. Individuals with EDs may also fast for a day or more or exercise excessively in an attempt to compensate for binge eating (*Diagnostic and Statistical Manual*, IV edition, Transitory Revision (DSM-IV-TR)). Individuals with diabetes mellitus and EDs may omit or reduce insulin doses in order to reduce the metabolism of the food eaten during binges, a very dangerous and life-threatening practice (Fairburn and Harrison 2003).

126.2.1 Anorexia Nervosa: Clinical Features

Diagnosis of AN is made in the presence of a refusal to maintain a minimally normal body weight (Criterion A), associated with intense fear of gaining weight or becoming fat (Criterion B), and significant disturbance in the perception of body shape or size (Criterion C). Amenorrhea (Criterion D) is usually a consequence of weight loss but sometimes it may actually precede it; in prepubertal females, the illness may delay menarche (DSM-IV-TR). The corresponding symptom in males is loss of libido.

Usually weight loss is accomplished primarily through reduction in total food intake, which may associate with purging (i.e., self-induced vomiting or the misuse of laxatives or diuretics) and increased or excessive exercise. For Criterion A to be satisfied, body weight must be consistently 15% lower than expected for the same height and age or the body mass index (BMI) must be 17.5 or lower.

When severe underweight induces depressive symptoms such as depressed mood, social withdrawal, irritability, and insomnia, the criteria for major depressive disorder (MDD) are often met. Intense obsessive-compulsive symptoms, either related or unrelated to food, can develop as well and may persist even after weight restoration (Kaye et al. 2000). Subclinical psychotic symptoms can occur during starvation, such as inflexible thinking, limited social spontaneity, and affective flattening expressed through overly restrained initiative and emotional expression.

The somatic symptoms of AN largely depend on restrictive diet (Mitchell and Crow 2006). Emaciation prevails, and there may be complaints of constipation, abdominal pain, cold intolerance, lethargy, and excess energy. There may also be significant hypotension with bradycardia, hypothermia, and dryness of skin, with some individual developing lanugo, a fine downy body hair, on their trunks. Peripheral edema may develop during weight restoration, often following the cessation of laxative and diuretic abuse. Hypertrophy of the salivary glands, particularly the parotid glands, may be present.

Severe general medical conditions may follow a semistarvation period, including impaired renal function (associated with chronic dehydration and hypokalemia), cardiovascular problems (severe hypotension, arrhythmias), dental problems, and osteoporosis (resulting from low calcium intake and absorption, reduced estrogen secretion, and increased cortisol secretion).

No laboratory abnormality is typical enough of AN to be used for diagnosis: leukopenia and mild anemia are common, as are elevated liver function tests; self-induced vomiting may lead to metabolic alkalosis (elevated serum bicarbonate), hypochloremia, and hypokalemia, and laxative abuse may cause a metabolic acidosis; low serum estrogen levels are present in females, low levels of serum testosterone in males; sinus bradycardia and arrhythmias can be observed. An increase in the ventricular-brain ratio secondary to starvation may be seen at brain imaging, and diffuse abnormalities at electroencephalography may result from significant fluid and electrolyte disturbances.

126.2.2 Bulimia Nervosa: Clinical Features

Diagnosis of BN is made in the presence of binge eating (Criterion A) and inappropriate compensatory methods to prevent weight gain (Criterion B); for diagnosis both behaviors must occur, on average, at least twice a week for 3 months (Criterion C); the self-evaluation of individuals with BN must be demonstrably influenced by body shape and weight (Criterion D).

People with BN show the same fear of gaining weight or becoming fat and the associated intense desire to lose weight and dissatisfaction with their bodies as those with AN, although they never

reach the extreme emaciation of AN, and when this does occur (BMI ≥ 17.5), the diagnosis of BN is not appropriate (DSM-IV-TR).

Mood disturbances often co-occur with BN: sometimes mood disturbance clearly precedes the onset of BN. Also, increased occurrence of anxiety and anxiety disorders does occur in association with BN. Personality disorders (PDs), particularly borderline PD, are often comorbid with BN (30–50% of cases) and substance abuse/dependence occurs in about one-third of the people suffering from BN (alcohol and stimulants more frequently) (Hudson et al. 2007; Preti et al. 2009).

No laboratory abnormality is typical of BN enough to be used for diagnosis: purging behavior can produce fluid and electrolyte abnormalities (hypokalemia, hyponatremia, and hypochloremia); the frequent induction of diarrhea through laxative abuse can cause metabolic acidosis; mildly elevated levels of serum amylase, probably reflecting an increase in the salivary isoenzyme, can be observed, and in some individuals the salivary glands, especially the parotid glands, may become notably enlarged.

Severe general medical conditions are less likely than in AN; however, rare but potentially fatal complications may occur, such as cardiac arrhythmias, esophageal tears, or gastric rupture (Mitchell and Crow 2006).

126.2.3 Subtypes of Eating Disorders

Two subtypes of AN are described: the Restricting type (AN-R), when weight loss is accomplished primarily through dieting, fasting, or excessive exercise; and the Binge-Eating/Purging type (AN-BP), when binge eating or purging (or both) occur during the current episode in addition to dieting and fasting. People affected by AN-BP are more likely than those with AN-R to have other impulse-control problems, to abuse alcohol or other drugs, to exhibit more mood instability, and to be sexually active or promiscuous.

Two subtypes of BN are described: the Purging type (BN-P), when the person regularly engages in self-induced vomiting or misuses laxatives, diuretics, or enemas during the current episode; and the Nonpurging type (BN-NP), where the only inappropriate compensatory behaviors are fasting or excessive exercise, and no self-induced vomiting or the misuse of laxatives, diuretics, or enemas occur during the current episode.

An additional diagnostic category for EDNOS concerns the EDs that do not meet the criteria of any subtype of AN or BN: most criteria are satisfied except one of those qualifying the disorder (DSM-IV-TR). BED, in particular, is characterized by recurrent episodes of binge eating (Criterion A), in the absence of regular recourse to inappropriate compensatory behaviors (Criterion E). In BED, patients manifest obvious distress concerning their eating behavior, so they eat alone because they feel embarrassed at overeating and feel intense disgust, depression, or guilt after a binge (Criterion B). Obvious and appreciable distress comes with binge eating behavior (Criterion C). To qualify for diagnosis, binge eating must occur on an average twice a week for at least 6 months (Criterion D).

126.2.4 Eating Disorders: Associated Features

Engaging in a diet is the main antecedent of EDs: indeed, obesity during childhood or adolescence may precede the development of EDs, particularly when recurrent episodes of binge eating and inappropriate compensatory behaviors do occur (Jacobi et al. 2004). Depression causes inappetence and

Table 126.1 Key facts of EDs

EDs are behavioral disorders characterized by disordered eating and body dissatisfaction, a high level of psychological distress related to eating behavior, and high comorbidity with other mental disorders, principally anxiety, mood, and substance use disorders.

Main features of EDs are:
1. A self-esteem highly dependent on body shape and weight.
2. Severe disturbances in eating behavior, from severe dieting and refusal to maintain a minimally normal body weight, to repeated episodes of binge eating followed by inappropriate compensatory behaviors as self-induced vomiting, misuse of laxatives, diuretics, or other medications, fasting, or excessive exercise.

There are two main syndromes of EDs, and a wide range of subclinical conditions called "eating disorders not otherwise specified" (EDNOS):
1. AN
2. BN
3. EDNOS (including the Binge Eating Disorder)

The etiology of EDs is complex and involves many factors: genetic predisposition, or premature birth and birth trauma might interact with chronic and acute stressful life events to precipitate the onset of an Eating Disorder.

EDs can be treated, with acceptable to good positive outcome involving up to 70% of treated patients after a 10-year follow-up in AN and a large fraction of recovered patients at short-medium term in BN, although with high risk of relapse

This table summarizes the main characteristics of EDs as they are described in current international classifications of mental disorders

AN anorexia nervosa, *BN* bulimia nervosa, *EDs* eating disorders

may precipitate an ED: low self-esteem, an oft-reported antecedent of EDs, might be a marker of depression as a predisposing factor for the onset of an ED. However, the etiology of EDs is complex and involves many factors: genetic predisposition, or premature birth and birth trauma might interact with chronic and acute stressful life events to precipitate the onset of an ED (Table 126.1).

