- Selective attention to food-related information has been demonstrated with both behavioral tasks and brain activity measures.
- Evolutionarily old brain systems allow for relatively simple motivational states and attentional influences on action, while their integration with more recently evolved structures enables more flexible, dynamic behavior.
- The MNS appears to play a role in translating seeing into doing and thus may help explain why people tend to eat more in the presence of others.
- Differences in how food motivation, attention, and action processes interact in the brain may help explain particular eating behavioral patterns, including those associated with eating disorders.

Key Terms

Feedback loop: A system that feeds some of its outputs back to itself as inputs. Positive feedback occurs when such input is excitatory, causing a continual increase in system activity, while negative feedback tends to stabilize system activity since the more active it is the more it opposes itself.

Hedonic theory of dopamine: A theory that argues that mesolimbic dopamine mediates the subjective pleasure associated with delivery of a reward.

Homeostasis: The tendency to maintain stability of an internal state by monitoring for changes and making adjustments to compensate for them.

Limbic system: A network of brain structures that is important for aspects of emotion, motivation, memory, and other behavioral functions.

Mirror neuron system: A network of frontal, parietal, and temporal lobe regions with neurons that increase firing rates during execution of an action or observation of a corresponding action performed by others. The MNS may be a neural basis for translating seeing into doing or performing a "simulation" of action without executing it.

Motivation: The goal-oriented force in behavior, contributing to its initiation, direction, intensity, and persistence in the face of obstacles.

Premotor theory of attention: A theory that argues that attention derives from an activation of the same circuits that process sensory and motor information.

Reward: A positive reinforcer; a stimulus whose presentation increases the future probability of behaviors leading to its delivery. The term "reward" can be controversial due to its connotation of subjective pleasure and the notion that such pleasure gives rewards their reinforcing quality.

Salience: The state or quality of standing out, for instance due to attentional selection, greater sensory intensity (sensory salience), or goal-relevance (motivational salience). According to

> Berridge (2009), rewards and the cues that predict them acquire "incentive salience," which leads to "wanting" them.
>
> **Selective attention:** The selection of some information for increased processing at the expense of other (unattended) information.
>
> **Spatial attention:** Attention selectively directed toward a location in space, conferring its information-processing benefits to stimuli at that location.
>
> **Triarchic model of attention:** A theory that argues that attention is a mechanism separate from information processing and that it consists of orienting, alerting, and executive subsystems.

Chapter 44
The Pleasures and Memory of Food and Meals

Paul Rozin and Dina Gohar

44.1 Food and Pleasure

The two fundamental needs that animals must continuously meet are the need for food and for air. While breathing occurs almost automatically, eating involves organized activity, including search and selection. For generalist animals that eat a wide variety of foods, learning plays a major role in the discovery of what is edible and what is not (Rozin 1976). The learned behavior that results in finding food is reinforced by the pleasure produced by the food itself. Thus, pleasure plays an important role in the experience of and learning about food. In contrast, breathing – or the "capture" of air – is associated with little pleasure; it is only the absence of air that rapidly produces a state of distress and displeasure. The special link between food and pleasure is well illustrated by the innate positivity of sweet tastes for many generalist mammals. Food generalists, like humans, have few innate signals that indicate nutrition; however, they do have an innate positive response to sweetness and an innate avoidance of things that taste bitter (Steiner 1979). Both of these in-born biases make nutritional sense, as sweetness signals calories while bitterness typically predicts toxicity. In addition, humans may have an innate preference for fatty textures, which, like sweetness, predict sources of calories.

44.2 Preadaptation

First, an understanding of preadaptation is necessary for a better grasp of the relationship between food and pleasure in humans. Preadaptation is a fundamental process in biological and cultural evolution by which something that evolves for one purpose is co-opted for another (Mayr 1960). A particularly appropriate example is the mouth and its various structures, such as the tongue and teeth, which clearly evolved for the predigestive processing of food. When language evolved in humans, however, the location of the mouth as the entry and exit point for air (in addition to food) led speech via the mouth to become the major means of communication. In this context, the teeth, tongue, and other food-adaptations in the mouth were used for the articulation of sound; that is, they were preadapted for language.

The major role preadaptation plays in biological evolution is dwarfed by its role in cultural evolution. After all, in the latter, there is purpose; that is, an individual can realize the potential of using

an existing practice for a new purpose and use that foresight to create the link. In biological evolution, on the other hand, the link to the new purpose has to initially arise by chance. Whether biological or cultural, preadaptation has played a key and dual role in the interplay of food and pleasure in humans. First, food and the food system – originally designed purely for nutrition – have become so elaborated in human cultures that food serves many purposes besides nutrition. Second, the pleasure system was originally designed as a response to certain sensory experiences (e.g., sweetness) so that continued interaction with such sensory events would be sought after and fostered (Pfaffman 1960). Pleasure was linked to energy homeostasis: likely sources of calories were pleasant experiences, especially in the face of hunger (Cabanac 1971).

Pleasure can be defined as a positive experienced state that we seek and try to maintain or enhance. However, the pleasure system became involved in many more cognitive and elaborate experiences as the human brain (and world) grew increasingly complex (Rozin 1999). That is, this basic pleasure system may have been co-opted, along with the development of human cognitive capacities, to become attached to entities other than sensory experiences that would potentiate greater success in negotiating the world. Thus, although humans may have a basic pleasure system similar to that of animals, its range of elicitors is much greater.

44.3 The Expansion of Pleasure

There are at least three types of pleasure that humans experience, and all three are expressed in the food domain. Take, for instance, the act of drinking wine. Karl Duncker (1941) asks whether the object of pleasure is the wine (the object), the drinking of the wine (the communication with the object), or the sensory experience of drinking the wine (the experience of communication with the object). In the case of wine, the answer is clearly the last: the experience of the flavor. Indeed, Jeremy Bentham (1789/1948) assigns a fundamental role to sensory pleasure, which forms the basis for other types of pleasure. Sensory pleasures, considered part of the primitive pleasure system, derive primarily from the contact senses that cover the body surface and apertures, such as the flavor for foods. In contrast, esthetic pleasures are not physically localizable and are more abstract, though they are also linked to sensory input. Mastery pleasures derive from achieving something of value through acquisition of some sort of skill or sophistication. Although much of eating involves sensory and fundamental pleasures, such as the feeling of chocolate melting in one's mouth, fully enjoying more complex dishes or becoming a wine connoisseur (to use an extreme example) clearly involves esthetic and mastery pleasures.

It is worth noting that sensory pleasure is more resilient than other types of pleasure, though. That is, one can frequently enjoy the same sensory pleasure without too much adaptation. Indeed, the taste of a piece of chocolate or the experience of sexual orgasm can provide pleasure over and over, and the level of pleasure typically remains high in the long-term. In the short-term, however, there is a tendency for the pleasure produced by a sensory experience to wane, a phenomenon termed sensory-specific satiety (Rolls et al. 1986). Nonetheless, components of the sensory pleasure system, particularly those involving pain as well as many positive skin and mouth sensations, generally show remarkably little hedonic habituation.

Combinations of sensory pleasures do not obey any simple, hedonic algebra. For instance, both meat and whipped cream are positive sensory pleasures for most Europeans and Americans, but their combination (when one is aware of how it was produced) typically results in an unpleasant sensory experience. Indeed, sensory pleasures may be relatively simple, but they are extremely context-dependent. For example, the good smell of a piece of cheese can rapidly turn negative if one discovers that the

smell is actually spoiled milk or coming from a body product, so a good sensory pleasure depends on its origin. Humans may also develop a liking for a variety of innately negative experiences, such as bitter tastes (e.g., coffee or bittersweet chocolate) and sensory irritants (e.g., chili pepper or scotch whiskey) (Rozin 1982). In such cases, through interactions with the food in question in a social context, one's initial negative response to a taste (e.g., the burn of chili pepper) undergoes a hedonic reversal and becomes positive (Rozin 1990). Billions of humans have experienced this particular hedonic reversal. We have called this reversal "benign masochism" because we believe that the enjoyment of such innately negative experiences depends upon our realization that the negative sensory experience is not actually threatening. This may be a case of "mind over body," we enjoy the experience because our body is signaling danger but we know, cognitively, that there is no danger. There is an element of mastery here.

44.4 Preadaptation and Food

In human cultural evolution, food has become involved in many aspects of human life (see Kass (1994) for a history of this evolution within Western culture). First, food plays a major role in social life: the capture of food often involves cooperation, and the consumption of food is typically a social occasion. Indeed, the meal is often the main period of family social interaction. Second, food becomes a signal of ethnic or national identity, as well as a social signal when it serves as a gift. Third, sharing food is a sign of intimacy, a literal sharing of substance. And, just as sharing substance with admirable or beloved folk is elevating, sharing with those seen as inferior can be considered degrading. Fourth, food becomes a moral substance to some degree. Food is quite explicitly moral in Hindu India (Appadurai 1981), but even in modern American culture, a particular food can stand for corporate greed, human cruelty (as with meat for moral vegetarians), or worker oppression among some individuals. Thus, it is clear that a comprehensive understanding of the role of food in the modern world involves far more than nutrition. The preadaptation of food as nutrition for other human activities is demonstrated in Fig. 44.2. One of the most striking aspects of food preadaptation is the use of food words as metaphors (which are, essentially, preadaptations), as when we say that, "Joan is a sweet person" or "Let's get to the meat of the argument." Kass (1994) captures the elaborate nature of food, in that food and eating, in addition to table manners, become signs of civilization: "We eat as if we don't have to. We exploit an animal necessity, as a ballerina exploits gravity" (p. 158).

Preadaptation and Functions of Food

Nutrition

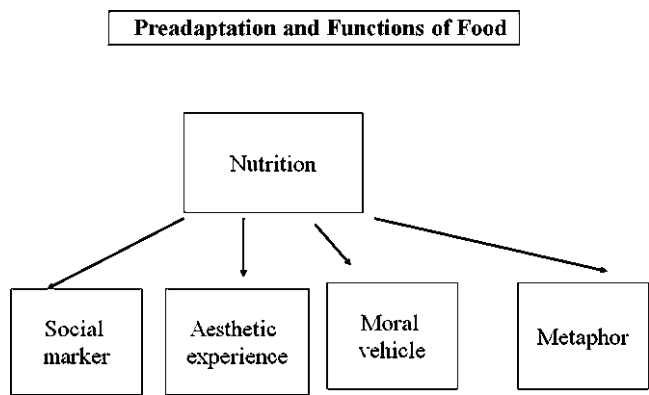
Social marker | Aesthetic experience | Moral vehicle | Metaphor


Fig. 44.1 Food and preadaptation. As a result of preadaptation, food has developed far greater meaning than nutrition; for instance, food is often used as a social marker, an esthetic experience, a moral vehicle, and as a metaphor

Fig. 44.2 A schematic model of food choice. A schematic model of food choice, based principally on a model developed by Sobal et al. (2006), but also includes an enlargement of the area designated "Person" as well as the sequence from "Person" to "Action/Choice"

44.5 Food in the Late Twentieth Century Developed World

The role of food and its associated pleasure has become even more complex in the late twentieth century developed world. That is, for the approximately 15% of living humans who do not fear a shortage of food and for whom food constitutes a minority of total expenses. This situation is surely the case for North Americans and Western Europeans, and has inverted the traditional human relation to food in many ways (summarized in Table 44.1).

Humans evolved in an environment similar to that of many other mammals; the search for food, its identification and selection, capture, and consumption were major activities. Food was scattered widely in the environment, and considerable energy was spent in finding adequate food. Generally, food-related problems involved finding enough food, as opposed to the risk of over-consumption. If our ancestors, like most other mammals, happened upon a rich source of energy and nutrients, the bias was certainly to consume it. However, in the late twentieth century developed world, food is plentiful and surrounds us. Moreover, food is cheap; in developed countries, less than a quarter of the

Table 44.1 Key points of the contrast between the human ancestral and the modern developed world food environments

Ancestral environment	Modern developed world environment
1. Food scattered and not abundant	Food plentiful
2. Obtaining food requires energy expenditure (optimal foraging)	Minimal energy needed to obtain food
3. Relatively few energy-dense natural foods other than animal products; fat and sweet rarely combined	Development of "super foods" such as chocolate
4. Modest variety of foods	Enormous variety of foods
5. Most deaths due to acute causes	Epidemiological revolution: Most deaths due to degenerative diseases
6. Relation between eating and its negative consequences is usually clear (e.g., food poisoning)	Relation between eating and its negative consequences is usually subtle, and occurs over decades

This table lists the key differences between the human ancestral food environment and that of the modern developed world

total amount of income is typically spent on food (Table 44.1, line 1). Therefore, humans, shaped by evolution to function in a world with scattered food, are now faced with abundant piles of it.

In this modern environment, the link between energy expenditure and energy consumed has also been broken. Food foraging typically required energy, making survival depend on spending less energy in foraging than is gained as a result. In fact, food foraging in most species (and data on this come from many species) is exquisitely calibrated so that the animal spends as little energy as possible to get the maximum energy yield, a phenomenon called optimal foraging. It is now possible, however, for the human optimal forager in North America to achieve the forager's dream: energy input without almost any expenditure. A weekly drive to the supermarket, or in the extreme, a few clicks of a computer mouse, can bring dinner or even a week's worth of food. Therefore, the second major change in the modern food world is that an organism built to minimize energy expenditure while obtaining sufficient food has created a world in which there is almost no energy cost of eating (Table 44.1, line 2).

The human generalist has certain innate biases that are useful in locating food. Two major biases are the preference for sweet and fatty foods, which are both characteristic of milk, the first food of mammals. In nature, sweet and fatty sensations usually occur at high levels in different foods. Yet, human ingenuity has led to the creation of an aromatic food that is both sweet and fatty: chocolate. Chocolate is representative of a whole set of "super foods" developed by humans to cater to their tastes. Nothing resembling milk chocolate grows on real trees or bushes, but the development of such super foods has resulted in a modern food world that tempts the palate more than nature ever could (Table 44.1, line 3).

A generalist animal, insofar as it consumes nonanimal foods, needs to consume a range of plants to obtain adequate nutrients. Thus, generalist animals tend to seek variety in their diet. Although there is a risk in trying new foods, since they may be toxic or imbalanced, the advantages of having a range of sources of energy and nutrient are great. In the modern food market, an unprecedented variety of foods is now available from all over the world. In general, variety promotes intake, so this is yet another force at work in the modern world that promotes food consumption (Table 44.1, line 4).

Finally, recent medical advances, particularly in the twentieth century, greatly increased longevity in the developed world. In particular, in what is called the epidemiological revolution, infectious diseases declined rapidly as a cause of mortality by the late twentieth century. This decline was due to a number of advances, including the development of antibiotics and the enactment of a variety of public health measures, such as the regulation of tap water processing (Table 44.1, line 5). As a result of these changes, what was often a palpable link between what one ate and its consequences

(e.g., the onset of illness within hours of consumption, typically gastrointestinal in nature) became a much more subtle link between patterns of food choice and the development of degenerative diseases taking place over decades (Table 44.1, line 6). No animal is designed to modify its current behavior based on the perception of modest risk changes that will manifest themselves in decades. Thus, in the modern developed world, humans rely on the medical community to provide information about the long-term risks of certain food consumptions and eating habits (e.g., overeating increasing the risk of obesity), but there are few salient consequences of engaging in the activities associated with long-term risks.

44.6 Food Choice in the Modern world

Food choice used to be easy: if a familiar and tasty food was available, it was eaten. In the modern world, though, there are so many eating opportunities that obesity is a common threat; thus, the modern-day individual is faced with far more complicated choices concerning food. Much of what we eat is due to habit or routine, or is simply determined by what is in front of us (as represented in Fig. 44.2, described below, by the line from environmental food options directly to action, bypassing the personal food system). The options, though, can be staggeringly large, whether we are facing our own opened refrigerator or a restaurant buffet. A number of investigators offer a framework for understanding food choice in terms of three components: the person, the food, and the situation/environment (Meiselman 1996; Sobal et al. 2006). This is a useful framework, so long as we keep in mind that, ultimately, both the food and the environment are filtered through the person. Consequently, it is the perceived product(s) and environment that influence choice. The sociologist Jeffrey Sobal and his colleagues (e.g., Sobal et al. 2006) have made the most complete attempt to describe the full context of the process of food choice. Their model is based primarily on interviews with adult Americans and is appropriately complex. A modified version of this model is presented in Fig. 44.2. Upon examination of this figure, the importance of social factors becomes clear. As Sobal et al. (2006) note: "This model assumes that a key process in selecting foods is the construction of food choices based on cognitions and social negotiations. Overall, people are assumed to construct food choices in a variety of ways by actively selecting what, when, where, with whom, and how to eat." The biggest determinants of what we eat and how much we eat are two environmental/economic variables: what is available and how much it costs.

In terms of the interaction between existing (affordable) food choices and the person, there are three major determinants of choice for developed world humans. First, the single most potent determinant of food choice for most people is the presumed palatability of the food; that is, the amount of pleasure (e.g., sensory effects, primarily flavor) anticipated to result from its consumption. Individuals across cultures share the universal, genetically determined preferences for sweet and aversion to bitter. As a child grows up, however, his or her tendency to consume anything that goes in the mouth and does not have an innately aversive taste is shaped and refined by experience and instruction, so that culture-wide practices are communicated and internalized (e.g., what to eat and when). Many of these cultural influences fall under the heading of either cuisine (Rozin 1982) or appropriateness (Schutz 1989). From these genetically based predispositions, culture-based rules, attitudes and practices, and personal experience, individuals develop particular sets of food-related beliefs, preferences, and practices, which have been termed `personal food systems' by Sobal and his colleagues (Sobal et al. 2006). The other two major determinants of food choice are convenience, including the ease of procurement, preparation, and actual ingestion (e.g., shelled peanuts are much more convenient than peanuts in shells), and anticipated health consequences. For many North Americans, food

choice is often a battle between pleasure and health concerns. The enormous number of health claims made on food labels in supermarkets testifies to the importance of such considerations for the consumer. Indeed, in part because of our predilection for sweet and fatty foods, there is generally a conflict between what we like and what we perceive to be healthy. Nevertheless, eating remains driven primarily by pleasure.