Both AN and BN are statistically more common among family members than in the general population and their prevalence is higher in monozygotic than in dizygotic twins, but a clear genetic effect emerges only after puberty (Klump et al. 2007). Several studies found childhood physical or sexual abuse as predisposing risk factors for EDs (Jacobi et al. 2004). Childhood trauma and other stressful experiences relate to impulsivity and higher risk of suicide and self-injury behavior (SIB) in patients with EDs (Vanderlinden and Vandereycken 1997).

After the onset of the disorder, criticism from parents and conflict between them might influence its course negatively (Wade et al. 2006).

Comorbidity, i.e., the association of two or more pathologies that might also have a genetic basis, recurs in patients with EDs and in their families. Affective disorders, and in particular bipolar and unipolar depression, are two to three times higher in families whose members have been diagnosed with EDs (Strober et al. 2000); substance use and abuse disorders are more likely in those with a bulimic variant of ED and in their relatives, three to four times more than in anorexics or in controls without a family history of EDs (Krug et al. 2009; Jacobi et al. 2004).

Serotonin dysregulation was reported in low-weight AN, and is implied in many disorders co-occurring with BN. Binge eating occurs with low levels of brain serotonin (also known as 5-HT = 5-hydroxy-tryptophan); conversely, increased levels of 5-hydroxyindolacetic acid (5-HIAA), the major metabolite of serotonin, were found after recovery in both AN and BN, further corroborating the idea that abnormal low levels of serotonin are in cause in the acute phase of EDs (Kaye et al. 2000).

Multi-impulsivity is a feature of EDs, particularly those with recurring episodes of binge eating. Impulsivity is linked to reduced functioning in serotonin circuits, and it is more likely in patients with

a history of childhood trauma, sexual abuse in particular. Since impulsivity might expose to negative life events, and negative life events can cause depression, some circularity might exist between serotonin dysregulation, impulsivity, depression, childhood trauma, and the development of EDs.

126.2.5 Eating Disorders: Epidemiology

A consistent finding is the peak in ED incidence during adolescence and early adulthood; in both the US National Comorbidity Survey Replication (NCS-R) and the European Study of the Epidemiology of Mental Disorders (ESEMeD), the majority of cases had their beginning between 10 and 20 years of age (Hudson et al. 2007; Preti et al. 2009). An age-effect might involve both hormonal effects linked to puberty and psychological effects related to changes in body appearance and form, causing weight and shape concerns, as well as the impact of the new expected sexual and social role.

Comorbidity with psychosis is rarer than with mood-, anxiety-, and substance-related mental disorders. Prevalence of schizophrenia in clinical samples of patients with EDs is below 10%, as against 0.8% in community samples, but patients with EDs are more likely to report subclinical symptoms of psychosis than controls and rigidity of thought, abnormal bodily perception, and behaviors based on superstition or wrong beliefs ("magical thinking") contribute to treatment resistance (Miotto et al. 2010).

Recent studies on the prevalence of EDs in the general population showed that they are not so rare as generally thought (Fig. 126.1).

In the NCS-R, the estimated prevalence for AN, BN, and BED was 0.9%, 1.5%, and 3.5% among women, and 0.3%, 0.5%, and 2.0% among men (Hudson et al. 2007). In the ESEMeD study, applying
Fig. 126.1 Lifetime prevalence estimates of eating disorders. The figure summarizes the most recent lifetime prevalence estimates of Anorexia Nervosa, Bulimia Nervosa, and Binge Eating Disorder in the USA and Europe, as derived from the US National Comorbidity Survey Replication and the European Study of the Epidemiology of Mental Disorders (six participating countries: Belgium, France, Germany, Italy, the Netherlands, and Spain), within the framework of the World Mental Health Survey Initiative (2004) (Data are from Hudson et al. 2007 (USA) and Preti et al. 2009 (Europe))

the same methodology, the estimates of prevalence were 0.93%, 0.88% and 1.92% in women, and 0%, 0.12% and 0.26% in men (Preti et al. 2009). Both studies revealed some evidence of increasing prevalence in younger than in older cohorts, with most of the effect for BN and BED.

Access to care is lower than expected because of role impairment and comorbidity, especially in the mental health sector (Hudson et al. 2007; Preti et al. 2009). Nevertheless EDs can be treated, with acceptable-to-good positive outcome involving up to 70% of treated patients after a 10-year follow-up in AN (Steinhausen 2002), and a large fraction of recovered patients at short-medium term in BN, although with high risk of relapse (Berkman et al. 2007); less data are available for BED and EDNOS. The associated comorbid mental disorders are treatable too therefore the risk of suicide can be reasonably reduced in those patients who receive adequate treatment and follow-up.

126.3 Suicidal Behavior: Definition

According to a consensus operational definition, *suicide* is any "death from injury, poisoning, or suffocation where there is evidence (either explicit or implicit) that the injury was self-inflicted and that the decedent intended to kill himself/herself"; while *suicide attempt* refers to "a potentially self-injurious behavior with a nonfatal outcome, for which there is evidence (either explicit or implicit) that the person intended at some (nonzero) level to kill himself/herself. A suicide attempt may or may not result in injuries" (O'Carroll et al. 1996, pp. 246–247).

There is no agreed definition of *suicidal gestures*, often considered self-harming acts with a very low lethal potential (e.g., inflicting superficial scratches on the wrist, overdosing on vitamins). Self-harm can be defined as "any act that causes psychological or physical harm to the self without a suicide intention, and which is either intentional, accidental, committed through ignorance, apathy, or poor judgment" (McAllister 2003, p. 178); deliberate self-harm (DSH) refers to self-harming behaviors that are intentional but not aimed at killing oneself (Mangnall and Yurkovich 2008), while SIB is a kind of self-harm which leads to visible bodily injury, and is on a continuum with suicidal behavior.

Having thoughts about engaging in suicide-related behavior and/or communicating these thoughts encompass the agreed definition of *suicidal ideation*.

Suicidal behavior is thought to occur alongside a continuum, from thoughts about life being not worth living to the expression of self-harming behavior with varying degrees of severity and lethality, until suicide attempt and completion (Fig. 126.2).

Hopelessness and helplessness, two cognitive antecedents of suicide ideation and attempt, and thoughts about death or life being not worth living are starting points in the progression from suicide ideation to suicide planning, attempt, and completion (Brown et al. 2000). Early detection of these feelings, therefore, can save lives, especially of those people who attempted but failed suicide, who are particularly prone to repeat the suicide attempts until they die (Tidelman et al. 2008).

Suicide ideation is the main correlate of suicide attempt, and quite always associates with a mental disorder: people with suicide ideation have a statistically higher risk of death by suicide compared to people who did not express suicide ideation (Harris and Barraclough 1997).

There is evidence that those who express low-lethal self-harming behavior are also prone to suicidal behavior: among both adolescents and adults SIB can associate to, and precede a suicide attempt (Favaro et al. 2007; Whitlock and Knox 2007).

Finally, suicide attempt represents the primary antecedent of completed suicide (Brown et al. 2000); indeed, those who attempted suicide had a 30–40 time higher risk of death by suicide compared to the general population (Harris and Barraclough 1997).

Death by suicide

126.3.1 The Epidemiology of Suicide

Death as result of self-inflicted injury accounts for 1.5–3% of total deaths in both sexes; in many
countries it ranks second among the major causes of death for people aged 15–34 years (Murray and
Lopez 1996).

Yearly suicide rates per 100,000 are higher among males than females, with very few exceptions
(for example, China: see He and Lester 1997); they are higher in older people than in the young and
the adults (Hawton and van Heeringen 2009). The risk of dying by suicide is higher among the sepa-
rated, the divorced, and the widowed than the married; among the unemployed; among those who
suffer from chronic, disabling and/or severely impairing mental or somatic disorders and in those
with substance abuse/dependence (Harris and Barraclough 1994, 1997; Preti and Miotto 1999).
Suicide rates show large differences by geographical region, with rates above 25 per 100,000 persons
in males and above 8 per 100,000 persons in females in Central and East Europe, to rates below

10 per 100,000 persons in males and below 3 per 100,000 persons in females in countries such as Italy, Portugal and Spain (Levi et al. 2003).

Higher suicide rates were recorded in rural areas than in urban areas: the reasons are unknown, but availability of psychiatric services and specialized medical surgery are the most likely contributing factors.