44.7 Applications to Areas of Health: The Interactions of Pleasure, Health, Convenience and Norms

A number of forces, as we have indicated, conspire to make the eating situation problematic in the developed world. Individuals are frequently faced with multiple options for highly palatable (often high calorie) inexpensive foods, easily delivered (high on convenience). Such an obesogenic environment confronts serious worries about long-term health. In fact, just the presence of a variety of foods often increases consumption. Research has documented that presenting humans with a variety of foods within a meal can increase meal size and the magnitude of this effect varies with the distinctiveness of the foods (Rolls et al. 1986) Moreover, the variety effect occurs whether the foods are presented sequentially or simultaneously Indeed, many have concluded that the problem of obesity lies primarily in the environment we have created (e.g., Brownell and Horgen 2004; Hill and Peters 1998; Levitsky 2005; Nestle 2002; Rolls 2003; Rozin 2005; Wansink 2004). The problematic nature of food is exacerbated for women, whose Western cultural norms include a distinct preference for thin bodies. Consequently, for example, 57% of a large sample of American college women report that they are often or almost always concerned about their weight (Rozin et al. 2003). However, such thin female ideals are themselves unrealistic, and often promote a level of thinness that is thinner than what most men desire.

Nevertheless, conflicting norms for thinness on esthetic grounds and restricted dietary choices to promote longevity are at odds with one another. Long-term health prospects, which are made prominent through the media and other cultural routes, now face off against the foods we like most. This conflict between tasty and healthy food is perhaps most exaggerated in North Americans. Although it is easy to divide foods into good and bad, such a division makes minimal nutritional sense. For instance, chocolate is not an unhealthy food, but is simply high in calories, and should thus be consumed (and savored) in modest amounts. Thus, a major problem, especially clear in North American women of European origin, is that eating, despite being an enjoyable necessity, is viewed as potentially more harmful than helpful. Of course, while eating can indeed be harmful to health, not eating is much more harmful, and has much more pressing serious health effects.

44.8 Cultural Solutions

Indeed, we are faced with a plethora of information about risks of certain dietary patterns, often with associated risk factors that are hard for laymen to understand, but we are not educated about how to assimilate such information. Thus, culture has to catch up in educating the human mind to negotiate the world of thousands of tempting choices. At present, there is minimal education about nutrition and the balancing of risks and benefits necessary for making intelligence choices (e.g., trying to eliminate fat or salt from the diet is not a realistic or even desirable option). Moreover, as with modern computer technologies, our ability to produce extraordinarily appealing foods, priming the pleasure side of eating, has not kept up with cultural inventions to properly control and direct food intake.

Nevertheless, cultures vary in their success at facilitating the basic activities of humans, For example, it is probably fair to say that the American higher education system is particularly good, but public transportation systems are more effective in Western Europe. There are corresponding differences is success of handling the plethora of delicious foods in the modern developed world. It is our belief, supported by research conducted by Paul Rozin and the French food sociologist Claude Fischler (Fischler and Masson 2008; Rozin 2005; Rozin et al. 2003) that French culture has handled the conflicts resulting from the modern developed food world much better than American culture. For instance, the French are notably less obese than Americans, and have a lower incidence of cardiovascular disease. Yet, this increased health does not result from a more restrictive or worry-ridden eating environment. On the contrary, the French spend more on food, and almost certainly have more food experience than Americans (because their meals typically last much longer). They seem to get more pleasure from food, and yet remain thinner. Our research, using surveys of French and Americans as well as observations of their food environments, has been directed at understanding this "French Paradox." Several factors, summarized in Table 44.2 below, contribute to the proclivity toward experiencing less stress and more pleasure from eating among the French as well as their lower rates of obesity.

Many of these cultural differences are also present in other continental Western European countries to some extent (Fischler and Masson 2008). While it may be difficult to get North Americans to change some of their attitudes to food, the effort is certainly worthwhile. In addition, changing the food environment is very likely to have a positive effect. For instance, salience can affect food choice within a meal (Stunkard and Levitz 1975), as dessert choices in a hospital cafeteria were affected by placement. Thus, changing the modern North American food environment by making less healthy food choices less accessible and reducing portion sizes, for example, may eventually curb the obesity epidemic. The unfortunate fact is, however, that virtually all humans like sweet and fatty foods, and prefer to procure such delicious foods without expending too much energy. Americans have been particularly good at delivering this type of food in inexpensive, attractive, and convenient ways to people, and this success seems to be spreading throughout the world. Strong cultural traditions about food and eating, as in France, may curb this tendency to eat almost continuously.

Table 44.2 Food-Related differences between the French and Americans

1. The French see food as more central to life and as more related to pleasure.
2. The French tend to think of food as something to be eaten and enjoyed, as opposed to something that will have effects on the body, like medicine.
3. The French have stronger collective food values (partly because the USA is a very multi-ethnic country); thus, there are stronger cultural guidelines about what is a proper meal. Partly as a result of this fact, the French have fewer food options.
4. The French feel more comfortable about eating and see it as a positive experience.
5. The French think of eating as a more social event, with longer meals and social interactions being an essential part of the meal.
6. The French tend not to snack between meals.
7. The French eat more slowly, but eat less, as their portion sizes are smaller.
8. The French standards for good eating focus more on quality while American standards focus more on quantity.
9. It is probably true, but not yet documented, that the French get more physical activity than Americans. This may be the case partly because of their traditional patterns of local shopping in several markets and partly because of their lower reliance on automobiles.

A summary of factors that contribute to the French tendency to gain more pleasure from eating, experience less stress related to eating, and have lower body weight on average, than do Americans (based on our research including surveys and observations of the food environment)

44.9 The Temporal Domains of Pleasure

As the human mind expands its capacities, there arises a distinct sense of the present, the past, and the future. That is, perhaps uniquely, humans can conceive of themselves as existing at an experienced moment in the present and simultaneously as individuals with a history and future of experiences. According to Aristotle, "What is pleasant is the activity of the present, the hope of the future, and the memory of the past" (Nichomachean Ethics, Book 9, Chap. 7); that is, at any point in time there are three temporal frames for pleasure. In fact, humans are sufficiently complicated that they can not only anticipate an event but also anticipate the pleasure of later remembering that event. In the food domain, the event in question is typically a meal.

44.10 The Meal as the Focus of Eating: Experienced, Anticipated and Remembered Food Experiences

The meal is a natural unit – a recognized semantic category across languages and cultures – by which we typically organize and remember our days (Pliner and Rozin 2000; Meiselman 2000). In fact, memory is an important determinant of meal initiation or continuation; unlike normal controls, amnesiacs who do not distinctly remember that they have just eaten will eat a second and even third full lunch if these are served in sequence with intervals of 10–30 min (Rozin et al. 1998). Memories are also important because when we make choice in the present – such as one about food – it is typically based on our memories of relevant past experiences with the same or similar foods, rather than on our actual experience with the foods. Thus, the relationship between the memorial representation of the meal and the actual experience of the meal is of particular importance. While we probably would not accurately remember an ordinary meal weeks later, we tend to remember special meals, either because of their remarkably high (or low) culinary quality or unusualness, or because of important events that occurred during them (e.g., first dates or proposals of marriage).

Yet, the study of pleasure, in the food and other domains, has focused almost entirely on the direct, actual experience of pleasure until recently. Following in Aristotle's footsteps, however, Daniel Kahneman and his colleagues (Kahneman et al. 1997) have pointed out that there are three temporal domains of pleasure: anticipated, experienced, and remembered. Experienced pleasure is on-line and momentary, whereas the pleasure accessed or reconstructed in remembered and anticipated pleasure is a mentally constructed entity termed integrated pleasure. Experienced pleasure and pain, in this view, function to influence or guide the behavior of the moment, while anticipated and remembered pleasure may guide ongoing behavior and play a role in decisions of future courses of action. Of course, a remembered pleasure may be sufficiently vivid to function in many ways as an experienced pleasure. Furthermore, in real life, we spend a fair amount of the present in thinking about the future and the past. The amount of pain we experience at the dentist, which lasts seconds, is surely experienced for much longer in our memory and anticipation. The same would be true for a superb and distinctive meal, which may take an hour or two, but may be "consumed" in memory for many more subsequent hours.

This tripartite distinction was also stressed by Jon Elster and George Loewenstein (1992) in their discussion of backward and forward consumption, and more recently by Bryant (2003) in his work adopting a temporal perspective on the process of savoring; that is, the pleasures of reminiscing about the past, savoring the present, and anticipating the future. This tripartite distinction is not only important

in and of itself, but also raises the question of the relations among experienced, remembered, and anticipated pleasure. In fact, the same experience can differ when considered from these three perspectives. For instance, a vegetarian can enjoy an eating experience, and then discover that there was meat in one of the dishes, thus ruining the memory of this formerly pleasant experience. In addition, there can be a mismatch between anticipated and experienced pleasure, such as when one looks forward to a meal that does not turn out to be very good. Indeed, Gilbert and colleagues (see Wilson and Gilbert 2003 for a review) have demonstrated that people overestimate the intensity and duration of their emotional reactions to future events in a variety of domains (including food), a phenomenon known as the impact bias. That is, an individual may anticipate experiencing much greater pleasure from a meal than actually ends up being the case. Moreover, people are very poor, almost random, at predicting how their liking for a new food or other product will change even over a week in which they will consume it (Kahneman and Snell 1992; Rozin et al. 2006), and they don't seem to get better at predicting their "hedonic trajectories" with time or age.

Thus, it is perhaps not surprising that Kahneman and colleagues maintain that the mapping functions between experienced and remembered or anticipated pleasure are complex and may be nonmonotonic. Their research, centered on experienced and remembered pain has demonstrated that two aspects of a painful experience powerfully determine the memories for it: the peak level (which disproportionately affects the remembered pain) and the rapidity of the offset (sharp offsets are remembered as more painful). In contrast, one important aspect of a painful episode is *not* well-represented in memory: duration. For example, five minutes of pain are represented in memory as about as unpleasant as ten minutes of the same pain. This phenomenon has been termed duration neglect (Fig. 44.3).

Most of the work generated by the experienced–remembered–anticipated framework has dealt with negative experiences. With respect to memories for meals, and particularly the remembered pleasure of meals, we know relatively little. This is particularly important because typically when we choose a meal, or when we recommend a meal or restaurant to others, we are consulting our memory of the experience. People seem to generally prefer experiences in which pleasure increases with time. Are certain parts of the meal disproportionately determinative of our evaluation of the meal? One study (Anderson and Norman 1964) showed a primacy effect for forecasted pleasure of a meal; that is, participants generally rated meals beginning with three high-rated foods followed by three low-rated foods as better than those presented in the reverse order. A few other studies (e.g., Rogozenski and Moskowitz 1982) have demonstrated that the main course has a disproportionate effect on meal liking. The disproportionate effect of the main dish in these studies, although it is in the middle of the meal, may be because the entrée is the largest amount of food served and thus consumes the most time, and is usually the most expensive part of the meal, too. The main dish is also often the most palatable and may, in many cases, represent the peak of liking. In addition, these aforementioned studies determined that dessert is the second most predictive meal component, which is compatible with the idea that end of a sequence also contributes disproportionately to memory, a phenomenon known as the recency effect. Thus, overall these studies support the notion that meal liking is not a simple unweighted linear function of components.

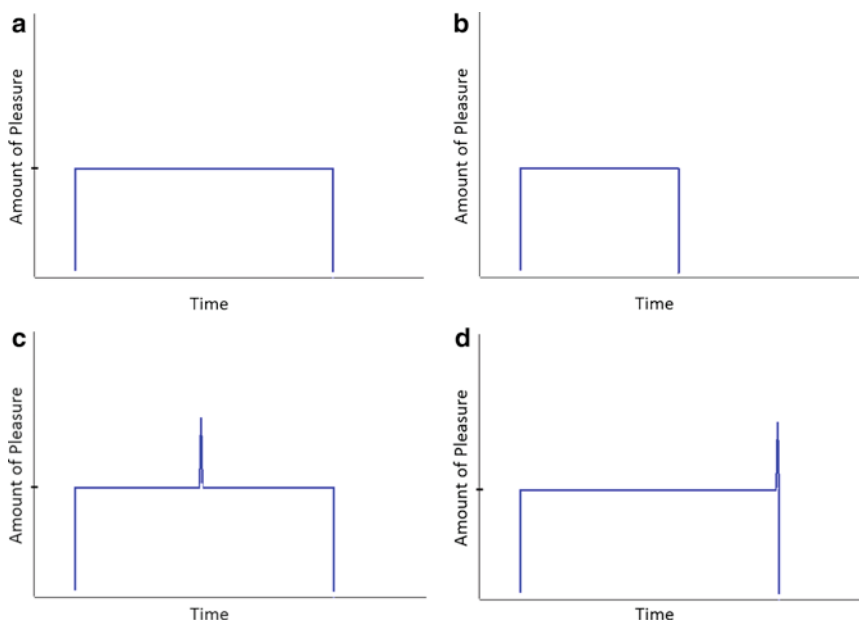
The question of whether duration neglect exists in meals (or more generally, the experience of sequences of foods) has also recently been studied. For instance, do we tend to rate meals with 4 versus 8 ounces of our favorite food as equally pleasurable afterward? A set of studies involving brief or full-meal eating experiences suggest that duration neglect holds for the memory of meals. That is, doubling the amount of a particular food in a meal (often the favored food) has no effect at all on the perceived pleasure of the entire meal (Rode et al. 2007). The existence of duration neglect with respect to food implies that, with respect to memories of a meal, small portions of a highly favored dish will have roughly the same memorial effect as large portions.


Fig. 44.3 Diagrammed examples of cognitive biases in memory for pleasure. (**a**) Is a representation of a standard pleasurable experience. (**b**) Duration neglect: The figure represents an experience that brings the same amount of pleasure as (**a**) (same height) but for half the period of time (half the length of (**a**)). Experience (**b**) is remembered as equally pleasurable as Experience (**a**), despite being shorter in duration. (**c**) Peak: Experience (**c**) is the same as experience (**a**) (same total area) except for a mid-peak of pleasure. However, this short peak of pleasure has a disproportionate effect on overall remembered pleasure of the experience: Experience (**c**) is remembered as significantly more pleasurable than experience (**a**) (or (**b**)). (**d**) Peak and End: Experience (**d**) is similar to Experience (**c**) except for a brief rising peak in pleasure at the end. As in experience (**c**), this peak has a disproportionate effect; even more so, since it occurs at the end (and is thus subject to the recency effect). Thus, Experience (**d**) is probably remembered as more pleasurable than Experience (**c**), and definitely deemed more pleasurable than Experience (**a**). For comparison, a standard experience (**a**) is depicted that brings a certain amount of pleasure (represented as the total area in the rectangle) for a certain amount of time. Experience (**b**) is remembered as equally pleasurable as experience (**a**) even though it occurs for half the time, a demonstration of duration neglect. Experience (**c**) demonstrates the disproportionate effect of peaks in pleasure, such that the total experienced pleasure is the same in (**a**) and (**c**), but (**c**) is retrospectively judged more pleasant. Experience (**d**) demonstrates that a peak in pleasure occurring at the end (recency or end effect) typically has the most remembered pleasure (with the same amount of experienced pleasure as (**a**), (**c**) and (**d**)). These schematic representations come primarily from work on negative pleasure (pain) as summarized in Kahneman et al. (1997) and Rozin (1999), but also include some parallel work on the pleasures of food (e.g., Rode et al. 2007)

44.11 Conclusion

Food intake and food choice represent major public health issues in the twenty-first century. We still do not have a satisfactory model for either what controls the amount of food humans eat, or how they make food choices. Nevertheless, it is clear that in both cases, pleasure plays a major role, but biological factors, individual experience, environmental effects, and cultural influences are also at work. A number of books also review the state of knowledge in this broad area. For the benefit of the reader, we cite some of them here (Barker 1982; Beardsworth and Keil 1995; Booth 1994; Meiselman 1996; Sobal 2006).

Summary Points

- The pleasure system, originally designed as a response to certain sensory experiences (e.g., sweetness), became involved in many more elaborate cognitive experiences as the human brain (and world) grew increasingly complex.
- Pleasure – a positive experienced state that we seek and try to maintain or enhance – plays an important role in the experience of and learning about food for humans
- As a result of preadapation, a comprehensive understanding of the role of food in the modern world involves far more than nutrition.
- The modern developed world food environment differs significantly from the human ancestral food environment in many ways that foster over-consumption and obesity. As a result, for many North Americans, food choice is often a battle between pleasure and health concerns.
- However, other cultures, such as the French, have done a better job of handling the conflicts resulting from the modern developed food world; as a result, the French experience more pleasure and less stress from eating as well as lower rates of obesity than Americans.
- Pleasure can also be studied using a temporal perspective; that is, in addition to on-line experienced pleasure, one can experience pleasure from anticipating a future event (e.g., a meal) or remembering a past one.
- Kahneman and colleagues have found that the mapping functions between experienced and remembered or anticipated pleasure are complex and may be nonmonotonic. The peak level and rapidity of offset disproportionately affect remembered pain, while duration has little effect.
- Similar studies in the food domain have documented the existence of duration neglect, suggesting that small portions of a highly favored dish will have roughly the same memorial effect as large portions.

List and Definition of Key Terms

Esthetic pleasures: Pleasures that are also linked to sensory input but are more abstract and are not physically localizable. For example, the enjoyment of a complex meal or music involves esthetic pleasures.

Mastery pleasures: Pleasures that derive from achieving something of value through acquisition of some sort of skill or sophistication. For example, becoming a wine connoisseur clearly involves mastery (as well as esthetic) pleasures.

Optimal foraging: A term used to describe the calibration of food foraging in most species such that the animal spends as little energy as possible to get the maximum energy yield. Humans in the modern developed world can now obtain food without any energy expenditure at all, which is partly why obesity is on the rise.

Pleasure: A positive experienced state that we seek and try to maintain or enhance.

Preadaptation: A fundamental process in biological and cultural evolution by which something that evolves for one purpose is co-opted for another. For example, the mouth, which originally evolved for eating, became preadapted for language as well.

Primacy effect: A cognitive bias that results from the disproportionate salience of initial stimuli or observations.

Recency effect: A cognitive bias that results from the disproportionate salience of final stimuli or observations.

Schematic model of food choice: A model first developed by Sobal et al. to understand food choice in terms of three components: the person, the food, and the situation/environment.

Sensory pleasures: Pleasures derived primarily from the contact senses that cover the body surface and apertures (e.g., the feeling of food in one's mouth and its flavor), which constitute the primitive pleasure system.

Super foods: High-calorie foods developed by humans to cater to their tastes; for instance, chocolate, which is both sweet and fatty.

Temporal framework of pleasure: Classification consisting of remembered, experienced, and anticipated pleasures, and the distinctive relations among them.

Duration neglect: A term used to describe the finding that the duration of an experience is neglected – that is, not well-represented – in the memory of that experience.

Chapter 45
Explicit and Implicit Attitudes to Food

Maria Czyzewska, Reiko Graham, and Natalie A. Ceballos

Abbreviations

BMI	Body mass index
IAT	Implicit Association Test
EAST	Extrinsic Affective Simon Task
TFEQ-R	Three Factor Eating Questionnaire-Revised
g	Grams
kg	Kilograms
EEG	Electroencephalogram
ERP	Event-related potentials
fMRI	Functional magnetic resonance imaging

This article reviews recent developments in our understanding of attitudes as predictors of eating behavior, with special emphasis placed on a newly introduced construct of implicit attitudes. Implicit attitudes are defined as automatic affective associations elicited by objects (e.g., environmental cues, words, images, etc.) that are often inaccessible to conscious monitoring and intentional regulation. They influence immediate, spontaneous responses to attitude-relevant stimuli encountered in the environment. In contrast, explicit attitudes reflect deliberate, self-reported evaluations of the afore-mentioned stimuli that are accessible to introspective scrutiny, and under intentional control (e.g., Greenwald et al. 1998; Fazio and Olson 2003).

45.1 Implicit Versus Explicit Attitudes: Theory

Several theoretical models have been proposed to explain relationships between both types of attitudes (e.g., Fazio and Towles-Schwen 1999; Wilson et al. 2000; Strack and Deutsch 2004; Gawronski and Bodenhausen 2006). The MODE model (e.g., Fazio and Towles-Schwen 1999; Fazio and Olson 2003) posits that attitudes can influence behavior via two types of processes: deliberate and spontaneous.

M. Czyzewska (✉)
Department of Psychology, Texas State University, 601 University Drive,
San Marcos, TX, USA
e-mail: mc07@txstate.edu

The deliberate mode involves systematic processing of relevant information (e.g., a cost-benefit analysis of potential behavioral responses), the outcome of which determines the impact of an attitude on behavior. The processes involved are effortful, and therefore require motivation and opportunity (e.g., sufficient time and cognitive resources). In contrast, spontaneous processes produce immediate responses through automatic activation of relevant attitudes.

These early dual-process ideas were partially adopted by the Reflective-Impulsive Model of behavior regulation (Strack and Deutsch 2004), which is of particular interest to researchers interested in implicit cognition in addiction and disordered eating. According to this model, implicit attitudes represent the evaluative component of the impulsive system, responsible for reactions to environmental stimuli. These automatic evaluations result from spreading of activation through a network of associations in a memory system, triggered by encountered stimuli and linked to spontaneous behavioral tendencies of approach or avoidance. In contrast, the reflective system requires attentional control and regulates deliberate behavior according to long-term goals and personal standards. In some circumstances, the systems can generate conflicting behavioral tendencies (e.g., a restrained eater who experiences the desire to consume an appetizing high-calorie dessert). The ability to overcome the impulsive reaction (i.e., to restrain from eating the dessert) depends on the strength of the impulsive tendency and the availability of control resources in the reflective system. Consequently, conditions that impair control resources such as stress, fatigue, information overload, or the influence of alcohol are expected to reduce the regulatory capacity of the reflective system and to increase the likelihood of impulsive behavior. The reactivity of the impulsive system to environmental stimuli is moderated by motivational states. For example, a state of deprivation (e.g., hunger) is predicted to increase accessibility of environmental and behavioral schemata associated with need satisfaction (i.e., establish a perceptual readiness and a behavioral preparedness) and temporarily enhance perceived attractiveness of need-relevant objects (e.g., food).

Both models suggest that situational circumstances differentially impact the predictive validity of explicit and implicit attitudes. Explicit attitudes are expected to be predictive of behavior if a person has available cognitive resources and motivation to exert self-control, whereas implicit attitudes are linked to behavior occurring in states of low motivation and/or conditions in which resources are reduced.

45.2 Implicit Attitudes: Assessment

Unlike explicit, consciously represented attitudes that are traditionally assessed by different forms of self-report methods (e.g., questionnaires, rating scales), the measurement of implicit attitudes requires an indirect approach to quantify the strength of evaluative associations with attitude-eliciting stimuli. Some researchers proposed the term *indirect measures* as a more adequate description of these assessment methods because it emphasizes the nature of the testing procedure without implying assumptions about the nature of the implicit test outcomes (e.g., De Houwer 2006; Fazio and Olson 2003).

Several experimental tasks have been developed over the last decade to assess implicit attitudes, such as the Implicit Association Test, IAT (Greenwald et al. 1998), the single category IAT (Karpinski and Steinman 2006), the affective priming task (Fazio et al. 1995), the Extrinsic Affective Simon Task (EAST; De Houwer 2003), and the Go/No-go Association Task (Nosek and Banaji 2001). Despite their diversity, all available implicit measures share several common features and theoretical assumptions, some of which remain controversial (for review see Gawronski et al. 2007; Wittenbrink and Schwarz 2007). All are computerized tasks that require fast responses to long sequences of stimuli (e.g., words or images), and indices of implicit attitudes are derived from reaction times. The underlying assumption for most of these tasks is that responses are facilitated if consecutive stimuli

are closely associated. Conversely, responses are expected to be slower when consecutive stimuli have conflicting features (i.e., they trigger antagonistic attitudes). Therefore, the response latencies to a configuration of stimuli, arranged according to a design unique to each implicit task procedure, are used to infer the strength and quality of implicit associations among the stimuli.

The tasks most commonly used to assess implicit attitudes include the Implicit Association Task, IAT (e.g., Greenwald et al. 1998), the affective priming task (e.g., Fazio 2001; Fazio et al. 1995; Hermans et al. 1994), and the Extrinsic Affective Simon task, EAST (De Houwer 2003).

45.2.1 Implicit Association Test, IAT

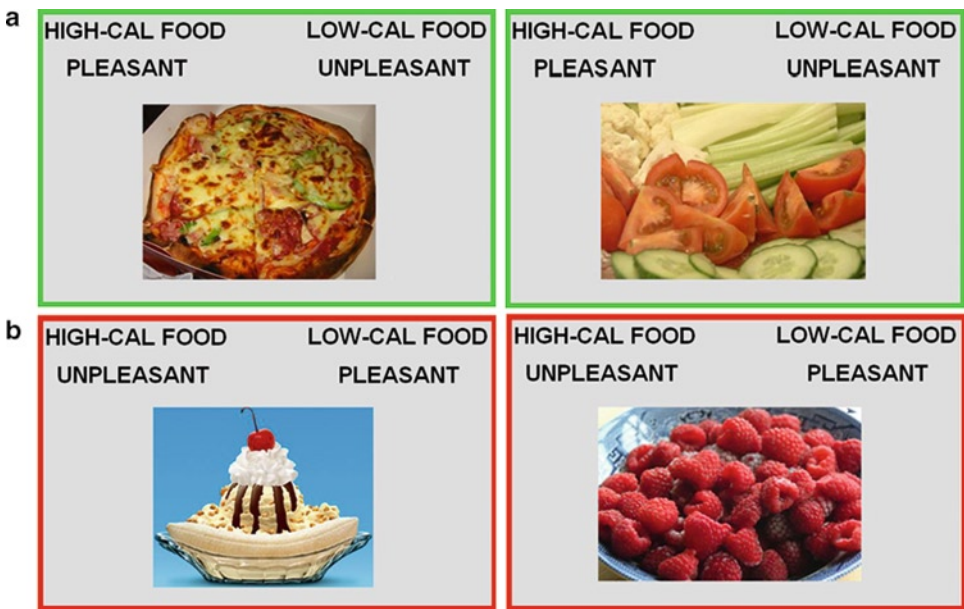
The Implicit Association Test (IAT) measures the strength of associations between targeted concepts (e.g., high- vs. low-calorie food) and evaluative valence concepts (e.g., pleasant vs. unpleasant) by comparing response latencies in a double categorization task (e.g., Greenwald et al. 1998, 2003). In a computerized version of IAT, a participant is shown a long sequence of stimuli (words or images) in the center of the computer screen and is required to classify each stimulus, as quickly as possible, into one of four classes: attribute category (e.g., pleasant) versus attribute contrast (e.g., unpleasant) or target category (e.g., high-calorie food) versus target contrast (e.g., low-calorie food). In the crucial segment of the test (i.e., double categorization) the labels of one target category (i.e., related to attitude object) paired with one attribute category (i.e., valence) are presented on both sides of the top of the screen, one pair on each side (e.g., left side: high-calorie food or pleasant, right side: low-calorie food or unpleasant; see Fig. 45.1). Participants complete the categorization task by pressing


Fig. 45.1 Schematic examples of congruent (**a**) and incongruent (**b**) IAT trials for typical food preferences (i.e., implicit attitudes to high-calorie foods are more positive relative to low-calorie). It is assumed that the categorization task of food stimuli is performed faster on congruent trials compared to incongruent. The difference in reaction times to congruent and incongruent pairings provides indirect evidence of implicit attitudes to high-calorie food relative to low-calorie

Table 45.1 Key facts of the implicit association test

1. The technique was developed by social psychologists in mid-1990s (Greenwald et al. 1995, 1998) to investigate implicit stereotypes

2. Since introduction, the method has received significant attention and been used in numerous studies in various research areas (e.g., social, clinical, health, and consumer psychology)

3. It is intended to measure the strength of association between targeted concepts (e.g., high- vs. low-calorie food) and evaluative attributes (e.g., pleasant vs. unpleasant)

4. It is a computerized task that requires classification of stimuli into one of four categories with two response keys; the differences in reaction time of specific segments of the task are used as indices of implicit attitudes

5. Examples of the IAT, procedural details and extensive links to relevant literature can be accessed at https//implicit.harvard.edu

6. The IAT typically outperforms alternative implicit attitude tests (e.g., affective priming task or EAST) in psychometric properties but the technique is not free of limitations

7. The controversial issues include:

    (a) IAT measures the *relative* implicit evaluation (e.g., evaluation of high- vs. low-calorie food) and therefore, the results have to be interpreted not as an absolute evaluation of one target (e.g., high calorie food) but in the context of a specific contrast category

    (b) IAT might primarily assess evaluative associations with *categories* used in the task (e.g., high- vs. low-calorie foods) instead of evaluation of individual exemplars (i.e., specific food stimuli)

    (c) IAT results are influence by choice of contrast categories and category labels (e.g., healthy vs. unhealthy food)

    (d) IAT assessment can be confounded by processes unrelated to implicit evaluation (e.g., familiarity of the stimuli or category labels)

8. Various modifications of the basic IAT procedure attempt to address some of the limitations (e.g., Single Target IAT, Go/No Go Association Test)

The table summarizes key facts of the Implicit Association Test (for more comprehensive discussion see Lane et al. 2007)

keys corresponding to the side of the screen that includes a category label relevant to presented stimuli. It is assumed that on trials in which pairing of the target category and evaluative attribute is congruent with person's attitude to a displayed stimulus (e.g., response to a picture of pizza when high-calorie food is paired with pleasant) the categorization task is easier and therefore performed faster than if the pairing is incongruent (e.g., high calorie and unpleasant). The difference in reaction times to congruent and incongruent pairings provides indirect evidence of how the attitude-related knowledge is organized (for more details about the IAT procedure and psychometric properties of the test, see Lane et al. 2007).

The key facts of the Implicit Association Tests are summarized in Table 45.1. As discussed in the literature, the limitations of the IAT include the fact that the results of the test are strongly influenced by the attributes made salient by the labels used in the stimuli categorization task (e.g., De Houwer 2001; Karpinski and Hilton 2001) and by contrast category in the double categorization task (e.g., Robinson et al. 2005). Also, some argue that the IAT primarily measures associations at the category level rather than at the level of individual exemplars (e.g., high-calorie food overall vs. ice cream; De Houwer 2002). Some of these limitations are addressed by experimenting with modifications to the basic IAT procedure, for instance, by using a single category IAT (Karpinski and Steinman 2006) or the Go/No-go Association Task (Nosek and Banaji 2001).

45.2.2 Affective Priming Task

The Affective Priming Task, unlike the IAT, allows for the measurement of affective associations to stimuli in a way that is unbiased by the bipolar categories used in a categorization task (e.g., Fazio and Olson 2003). The task involves presentation of a prime that is evaluatively consistent or inconsistent
Fig. 45.2 Schematic example of a single trial of the affective priming task. It is assumed that the responses to target words (e.g., miracle) are faster if their valence is consistent with the implicit attitude to primes (e.g., positive to apple pie) compared to trails in which an automatic evaluation of the prime is inconsistent with the target word valence

with a subsequently presented target. The presentation of a stimulus (e.g., words or images related to food) as a prime is expected to activate associated evaluations and, therefore, to facilitate responses to evaluatively consistent targets (e.g., Fazio 2001). In this computerized task, participants are asked to evaluate a long sequence of rapidly presented stimuli (words or images) using bipolar valence categories (e.g., good vs. bad, positive vs. negative, pleasant vs. unpleasant). Participants respond by pressing designated response keys, and reaction time data are recorded. The presentation of each evaluated stimulus is primed (i.e., preceded) by an attitude-related stimulus (e.g., word or image related to different types of food) or a control item (i.e., word or image not related to food). The reaction times to evaluated stimuli that are primed by affectively consistent attitude-related stimuli (e.g., food pictures) are expected to be shorter than they would be if the prime/evaluated target combination were incongruent in valence. Figure 45.2 shows an example of a single trial of an Affective Priming task designed to assess attitudes to different types of food.

In this task, the difference in average reaction time to positive versus negative words preceded by the same food primes indicated the direction of implicit attitudes toward these foods (e.g., if a person has a positive implicit attitude to a high-calorie food, then his/her reaction time to a positive word primed by that high-calorie food image was expected to be shorter than his/her reaction time to a negative word primed by the same high-calorie food image).

The affective priming task has been successfully applied to examine existing and newly acquired food preferences (e.g., Lamote et al. 2004; Verhulst et al. 2006; De Houwer et al. 2009 for discussion of the psychometric properties of this test).

45.2.3 The Extrinsic Affective Simon Task, EAST

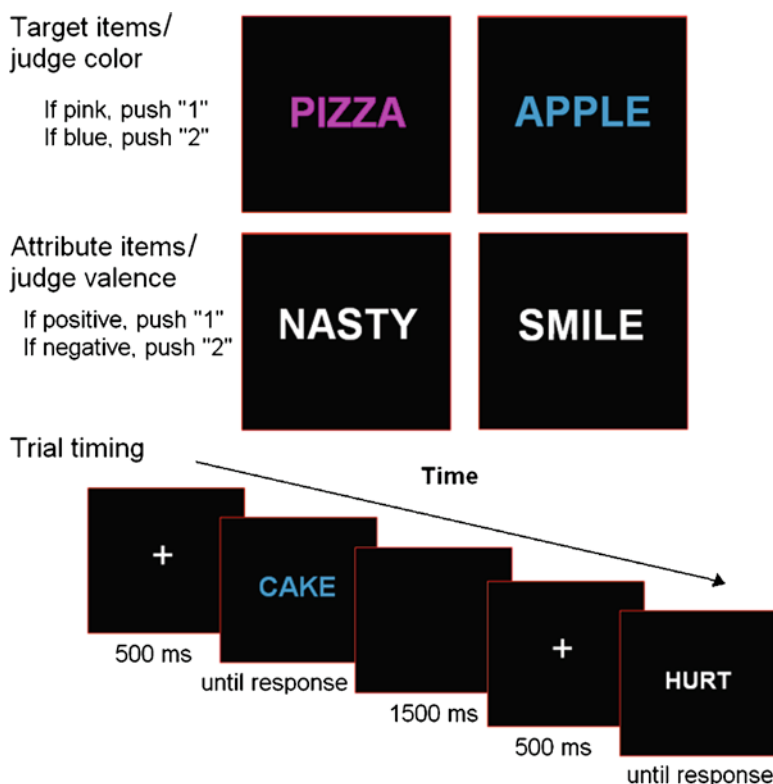
The Extrinsic Affective Simon Task (i.e., EAST) was developed as a modification of the original IAT paradigm in order to avoid problems with the potential biasing effects of category labels (De Houwer 2003). Unlike the IAT, the EAST procedure requires participants to choose between a positive or negative response to an attitude-related stimulus (word or image) on the basis of a nonevaluative


Fig. 45.3 Schematic example of the trial types and timeline used in the EAST. The four trial types are randomly presented and response type (color vs. valence judgments) is signaled by font color (white = valence judgment, blue or pink = color judgment). Response keys and target item font color are counterbalanced across subjects

feature. A part of the task is designed to develop extrinsic associations between a specific response key (e.g., right vs. left) and an evaluative meaning (e.g., positive vs. negative), resulting in the establishment of an extrinsically positive key (e.g., right) and an extrinsically negative key (e.g., left). In the subsequent segment of the task, participants are asked to categorize attitude-relevant stimuli (e.g., food-related) with respect to an irrelevant-to-stimulus valence property (e.g., color or shape) using the same two response keys (see Fig. 45.3).