Suicide attempt rates are typically higher among females than males, and peak in young adults (18–24 years old). Unmarried or widowed people, the unemployed, those with a severe mental disorder or a PD, and those with substance abuse/dependence have an enhanced risk of attempting suicide (Bernal et al. 2007; Nock et al. 2008). In 2004 the lifetime prevalence of suicide attempt was estimated at 2.7% worldwide, varying from 0.5/0.7 to 4.7/5.0% according to the country (Nock et al. 2008).

As for suicide ideation, in 2004 prevalence estimates were 9.2% (3.0–15.9%, according to the country), while the prevalence estimates of suicide plan were 3.1% (0.7–5.6%) (Nock et al. 2008).

There are no reliable estimates of suicidal gestures in the population. Some groups have a very high occurrence of non-lethal suicidal gestures, for example people detained in prisons, with rates as high as 7.6% in men and 19.0% in women (Preti and Cascio 2006).

Nonfatal suicidal behavior is related to being female, of younger age, having fewer years of formal education, and being single/never married; age, in general, is inversely related to nonfatal suicidal behavior (Nock et al. 2008), with some differences across countries (Bernal et al. 2007). Having a major mental disorder is the most significant clinical correlate of suicide ideation, plan, and attempt, especially MDD and alcohol-related problems (Bernal et al. 2007; Nock et al. 2008).

In those with a mental disorder, earlier age-of-onset is significantly associated with a higher risk of suicidality, especially in the first year since onset of ideation. Overall, high rates of both attempted and completed suicide are associated with acute episodes of the illness, particularly in those recently discharged from hospital, or with comorbid substance abuse, past episodes of nonfatal self-harm, and living alone (Tidelman et al. 2008).

Suicide is sometimes hidden in many societies, particularly when negative stigma is attached to it, and may be underreported (Phillips and Ruth 1993). Due to this stigma, some people are hesitant in disclosing information on past episodes of nonfatal self-harming or suicidal gestures, and on suicide ideation and planning, but the vast majority is glad to have the opportunity to discuss with someone these very distressing feelings about killing themselves. The reliability of information from self-reports or interviews cannot be taken for granted; therefore, when assessing a patient with an evolving severe mental disorder, a close informant should be inquired, too. Missing information on past episodes of self-harm might have fatal consequences.

126.4 Risk Factors for Suicide

A common fallacy is to consider suicide as a rational choice made in face of adverse circumstances not amenable to change. In fact, most people experiencing very distressing stressful events never attempt suicide, nor consider taking their lives.

According to statistical data, in up to 90% of cases the people who died by suicide suffered, at that moment, from an active mental disorder (Cavanagh et al. 2003), although most people with a mental disorder do not attempt nor die by suicide. Suicidal behavior is a complex, multidimensional phenomenon, which has many "causes" as well as several biological, psychosocial, and cultural components.

The reasons why an individual wishes to die differ according to the type of suicidal behavior; nevertheless, some recurrent reasons may be reconstructed from the stories of those who survived a severe suicide attempt (Table 126.2).

Table 126.2 Motivations of suicide drawn from the case reports of survivors to severe suicide attempts (Modified from Preti and Miotto 2005)

Primary reason	Will to stop an unbearable suffering
	Will to detach oneself immediately from life circumstances
	Will to rejoin loved dead people
	Will to get revenge through the consequences of one's own death
Secondary or associated reason	Will to punish oneself
	• Out of guilt
	• Out of shame
	• Out of a sense of unworthiness
	Will to leave a strong and long-lasting impression on those who will remain alone after the death of the attempter
	Will to suppress an internal mental object, which is no longer satisfying or which is perceived as persecutory
	To force someone to help (cry for help)
Unclassified	Self-sacrifice, altruism
	Demonstrative, for political reasons
	Vexation
	To rouse compassion

The table lists the most frequent reasons for dying, reconstructed from the case histories of those who survived a severe suicide attempt: the reasons "why" an individual wishes to die differ according to the type of suicidal behavior, with different constellations of underlying "causes" corresponding to different circumstances of suicide

Suicidal events are often classified on the basis of the following elements:

- The *intent to die*, which relates to the desire to die as opposed to the desire to live, and is expressed through the degree of planning and the chances of being discovered, as resulting from the efforts to hide the attempt from discovery and intervention.
- The *lethality*, which is the degree of medical damage resulting from the attempt which largely depends on the method used for the attempt.

Women tend to use less lethal means of suicide, which implies a higher chance of survival. Women tend to behave so as to favor discovery and rescue and this is often interpreted as a "cry for help". However it is incorrect to consider a "cry for help" less dangerous, since people using this strategy also tend to repeat the attempt, and some patients could not appreciate the intrinsic lethality of the method used, or may overlook the real ability of rescue of their social network; moreover, low lethal methods can become fatal in someone whose body is otherwise harmed by somatic illnesses, as in the elderly, in people with chronic somatic disorders, or in patients with EDs.

There is some evidence that different circumstances of suicide correspond to different typologies of suicidal behavior, with different constellations of underlying "causes". The people who take their lives out of a sudden impulse might differ in their psychological dynamics from those who plan their killing in advance, and behave so as to hide their intention, also taking precautions not to be discovered, and avoid rescue.

Sometimes people make a suicidal pact with someone they trust and who chooses to share with them the same mechanics of death. There is also a subgroup of suicides that accomplishes the explicit intention of the victim to avenge himself / herself of a wrong not amenable to legal prosecution: this "suicide by revenge" or "suicide with hostile intent" encompasses a large set of highly lethal behaviors aimed at harming the others (Preti 2006).

Knowing the "reason why" of suicide is not enough to prevent it: over time, a large range of variables has been investigated as possible risk factors for suicide (Table 126.3). Some of these risk factors are amenable to treatment and their identification is therefore mandatory for prevention.

Table 126.3 Risk factors for suicide, with relative hierarchy of risk

Suicide risk factors	Risk
Clinical risk factors, often amenable to treatment	
Current axis I mental disorder	High
History of past suicide attempt	High
Current suicidal ideation	High
Co-morbid axis II personality disorder	High
Alcohol/substance abuse/dependence	High
Family history of suicide	High
Psychosocial risk factors, less likely to be treatable	
Adverse childhood experiences	Low to high
Persistent adverse life situation	Low to high
Acute stress	Low to high
Social isolation	High
Demographic risk factors, not amenable to change	
Male gender	Low to high
Adolescence or old age	Low to high
Minority status	Low to high

The table lists the most often reported risk factors for suicide: suicide mainly occurs in the course of a mental disorder, but displaying suicide behavior requires additional risk factors, because the majority of patients diagnosed with a mental disorder never attempt suicide

126.4.1 Clinical Risk Factors for Suicide

Up to 90% of those who died by suicide had an active mental disorder at the moment of the act, often undertreated or unrecognized (Cavanagh et al. 2003).

The mental disorders with the highest risk are: depression, particularly the depressive phase of bipolar disorder (BD), with higher risk in bipolar II than in bipolar I; schizophrenia; alcohol abuse and dependence, often comorbid with another axis I or II mental disorder; PDs, especially those in cluster B (borderline and antisocial PD); drug abuse and dependence; AN (Harris and Barraclough 1997).

Some chronic, disabling, or highly impairing somatic diseases too are linked with an enhanced risk of suicidal behavior: epilepsy, some types of cancer, spinal or brain lesions (head injury), AIDS and related diseases, diabetes, multiple sclerosis, disabling renal or cardiovascular diseases (Harris and Barraclough 1994). Secondary depression is considered the main reason of the higher risk of suicide in people with chronic somatic illness, while people suffering from severe mental disorders are at higher risk of developing chronic somatic illnesses, both because of maladaptive behavior associated with the psychopathology – for example the enhanced risk of alcohol and/or substance abuse – and of the long-term consequence of drug therapy.

A co-occurring SUD increases the risk of suicide in those with mental disorders. Alcohol abuse, in particular, is a risk factor for suicide independently from a comorbid mental disorder and should be treated aggressively. Tobacco smoking was reported as an additional risk factor for suicidal behavior (Hawton and van Heeringen 2009). Comorbid PDs, too, are associated with an enhanced risk of suicide in people diagnosed with a mental disorder, because they reduce attendance to care and compliance with treatment, and they increase the risk of SUDs. In the youngest cases, a history of conduct and emotional symptoms (anxiety mostly), as recorded in parent and teacher reports, is the most important predictor of attempted and completed suicide (Sourander et al. 2009).

126.4.2 Psychosocial Risk Factors for Suicide

The triad of hopelessness, pessimism, and low self-esteem represents a cognitive risk factor to be cared for, since it traps patients in an unfortunate loop: they think they are unable to change their lives and, in the meanwhile, are afraid they cannot receive nor deserve the help they feel necessary to improve. Hopelessness, per se, has emerged as a predictor of suicide attempt and completion in clinical samples (Beck et al. 1985).

In people affected by depression, the affective symptoms of irritability, inquietude, or worrisomeness until agitation, and/or a general state of mood instability are an indicator of possible bipolarity, and must be followed for with great care, since mixed/agitated depression often associates to impulsive suicidal behavior.

Guilt and shame are "moral emotions" frequently reported by patients with mental disorders: they can restrain a patient from admitting suicidal ideation, thus complicating the assessment. Their identification suggests the opportunity of inquiring with tact the presence of suicidal ideation in these patients.

Aggressiveness, conceived as the propensity to engage in assault or aggressive behavior towards things or people – associates to suicidal behavior: the reason could be the higher occurrence of aggressive behavior in people with mental disorders that are comorbid with PD and/or SUDs, as well as the higher chance of relational difficulties in aggressive people, with a worse conflict with peers and police or legal authorities, hence a higher risk of stressful events, on the one side, and less supportive relations on the other.

Persistent adverse life events, such as social and economic disadvantage, and acute stressors can both impact the risk of suicide (Haw and Hawton 2008), principally by increasing the occurrence of symptoms of depression, often mixed with demoralization (loss of positive emotions like hope or confidence, as the result of situations in which one feels powerless), or favoring the onset of a mental disorder in those constitutionally at risk. People with mental disorders, especially those with comorbid PD or SUDs, are more likely to incur in stressful events: mental disorders lead to social, economical, educational, and working difficulties, increasing the chances of losing a job and decreasing those of finding a new one; this leads to financial difficulties, which further negatively impact the life of people with mental disorders, particularly when deprived of social security protection.

People with mental disorders are also more likely to remain single, or to break affective relationships, with higher rates of separation/divorce, thus losing the support and the guidance offered by a partner. Being single entails a 25% higher risk of suicide: this can depend on singleness being a marker of severe mental disorder, but also as a consequence of reduced support, guidance, surveillance, and prompt rescue in case of suicide attempt (Qin et al. 2003).

Impulsivity, the propensity to engage in unplanned, poorly conceived, or inappropriate behaviors, often ending up in an unwanted or deleterious outcome, is a common trait to a large fraction of people with suicidal behavior (Mann 2003). Impulsivity frequently occurs in those with a PD as a feature of the disorder, particularly borderline or antisocial PD. People with SUDs, too, are prone to impulsive behavior, both as a constitutional predisposition to developing substance-related disorders, and as a result of substance abuse/dependence, consequent to the deregulation of the neurochemical circuits damaged by the abuse (Dougherty et al. 2004).

Impulsive behavior also recurs in people with BD, especially during the manic phase, and associates to the risk of developing SUDs (Tondo et al. 1999).

In adolescence, the gender-identity conflict might trigger suicidal ideation and behavior: the lack of experience makes adolescents more likely to consider a conflicting situation or a loss as irrecoverable events.

126.4.3 Availability of Lethal Means and Imitation

The availability of lethal means is a key factor in suicide, since intense, acute suicidal ideation rarely lasts more than 24 h (although it can recur and lead to planning) (Bridge 2006). In the UK, suicide rates were reduced by the detoxification of domestic gas and by the reduction of the number of analgesics in a packet, analgesics being often used for suicide by overdosing on them; other interventions, which succeeded in reducing suicide rates, were restriction laws in the prescription and sale of barbiturates, the mandatory use of catalytic converters in motor vehicles, the construction of barriers at jumping sites and the use of new, less toxic antidepressants (Mann et al. 2005). Some controversial evidence suggests that gun-control laws are having some impact, too.

Merely restricting access to lethal means could not be enough to prevent suicide, since someone who has decided to kill himself/herself can still shift to other means if the chosen method is no longer available. Surveillance must always be added to avoid suicide in those identified at higher risk.

Imitation is a controversial mechanism that can play some role in certain circumstances. Indeed, the degree of publicity given to a suicide story seems to be directly related to the number of subsequent suicides, with celebrity suicides having a particularly strong impact (Stack 2003). Media guidelines have been proposed in order to reduce the impact of suicide by imitation, particularly as far as the disclosing of the method used for suicide is concerned; currently, the impact of the Internet is under scrutiny, since people can be encouraged to attempt suicide by the provision of instructions concerning suicide methods and the active solicitation of suicide-pact partners in suicide chat rooms (Mann et al. 2005).

126.4.4 Neurobiological Risk Factors for Suicide

A family history of suicide is an important risk factor for suicidal behavior, suggesting that some genetic component is involved. Monozygotic twins have a significantly higher concordance rate for completed and attempted suicide than dizygotic twins; among the biological relatives of an adoptee who committed suicide, the rate of suicide is about several times higher than for the biological relatives of non-suicidal adopted persons (Baldessarini and Hennen 2004). However, it is still unresolved whether the familial aggregation of suicidal behavior is a reflection of genetic components, as is suggested by twin and adoption studies (Brent and Mann 2005), or whether social learning has a role, too, by means of social contagion and/or imitation (De Leo and Heller 2008). The recurrence, within a family, of some risk factors known to be associated with suicide, such as economic and financial strain, exposure to sexual and physical abuse, availability of psychoactive substances, and poor social support can contribute to the transmission of suicidal behavior in the family.

The liability to mental disorders does not seem to be the sole mechanism involved in the heritability of a propensity to suicidal behavior: for example, the parents of youth suicide victims have higher rates of suicidal behavior independently of the presence of psychopathology (Brent et al. 1996).

Abnormal serotonergic function is the most likely candidate to form the basis for the specific heritable liability to suicidal behavior. The first evidence came from studies investigating cerebrospinal fluid (CSF) levels of 5-HIAA, the major metabolite of serotonin: they were found to be lower in persons who had made serious suicide attempts than in psychiatrically matched controls (details in Mann 2003). Some studies reported up-regulation of postsynaptic serotonin 5-HT$_{1A}$ and 5-HT$_{2A}$ receptors in the prefrontal cortex of suicide victims; postsynaptic serotonin receptor up-regulation often occurs as a compensatory response to the low activity of serotonin neurons (Mann 2003).

Further postmortem brain receptor mapping studies found indicators of reduced serotonergic input to the orbital prefrontal cortex, an area involved in behavioral inhibition: this might find expression in a general propensity towards aggressive and impulsive behaviors, including suicidal behavior (Mann 2003).

Low serotonergic function may be a trait marker of the propensity to suicidal behavior: indeed, low CSF levels of 5-HIAA predict future suicide and suicide attempts in patients with mental disorders independently from the diagnosis (Mann 2003).

The noradrenergic or dopaminergic systems were less investigated. The main findings were: decreased noradrenalin (NA) levels in brainstem and increased alpha2-adrenergic receptor density, which might depend on up-regulation due to NA deficit. As for molecular genetic studies, so far the replication of findings concerning a candidate gene in association studies has been difficult, with the notable exception of the serotonin transporter gene promoter polymorphism, linked to suicidal behavior (Currier and Mann 2008).

In nonhuman primates, a low cholesterol diet results in lower serotonergic activity and higher impulsivity and aggressive behavior; in humans, clinical and epidemiological studies reported a modest but consistent link between low cholesterol levels and suicidal behavior, both in spontaneously occurring low cholesterol blood levels and when cholesterol was lowered through diet or drug treatment (Mann 2003).

Finally, suicide is associated with larger adrenal glands and less prefrontal binding of Cortical Releasing Factor (CRF): this might depend on suicide being the cause of death in people suffering from chronic, disabling and highly stressful conditions. Indeed, overactivity of the hypothalamic pituitary adrenal (HPA) axis is typically observed in patients with MDD and in victims of physical and/or sexual abuse (Mann 2003).

126.4.5 Precipitating Factors for Suicide

The continuum of suicidal behavior ranges from ideas to gestures, to risky lifestyles, suicide plans, suicide attempts, and, finally, suicide completion (Mann 2003). Suicide occurs principally in the course of a mental disorder, but displaying suicide behavior requires additional risk factors, because the majority of patients diagnosed with a mental disorder never attempt suicide (Mann 2003; Mann et al. 2005).