The four trial types are randomly presented and response type (e.g., color vs. valence judgments) is signaled by font color (white = valence judgment, blue or pink = color judgment). Response keys and target item font color are counterbalanced across subjects.

For example, in the first part of the task (i.e., the extrinsic association component) participants could be asked to perform a typical stimulus evaluation task by pressing the right key if the presented word corresponds to positive attribute (e.g., friendly) or negative attribute (e.g., hostile). The following segment would instruct participants to categorize words based on their color using the positive response key if the word is printed in red and using the negative response key if the word is printed in green (the matching of colors/valence of the response key is counterbalanced across participants). The color words consist of attitude-related stimuli (e.g., names of food items) and controls (i.e., attribute words printed in white) to which participants are instructed to respond by indicating their valence (i.e., press a key designated as positive or negative in the previous, evaluative categorization part of the task). Subsequently, the implicit association effect is defined as the reaction time difference

in responding to food related items with a positive valence key (i.e., printed in red) versus a negative valence key (i.e., printed in green).

The EAST paradigm has been used to investigate implicit cognition in addiction (e.g., De Houwer et al. 2004; Ames et al. 2007; Birch et al. 2006) and attitudes to food (e.g., Craeynest et al. 2005; Roefs et al. 2005a; Seibt et al. 2007); however, psychometric characteristics of this method remain largely unexamined. There is evidence that the IAT outperforms the EAST in terms of reliability and predictive validity (De Houwer and De Bruycker 2007).

45.3 Individual Differences in Implicit Food Attitudes (Quasi-Experimental Designs)

Several studies have examined differences in explicit and implicit attitudes to food among participants who were expected to vary in food preferences or in their ability to control eating behavior (e.g., eating disordered vs. nonclinical or obese vs. normal weight individuals). The results of these studies, which attempted to reveal interindividual differences in automatic food preferences by comparing groups in quasi-experimental designs, have not produced conclusive results.

Roefs and Jansen (2002) examined implicit and explicit attitudes toward high-fat foods among obese versus normal weight individuals using an IAT with two target categories: high-fat versus low-fat food words and an evaluative attribute (positive vs. negative). Contrary to expectations, the results revealed a significantly stronger *negative* implicit attitude toward high-fat foods among obese participants compared to normal-weight controls. No differences were found between the groups in explicit attitudes to food: all participants reported a higher preference for low-fat versus high-fat foods. However, a subsequent study conducted in the same laboratory, but with different implicit measures (i.e., an affective priming task instead of an IAT), failed to replicate the original results, finding no significant differences between obese and normal weight adults in implicit evaluations of foods varying in fat content or palatability (Roefs et al. 2005b (Experiment 2), 2006).

Czyzewska and Graham (2008) extended previous research on high versus low fat foods by comparing implicit and explicit attitudes to three types of foods: high-calorie nonsweet, high-calorie sweet, and low-calorie foods. Female participants, varying in body mass index (BMI) status (healthy weight, overweight, and obese), completed an affective priming task (implicit) with pictures of food as primes and positive and negative words as targets of evaluative categorization. This procedure was followed by explicit rating of the same food images. The results showed a significant interaction between BMI status and type of food in terms of implicit food preferences. Implicit attitudes to high-calorie sweet foods (e.g., ice cream, cake) were significantly more *negative* in the obese group compared to healthy weight and overweight groups. However, relative to other weight groups, the obese participants exhibited significantly more *positive* implicit attitudes to high calorie nonsweet foods (e.g., pizza, steak meal). Regardless of BMI group, all participants exhibited negative implicit attitudes to low calories foods. In contrast to implicit measures of food preference, analysis of explicit ratings revealed no interaction between food type and BMI status: all participants rated high calorie nonsweet foods significantly lower than high calorie sweet and low calorie foods. A similar pattern of implicit food preferences across groups with different body weight status has also been demonstrated in a Mexican population (Czyzewska et al. 2009). Overall, the results of both studies suggest that implicit attitudes to high-calorie food, assessed by affective priming, are better predictors of unhealthy body weight, as compared to measurement of corresponding explicit attitudes. However, these findings are limited, as the behavioral consequences of differences in implicit attitudes to food across BMI groups (e.g., eating disinhibition) were not addressed.

Similar to research conducted with adults, studies examining implicit and explicit food preferences among children of different body weight statuses has produced inconsistent outcomes. A study investigating children's attitudes to healthy and unhealthy food (Craeynest et al. 2005) showed that obese children have more positive implicit attitudes to food in general (i.e., healthy and unhealthy food alike) as compared to their normal weight peers. However, across groups, no evidence of differential implicit preferences to specific types of food was found. Furthermore, no significant differences were noted between groups in their explicit attitudes to food. The implicit food preferences were measured with the EAST using food names of three healthy foods (e.g., tomato) and three unhealthy foods (e.g., crisps) as target stimuli. All target stimuli were also explicitly rated by participants. The same food attitude assessment methods were used in a longitudinal study designed to evaluate the outcomes of youth obesity treatment (Craeynest et al. 2008a). However, results indicated that participants' body weight loss in the course of the treatment was not accompanied by any significant changes in either explicit or implicit attitudes to food. In another study involving children of different BMI statuses, Craeynest et al. (2008b) investigated implicit associations between arousal and food varying in fat content using a modified version of the IAT. The modified IAT was used to assess associations between high- versus low-fat food (target category) and calm versus active (arousal attribute category). There were two versions of the IAT, one with positive words that varied in arousal (e.g., quick – high; relaxed – low) and another with negative words (e.g., impatient – high; drowsy – low). The exemplars of target category were images of lean and high-fat foods. The results revealed significant implicit associations between high-fat foods and arousal in both positive and negative versions of the IAT, which did not differ between the overweight and control groups.

Similarly, researchers examining implicit attitudes to high-fat versus low-fat food in clinical groups have found no support for the hypothesis that restrained eaters displayed greater implicit liking for high-fat palatable foods, as compared to unrestrained eaters (Roefs et al. 2005a). Another study revealed implicit preferences for palatable foods over unpalatable, independently of the food fat content, among unrestrained eaters but not among anorexia nervosa patients. According to the authors, these findings might indicate an overall decrease of the rewarding properties of food in this clinical group (Roefs et al. 2005b Experiment 1).

45.4 Situational Moderators of Attitudes as Predictors of Impulsive Eating (Experimental Designs)

Recently, several studies have attempted to verify the theoretical prediction that situational factors moderate the predictive validity of implicit versus explicit food attitudes.

Hofmann et al. (2007) demonstrated that reducing self-regulation capacity by performing an ego-depleting task (e.g., Baumeister et al. 2007) increases the relationship between implicit attitudes to candies and subsequent eating behavior. In contrast, among participants whose self-regulation capacity was not impaired by experimental manipulation, the amount of consumed candies was predicted by explicitly expressed dietary restraint standards but not by implicit attitudes.

Hofmann and Friese (2008) demonstrated that alcohol moderates the relative influence of implicit versus explicit attitudes on eating behavior. Using a single category variant of the IAT, the researchers showed that implicit attitudes to M&M's predicted amount of candies eaten, but only among participants who had previously consumed alcohol (experimental condition: acute administration of 0.4 g alcohol/kg in a vodka and orange juice mix). The eating behavior of participants without acute alcohol consumption (control condition) was primarily determined by explicit attitudes (i.e., self-reported restrained eating assessed by the Cognitive Restraint subscale of the Three Factor Eating

Questionnaire-Revised [TFEQ-R], Stunkard and Messick 1985). These results appear consistent with the model of impulsive-reflective behavior regulation (Strack and Deutsch 2004). Candy consumption was primarily regulated by explicit attitudes (i.e., reflective system) when the capacity to control behavior was uncompromised by alcohol. However, when control resources were diminished by alcohol, the automatic evaluation of M&M's (i.e., implicit attitudes) had a stronger impact on eating behavior (i.e., candy consumption became regulated by the impulsive system). However, as noted by Hofmann and Friese (2008), the mechanisms underlying the observed effects of alcohol on the relationships between implicit versus explicit attitudes and eating behavior cannot be determined conclusively. One explanation for these results is that alcohol could impair reflective regulation; however, it is equally likely that alcohol amplified impulsiveness (i.e., the strength of impulsive regulation), or both (for details see Hofmann and Friese 2008). Further investigation is needed to clarify the role of alcohol in the regulation of eating behavior. Nevertheless, the study lends credence to the idea that certain states (e.g., with alcohol-consumption vs. without) can elicit dissociations between implicit versus explicit attitudes as behavioral predictors and validates the distinction between these two constructs (i.e., two types of attitudes).

Friese et al. (2008) obtained further evidence supporting the notion that the relative predictive validity of explicit versus implicit food attitudes depends on the availability of executive/control resources. The availability of control resources was experimentally manipulated by introducing a concurrent cognitive load at the time of food selection (i.e., impairment of cognitive capacity – Experiment 1), or suppression of emotion while viewing a disturbing movie (i.e., impairment of self-regulatory resources – Experiments 2 and 3). The implicit attitudes to targeted foods/drinks (i.e., chocolate vs. fruits – Experiment 1; potato chips and beer – Experiment 2 and 3, respectively) were measured with standard or one-category IATs. Explicit attitude measures consisted of rating scales. At the end of the testing sessions, all participants were given the opportunity to sample items corresponding to foods targeted by attitude assessment (e.g., chocolates). The findings across all three studies confirmed researchers' expectations: implicit attitudes were predictive of participants' food choice behavior but only in conditions of reduced control resources. Conversely, explicit attitudes were predictive of behavior under conditions of full resources.

Several studies have examined the effect of hunger on automatic attitudes to food (Seibt et al. (2007); Safford and Scheffler 2008). In a series of three experiments, Seibt and colleagues demonstrated that participants who reported having a last meal more than 2 h earlier (i.e., deprived group) exhibited more positive implicit attitudes to food compared to a satiated group (last meal less than 2 h earlier). The effect of food deprivation on implicit food evaluation was assessed with the IAT using names of food and sport-related words as categorized stimuli (Experiment 1) and replicated with the EAST (Experiment 2). This approach allowed researchers to establish the robustness of the effect across different assessment methods and food-related stimuli (see also Stafford and Scheffer 2008 for similar findings).

The nature of the relationship between implicit attitudes toward food and attentional capture by food images remains an intriguing research question. Mogg et al. (1998) examined the effects of hunger on attentional biases toward food-related stimuli (words) using a dot-probe task and found that hungry participants were more likely to shift their attention toward food-related words relative to control words. Furthermore, the magnitude of this attentional effect was predicted by subjective hunger ratings. Further delineation of the relationships between implicit attitudes, attentional capture by food-related stimuli, hunger, and subsequent eating behavior will help to elucidate the exact means through which implicit attitudes may affect behavior.

Researchers have shown that these changes in automatic evaluative response to food-related stimuli under deprivation are accompanied by increased disposition to approach responses among participants with and without eating disorders (Seibt et al. 2007). For instance, when the EAST procedure

was modified so that the evaluative response was indicated by either pulling (approach) or pushing away (avoidance) the lever of a joystick in response to pictorial food stimuli, approach responses (toward the participant) were significantly faster among hungry participants compared to satiated participants (Seibt et al. 2007). In addition, a recent study (Harmon-Jones and Gable 2009) examined the neural correlates of approach-motivated processing elicited by pictures of desserts by examining electrical brain activity (EEG) during a selective attention task. In this study, female participants were required to identify either global or local features of Navon letters (large letters made up of closely spaced smaller letters) preceded either by dessert pictures or by neutral pictures. The purpose of this study was to examine how approach-related stimuli (desserts) affect attention and how this might be manifested in the brain. Processing of dessert pictures was associated with a narrowing of attention (an advantage for local features or the smaller letters), accompanied with increased activity over left frontal brain areas, which has been hypothesized to reflect approach-related motivation (Davidson 1995). Furthermore, these effects were positively correlated with individual differences in the number of minutes since last eating, corroborating the notion that, in addition to implicit attitudes, approach responses to food are moderated by hunger.

Taken together, the findings that hunger temporarily enhances automatic valence and approach responses to food-related words and images suggest that need states such as hunger exert their effects through the impulsive system, consistent with the Reflective-Impulsive Model (Deutsch and Strack 2006). According to this model, deprivation states modulate reactivity of the impulsive system by increasing behavioral preparedness (e.g., increased accessibility of behavioral schemata, appropriate for need satisfaction) and perceptual readiness for need-relevant stimuli (e.g., lower perceptual thresholds). Furthermore, deprivation temporarily increases the automatic valence of need-related objects (e.g., food items) and behaviors leading to need satisfaction (e.g., eating). For instance, a recent study (Stockburger et al. 2008) examining event-related electrical potentials as recorded at the scalp (ERPs) found that food deprivation specifically modulated ERPs elicited by food pictures early in the processing stream (approximately 170–300 ms after picture onset). This effect was most likely due to enhanced activity in the occipito-temporal brain regions associated with visual processing. Similar early effects in posterior brain regions have also been observed with food-related words (Leland and Pineda 2006).

Neuroimaging studies also support the notion that hunger is related to increased reactivity in the impulsive system. For example, LaBar et al. (2001) observed that food deprivation resulted in increased activity to food pictures in the amygdala, a subcortical limbic structure known to be involved in processing emotional/highly arousing stimuli, and in visual-associative regions in inferotemporal cortex. Hungry states in both adults (Morris and Dolan 2001) and children and adolescents (Holsen et al. 2005) elicit similar activations, not only in the amygdala and visual areas, but also in orbitofrontal cortex and the insula (areas associated with reward and interoception), suggesting that the patterns of neural activity that underlie food motivation are set relatively early in development (i.e., during childhood).

Hoefling and Strack (2008) have expanded upon the aforementioned work by examining the interaction between food deprivation, implicit/explicit attitudes, and disinhibition/restrained eating. The restrained and unrestrained eaters' explicit ratings and implicit evaluations of high- and low-calorie foods were examined both in food-deprived and satiated states with the EAST (De Houwer 2003). Among all participants, food deprivation increased the implicit valence of foods independent of caloric content. This effect was not significant for explicit evaluations of food items. Consistent with the authors' hypotheses, restrained eaters revealed a dissociative pattern of negative explicit but positive implicit attitudes towards high calorie foods, but not towards low calorie foods. Furthermore, the restrained eaters' explicit ratings of high calorie foods were more negative than those obtained from the unrestrained eaters, but the opposite pattern was exhibited for implicit evaluations (i.e., more positive among restrained vs. unrestrained). These conflicting evaluations arising from the reflective

and impulsive systems and the factors affecting the resolution of this conflict (the predominance of one system over another) are of critical importance to healthy food choices, particularly in individuals with weight management issues (restrained eaters).

In a related study, Stewart and Samoluk (1995) compared the acute effects of food deprivation and the chronic effects of restrained eating on the processing of appetitive cues (food and alcohol words) relative to control words (leisure words) using a modified version of the Stroop task. In this task, participants were required to name the font color of various words as quickly as possible, while ignoring their semantic content. Slowed color-naming reaction times for appetitive cues relative to control cues are indicative of interference (the automatic capture of attention by the to-be-ignored dimension). Longer latencies for appetitive cues as a function of hunger state were not observed (but see Channon and Hayward 1990; Lavy and van den Hout 1993). Rather, dietary restraint was associated with attentional capture by appetitive cues such that highly restrained eaters had significantly longer color-naming latencies compared to moderate or low restraint eaters. Thus, chronic dietary restraint seems to exert effects that are independent of hunger, possibly reflecting an underlying preoccupation with food (Stewart and Samoluk 1995) that has been observed with self-report measures (e.g., Herman and Polivy 1980). This finding may also account for similar effects (i.e., increased color-naming latencies for food-related words) observed in individuals with anorexia and bulimia relative to controls (e.g., Channon et al. 1988; Cooper et al. 1992).

45.5 Application to Other Areas of Health and Disease

The interplay between explicit and implicit attitudes and their effects on eating behaviors have important implications for health, ranging from the control of obesity (and diseases for which obesity is a significant risk factor) to eating disorders and disorders of body image. Results from the 2003–2004 National Health and Nutrition Examination Survey estimate that 66% of US adults are either overweight or obese, while approximately 17% of children and adolescents aged 2–19 years are overweight (Ogden et al. 2006). Recent data from the World Health Organization (2002) suggest that obesity is a major global health issue. With its accompanying risks for serious health problems, such as coronary heart disease, diabetes, skeletomuscular and respiratory problems, it is not surprising that obesity has been targeted as a major health issue (World Health Organization 2002). Emphasis has been placed on weight management and physical activity as the primary means of ameliorating this problem. As a consequence, dietary restraint (i.e., restricted eating) will be at the forefront of many weight management strategies. Understanding how food attitudes interact with other factors like motivational states to influence eating behaviors will give us a better understanding of the situations that elicit unhealthy food choices, leading to more effective strategies to minimize impulsive, and often unhealthy, behaviors.

Our understanding of disordered eating, whether that which accompanies anorexia or bulimia nervosa, or that which arises as a result of psychiatric illness (e.g., major depression) or emotions such as stress, will also benefit from clarification of how implicit and explicit attitudes interact to affect eating behaviors. As mentioned previously, attentional biases towards food-related stimuli (i.e., increased color-naming latencies for food-related words) have been observed in individuals with anorexia and bulimia relative to controls (e.g., Cooper et al. 1992; Channon et al. 1988). Both behavioral and neuroimaging studies suggest that disordered eating may arise in part from heightened reactivity of the impulsive system.

A recent neuroimaging study examining neural responses to food pictures in females (grouped as those with binge-eating disorder, bulimia, overweight and normal weight) after a 12-h fasting period

(Schienle et al. 2009) found that food images were rated as more pleasant and arousing than control pictures and evoked a general pattern of activity in orbitofrontal, anterior cingulate, and insular cortices consistent with hunger responses reported in other neuroimaging studies (LaBar et al. 2001; Morris and Dolan 2001; Holsen et al. 2005). However, orbitofrontal activations were most pronounced in the binge-eating group, which was interpreted as reflecting the heightened incentive value of food images in this group (Schienle et al. 2009). In contrast, bulimics showed enhanced insula and anterior cingulate activation to food pictures relative to other groups. This finding is intriguing, given the involvement of the insula in food-related responses in general, and in the interoceptive aspects of emotional experience (Craig 2008), while enhanced cingulate activity could reflect the recruitment of selective attention (Schienle et al. 2009).