Most of these risk factors can act in an additive way, but some of them might interact in a synergistic fashion (Fig. 126.3); moreover, they are often not independent: for example, there is a circular relationship between aggressive or impulsive traits, suffering from depression, developing substance abuse, and cigarette smoking.

Triggering and precipitating factors are often, but not always, necessary for suicide to be committed. Common precipitants of suicidal acts include the onset or acute worsening of a mental disorder, interpersonal losses or conflicts, financial troubles, and job problems.

The suicidal crisis is a time-limited window in which the highest risk of suicide occurs: accurate assessment and intervention is mandatory in this circumstance, since most suicidal acts occur in a while. According to some studies, about 50% of those who attempt suicide make their decision within 5–10 min before acting, and up to 75% take less than 1 h to make the decision of killing themselves. In the case of alcohol or drug intoxication, the decision is made quickly, less than 30 min in about 90% of cases; on the other hand, after 24 h, about two thirds of those who intensely thought about suicide, lose the urge to kill themselves (Bridge 2006).

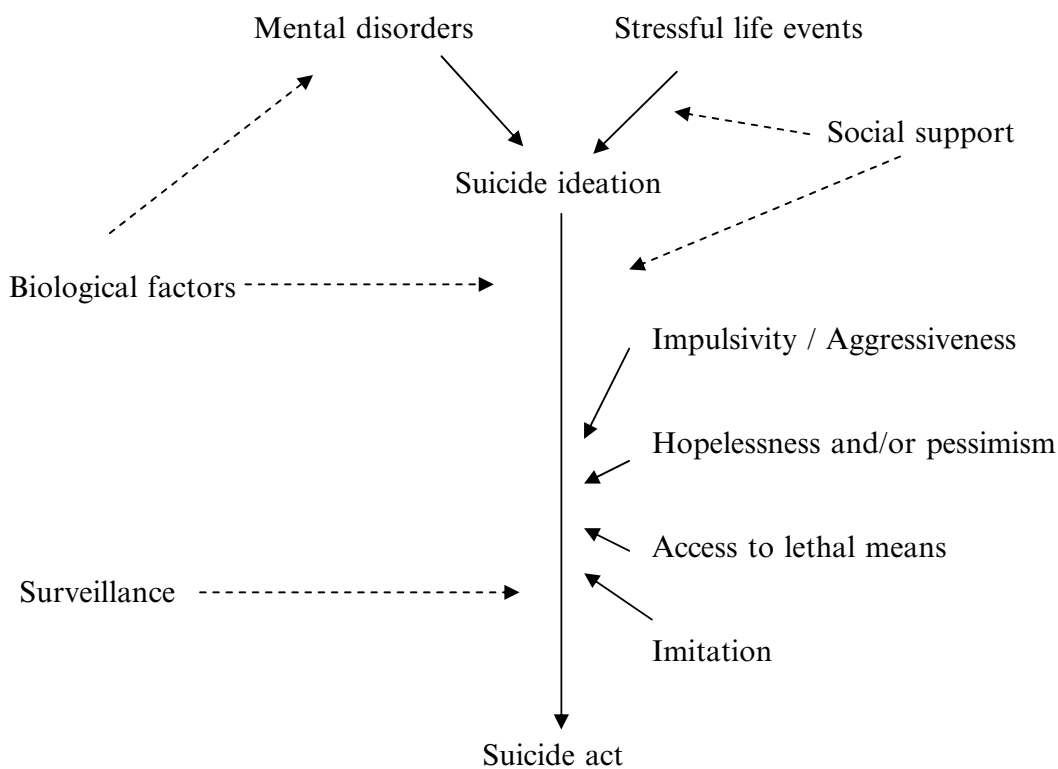
The most common triggers are recent negative events, particularly when caused by the person's behavior, such as a relational loss precipitated by anger outburst or recurrent conflicts, or a financial


Fig. 126.3 Interacting risk factors for suicide. The figure displays a scheme of risk factors for suicide, considering antecedents, precipitating factors, and correlates of suicidal behavior

loss due to excessive or poor spending habits associated with impulsivity or excitement. The awareness of one's own responsibility in these events can confirm a negative image of oneself, further lowering self-esteem and increasing hopelessness and pessimism. Feelings of abandonment, unworthiness or repulsion, mixed with hopelessness, anger, frustration, guilt, shame, or humiliation might be a lethal admixture especially in case of low social support and/or isolation. Increasing anxiety, sleepiness, and uncontrollable anger outbursts are important predictors of impulsive suicide acts. In contrast, those who develop a detailed plan can become suddenly calm and relaxed, although mood instability is a clear indicator of risk in these people: apparently, they regain interest in life, often expecting to set or reorganize their own things; sometime, a sudden, unforeseen but long-planned highly lethal suicide attempt follows the completion of these tasks (Table 126.4).

126.5 Eating Disorders and Suicidal Behavior

EDs fit with the profile of the afore summarized risk: patients with EDs suffer from comorbid depression and PDs, mainly in the Cluster B spectrum (borderline PD) (Hudson et al. 2007; Preti et al. 2009); they are likely to behave impulsively, and anger outbursts are features of disorders presenting with binge eating, i.e. AN-BP and the two variants of BN (Miotto et al. 2008). Childhood physical or sexual abuse, two causes of intense distressful feelings and psychopathology, are known antecedents of EDs (Jacobi et al. 2004), even at subclinical level (Preti et al. 2006). Substance abuse or

Table 126.4 Key points of suicide

| |
|---|
| Suicide is any death resulting from injury, which was self-inflicted with the intent of ultimately causing the death. |
| Suicide is thought to be at the extreme end of a continuum, from thoughts about life being not worth living, to the expression of self-harming behavior with varying degrees of severity and lethality, until suicide attempt and completion. |
| Suicide occurs principally in the course of a mental disorder, but displaying it requires additional risk factors, among others: |

 1. Low cerebrospinal fluid 5-hydroxyindolacetic acid levels
 2. Low blood cholesterol levels
 3. Alcohol and/or substance abuse
 4. Tobacco smoking
 5. Cluster B Personality Disorders
 6. Somatic illnesses
 7. A family history of suicide
 8. A childhood history of physical and sexual abuse
 9. Low self-esteem
10. Hopelessness
11. Impulsiveness
12. Aggressiveness
13. Marital isolation
14. Not living with a child under age 18

This table lists the key facts about risk factors for suicide, across the domain of clinical, psychosocial, and neurobiological dimensions

dependence recurs in the history of patients with EDs and in their close relatives, thus representing additional risk factors for suicide (Krug et al. 2009).

Most of these risk factors for suicidal behavior interact with each other: they largely share a common genetic basis, which impacts on abnormal dieting behavior of the patients, thus aggravating a preexisting dysregulation of neurochemical circuits, especially in the serotonin system, and disrupting the delicate neurohormonal equilibrium (Kaye et al. 2000). Abnormal eating, with the restriction of some types of food, can cause reduced intake of monoamine precursors, like tryptophan, and of vitamins, thus further disrupting neurobiological functioning; a balanced supply of the essential amino acids, especially from meat, is needed for the continuous replacement of serotonin and norepinephrine and for proper brain functioning (Sullivan et al. 2006). On the other hand, fruit, vegetables, and meat are consistently underconsumed by adults who have attempted suicide (Li et al. 2009), and iron deficiency, the most common cause of mild anemia in EDs, can contribute to poor impulse control in those who are genetically vulnerable.

The use of inappropriate compensatory behaviors, such as self-induced vomiting, or the misuse of laxatives and/or diuretics can induce abnormalities in fluid and electrolytes, another cause of neurochemical unbalance, which might negatively impact on impulse control and mood. EDs are also linked to an enhanced risk of stress, principally of a social nature, with a higher chance of conflict with family members, friends and acquaintances: this may induce alterations in the HPA axis, thus increasing the levels of cortisol and related hormones, with cortisol inhibiting serotonergic functions.

126.5.1 Evidence on Suicide in AN

Suicide represents the main cause of death in AN, besides medical complications of the disorder. In two large meta-analyses, suicide was the cause of death in deceased patients with AN in 27% (Sullivan 1995) and 32% (Harris and Barraclough 1997) of cases, respectively. In a meta-analysis of

11 outcome studies on AN including 2,240 patients with available follow-up between 5 and 22 years (mean: 10.7), 28 suicides were found (0.119 per 100 person-years of exposure risk), representing 22.7% of all observed deaths (Signorini et al. 2007). In another meta-analysis comparing data from nine outcome studies on AN including 1,538 patients with available follow-up between 5 and 23 years (mean: 13.6), 36 suicides were reported (0.172 per 100 person-years of exposure risk), as against 28 expected suicides (0.028 per 100 person-years of exposure risk) amongst 100,000 persons of age 14–25 without AN (Pompili et al. 2004).