Emotions can also differentially moderate appetitive responses associated with the impulsive system. Killgore and Yurgelun-Todd (2006) examined the neural responses of normal weight women who viewed photographs of high- and low-calorie foods while undergoing functional magnetic resonance imaging (fMRI). Self-reported levels of positive and negative affect had differential effects on several important appetite-related regions, most notably the orbitofrontal cortex, depending on the calorie content of the food images. When viewing high-calorie foods, women in good moods exhibited increased activity in satiety-related regions (lateral orbitofrontal cortex), but when viewing low-calorie foods, positive affect was associated with increased activity in hunger-related regions (in particular, the medial orbitofrontal, anterior cingulate, and insular cortices). The opposite pattern of activity was observed for negative affect: negative affect was associated with decreased activity in satiety-related areas in response to high-calorie foods and decreased activity in hunger areas in response to low-calorie foods. Although these results await replication, they suggest a possible neural mechanism underlying emotional eating and may explain why cravings for high calorie foods are often reported after experiencing heightened negative emotions.

45.5.1 Interaction of Food-Related Behaviors and Addiction

Further, viewing food-related pathology in terms of an "addiction" to food could provide an innovative approach to the understanding and treatment of conditions such as binge eating and obesity. Although several neurotransmitters are thought to play a role in regulating food intake, dopamine is of particular interest due to its importance in modulating food reward via the mesolimbic pathway of the brain (from the ventral tegmental area in the brainstem, via the nucleus accumbens, into the orbitofrontal cortex). From a neurobiological perspective, addiction is thought to progress through a process of "incentive sensitization" in which appetitive motivations are important (e.g., Robinson and Berridge 1993). In this framework, the term sensitization refers to the hypersensitization of the reward circuitry of the brain (namely, the amygdala, nucleus accumbens, anterior cingulate, and orbitofrontal cortices) to the effects of addictive substances and stimuli associated with addictive substances. This sensitization effect occurs through the release of the neurotransmitter dopamine, which is elicited not only by "rewards" such as addictive substance (e.g., alcohol, tobacco, and illicit drugs), but also by "natural" rewards such as food and sex. Such hypersensitization or hyperarousal to implicit associations may influence behavior without conscious awareness (e.g., Robinson and Berridge 1993). That is, once an individual uses and becomes sensitized to a substance, neurotransmitter systems within the reward/addiction centers of the brain will be more likely to be activated by the presence of that substance, or even to related cues such as the sight or smell of a substance.

Applying the incentive-sensitization theory to the case of food-related addictions, the exposure to specific foods (such as high-calorie desserts) may sensitize the brain's addiction circuits, leading

to hyperarousal in the presence of these foods or in response to dessert-related cues such as words (e.g., cheesecake, pie, or candy), images (e.g., pictures of cheesecake pie or candy) or other sensory stimuli (e.g., the smell of cheesecake, pie, or candy). Eventually, with increased consumption of high calorie desserts, addictive behaviors may develop, in part through mechanisms that are below the level of conscious control (e.g., implicit, impulsive, and automatic; Houben and Wiers 2008; Evans and Coventry 2006). In keeping with this hypothesis, Wang and colleagues (2001) found that striatal D2 dopamine receptor availability (including D2 availability in the nucleus accumbens) was significantly lower in severely obese individuals relative to controls – a pattern that is also observed in drug-addicted individuals. Furthermore, individual differences in D2 receptor availability were negatively correlated with BMI across all subjects. These findings raise the possibility that "food addicts", especially those who are obese, may persist in engaging in pathological (but rewarding) behaviors such as overeating as a way of compensating for decreased activation in these reward circuits.

In summary, recognizing the potentially common pathways between overindulgence in dopamine-eliciting substances and activities could lead to new and innovative means of measuring, preventing, and treating a wide range of health risk behaviors.

Summary Points

- Theory predicts that explicit (i.e., self-reported) attitudes are predictive of deliberate behaviors (e.g., intentional food choices) and implicit (i.e., automatic) attitudes are linked to impulsive actions (e.g., disinhibition in eating).
- Explicit attitudes are expected to be predictive of behavior if a person has available cognitive resources and motivation to exert self-control, whereas implicit attitudes are linked to behavior occurring in states of low motivation and/or conditions in which resources are reduced.
- Several computerized tasks have been developed over the last decade to indirectly assess implicit attitudes based on a response time to attitude-related stimuli; IAT, Affective priming task and EAST are among those most commonly used by researchers interested in studying eating behavior.
- Results of studies that attempted to reveal interindividual differences in implicit food attitudes by comparing groups in quasi-experimental designs (i.e., obese vs. normal weight individuals or eating disordered vs. nonclinical) have not produced conclusive results.
- More consistent and promising are results emerging from experimental studies, which tested theoretical prediction by manipulating the availability of self-regulatory resources or motivational states (i.e., food deprivation).
- Depletion of cognitive resources, whether via ego-depletion or alcohol administration, appears to facilitate the implicit valence of food and increase the influence of implicit (automatic) versus explicit (reflective) attitudes on eating behavior (see Tables 45.2–45.4 for summary).
- Food deprivation appears to temporarily enhance automatic valence and approach responses to food-related stimuli, suggesting that need states such as hunger exert their effects through the impulsive system, consistent with the Reflective-Impulsive Model predictions.
- Neuroimaging studies also support the notion that hunger is related to increased reactivity in the impulsive system (see Table 45.5 for summary).
- Viewing food pictures while hungry leads to increased neural activity in the amygdala, a subcortical limbic structure of the brain known to be involved in processing emotional/highly arousing stimuli, and in visual-associative regions in the brain's inferotemporal cortex.
- Viewing images of food appears to evoke neural activity within several brain regions including the orbitofrontal cortex, the anterior cingulate, and the insular cortices. Positive and negative

Table 45.2 Summary of food-related studies using implicit association tests

Authors	Task description	Population(s)	Study design	Outcome
Roefs and Jansen (2002)	Target: high-fat vs. low-fat food words Evaluative attribute: positive vs. negative words	Obese vs. normal-weight adults	Quasi-experimental, cross-sectional	More *negative* implicit attitudes to high-fat foods among obese participants vs. normal-weight controls
Craeynest et al. (2008b)	Targets: high- vs. low-fat foods Arousal attributes: calm vs. active words	Overweight vs. normal-weight adults	Quasi-experimental, cross-sectional	Implicit associations between high-fat foods and arousal but no group differences
Hofmann et al. (2007)	Targets: pictures of M&Ms. Evaluative attribute: positive/negative pictures and words	Healthy adults	Experimental, Cross-sectional *Manipulation: Ego depletion*	Ego-depletion increased the relationship between implicit attitudes to candies and subsequent eating behavior
Hofmann and Friese (2008)	Targets: pictures of M&Ms. Attribute stimuli: positive pictures and words, negative pictures and words	Healthy adults	Experimental, cross-sectional *Manipulation: alcohol administration*	With alcohol administration, implicit attitudes to M&M's predicted amount of candies eaten
Friese, Hofmann, and Wanke (2008)	Targets: foods/drinks (i.e., chocolate vs. fruits – Experiment 1, potato chips and beer – Experiment 2 and 3) standard or one-category IATs	Healthy adults	Experimental, cross-sectional *Manipulation: cognitive load or emotion suppression*	Implicit attitudes were predictive of participants' food choice behavior but only in conditions of reduced control resources
Seibt, Hafner, and Deutsch (2007, Experiment 1)	Targets: foods vs. sport-related words Evaluative attribute: positive vs. negative words	Healthy adults	Experimental, cross-sectional *Manipulation: hunger*	The satiated group exhibited more positive implicit attitudes to food compared to a deprived group

This table provides the reader with a comprehensive overview of studies that have used IATs for implicit attitudes assessment to investigate reactions to food-related stimuli, along with descriptions of study populations, designs, and main outcomes

Table 45.3 Summary of food-related studies using Extrinsic Affective Simon Tasks

Authors	Task description	Population(s)	Study design	Outcomes
Roefs et al. (2005a, Experiment 2)	Target stimuli: palatable vs. unpalatable food names	Restrained and unrestrained eaters	Quasi-experimental, cross-sectional	Null: The hypothesis that restrained eaters would show a stronger liking for (high-fat) palatable foods was not supported
Craeynest et al. (2005)	Target stimuli: food names of healthy foods and unhealthy foods	Obese and normal weight children	Quasi-experimental, cross-sectional	Null: Across groups, no evidence of differential implicit preferences to specific types of food was found
Craeynest et al. (2008a)	Target stimuli: food names of healthy foods and unhealthy foods	Children undergoing a youth obesity treatment program.	Quasi-experimental, longitudinal	Null: Participants' body weights were not accompanied by significant changes in attitudes to food
Seibt, Hafner and Deutsch (2007, Experiment 2)	Target stimuli: flower names, food names, and non-words	Healthy adults	Experimental, cross-sectional *Manipulation = hunger*	The satiated group exhibited more positive implicit attitudes to food compared to a deprived group
Hoefling and Strack (2008)	Target stimuli: high-calorie and low-calorie food-related words and control words	Restrained and unrestrained eaters	Experimental, cross-sectional *Manipulation = hunger*	Across groups, hunger increased the implicit valence of foods, independent of caloric content. Restrained eaters: dissociative patterns of explicit and implicit attitudes toward high-calorie foods

This table provides the reader with a comprehensive overview of studies that have used EASTs for implicit attitudes assessment to investigate reactions to food-related stimuli, along with descriptions of study populations, designs, and main outcomes

Table 45.4 Summary of food-related studies using affective priming tasks

Authors	Task description	Population (s)	Study design	Outcome
Roefs et al. (2005a, Experiment 1)	Primes: High- and low-fat food words; Targets: Positive and negative words	Restrained and unrestrained eaters	Quasi-experimental, cross-sectional	Null: No differences in implicit attitudes to high/low fat food between groups
Roefs et al. (2005b, Experiment 1)	Primes: high/low fat and palatable/unpalatable food words; Targets = negative and positive words	Female Anorexia nervosa patients and unrestrained eaters	Quasi-experimental, Cross-sectional	Unrestrained controls only: implicit preference for palatable foods vs. unpalatable foods
Roefs et al. (2005b, Experiment 2)	Primes: High/low fat and palatable/unpalatable foods; Targets: Negative and positive words	Obese adult females and unrestrained eaters	Quasi-experimental, cross-sectional	Null: no group differences in implicit attitudes to food
Roefs et al. (2006)	Primes: high/low-fat and palatable/unpalatable food words; Targets: Positive and negative words	Obese and normal weight adults	Quasi-experimental, cross-sectional	Null: no significant differences between obese and normal weight adults in implicit evaluations of foods varying in fat content or palatability
Czyzewska and Graham (2008)	Primes: Pictures of high/low calorie and sweet/savory foods; Targets: Positive and negative words	Female participants, varying in BMI status	Quasi-experimental, cross-sectional	Differential pattern of implicit attitudes to food categories between BMI groups but no differences in explicit attitudes

This table provides the reader with a comprehensive overview of studies that have used affective priming tasks for implicit attitudes assessment to investigate reactions to food-related stimuli, along with descriptions of study populations, designs, and main outcomes

Table 45.5 Summary of food-related studies using electroencephalographic (EEG), event-related potential (ERP) and neuroimaging methodologies

Authors	Task description	Population	Study design	Outcome
LaBar et al. (2001)	Participants viewed images of food, tools and Gaussian-blurred objects and detected blinking stimuli	Healthy adults	Experimental, Cross-sectional Methodology: fMRI, *Manipulation: hunger*	Food deprivation was associated with increased activity to food pictures in the amygdala and in visual-associative regions of the inferotemporal cortex
Stockburger et al. (2008)	Participants passively viewed food and nonfood pictures	Healthy adults, males only	Experimental, Cross-sectional Methodology: ERP, *Manipulation: hunger*	Food deprivation modulated ERPs elicited by food pictures 170–300 ms after picture onset, likely due to enhanced activity in the occipito-temporal brain regions
Harmon-Jones and Gable (2009)	Selective attention task. Global or local features of Navon letters were identified, preceded either by dessert or neutral pictures	Healthy adults, females only	Experimental, Cross-sectional Methodology: EEG	Processing of dessert pictures was associated with a narrowing of attention and increased activity over left frontal brain areas
Schienle et al. (2009)	Participants passively viewed pictures of high-calorie food, disgust-inducing items, and neutral items	Females with binge-eating disorder, bulimia, overweight and normal weight	Quasi-experimental, cross-sectional Methodology: fMRI	Food images evoked activity in orbitofrontal, anterior cingulate, and insular cortices. Orbitofrontal activations were most pronounced in the binge-eating group. Bulimics showed enhanced insula and anterior cingulate activation
Killgore and Yurgelun-Todd (2006)	Participants viewed images of high- and low-calorie foods, as well as nonedible food-related utensils	Healthy adults, females only	Experimental, Cross-sectional Methodology: fMRI	Self-reported levels of positive and negative affect had differential effects on appetite-related brain regions depending on the calorie content of the food images; the opposite for negative affect

This table provides the reader with a comprehensive overview of studies that have used EEG, ERP, and/or neuroimaging methodologies to investigate reactions to food-related stimuli, along with descriptions of study populations, designs, and main outcomes

mood states may have an important effect on the activity of these brain regions, depending on the calorie content of food images.
- In some cases, unhealthy eating behaviors may be viewed as a "food addiction" in which the exposure to specific foods may sensitize the brain's addiction circuits leading to hyperarousal in the presence of these foods or related cues.
- A better understanding of the roles of implicit and explicit attitudes in eating behavior regulation (i.e., impulsive vs. deliberate actions) will help us to better understand why diets so often fail and may inform about the factors affecting the development and treatment of disordered eating in general.

Definitions of Key Terms

Explicit attitudes: Deliberate, self-reported evaluations of the attitude-related objects (e.g., food) that are accessible to introspective scrutiny; traditionally assessed by different forms of self-report methods (e.g., questionnaires, rating scales).

Implicit attitudes: Automatic affective associations elicited by objects (e.g., environmental cues, words, images, etc.) that are often inaccessible to conscious monitoring and intentional regulation and influence immediate, spontaneous responses to attitude-relevant stimuli encountered in the environment.

Control resources: A construct used in psychology to describe a capacity to exert volitional control on behaviors and mental states (e.g., emotions).

Reward value: The hedonic value or amount of pleasure derived/anticipated from a particular behavior (e.g., eating, doing drugs). Objects with high reward value are assumed to capture attention and elicit approach-related behaviors. It is speculated that objects with high reward value (e.g., high calorie foods) exert their effects on attention and behavior via the impulsive system.

Orbitofrontal cortex: An area of the frontal lobes, behind the eyes, that receives inputs from sensory and emotional processing regions of the brain. Although the functions of the orbitofrontal cortex is not well understood, it is thought to be involved in sensory integration, representing the reward value of stimuli, in decision-making and the formation of expectations, and in the regulation of behavior, in particular with regard to reward and punishment (Bechara et al. 1994).

Amygdala: A subcortical structure of the limbic system located in the medial temporal lobes with rich interconnections with other areas of the limbic system that control emotional responses and the insular, anterior cingulated sensory and frontal areas. The amygdala plays a central role in coordinating behavioral, autonomic, and hormonal responses to stimuli with motivational significance.

Insular cortex: An area of the cerebral cortex that is hidden from view, lying underneath the frontal and anterior temporal lobes. This region receives inputs from the autonomic and somatosensory nervous systems, as well as areas involved in processing emotion, and is thought to be involved in processing information about an individual's current interoceptive state (see Craig 2008 for a review), including hunger, cravings, and satiety. This region is thought to play key role in emotional processing and a role in decision-making on a "gut level" in general.

Anterior cingulate cortex: The frontal region of cingulate cortex, which is situated above the corpus callosum in the medial areas of the brain which is interconnected with emotional regions (limbic system) and appears to play a role in a wide variety of functions, such as regulating autonomic activity, selective attention, reward anticipation, decision-making, and the resolution of conflict.

Chapter 46
Impact of Eating and Lifestyle Behaviors on Body Weight: Beyond Energy Value

Vicky Drapeau, Marion Hetherington, and Angelo Tremblay

Abbreviations

BMI   Body mass index
RMR   Resting metabolic rate
SQ   Satiety quotient
STR   Sensitivity to reward
TFEQ   Three-factor eating questionnaire
VAS   Visual analogue scale

46.1 Introduction

The excess body fat characterizing obesity is well recognized for its conformity with the first law of thermodynamics. Specifically, this notion stipulates that a large body fat deposition is necessarily the outcome of an excess energy intake over expenditure over time. For many scientists and health professionals, this observation is sufficient to deduce that an unhealthy diet with a high fat content and lack of physical activity should be the main causes of obesity. However, recent research reveals that factors with "no energetic value" might have a better predictability of variations in body fat.

Eating behaviors are part of these factors which have been identified to play an important role in the regulation of energy balance and thus body weight. In this chapter, we describe eating behaviors by referring to experimental research and related clinical experience which are generally overlooked in obesity treatment. The intention is not to provide a full review of the literature regarding behaviors implicated in body weight variations, which has been done elsewhere (Elfhag and Rossner 2005), but rather to highlight some eating behaviors that could be assessed in a clinical context. Another aim of this chapter is to provide potential solutions which could help health professionals in obesity treatment and prevention.