Available data indicate that in patients with AN, completed suicide nearly always occurs in adult age. In a study investigating 246 women with EDs (136 with AN), four cases of suicide occurred within a 5-year follow-up, all in patients with AN (three AN-R, one AN-BP): the mean age at death was 35 years (Keel et al. 2003). In a study on 6,009 women with AN followed-up for a mean time of 13 years, the total deaths were 265, including 84 deaths by suicide (31.6% of all deaths): the mean age at death was 34 years (Papadopoulos et al. 2009).

However, a higher risk of suicide in AN compared to the appropriate control population is not universal. In a US study on data from 1986 to 1990, Coren and Hewitt (1998) found 8 suicides in 571 women who had AN as an underlying cause of death, as against 70 in 1,713 matched deceased controls. Thus, the relative risk of suicide was higher in controls (4.1%) than in patients with AN (1.4%): 2.93 (95% confidence interval (CI) = 1.38–5.85). In a long-term survival analysis of 208 patients with AN diagnosed in Rochester, Minnesota (USA) from 1935 through 1989, and monitored for up to 63 years, mortality was not higher in those patients than expected by age and sex: in this study, 2 suicides occurred in women, representing 14.2% of all deaths (Korndörfer et al. 2003).

As a matter of fact, a changing pattern in the causes of death was observed in follow-up studies from 1940–1949 to 1970–1979, with fewer deaths from medical complications of AN and more from suicide in later periods (Nielsen et al. 1998); thereafter, in more recent surveys, from the early 1980s onwards, a decrease in suicide rates was observed in a sample of patients with AN (Lindblad et al. 2006). These changes might reflect improvements in medical treatment over the last 50 years and the very recent improvement in the psychiatric treatment of AN: indeed, a better identification of cases needing treatment and the access to specialized units of care were suggested as the main factors in this effect (Lindblad et al. 2006). A recent national Swedish study based on official hospital registers reported a decrease in mortality over the last 2 decades, but still patients with AN had a significantly increased SMR for suicide: 13.6 (95% CI = 10.9–16.8), corresponding to 0.104 per 100 person-years of exposure risk (Papadopoulos et al. 2009).

For these reasons, suicide is still a matter of concern in AN, but it can be prevented essentially by increasing the identification of cases in need of care and by aggressively treating comorbidity, mainly depression, substance abuse, and impulsivity-related PDs.

126.5.2 Evidence on Suicide in BN

Overall, the risk of death in BN is much lower than in AN: a meta-analysis of 43 follow-up studies of patients with BN retrieved a not significantly enhanced SMR of 1.6 (95% CI: 0.8–2.7) (Nielsen 2003). A review of 2,194 patients with BN, drawn from 88 follow-up studies, reported two deaths by suicide representing 28.5% of all deaths (n = 7) (Keel and Mitchell 1997). Studies based on long-term follow-up studies confirmed the lack of deaths due to suicide in a sample of patients with BN (Keel et al. 1999). This is at odds with the very high occurrence of suicide attempts in patients with BN (Franko and Keel 2006).

126.5.3 Evidence on Suicide Attempts in EDs

The lifetime prevalence of a history of suicide attempts in patients with AN or BN is not statistically lower than in patients with MDD: 27%, 31% and 36%, respectively (Bulik et al. 1999). Minor differences do occur between subtypes of EDs: in 246 outpatients, 12% with AN-R (n = 51), 13.8% with AN-BP (n = 85), and 9% with BN (n = 110) reported one or more suicide attempts at assessment (Herzog et al. 1999). In an Italian study, 9% of AN (n = 166), and 18% of BN (n = 205) patients had a history of suicide attempt (Favaro and Santonastaso 1997).

Studies with follow-up show that there are differences depending on the sample and the geographical location, but patients with AN do not relevantly differ from those with BN as far as the risk of attempting suicide over time is concerned (Table 126.5).

In patients with EDs who have made one or more suicide attempts, there are a few recurring associated features: purging behavior and comorbidity with affective disorders and/or cluster B PDs (Franko et al. 2004; Milos et al. 2004). A co-occurring history of alcohol and/or substance abuse/dependence is another important correlate and a predictor of suicide attempt in patients with EDs (Franko and Keel 2006). In both AN and BN, a history of childhood abuse is an antecedent of severe suicide attempts, as well as of recurrent non-lethal self-harming behaviors (Favaro and Santonastaso 1997; Franko and Keel 2006).

Lower cholesterol levels, which may result from severe dieting, were found in patients with AN who had a history of suicide attempts and/or current suicide ideation than in patients without suicidality (Favaro et al. 2004).

126.5.4 Suicidal Gestures and Suicide Ideation in EDs

Patients with EDs often engage in SIB. In a Belgian female inpatient sample, a history of SIB was reported by 26.1% with AN-R (n = 23), 28.8% with AN-BP (n = 18), and 55.2% with BN (n = 29) (Claes et al. 2003). In an Italian sample, a history of SIB was reported by 59% with AN-R (n = 155),

Table 126.5 Follow-up studies on suicide attempt in eating disorders – sorted first by location and then year of the study

Study	Location	Diagnosis	n sample	Follow-up (years)	n attempts	Suicide attempt rate [a] (%)
Favaro and Santonastaso (1997)	Italy	AN	167	6	15	1.49
Kreipe et al. (1989)	USA	AN	49	6	2	2.04
Bulik et al. (1999)	USA	AN	70	3	19	9.04
Franko et al. (2004)	USA	AN	136	8	30	2.75
Favaro and Santonastaso (1997)	Italy	BN	210	6	38	3.01
Garfinkel et al. (1980)	Canada	BN	155	8	36	2.9
Bulik et al. (1999)	USA	BN	152	3	47	10.3
Franko et al. (2004)	USA	BN	110	8	12	1.36

The table illustrates major results from studies on suicide attempt in Eating Disorders with enough follow-up length to observe an event. To date, available data involve a scant number of countries, with no information on Eating disorder not otherwise specified and Binge Eating Disorder, despite the fact that these disorders prevail in the community and in clinical samples

AN anorexia nervosa, *BN* bulimia nervosa

[a]The suicide attempt rate is expressed as percentage per person x years of exposure to the risk of attempting suicide

68% with AN-BP (n = 81), 76% with BN-P (n = 139), and 61% with BN-NP (n = 36) (Favaro and Santonastaso 2000).

Especially in patients with BN, SIB is associated with suicide attempts, a history of sexual abuse, and depression (Favaro and Santonastaso 1999). Overall, the reported prevalence of SIB in patients with EDs is, on average, between 25.4% and 55.2% (Svirko and Hawton 2007) and it is observed in patients with EDNOS, too (Paul et al. 2002). SIB is used to reduce distress or tension and to end uncomfortable feelings; other reported functions are: to reduce anger, to self-punish, and to feel bodily instead of emotional pain (Paul et al. 2002).

In community samples, SIB is on a continuum with suicidality (Favaro et al. 2007), and those reporting SIB are more likely to report suicide ideation, plan, gesture, and attempt (Whitlock and Knox 2007).

Suicidal ideation, the most important correlate of attempted and completed suicide, is frequent in patients with EDs. In 495 Italian outpatients with EDs, 29% reported current suicidal ideation (Favaro and Santonastaso 1997). In a sample of 1,009 French inpatients, current suicidal ideation was more frequent in those with BN and with AN-BP than in AN-R (Fedorowicz et al. 2007), but in an Italian female outpatient sample (Miotto et al. 2008), patients with AN (n = 61) were more likely to report severe suicidal ideation than patients with BN (n = 51): 14.8% versus 3.9% (unpublished data). Suicide ideation was positively related to levels of bodily dissatisfaction, as measured by the Body Attitudes Test (Probst et al. 1995), in young people with subclinical symptoms of EDs (Miotto et al. 2003). Subclinical eating disturbances are predictive of suicidal ideation and attempts in female, but not male, adolescents (Crow et al. 2008).

126.6 Suicidal Behavior in EDs: A General Overview

Suicidality is undoubtedly high in patients with EDs: patients with AN experience a higher risk of death by suicide than patients with BN, despite a comparable prevalence of predictors of completed suicide, such as suicidal gestures, including SIB, and suicide attempts (Table 126.6).

Two reasons for the greater risk of dying by suicide in AN compared to BN are the higher chance of a lethal outcome of the attempt because of a compromised body condition due to medical complications secondary to starvation and unhealthy purging behavior, and the more severe suicidal ideation in

Table 126.6 Key points of risk factors for suicide in EDs

Patients with EDs present a wide range of factors related to the risk of suicide, among others:

1. Comorbid depression
2. Comorbid personality disorders
3. Comorbid substance use disorders
4. Impulsive and aggressive behavior
5. A history of physical or sexual abuse during childhood
6. Negative consequences of abnormal eating on monoamine metabolism

Evidence on suicidality in EDs

1. Patients with AN experience a higher risk of death by suicide than patients with BN, despite a comparable prevalence of predictors of completed suicide, such as suicidal gestures, including self-injuring behavior, and suicide attempts
2. In recent decades the risk of death by suicide has decreased in AN, principally because of greater detection of the cases in need of treatment and the establishment of specialized units of care.

This table lists the key facts about risk factors for suicide in EDs, detailing the main change occurred in recent decades, i.e. the substantial decrease in the risk of death by suicide in AN, as a result of better access to care

AN anorexia nervosa, *BN* bulimia nervosa, *EDs* eating disorders

patients with AN than in those with BN. One study assessed the first hypothesis, and found that in patients with AN, death after a suicide attempt is more likely to result from the use of lethal means rather than by the impact of the attempt on an already deteriorated physical state (Holm-Denoma et al. 2008). Therefore, severe current suicidal ideation might be the cause of greater lethality of the attempt in AN than in BN, but there are no detailed studies on this.

Comorbidity is another important reason for the higher lethality of suicide attempts in AN: in a sample of patients with EDs, current suicidal ideation is linked to Axis I and II comorbidity (Bulik et al. 2008; Milos et al. 2004), and both MDD and PDs with impulsive dyscontrol are associated with a higher risk of suicide. The impact of depression and/or impulsivity might be more severe in AN, owing to nutritional abnormalities secondary to starvation: indeed, low cholesterol levels have been associated with suicidal behavior in patients with AN (Favaro et al. 2004).

126.7 How to Deal with the Risk

Prevention of suicidal behavior deals with the identification of those at risk, the treatment of conditions that can be corrected, and the protection of those who have already made a suicide attempt. Unfortunately, patients with EDs are less prone to seek help from mental health care professionals (Hudson et al. 2007; Preti et al. 2009) and they are seen more often in the general medical sector or in nonmedical settings.

Increasing awareness on these disorders and reducing stigma and myths about them is mandatory to improve access to care for those in need. The multiplication of points of access can be appropriate, especially for adolescents, who are less likely to access mental health facilities for their troubles. With the establishment of specialized units of care, the risk of suicide in EDs has been considerably reduced in the areas served by them (Lindblad et al. 2006).

126.7.1 Identification of the Risk

People at risk of suicide can be identified with appropriate queries, but those who are not mental healthcare professionals can feel less comfortable in enquiring about issues related to suicidal ideation and planning. A simple question, "During the last week, have you experienced thoughts of suicide, or the idea of taking your own life?" can be enough for the purpose of assessment, but it is better to start with more general questions concerning "thoughts about death".

There is no evidence that screening young people for suicide induces suicidal thinking or behavior: on the contrary, some studies found an increased identification of cases after screening for suicide in a primary care setting (Mann et al. 2005). However, since it is inappropriate to enquire of everybody if they have thoughts about suicide, the first step in the prevention of suicidal behavior is the identification of cases with a potential risk: i.e., those who suffer from a mental disorder linked to an enhanced risk of suicide.

People with symptoms indicative of a severe mental disorder should always be asked about suicidal thoughts and past suicidal behavior: if they screen positive for suicidal ideation, then they should be asked about suicide planning (Mann et al. 2005).

Patients with EDs are largely underdiagnosed: the identification of EDs in the general medical sector occurs in a half of the cases with AN, and one in ten cases with BN (Hoek 1991). This leads to a dramatic overlooking of the risk associated with abnormal eating.

More often, people at risk of suicide are identified because they report symptoms of depression or show the distress associated with a recent stressful event.

When an ED case is detected, or symptoms of mood or other psychiatric disorders are evident, additional risk factors for suicide must be investigated. The most obvious is current suicidal ideation, which imposes a query on past suicidal gestures and attempts. Additional risk factors in people with EDs are: cluster B PDs, a history of alcohol or substance abuse, a history of impulsivity, a family history of mental disorders, particularly if severe and/or associated with suicidal events.

Whenever suicide planning is suspected, or when faced with a history of past suicide attempts, access to lethal means should be investigated and the possibility of surveillance should be ascertained, especially in teens.

126.7.2 Intervention Strategies

The treatment of mood and other psychiatric disorders is a central issue of suicide prevention. Antidepressants are effective in alleviating symptoms of depression and anxiety: Selective serotonin reuptake inhibitors (SSRIs), in particular, have been found to decrease the risk of suicide in adults and older people, although caution is still reported about their use in adolescents (Barbui et al. 2009). Patients with EDs are comorbid with BD, and often report subclinical symptoms of psychosis: however, it is difficult to use lithium in patients who self-induce vomiting or use laxatives, since these practices induce significant fluid and electrolyte disturbances, thus increasing lithium toxicity; symptoms of psychosis in EDs rarely achieve levels justifying the use of clozapine, which was found effective in protecting against suicide in schizophrenia (Mann et al. 2005).

Patients who manifest alcohol and/or substance abuse/dependence must be treated aggressively, since SUDs negatively impact on other risk factors for suicide.

Thoughts about suicide are often worse at night: treating insomnia is mandatory in patients at risk.

Some reports indicate that in selected samples of patients, psychotherapy can improve adherence to treatment, thus indirectly reducing the risk of suicide by improving compliance and regular attendance to appointments (Mann et al. 2005). Other, more direct effects are still in need of replication in well-conducted studies.

Patients who have made a suicide attempt are prone to repeat it, therefore improving follow-up care after a suicide attempt, with maintenance care including psychiatric hospitalization, if necessary, is an intuitive option for prevention. However, studies on the real effectiveness of the proposed measures have produced mixed results, with positive findings for case management and programmed long-term care, but uncertain evidence for less expensive interventions such as telephone follow-up, psychosocial follow-up, and video education plus family therapy (Mann et al. 2005).

126.7.3 Further Indications

A "chain of intervention" has been suggested to reduce the risk of suicide in the community, with guidelines concerning each step in the risk of suicide, from predisposing factors to precipitants and correlates (Table 126.7).

Each intervention could be tailored to the population of people with EDs, starting with awareness campaigns aimed at increasing knowledge of the problem and its consequences, as well as disseminating guidelines for treatment.

Table 126.7 Chain of interventions aimed at preventing suicidal behavior

Target condition or symptom	Type of intervention	Main objective
Access to care	Education and awareness program • Primary care physicians • General public • Gatekeepers, including school personnel staff	To increase knowledge of the problem and its treatment
Recognition of cases in need of treatment	Screening of individuals at high risk	To increase detection of hidden cases
Stressful life events	Screening of individuals at high risk	To increase detection of hidden cases

Mental disorders	Treatment
	• *Pharmacotherapy*
	  1. Antidepressants
	  2. Antipsychotics
	• *Psychotherapy*
	  1. Psychosocial programs for SUDs
	  2. Cognitive behavioral therapy
		To improve course of the disorder
		To increase adherence to therapy

Suicidal ideation Impulsivity	Screening of individuals at high risk
	Treatment
	• *Pharmacotherapy*
	  1. Antidepressants
	  2. Antipsychotics
	• *Psychotherapy*
	  1. Psychosocial programs for SUDs
	  2. Cognitive behavioral therapy
		To increase detection of hidden cases
		To improve course of the disorder
		To increase adherence to therapy

Hopelessness/Pessimism	Treatment • Pharmacotherapy • Psychotherapy	To reduce disinvestment To increase participation in programs of care
Access to lethal means	Restriction measures and surveillance	To decrease the chance of lethal outcome after an attempt
Suicidal act	Close follow-up care	To reduce the risk of dropping out from treatment

The table provides a list of interventions that have been suggested for preventing the risk of suicide in the general population

SUDs substance use disorders

Creating accessible networks of social support, and replacing defective ones, could be effective helpful adjuncts in adolescents and young adults. Targeting social dysfunction is critical, since many patients who are contemplating suicide could be saved by efficient social support and surveillance, which is the limiting step in the prompt rescue after an attempt.