46.2 Eating and Lifestyle Behaviors Influencing Body Weight

46.2.1 *Restriction and Attempts to Lose Weight*

Restrained eating and attempts to lose weight are experienced by a large proportion of obese individuals referred within clinical settings. This is not surprising since energy or specific macronutrient restriction is the main strategy recommended in most popular diets (Freedman et al. 2001; Volpe 2006) and that moderate energy restriction (–500 kcal/day) remains one of the main weight loss strategies recommended in the last Canadian obesity guidelines (Lau et al. 2007). Although this seems to be the most convenient solution to create an energy deficit, it is maybe counterproductive in the long term since most of the weight loss interventions which include restriction showed a low rate of success for weight loss maintenance in the long term (Wadden 1993; Freedman et al. 2001; Wing and Hill 2001; Gilden Tsai and Wadden 2006; Sherer and Sherer 2008). These observations are consistent with the controversy surrounding restrained eating and body weight. Indeed, restrained eating has not always been associated with lower energy intake or lower body weight (Lawson et al. 1995; Lindroos et al. 1997; Hays et al. 2002; Provencher et al. 2003). Instead, some studies have shown higher body weight gain over time in individuals with high restraint scores compared to those individuals with a lower restraint score (Klesges et al. 1992; Stice et al. 1999; Drapeau et al. 2003).

It is also relevant to question whether dietary restriction and weight loss behaviors could be responsible for the increase in hunger and negative affect associated with weight loss (Stein et al. 2007). Accordingly, it has been observed that hunger increases in obese individuals submitted to a moderate energy restriction (Doucet et al. 2000b) and represents a predictor of weight regain in weight-reduced obese individuals (Pasman et al. 1999). The relationship between energy restriction and changes in appetite sensations has been observed in many studies. Recently, Gilbert et al. quantified this relationship in a group of obese women subjected to a moderate energy restriction (–2,900 kJ/day). They estimated that for each kilogram of body fat loss, a 5.8 mm increase in desire to eat and a 3.6 mm decrease in fullness on a 150 mm line scale were predicted (Gilbert et al. 2009). In another study, Chaput et al. (2007c) investigated the impact of weight loss until weight loss plateau (no further weight loss during a 1-month period) on changes in hunger, restrained eating, and depression. After 7–14 months of intervention and a body weight loss of 11.2% baseline level, appetite sensations such as the desire to eat, hunger, and prospective food consumption increased along with restrained eating. Interestingly, depression, as measured with the Beck Depression Inventory (Beck 1961), also increased between baseline and the plateau.

Energy restriction could also lead to more severe eating behavior problems such as binge eating. Accordingly, Wadden et al. (2004) reported in a randomized control trial comparing two levels of energy restriction (1,000 kcal/day meal replacement or 1,200–1,500 kcal balanced deficit diet) that more individual cases of binge eating episodes were observed in the 1,000 kcal/day meal replacement condition. Even though binge eating episodes can be observed after severe energy restriction (Wadden et al. 2004), and moderate energy restriction can enhance, in some individuals, the negative affect and subjective sensations of hunger (Chaput et al. 2007c) (which could lead to binge eating), it is important to note that energy restriction per se is not sufficient to produce binge eating. Indeed, almost half of binge eaters report that their first binge eating episode occurred at a time when they were not dieting (National Task Force on the Prevention and Treatment of Obesity 2000). In support of this observation, a recent study observed that negative mood and hunger were both significantly higher during prebinge than during nonbinge periods, and that negative mood was even higher after binge eating (Stein et al. 2007). However, binge episodes were more frequently attributed by participants to mood

than to hunger or abstinence violation (Stein et al. 2007). Consequently, binge eating could emerge as a function of attempts to restrict intake, difficulty to resist temptation to eat, and to comply with even a moderately energy-restricted diet, particularly when this influences negative affect and hunger.

It is interesting to note that restrained eating is often coupled with disinhibition which means that efforts to restrict coexist with the tendency to abandon such efforts resulting in overeating. This can be particularly true for rigid restraint, i.e., an all-or-nothing approach to eating, dieting, and weight management. Rigid application of restraint has been associated with higher disinhibition, higher body mass index (BMI), as well as to more frequent and more severe binge eating episodes (Westenhoefer et al. 1999). However, it is not clear whether restrained eating occurs in response to the obese/overweight state, to unwanted weight gain in lean individuals, or the desire to prevent future weight gain. Thus, restrained eating and attempts to lose weight may reflect a general susceptibility to weight gain. Part of this susceptibility is evidenced in the tendency to break (cognitive) restraint (or dieting) and to overeat (disinhibition).

Beside their impact on energy intake and binge eating episodes, restrained eating and multiple attempts to lose weight can also modulate the biological environment in a manner that they render individual efforts to lose weight useless. Accordingly, intervention studies have shown that the decrease in energy expenditure during energy restriction and weight loss can be much higher than that predicted from body weight or body fat loss under conditions of standardized physical activity (Leibel et al. 1995; Doucet et al. 2001). This phenomenon is also called "adaptive thermogenesis" (Major et al. 2007). In one study, measured resting metabolic rate (RMR) had fallen by 469 and 635 kJ/day more than predicted after only 2 weeks of energy restriction in men and women, respectively, and this difference reached 953 and 614 kJ/day after 8 weeks of treatment (Doucet et al. 2001). This adaptation does not necessarily return to normal after body weight stabilization and can be observed without initial body weight loss. Thus, it has also been observed that changes in RMR remain below predicted levels in men (–622 kJ/day) once body-weight stability recovered (Doucet et al. 2001). In some cases, this phenomenon could explain why little or no weight loss is observed in response to energy restriction. Indeed, a decrease in RMR has also been observed in response to energy restriction without significant body weight loss (Prentice et al. 1991; Wadden et al. 1996). An example of this phenomenon is the case of an obese woman who was resistant to weight loss when submitted to a traditional energy deficit of 2,100 kJ/day (Tremblay et al. 2007) in our clinical settings. Even though this woman reported good compliance, she did not lose weight at the end of the weight loss program intervention. Measured RMR before and after the intervention showed a decrease equivalent to the energy deficit (2,100 kJ), which could explain the resistance to weight loss. This case may well represent an exception but it emphasizes the importance of considering adaptive thermogenesis as a phenomenon that has the capacity to compensate for the prescribed energy restriction and thus limit the efficiency of weight reduction programs. It is also important to note that this adaptive thermogenesis in response to energy restriction can be observed in any component of total energy expenditure (Major et al. 2007).

In a clinical context, a greater than predicted decrease in energy expenditure can complicate weight loss, its maintenance, and the clinical care of the patient because it is generally not considered by health professionals treating obesity. Often, it is identified as "underreporting" or even "lying" when weight loss does not occur. Because restriction represents an important component of weight loss interventions, health professionals should be aware that adaptive thermogenesis may explain weight loss difficulty in some individuals as well as a related restraint behavior. Thus, for some individuals, restrained eating and actual efforts to lose weight, which represent no energy value per se, can have significant influence on energy balance (intake or expenditure) and influence body weight.

Table 46.1 Key features on resting metabolic rate and adaptive thermogenesis

1. Basal metabolic rate which represents the energy used by the vital organs of the whole body while at rest is the most important component of total energy expenditure contributing up to 70% of total energy expenditure. The thermic effect of food contributes for about 10% of total energy expenditure and activities for about 20% of total energy expenditure. Each component of energy expenditure can adapt according to variations in energy balance
2. Basal metabolic rate is not commonly measured in research settings because it necessitates very restrictive circumstances when a person is awake. A more common measurement, used under less strict but standardized conditions, is resting metabolic rate (RMR). Consequently, RMR is slightly greater than basal metabolic rate
3. Many factors can influence resting metabolic rate: lean body mass, age, heredity, physical activity, and gender. Lean body mass is the most important predictor of RMR
4. A general estimate of RMR for an adult is about 1 kcal/day which represents about 1,440 kcal/day
5. Normally, RMR decreases during weight loss as a function of the decrease in lean tissue. This decrease is sometimes more important than what could be predicted by the loss of lean tissue. This phenomenon has been described as adaptive thermogenesis
6. In some individuals, this phenomenon can exceed what is recommended by a nutritionist and may explain why some individuals are resistant to body weight loss. From a clinical standpoint, such adaptive response represents a major obstacle for weight loss intervention aimed to modify feeding behaviors and energy intake

This table lists the key features of resting metabolic rate including the components of energy expenditure, the difference between basal and resting metabolic rate, the definition of resting metabolic rate, and the impact of weight loss on this variable

46.2.2 Disinhibition, Impaired Satiety Signals and Vulnerability to Food Cues

It is common to find obese individuals who report difficulties in recognizing hunger and/or satiation during the course of a day (Drapeau et al. 2000). Those individuals often claim that their eating is out of control even though they do not present with an eating disorder such as *binge eating*. This is consistent with what can be observed in a more standardized context. Accordingly, obese individuals have been characterized with impaired satiety signals when submitted to a test meal compared to normal weight controls (Blundell and Gillett 2001; Barkeling et al. 2007). Moreover, higher disinhibition and hunger scores have also been observed in a group of obese individuals claiming problems with appetite sensations compared to lean or obese controls (Barkeling et al. 2007). This probably explains why disinhibition has been associated with body weight gain or regain over time (Karlsson et al. 1994; Fogelholm et al. 1999; McGuire et al. 1999; Hays and Roberts 2008). Recently, Bryant et al. (2008) proposed that disinhibition is representative of a thrifty phenotype suggesting an important role of this behavior in body weight regulation.

In our clinical setting, we observed that about 10% of obese individuals consulting for weight loss difficulties express either very little or no change in appetite sensations when submitted to a standardized breakfast. A stimulation of appetite sensations following the test meal has also been observed in some individuals who reported that food can sometimes "stimulate" their appetite (Fig. 46.1). This test meal includes the consumption of a standardized breakfast (i.e. 2,504 kJ for women and 3,066 kJ for men) after 12 h of fasting and the completion of visual analog scales (VAS) on appetite sensations before and after the meal (see Drapeau et al. 2005 for more details). With this evaluation, individual satiety signals have been assessed by calculating the satiety quotient (SQ), which is the difference between appetite sensations measured before and after a test meal divided by the energy content of the meal (a high SQ would indicate a normal/high satiety signal, whereas a low SQ indicates impaired satiety signals). Using this marker, we were able to identify obese individuals who were more susceptible to overeating (Drapeau et al. 2005). Accordingly, SQ for fullness was negatively associated with total energy intake as well as relative energy intake (total energy intake – metabolic rate). These results were confirmed in a second study conducted in a larger cohort of men
Fig. 46.1 Hunger levels before (PRE) and after (POST) a standardized test meal in men and women
Visual analog scale (*VAS*) scores for hunger in men (*n* = 98) and women (*n* = 68) before (PRE) and after (POST) the meal test. PRE values represent appetite sensations in a fasting state and POST values represent the mean of the 60 min postmeal appetite sensation recordings. Bold lines represent participants with impaired satiety signal capacity or with low satiety quotient

and women who were tested twice (before and after a weight loss program) (Drapeau et al. 2007). In this case, the negative relationship between SQ for fullness and total energy intake was stronger for women. It is important to note here that there was no significant relationship between the meal-induced change in appetite sensations and BMI in both men and women.

Based on these observations, it can be hypothesized that impaired satiety signals could favor overconsumption and thus increase the risk to gain weight over time in some obese individuals. This hypothesis is supported by studies that show an impaired hypothalamic response after a glucose load (Matsuda et al. 1999) and a different neuronal activity in response to satiety (Gautier et al. 2001) or to visual and auditory stimuli of binge type foods (Geliebter et al. 2006) in obese individuals compared to nonobese. Impaired satiety signals could also explain body weight loss variability in some individuals engaged in a weight loss program or weight regain. This is consistent with the observation of an increase in hunger after weight loss (Doucet et al. 2000b) and its association with weight regain (Pasman et al. 1999).

It has also been argued that some individuals are disproportionally vulnerable to food cues in the environment. These individuals may express a general tendency to be impulsive (Nasser et al. 2004) but specifically have difficulty resisting foods which are energy dense and highly palatable (Davis et al. 2007). Clearly, this will have important consequences for the treatment of the obese patients since some individuals are highly primed toward food cues. Indeed, energy restriction may exacerbate an underlying tendency to seek out these foods and to overconsume them. An investigation of sensitivity to reward (STR) and weight status revealed a strong relationship between STR, overeating, and BMI (Davis et al. 2007). STR was also associated with preference for high energy density foods including those high in fat and sugar (Davis et al. 2007). Thus, personality traits such as vulnerability to food cues or sensitivity to reward may be indirectly linked with BMI through their effects on eating behavior including the tendency to overeat and expressed preference for high energy density foods. This is an important argument in support of personalized treatment strategies since dispositional traits cannot be changed but their impact on eating and weight loss can be managed

(Hetherington 2007). It is also plausible that individuals expressing impaired satiety signal or presenting high disinhibition scores could be more vulnerable to food cues or sensitivity to reward. Therefore, the detailed characterization of these phenotypes could lead to more specific behavioral interventions that aim to decrease the power of food cues or include a specific medication known to influence sensitivity to reward centres.

46.2.3 Attention Toward Food and Distraction

Attention during eating represents another eating behavior that has the potential to influence appetite control and energy intake. During the meal, there is the opportunity to monitor the moment by moment changes in appetite sensations. For example, the subjective appeal of a food (pleasantness and/or desire to eat) tends to decline from the beginning to the end of a meal or snack (Hetherington et al. 2006). This phenomenon has been termed "sensory specific satiation" since the changes in pleasantness tend to affect the eaten food and foods which share sensory properties whilst leaving the pleasantness and desire for other foods largely unchanged. Introducing a different food during intake of a snack or meal appears to delay the development of satiation and can increase meal size. To examine the impact of introducing variety within a snack, we conducted an experiment involving four laboratory sessions to eat popcorn. In one session participants ate the snack with no interruptions (control), in another they ate the snack but rated the pleasantness of that snack during eating (same condition), and in the remaining sessions they ate the snack but at 1 min intervals were interrupted to taste and rate an alternative food either in the same taste domain (congruent) or a different domain (incongruent). Focussing on the eaten food to taste and rate at intervals appeared to inhibit intake compared to introducing other foods to taste and rate (Hetherington et al. 2006). Similarly ratings of pleasantness decreased as predicted in this condition but remained higher in the congruent and incongruent conditions. This suggests that having attention drawn to the pleasantness of the food as it is eaten will reduce both its appeal and the amount consumed.

Attention to the food whilst eating seems to be important in the development of satiation, since providing distractions during a meal appears to extend the duration and size of the episode. Wansink has termed this phenomenon "Mindless Eating" (Wansink et al. 2006). Thus, eating a meal or snack with the radio or TV on seems to increase the amount eaten compared to eating alone with no distractions. For example, Bellisle and her colleagues have conducted two experiments examining the effects of listening to the radio (Bellisle and Dalix 2001) or watching television (Bellisle et al. 2004) during a meal and found that both "distracters" increase energy intake compared to eating the meal alone without distraction. In the first of these experiments, it was reported that restrained eaters were especially susceptible to the impact of distraction and there was a significant correlation between restraint score and the difference in energy intake between the control and radio conditions (Bellisle and Dalix 2001). This indicates that there may be individual differences in the extent to which distracters influence food intake. Ironically, behaviors associated with limiting food intake such as dietary restraint appear to increase individual vulnerability to the effects of distraction.

Similarly, restraint is associated with overeating under conditions of stress (Lattimore and Maxwell 2004; Wallis and Hetherington 2004). This phenomenon seems to be stronger when restraint is combined with high disinhibition levels (Haynes et al. 2003). Stress imposes a relatively high level of cognitive demand on the restrained eater and this interferes with intake monitoring (Ward and Mann 2000). Given that limiting food intake in order to lose or maintain body weight is effortful, if restrained eaters are engaged in an activity which has a high cognitive load, then this may disinhibit

intake by preventing monitoring required to maintain strict dietary restraint. On the other hand, if restrained eaters are reminded of their plans to restrict intake and cues for maintaining behavioral control are made salient, this tends to enhance restraint (Ward and Mann 2000). Clearly, attention plays an important role both in the normal development of satiation and in the ability of those restricting food intakes to maintain behavioral control around food. In normalizing eating control, clinical management of obese individuals might include recommendations to focus on eating (without distraction) and to pay attention to the sensations of hunger and fullness as these change during the eating episode.

46.2.4 Modern Lifestyle and Eating Behaviors

Even if epidemiological evidence revealed a relationship between sleep duration and the risk of weight gain many years ago (Locard et al. 1992), the scientific community has awaited laboratory experiments before paying significant attention to short sleep duration as a risk factor of obesity. This demonstration involved the study of feeding behaviors and related hormones. Specifically, the experimental reduction of sleep time was found to increase plasma ghrelin concentration and to decrease plasma leptin level (Spiegel et al. 1999, 2004). As expected, an increase in some appetite sensations, e.g. hunger and desire to eat, also resulted from sleep deprivation. This agrees with data collected in the Quebec Family Study which showed that short sleepers displayed plasma leptin concentrations which were lower than those predicted by their body fat (Chaput et al. 2007b). More recently, results of this study indicated a greater propensity to hypoglycemia in short sleepers (Chaput et al. 2009a), which has been interpreted as concordant with the glucostatic theory of appetite control(Chaput and Tremblay 2009b). It is also noteworthy to emphasize that the same proneness to hypoglycemia and weight gain was observed in long sleepers tested in the Quebec Family Study (Chaput et al. 2007a, 2009a) and who may represent a subgroup of individuals with suboptimal sleep quality. Taken together, these observations suggest that suboptimal sleep duration, particularly short sleeping, may represent an important risk factor of weight gain, as shown in Table 46.2. Since mean sleep duration has decreased by more than an hour over the last decades, short sleeping appears as a modern lifestyle behavior which also significantly affects feeding behaviors.

Modernity has also accentuated the importance of cognitive effort in daily labor activities. Although mental work does not increase energy expenditure to a quantitatively significant extent (Chaput and Tremblay 2007), it exerts a profound effect on spontaneous energy intake and related metabolic variables. In a first study that we initiated to document this issue, Laval University female students increased by 229 kcal their mean energy intake during a buffet-type meal compared to control session (Chaput and Tremblay 2007). In a subsequent study (Chaput et al. 2008), this effect was confirmed and was accompanied by an increase in cortisolemia and plasma glucose instability. When subjects of this study were subdivided on the basis of the intensity of their cognitive effort, the increase in energy intake and glycemic instability (Chaput and Tremblay 2009b) as well as in cortisolemia (Chaput and Tremblay 2009a) was found to be greater in those for whom mental work was more demanding. Surprisingly, the hyperphagic effect of mental work was at least partly dissociated from changes in appetite sensations (Chaput et al. 2008), suggesting that demanding mental work can negatively influence the perception of satiety signals.