Since stress and adverse circumstances are an oft-reported precipitant of a suicidal act, it could be appropriate to provide space for the open discussion of one's personal problems and difficulties, as well as to offer empathic supportive attention and problem-solving indications.

People hardly ever take their life when they are in company: people experiencing suicidal ideation should be encouraged to keep contacts with a friend or a family member, and they should be informed on the availability of telephone helpline services, when in need (Bridge 2006).

Even when there is not a clearly ongoing SUD, people with suicidal ideation should be advised to avoid alcohol and illicit drugs, since their use can precipitate an attempt by increasing impulsivity or by influencing the mood.

Family members should be informed of the risk, especially in teens: it is advisable to provide family support when needed.

When the risk is very high, hospitalization should be frankly discussed with the patient: the aim is to keep the patient alive, although hospitalized patients incur the highest risk of suicide after discharge, both because of the interruption of the continuity of care and because people are hospitalized when they have very severe mental disorders, most likely to end up in suicide.

Building up individual resilience and self-esteem is an essential part of recovery: patients must be encouraged to pursue their personal interests and objectives while they are recovering from their main disorder.

126.8 Application to Other Areas of Health and Disease

Findings on suicide in EDs are of great importance for other areas of health and disease: first and foremost, patients with EDs are often clients of health professionals who are not mental health experts. It is not rare that patients with evolving EDs require advice to pursue their aims of losing weight; they must be detected in order to avoid iatrogenic effects on their psychopathology. Overall, they pose a great challenge in terms of detection and correct treatment: when necessary, the patient has to be addressed to the appropriate unit of care. Continuing education on the features of these disorders is mandatory, especially in the general medical sector, in pediatrics, in gynecology, and in dentistry, as well as among staff professionals involved in counseling and social work.

Moreover, eating disturbances are frequent in the general population, particularly among women and adolescents. There is evidence that poor diet can be associated with suicidal behavior (Li et al. 2009), therefore appropriate nutritional advice can correct abnormalities that might impact on constitutional risk factors for mood and impulse dyscontrol disorders, the main clinical risk factors for suicide. Many somatic diseases, particularly cancer, lead to abnormal dieting, both as a result of the disorder and as a side effect of treatment, and this could be an additional risk factor for suicide in these diseases.

Data on suicidality in EDs are relevant for psychiatry too. EDs are frequently overlooked as a reason for suicide in adolescents and youths: the investigation on suicidal tendencies in young people might benefit from including measures of EDs to prevent the worst outcomes of minor psychological distress (Crow et al. 2008). Moreover, a past ED can be an antecedent of severe psychopathology in adulthood, mainly in the affective disorder spectrum: subclinical eating disturbances can persist despite resolution of the main symptoms, and a more detailed assessment should be undertaken to identify hidden risk factors for suicide, including nutrition-related ones.

There is a paucity of studies concerning the impact of dieting and purging on suicidal behavior: most studies are based on symptoms reported by the patients, but this could be misleading; objective measures should be necessary, also to identify deficits to be corrected. Particularly critical is the effect of stress on appetite and nutrition (Takeda et al. 2004), but again there is a lack of studies investigating the interaction of stress, nutrition, and suicidal behavior in EDs.

Moreover, there is a paucity of studies on suicidal behavior in EDNOS, including BED, despite the fact that these disorders prevail in the community and clinical samples.

Finally, there is sparse evidence regarding the effectiveness of treatment to prevent suicidal behavior in patients with EDs and on the role of stress and nutrition in suicidality: studies on these topics are advisable, due to the complex links between stress and eating disturbances on one side and suicidal behavior on the other side.

Summary Points

- The definition of eating disorders (EDs) is given to a set of behavioral disorders characterized by disordered eating and body dissatisfaction, with a high level of psychological distress related to the eating behavior and high comorbidity with other mental disorders, principally anxiety, mood, and SUDs.
- EDs might be not as rare as currently thought: in recent studies, the lifetime prevalence estimates for Anorexia Nervosa (AN), Bulimia Nervosa (BN), and Binge Eating Disorder (BED) in women were 0.9%, 1.5%, and 3.5% in the US, while they were 0.93%, 0.88% and 1.92% in Europe.
- Patients with EDs present a wide range of factors related to the risk of suicide, among others: comorbid depression, PDs, and SUDs; impulsive and aggressive behavior; a history of physical or sexual abuse during childhood; negative consequences of abnormal eating on monoamine metabolism.
- Suicidal behavior may be best understood as occurring along a continuum, ranging from ideas to gestures, to risky lifestyles, suicide plans, suicide attempts, and, finally, suicide completion.
- A large majority of people who died by suicide suffered at that moment from an active mental disorder, up to 90% of cases according to the statistics.
- Triggering and precipitating factors are often, but not always, necessary for a suicidal act to be pursued: common precipitants of suicidal acts include the onset or acute worsening of the mental disorder, interpersonal losses or conflicts, financial troubles, and job problems.
- In a community sample, those reporting self-injury behavior (SIB) are also more likely to report suicide ideation, plan, gesture, and attempt; the reported prevalence of SIB in patients with EDs is between 25.4% and 55.2%, being an important antecedent of suicide attempt.
- The lifetime prevalence of a history of suicide attempts in patients with AN or BN is not statistically lower than in patients with major depression: 27%, 31%, and 36%, respectively.
- Suicide represents the main cause of death in AN, besides medical complications of the disorder; the risk of suicide in BN is much lower than in AN, despite a comparable prevalence of predictors of completed suicide, such as suicidal gestures, including SIB, and suicide attempts.
- In recent decades the risk of death by suicide has been decreasing in AN, principally because of an increased detection of the cases in need of treatment, and the establishment of specialized units of care.
- Suicidal behavior cannot be easily predicted; however, it can be prevented, essentially by increasing the detection of cases in need of care and by aggressively treating comorbidity, mainly depression, substance abuse and impulsivity-related PDs.
- Patients with EDs are less prone to seek help from mental healthcare professionals, and they are seen more often in the general medical sector or by nonmedical professionals: increasing awareness on these disorders, and reducing stigma about them is mandatory to favor access to care of those in need.
- The multiplication of points of access to care can be appropriate, especially for adolescents, who are less likely to access mental health facilities for their troubles. With the establishment of specialized units of care, the risk of suicide in EDs has been considerably reduced.
- EDs are frequently overlooked as a reason for suicide in adolescents and youth: the investigation on suicidal tendencies in young people might benefit from including measures of EDs to prevent the worst outcomes of minor psychological distress.
- There is sparse evidence regarding the effectiveness of treatment to prevent suicidal behavior in patients with EDs, and on the role of stress and nutrition in suicidality: studies on these topics are advisable, due to the complex links between stress, eating disturbances, and suicidal behavior.

Key Terms

Body mass index or BMI: It is the ratio of weight to height, and it is calculated as weight (Kg) divided by height (m) squared.

Deliberate self-harm: Often abbreviated as DSH, the expression refers to self-harming behaviors that are intentional but not aimed at killing oneself.

Incidence rate: The total number of new cases of a disease or a disorder arising in a specific population at a point in time.

Lethality: The degree of medical damage resulting from a suicide attempt.

Prevalence rate: The total number of cases of a disease or a disorder in a specific population at a point in time.

Rate: A quantity measured with respect to another measured quantity, and in medicine the term refers to the proportion between the number of events of a given condition and the total number of people who may be exposed to it in a given area and during a given interval of time.

Standardized mortality ratio or SMR: It is the ratio of the number of deaths observed in a sample to the number of deaths expected in the population, correcting for age and sex.

Self-injury behavior: This expression refers to acts of self-harm leading to visible bodily injury, on a continuum with suicidal behavior.

Suicidal behavior: This expression refers to acts of self-harm with a fatal (suicide) or a nonfatal (attempted suicide; suicidal gestures) outcome.

Suicidality: This term refers to the occurrence of suicidal thoughts (or suicidal ideation) or suicidal behavior.

Suicidal ideation: This term refers to thoughts, ideas, or cognitions about engaging in suicide-related behavior, and/or communicating these thoughts, intentions or plans.