In summary, modern lifestyles and globalization have promoted a new way of living that produces obesogenic effects. These may include an increase in the concentration of orexigenic hormones such

Table 46.2 Impact of different eating and lifestyle behaviors on weight gain (kg)[a] over a 6-year follow-up period relative to the reference category [b,c]

Risk factors	Mean weight gain relative to the reference category (kg)	(95% confidence interval)
• High alcohol intake (≥10 g/day)	0.39	(0.07–0.74)
• High dietary lipid intake (≥40% fat/day)	0.61	(0.06–1.18)
• Nonconsumption of multivitamin and dietary supplement	0.87	(0.37–1.41)
• High dietary restraint behavior (≥8 TFEQ scores)	1.09	(0.59–1.63)
• Nonparticipation in high-intensity physical exercise	1.23	(0.63–1.88)
• High susceptibility to hunger behavior (≥5 TFEQ score)	1.28	(0.68–1.94)
• Low dietary calcium intake (<600 mg calcium/day)	1.3	(0.70–1.98)
• High disinhibition eating behavior (≥6 TFEQ score)	1.46	(0.96–2.05)
• Short Sleep duration (<6 h/day)	1.65	(1.05–2.31)

[a]Model adjusted for age, sex, baseline body mass index, length of follow up, socioeconomic status, and all other risk factors. TFEQ: Three-Factor Eating Questionnaire, $N = 283$ (Adapted from Chaput et al. 2009b)
[b]Reference categories: Alcohol: ≥10 vs 0 g/day; Lipid intake: ≥40% vs <30% kcal/day; Multivitamin and dietary supplements: nonconsumers vs consumers; Dietary restraint: ≥8 TFEQ score vs ≤4 TFEQ score; Intense physical activity participation: 0 vs 30 min/day; Susceptibility to hunger: ≥5 TFEQ score vs ≤2 TFEQ score; Calcium intake: <600 vs ≥1,000 mg/day; Disinhibition eating: ≥6 TFEQ score vs. ≤3 TFEQ score; Sleep duration <6 vs ≥7 h/day
[c]The data present the mean weight gain (kg) above baseline weight over time for individuals with the risk factors relative to the reference category. For instance, after adjustment, short-duration sleepers gained 1.65 kg more than those reporting sleeping >7 h a day. High disinhibition behavior and short sleep duration were the best predictors of body weight fluctuations over time

as ghrelin, the decrease in the concentration of anorexigenic hormones such as leptin, an increase in energy intake with or without concordant changes in appetite sensations, and a decrease in the precision of some regulated processes such as glycemic stability.

46.2.5 Eating and Lifestyle Behaviors in Body Weight Regulation

The literature summarized above suggests many factors can themselves promote a positive energy balance and body weight gain. In some cases, the impact on energy balance can be more important than traditionally recognized factors such as high lipid intake. To pursue this idea further we recently analyzed data of the Quebec Family Study to examine the importance of lifestyle factors in body weight changes compared to dietary factors either within a cross-sectional context or over a 6-year follow-up (Chaput et al. 2009b). In the cross-sectional context, short sleep patterns and high disinhibition behavior represented the two factors associated with the higher risk of overweight and obesity (odd ratio of 3.80 and 3.81, $p < 0.01$, respectively). Moreover, as shown in Table 46.2, high disinhibition behavior and short sleep duration were the best predictors of body weight fluctuations over time. The trend to adopt restrained eating behavior was also a good predictor of body weight fluctuations compared to more traditional risk indicators of weight gain such as high fat diet and low participation in vigorous physical activities. In other words, this reanalysis of data of the Quebec Family Study demonstrated that the best predictors of weight gain are factors with no intrinsic energy value such as suboptimal feeding behaviors. They are also factors that are generally overlooked in weight control interventions.

46.3 Potential Solutions

46.3.1 Satiating Meals

The failure to promote long term weight loss with energy restriction together with the impact of disinhibition, distraction, and impaired satiety signals on body weight emphasize the need for less restrictive strategies which could help to control eating behaviors and body weight. Functional foods which combine the key nutrients and food ingredients to promote a short term increase in satiety and/or a spontaneous decrease in energy intake (Table 46.3) could represent a good alternative to minimize the increase in hunger while inducing an energy deficit. We thus tested functional meals specifically designed to increase satiety and decrease spontaneous energy intake in healthy men (Poortvliet et al. 2007). Results showed that a functional food served as the main course of a meal acutely decreased energy intake during the rest of the meal (–744 kJ) as well as hunger, desire to eat, and prospective food consumption after the meal, compared to a control meal. This was observed without compromising the palatability of the functional food. Also of interest is the fact that spontaneous energy intake was also decreased in the subsequent meal. These results suggest that vulnerable individuals, i.e. those with impaired satiety signals or high disinhibition, could benefit from less restriction and more satiating nutritional strategies such as the consumption of foods with enriched nutrient content favoring satiety, resulting in a reduced total energy intake.

Since the complete elimination of restriction is difficult to achieve in a weight loss context, individuals characterized by vulnerable phenotype could be encouraged to practice more flexible restriction (i.e. eating smaller portions) which has been associated with lower BMI (Westenhoefer et al. 1999), higher weight loss (Provencher et al. 2007), and a better weight control over time (Hays and Roberts 2008).

46.3.2 Clinical Evaluation

Considering the impact of these eating behaviors and influences on energy intake and body weight, the characterization of these patterns could be important in the development of more individualized weight control interventions. In this context, there is a need to develop and validate clinical tools

Table 46.3 Key nutrients of satiating meals

Nutrients	Reference
• Low lipid content	(Lissner et al. 1987; Tremblay et al. 1989, 1991)
• Low energy density and large food volume	(Stubbs et al. 1995; Bell et al. 1998; Rolls et al. 1998, 1999a, b,, 2005)
• Low glycemic index carbohydrates	(Ludwig 2000; Roberts 2003; Warren et al. 2003)
• Minimal alcohol content	(Tremblay et al. 1995; Tremblay and St-Pierre 1996)
• High protein content	(Skov et al. 1999; Eisenstein et al. 2002)
• High dietary fiber content	(Howarth et al. 2001; Pereira and Ludwig 2001; Koh-Banerjee and Rimm 2003)
• Optimal level of vitamins and minerals	(Doucet et al. 2000a; Johnston 2005)
• High calcium	(Zemel et al. 2000; Jacqmain et al. 2003)
• Capsaicin	(Yoshioka et al. 2001)
• Oolong tea	(Rumpler et al. 2001)
• Green tea catechins	(Dulloo et al. 1999; Berube-Parent et al. 2005; Diepvens et al. 2005; Westerterp-Plantenga et al. 2005)

This table presents the key nutrients which can produce a short-term increase in satiety and/or a spontaneous decrease in energy intake

which could help to characterize individuals who may be more at risk of overeating under these influences.

The evaluation of appetite sensations before and after a standardized meal could represent a first step in the characterization of obese individuals with impaired satiety signals and possibly more vulnerable to "eating distracters". As shown before, VAS appetite sensations measured before and after a meal can be useful to identify individuals more susceptible to excess energy intake (Drapeau et al. 2005, 2007). If more generally applied in the clinical context, a standard test meal could improve the identification of those individuals with specific impaired appetite perception leading to more individualized treatment strategies to improve weight loss efficacy. For example, these individuals could benefit from a pharmaceutical agent such as Sibutramine since it has been shown to decrease both hunger and anticipated food consumption, and to increase satiety scores (Hansen et al. 1999).

Since eating when distracted can increase energy intake, dietary records including "activities during meals" could also help to identify problematic eating episodes and individuals more susceptible to overeat during distraction. This tool, often used in behavioral therapy, can also help individuals to be more vigilant about eating and aware of their appetite sensations. Greater vigilance during eating and focus on changes in appetite may facilitate satiation. Therapists treating patients presenting with overeating are often advised to pay more attention both to the general experience of hunger and fullness as well as how these alter during a meal. In particular, therapists encourage patients to eat only when hungry, to eat slowly to savor each mouthful of food, and to stop eating before they feel full. This requires a great deal of attention and involves forming new habits to control appetite and meal size (Verplanken 2006). The identification of eating distracters will also necessitate recommendations to focus on eating and the sensation of hunger and fullness as these alter during the eating episode.

Finally, other lifestyle factors such as short sleep duration and a knowledge-based work environment should also be considered in a clinical context since they can, through their effect on eating behaviors and physiological systems, favor a positive energy balance.

46.3.3 Physical Activity

Physical activity provides stimulation that can modify feeding behaviors. To our knowledge, King et al. (1994) were the first investigators who performed a clear demonstration of the acute decrease in hunger feeling following exercise. More recently, we have studied the effect of exercise intensity on spontaneous food intake and related feeding behaviors under conditions of exercise sessions of similar energy cost but strongly differing in the intensity of the exercise stimulus (Imbeault et al. 1997). The assessment of *ad libitum* food intake after exercise revealed that the short-term energy compensation was lower after the high compared to the low intensity exercise, even if ratings of appetite sensations were comparable. This suggests that vigorous physical activity may promote a beneficial effect on satiety quotient, i.e. by promoting satiety with a reduced postexercise energy intake. Our clinical experience also demonstrates that this effect is not without limits, particularly in response to weight loss (Doucet et al. 1999).

46.4 Conclusion

The increasing obesity prevalence worldwide emphasizes the need to develop new strategies to control body weight. The multifactorial aetiology of obesity indicates that the individualized predisposition to gain weight is driven by factors which can be different from those promoting excess body weight in another individual. This multifactorial aspect of obesity development also implies

that the excess energy intake over expenditure is not only the consequence of environmental factors having an "energy value" per se, e.g., high fat-high energy dense diet and low participation in vigorous physical activities. This energy imbalance can also result from nonenergetic factors that are a source of stimuli promoting overeating. In this article, we have presented often overlooked eating behaviors which have the potential to influence energy balance based on recent experimental research and related clinical experience. Accordingly, some individuals can overeat when attention is distracted away from food while others are more prone to overeating either through disinhibition, impaired satiety signals, restrained eating, and attempts to lose weight or through an enhanced sensitivity to food cues. We also presented some related factors such as short sleep patterns and mental work that can significantly influence eating behaviors and thus body weight. These vulnerable phenotypes require personalized treatment to tackle specific difficulties which could influence food intake. This is justified by the observation that for some, vulnerability to weight gain is higher than what can be explained by an unhealthy diet composition and sedentariness.

In this context, it becomes obvious that a "one size fits all" approach to weight loss is not appropriate. Personalized approaches to weight loss may represent a long-term solution to overcome obesity. The clinical corollary of this reality is that a successful obesity treatment should be based on a data set that helps health professionals to identify the vulnerable phenotype(s) of a patient and to prescribe a weight reducing strategy that takes into account individual differences. In reality, most health professionals do not have limitless resources or optimal working facilities to adequately identify specific vulnerability phenotypes. Therefore, a more comprehensive but focussed clinical evaluation program which could identify behaviors that have the potential to influence body weight is needed to personalize and improve obesity treatment.

46.5 Authorship and Conflicts of Interest

Each author contributed to drafting the manuscript and reviewed it. None of the authors had any conflict of interest.

Summary Points

- Best predictors of weight gain are not always traditional factors having an energetic value
- Restriction and attempts to lose weight are counterproductive for body weight control as they can increase the risk of disinhibition, negative affect, binge eating episode, as well as decrease resting metabolic rate
- Attention toward food seems to help control eating behaviours
- Eating in the presence of distractors can increase the amount of food eaten. This can be exacerbated in some individuals such as restrained individuals
- Disinhibition represents an eating behavior predicting weight gain and could reflect obese individuals with impaired satiety signals
- Individuals expressing impaired satiety signal may represent vulnerable phenotype to food cues and to reward
- It seems that modern lifestyle behaviors such as short sleeping pattern and mental work can increase energy intake by altering the concentration of orexigenic/anorexigenic hormones such as ghrelin and leptin and other regulated processes such as glycemic stability

- Satiating meals could represent a less restrictive strategy which could help control eating behaviors and body weight particularly in individuals displaying impaired satiety signals
- A clinical evaluation which aims to characterize traditional and less traditional factors influencing body weight could be important in the development of more individualized weight control interventions
- Vigorous physical activity can help control or modify eating behaviors

---

Key Terms

Restriction: Restriction refers to cognitive dietary restraint and reflects the intent to restrict food intake in order to control body weight. It can be measured with the Three-Factor Eating Questionnaire

Disinhibition: Disinhibition represents overconsumption of food in response to a variety of stimuli, such as emotional stress, associated with a loss of control on food intake. It can also be measured with the Three-Factor Eating Questionnaire

Hunger: Or susceptibility to hunger refers to food intake in response to feelings and perceptions of hunger. It can also be measured with the Three-Factor Eating Questionnaire

Eating distracters: Situation (e.g. stress) or environmental cues (e.g. TV) which decreased the attention toward food while eating. Action also referred as "Mindless eating"

Satiating meal: Functional food characterized by healthy and satiating attributes. See Table 46.2 (also referred as healthy meal course)

Mental work: Knowledge-based demanding tasks such as writing with computer imposes a significant cognitive effort

Food cues: Environmental stimuli associated with food intake

Body mass index: Index for relating a person's body weight to their height. It is calculated by dividing a person's weight in kilograms (kg) by their height in meters (m) squared

RMR: Minimal energy required to perform vital body functions such as respiration and heart rate while the body is at rest (see table 46.1)

Satiety quotient: Index of individual's satiety signal capacity

STR: Individuals who are inherently highly sensitive or more vulnerable to food cues

TFEQ: Questionnaire used to access three main eating behaviors in adults: cognitive restraint, disinhibition and susceptibility to hunger

VAS: Testing technique for measuring subjective or behavioral phenomena. i.e. appetite sensations. For example, an individual would indicate, on a 150 mm scale, how he felt at the moment of completing the following question: How strong is your desire to eat? (very weak (0 mm) to very strong (150 mm))

FNS	Food Neophobia Scale
FNSC	Food Neophobia Scale for Children
FSQ	Food Situations Questionnaire
SS	Sensation Seeking
SSS	Sensation Seeking Scale
UFST	Unknown Flavor Sampling Test
VARSEEK	Variety Seeking Tendency Scale
WTNF	Willingness to Taste Novel Food test

Food neophobia, a reluctance to eat unfamiliar foods, is a common trait that has been widely studied in birds and mammals. Humans are among the many species that display food neophobia, and despite the relative safety and availability of most food items in modern society, uncertainty about unfamiliar foods continues to have an important impact on dietary intake. Research on humans has revealed sizable and, to some extent, predictable individual differences in the prevalence and severity of food neophobia. One particularly notable predictor is the personality trait of *sensation seeking (SS)*, simply defined as a person's willingness to take risks in order seek out novel or intense stimuli. This chapter presents a review of food neophobia as it influences food choice and diet, and examines the role of sensation seeking as well as several other factors that have an effect on *food neophobia*, such as age and sex.

47.1 The Omnivore's Dilemma and Food Choice

The koala bear doesn't worry about what's for dinner: If it looks and smells and tastes like a eucalyptus leaf, it must be dinner. The koala's culinary preferences are hardwired in its genes. But for omnivores like us… a vast amount of brain space and time must be devoted to figuring out which of all the many potential dishes nature lays on are safe to eat. We

e-mail: willet@musc.edu

rely on our prodigious powers of recognition and memory to guide us away from poisons (Isn't that the mushroom that made me sick last week?) and toward nutritious plants (The red berries are the juicier, sweeter ones).

(Pollan 2006, p 3–4)

Being omnivores, humans eat a wide variety of foods. Such diversity has a number of benefits, most notably including (1) a greater likelihood of consuming our required nutrients and (2) less chance of going without something to eat despite changes in seasons, climate (e.g., droughts), prey density, etc. However, a willingness to eat a wide variety of foods also has potential costs. Each time we are presented a food item with which we have little or no familiarity, we must weigh the risk of not consuming the item (and possibly missing out on a good food source) with the risk of ingesting something potentially dangerous (e.g., allergens or poisons), or that will produce an unpleasant sensory experience. This approach/avoidance conflict when facing unfamiliar potential foods was discussed in a landmark 1976 paper by Paul Rozin and is termed the "omnivore's dilemma". The above quote from Michael Pollan's book, *The Omnivore's Dilemma* (2006), highlights this risk.

It has been demonstrated that humans show interest in unfamiliar foods; however, deciding to eat novel foods is often coupled with fear and anxiety (Rozin 1976), and laboratory research shows that people do tend to see novel foods as a bit more dangerous than familiar ones (Pliner et al. 1993). In modern society, where foods are generally safe, the continued presence of food neophobia (a psychological trait characterized by a general reluctance to eat new/unusual foods) actually has an adverse effect on diet/food choice. The evolutionary adaptation to avoid potential dangers associated with novel foods results in a human tendency to reject unfamiliar foods (Rozin 1976; Domjan 1977), thus limiting our diet to the familiar even though our diet could, and often should, be far more varied. In addition, food neophobia must not stop infants from acquiring preferences for new foods during weaning.

47.2 Neophobia: Measurement Tools and Psychometrics

A number of methods have been used to measure neophobia, most using questionnaires. The most commonly used scale to measure food neophobia in adults is the *Food Neophobia Scale* (FNS) developed by Pliner and Hobden (1992; Table 47.1). This 10-item scale has acceptable test-retest reliability and internal consistency (Pliner and Hobden 1992; Knaapila et al. 2007), and has been translated into several languages including French (Ton Nu 1996 – Unpublished, as reported in Reverdy et al. 2008), Swedish (Koivisto and Sjoden 1996), and Finnish (Pliner et al. 1998). FNS scores are not significantly

Table 47.1 The ten-item Food Neophobia Scale (FNS)

1. I am constantly sampling new and different foods[a]
2. I don't trust new foods
3. If I don't know what a food is, I won't try it
4. I like foods from different cultures[a]
5. Ethnic food looks too weird to eat
6. At dinner parties, I will try new foods[a]
7. I am afraid to eat things I have never had before
8. I am very particular about the foods I eat
9. I will eat almost anything[a]
10. I like to try new ethnic restaurants[a]

Each item requires a rating on a 7-point Likert scale: disagree strongly, disagree moderately, disagree slightly, neither disagree nor agree, agree slightly, agree moderately, and agree strongly

[a]Five items on this scale are reverse scored (Pliner and Hobden 1992)

related to pickiness (Pliner and Hobden 1992), which will be briefly discussed later. The scores are related to responses to novel, but not familiar foods (Pliner et al. 1998). Confirmatory factor analysis and other techniques have shown an acceptable or better fit of cross-cultural data from the USA, Finland, and Sweden for the FNS, although suggesting that a smaller number of items may work better (Ritchey et al. 2003). There is ample evidence of validity for the FNS in the form of correlations with food selection and diet, as discussed in the following section.

For young children, Pliner (1994) has developed the Food Neophobia Scale for Children (FNSC). This 10-item scale is completed by mothers and includes items such as "My child will eat almost anything". A self-report scale for children has been developed and tested in France (Rubio et al. 2008). Both scales have been validated with behavioral tests of food neophobia. Older children, between the ages of 7 and 12, may complete the Food Situation Questionnaire (FSQ) developed by Loewen and Pliner (2000; see Table 47.2). In so far as they have been examined, all of these scales have good psychometric properties.

Other survey instruments have been used to measure food neophobia or similar traits such as "food adventurousness". Ullrich et al. (2004), measured "food adventurousness" with a single question: "How often do you try unfamiliar foods?" Even this simple measure produced significant predictions of liking for spicy foods and bitter fruits and vegetables. Van Trijp and Steenkamp (1992) developed the more sophisticated Variety Seeking Tendency Scale (VARSEEK) scale to measure the tendency of consumers to seek variety in food choices. The 8-item VARSEEK-scale has high internal consistency and has been used successfully to predict some of the variation in reported cheese consumption and in the exploration of varieties of cheeses, among Finnish adults (Van Trijp et al. 1992). VARSEEK scores are significantly correlated with those on the FNS (Meiselman et al. 1999). Finally, Frank and van der Klaauw (1994) developed the Food Attitude Survey (FAS) to assess food preference patterns. Subjects were asked to evaluate an extensive list of food items and indicate their opinion of each food item

Table 47.2   The Food Situations Questionnaire (FSQ)

LO-STIM subscale

1. "If your Mom or Dad made something for dinner that you had never tasted before, how would you feel about eating that?"
2. "If your Mom made a new and different kind of sandwich for your lunch box, how would you feel about eating the sandwich?"
3. "If you went on a picnic with your friend's family, and they brought a food that you had never seen before, how would you feel about having some of their food?"
4. "If your family went on a trip to a new place and all the food there was stuff you'd never had before, how would you feel about eating the food ?"
5. "If your Mom served a new kind of vegetable for dinner, how would you feel about eating that?"

HI-STIM subscale

6. "If dessert at your friend's house was cannoli with chocolate sauce, how would you feel about eating that kind of dessert?"
7. "If you went to a friend's birthday party and they had cassava chips there for you to try, how you feel about trying some of those?"
8. "If your favorite aunt or uncle took you out for lunch and bought you kirschenkeks, how would you feel about eating that?"
9. "If you went on a school trip with your class and for dessert you got chocolate cake with frangelico icing, how would you feel about eating that kind of cake?"
10. "If there was a Halloween party at school and the teacher brought some chayote for the children, how would you feel about trying some of that?"

Each item describes hypothetical situations in which novel foods might be encountered. Subjects (children) must report how they would feel about tasting or eating each item. The two subscales represent willingness to try novel foods in nonstimulating (LO-STIM) and highly stimulating (HI-STIM) circumstances (Loewen and Pliner 2000)

based upon its familiarity and their willingness to consume it using a 5-point scale. The scale ranged from "I really like this food. I think it tastes good" to "I've never tried this food, and never intend to try it." Using the original 1994 scale as well as a shortened version (Raudenbush et al. 1995), Frank et al. were able to identify individual differences in responses or attitudes toward foods, similarly to the FNS, and grouped people into categories similar to neophobic ("won't tryers") and neophilic ("likers"), with an additional intermediate group of "dislikers". The FAS has good reliability (Frank and van der Klaauw 1994). Meiselman et al. (1999) found high stability over a period of 1–2 years in a longitudinal study of college students using both the FNS and VARSEEK scales.

One potential shortcoming of survey instruments such as the FNS is that they present food selection in a hypothetical manner. While survey methods have, on the whole, been well supported by examination of the actual food choices of respondents (see below), the method is indirect in that the questions ask what a person *would do* in a given scenario rather than presenting the situation itself and then assessing how the person actually responds. Moreover, some exceptions have been reported, such as the finding that variety-seeking tendency (VARSEEK) does not always predict food choice behavior (Lähteenmäki and Van Trijp 1995). For such reasons, a number of studies have used tests of actual (i.e., "behavioral") neophobia. That is, various methods have been developed to determine actual behavioral responses (selection or avoidance) of unfamiliar foods. For example, Reverdy et al. (2008) used both the FNS (French adaptation) and an assessment of the actual willingness to taste novel food (WTNF), testing 180 French children (8–10 years old). WTNF was evaluated by presenting eight unknown/uncommon food items to the participants. Each child would then have to separate the food items into two groups based on whether or not they would be willing to sample the item. Further, all subjects were told that after they had sorted all of the items, they would have to actually taste one of the items they selected as "willing to eat". Scores from the adapted FNS were positively correlated with the WTNF test ($r = 0.421$, $p = 0.000$).

Another behavioral test of food neophobia is the Unknown Flavor Sampling Test (UFST) (Potter and Alley 2009). For this test, participants (college students) were presented with eight small containers with distinctly and unusually colored jellybeans (small candies) in each. They were then given the instructions to "evaluate each container, but not yet eat the items" and indicate (1) if they thought they knew what the flavor was ("yes" or "no") and (2) if they would be willing to try it. It is important to note that while the participants did not actually eat the jellybeans, they were given the impression that they might have to eat them. Because many participants believed that they knew the flavor of the jellybeans, which were supposed to be unknown, the UFST score was calculated as the ratio of the number of unknown, rejected beans to the total number of unknown beans (M = 0.31, SD = 0.32). FNS scores of these students were highly correlated with scores from the UFST ($r = 0.634$, $p = 0.000$; see Fig. 47.1).

In the next section, we review some of the group and individual differences in food neophobia. Before proceeding, it is important to make a distinction between *food neophobia* and *pickiness*: people with food neophobia are reluctant to eat novel foods, whereas picky (or "finicky") eaters resist eating many familiar foods (Galloway et al. 2003). Food neophobia is specifically a reluctance to consume a food item that is unfamiliar, while pickiness may be influenced by a number of other variables (e.g., texture). In essence, one can exhibit pickiness and food neophobia, but pickiness is not necessarily a part of neophobia (for a review see Dovey et al. 2008). Psychometric analysis has repeatedly found that pickiness and neophobia are distinct traits (cf. Pliner and Salvy 2006). Parents commonly complain about the "pickiness" of their children, with one study finding that 50% of mothers of 19–24-month-old infants judged them to be "picky" (Carruth et al. 2004), but the problem may often be neophobia. Education may prove useful, leading parents to see the importance of early eating experiences and learning about foods. Better parenting should follow if parents realize that children like familiar foods but can learn to accept new foods if they are provided repeatedly and without threat of punishment or enticement of rewards.
Fig. 47.1 Students' showed similar responses when asked about their neophobic tendencies using the more hypothetical FNS as well as during an actual behavioral assessment (UFST). FNS and UFST scores were highly correlated ($r = 0.634$, $p = 0.000$) (Potter and Alley 2009)

47.3 Food Neophobia and Diet: A Dual Relationship

47.3.1 Food Neophobia Influences Diet

Certainly a reluctance to eat unfamiliar foods can have an impact on diet. Validity studies of the FNS bear this out: Overall, scores on the FNS and other measures of neophobia appear to have good predictive validity. For instance, a French study of 603 children (Rubio et al. 2008) found that the children's choices and their willingness to try new types of food were significantly correlated with scores on the authors' neophobia questionnaire, and Pliner, Lähteenmäki, and Tuorila (1998) found FNS scores to be related to willingness to eat and anticipated liking for novel foods. Likewise, FSQ scores have predicted actual willingness to taste novel foods in a laboratory setting and, in fact, predict such willingness better than parents' reports of their own children's neophobia (Loewen and Pliner 2000). Also, as mentioned previously, FNS scores are significantly correlated with behavioral expression of food neophobia (WTNF: Reverdy et al. 2008 and UFST: Potter and Alley 2009). Perhaps most impressive are results from a longitudinal study showing that food neophobia scores predict later food preferences and variety. Specifically, Skinner et al. (2002) found the best predictor of the number of foods liked at age 8 to be the food neophobia scores at age 4 (as well as the number liked at that age).

By restricting intake of unfamiliar foods, food neophobia can increase the safety of one's diet. However, by reducing the number and variety of attractive foods, neophobia also can be expected to have an adverse impact on diet. Research supports this expectation. For instance, children who exhibit higher food neophobia consume lesser amounts of vegetables (Galloway et al. 2003) and, compared to neophilic individuals, have significantly less variety in their diets (Carruth et al. 1998; Falciglia et al. 2000). Another study demonstrated that Finns with high food neophobia were less likely to have tasted or eaten a sample of 20 foods than were those with low food neophobia, and their FNS scores significantly predicted the willingness to try unfamiliar foods and even some familiar

foods (Tuorila et al. 2001). Similarly, greater food neophobia was correlated with a higher frequency of untried foods (Russell and Worsley 2008) and with less frequent visitation to ethnic restaurants (Olabi et al. 2009). Lähteenmäki and Van Trijp (1995) found similar results with the VARSEEK scale: variety-seeking tendency was positively correlated with the self-reported number of well-liked alternatives on a list of 38 sandwich fillings ($r = 0.35$) and with the number of fillings that were reported to be eaten at least once or twice per month ($r = 0.37$).

Food neophobia appears to have differential effects on diet, affecting some food groups more than others. Russell and Worsley (2008) found the strongest effects of food neophobia for vegetables, followed by meats and fruit. The same three food groups were associated with neophobia in a study by Cooke et al. (2003), who suggest that these three food groups are particularly dangerous (i.e., prone to cause illness or initiate allergic reaction). They surmise that this pattern for stronger neophobia for such items is evolutionarily adaptive, and thus has been retained. Given the toxins in many plants, and the bacteria in meats, the argument seems sound for vegetables and meat. Fruits, however, are not particularly dangerous, but Cooke et al. argue that many children consider fruits and vegetables to be similar, and, consequently, extend their rejection to these as well. Moreover, both fruits and vegetables can have a strong bitter taste component, and our innate negative response to bitter taste is believed to be an adaptive trait useful for avoiding toxins. Rejection of bitter taste can be overcome with experience, but it appears this may be less likely in people with food neophobia, resulting in more rejection of bitter fruits and vegetables (see Ullrich et al. 2004).

47.3.2 Diet Influences Food Neophobia

Just as neophobia can affect diet, diet can affect neophobia. If the cause of food neophobia is avoidance of dangerous or unpleasant foods, then sampling new foods, as long as they are safe and palatable, should allow for learning that will reduce neophobia. Research clearly demonstrates that repeated exposure to a food can increase one's willingness to consume it. For example, Sullivan and Birch (1994) demonstrated that repeated exposure to a novel food increased acceptance of that food item by infants. This reflects, at least in part, the mere-exposure effect (Zajonc 1968, 2001) whereby repeated exposure to a particular pattern of sensory input increases liking for that pattern.

Even a single sampling of a novel food can be sufficient to reveal pleasant sensory effects and to suggest its safety. Hence, it would not be surprising if a single exposure could overcome the neophobia, as some research indicates (Pliner and Hobden 1992), but other research finds multiple exposures to be necessary. Based on two studies (Birch and Marlin 1982; Pliner 1982) that used multiple exposures to previously novel foods (up to 20), it appears that as many as ten exposures may be required to overcome avoidance of an unfamiliar food. This estimate is based on the average result, so one may expect fewer exposures to be needed for individuals who are less neophobic than average. Furthermore, when persuaded to try an unfamiliar food, people who are more neophobic (higher FNS scores) tend to rate the foods as less pleasant (Arvola et al. 1999; Raudenbush and Frank 1999). Thus, even after sensory information about an unfamiliar food is obtained by direct experience, the neophobic's negative response toward the food may be reduced but not eliminated. A more positive perspective on overcoming food neophobia is provided by a recent study that expanded the range of novel foods available to participants (Williams et al. 2008). This study demonstrated that the number of exposures required for voluntary consumption of novel foods decreases as more foods are added to the diet. That is, fewer exposures are needed to render unfamiliar foods acceptable as the number of acceptable foods increases. This result is based on a small clinical sample and should be replicated, but it may reveal a pathway to reduced food neophobia that could make interventions by parents and dietitians easier and more effective.

A similar finding is that food neophobia is negatively associated with "expected pleasantness" of a novel food item (Tuorila et al. 1994; Raudenbush and Frank 1999), and that once a novel food is actually tasted, the phobia can be overcome (Pliner and Hobden 1992). The fact that neophobia tends to decrease with age from early childhood well into adulthood (see next section) provides additional, albeit indirect, evidence for this claim in that more food experiences come with increasing age. Additional indirect evidence is the finding that food professionals have low food neophobia scores compared to non-specialists or to students enrolled in food service training courses (Frank and Kalisewicz 2000), and that neophobia is lower in adults with more international travel experience (Olabi et al. 2009).

The specificity of the effects of experience on neophobia remains unclear. That is, does repeated exposure to novel foods promote a general reduction in food neophobia, or does it only affect those specific foods to which one is exposed? The mere-exposure effect is typically capable of producing more positive responses not only to the specific exposed stimuli, but also to similar stimuli (Zajonc 2001). A generalized mere-exposure effect can explain the data of Pliner, Pelchat, and Grabski (1993) that indicate a general reduction in neophobia following "forced" exposure to tasty novel foods.

The results of at least one study, however, indicate that generalization does not always occur. Sullivan and Birch (1994) investigated the effects of repeated exposure to one of three variants (sweetened, salted, or plain) of a novel food (tofu) on children's preferences. After 15 tasting sessions, the children showed increased preference only for the particular flavor/food combination they had repeatedly tasted, with a decreased preference for the other versions. These results indicate that it is not just particular foods themselves that become more acceptable with experience, but the specific flavors associated with them. This much more specific effect of exposure than typically expected for a mere-exposure effect (see above) may be age related. Pliner et al. (1993) tested adults, whereas Sullivan and Birch (1994) tested infants. Moreover, a more recent study (Loewen and Pliner 1999) tested both older (10–12-year-old) and younger (7–9-year old) children, finding that exposure to unfamiliar foods increased willingness to try a different group of novel foods only for older children.

More research is needed. Whether food-specific, flavor-specific or general, it also remains unclear whether the reduction in food neophobia is temporary, and whether occasional exposure to unpleasant or harmful novel foods might counter this effect. We do know that consuming novel foods or flavors that are followed by an adverse physiological reaction typically produces an immediate (single exposure), strong, and long-lasting aversion in humans and many other species. Learning to avoid an item following even a single negative encounter is beneficial from an evolutionary perspective, since an immediate and long-lasting aversion to toxic foods is highly adaptive. FNS scores have been found to be higher in adults with a history of getting sick after eating a new food (Olabi et al. 2009), although they are not correlated with the tendency to suffer from motion sickness (Alley et al. 2006). An adverse sensory experience may produce a relatively strong and long-lasting effect as well, particularly if a bitter taste component is involved since, in our evolutionary past, bitter tastes often signaled toxins.

In brief, it appears that the trait of food neophobia presents a tendency to both avoid and to dislike novel foods, and to see more unfamiliar foods as disgusting. In combination, these tendencies should substantially increase the resistance of dietary change in neophobic individuals as compared to neophilics.

47.4 Factors that Influence Food Neophobia

Factors affecting reactions to novel foods are of constant interest to nutritionists, health educators, and food marketers, all of whom try to influence people to incorporate novel foods into their diets. The preceding section showed that gaining familiarity with a food can remove the neophobic

rejection, but neophobia may block consumption in the first place, and exposure (consumption), particularly if not repeated, may not change preferences enough to alter diet or preferences. Other factors are known to influence food neophobia. Unfortunately, many such factors are not amenable to manipulation: that is, one cannot change the age, sex or genetics of a neophobic individual.

47.4.1 Age Differences and Developmental Trends

In general, food neophobia tends to decline as a person ages (cf. Pliner and Salvy 2006). For example, a study of Swedish families found that younger children had higher food (and general) neophobia than older children, and also that those children were more neophobic than their parents (Koivisto-Hursti and Sjoden 1997). Likewise, McFarlane and Pliner (1997) tested people 10–79 years old, finding that older subjects were generally more willing to try novel foods than younger ones (but with no change in willingness between the age group of 23–39 years old and that of 40 years and older).

There appears to be two significant exceptions to this developmental trend. First, there is a period of relatively low food neophobia in infancy up to around the age of 2 years whereupon it rises rapidly peaking sometime around age 4. Second, there is an increase in neophobia seen in many elderly individuals. From the perspective of influence on lifelong behavior, the most important exception includes the period in infancy when children normally are making the transition to solid foods. While humans begin life consuming a single food that provides all nutrients, they must eventually shift to a much more complex diet in which a variety of foods must be consumed in order to fulfill our nutritional requirements. Food neophobia could pose a serious hurdle for this important developmental transition but, fortunately, there is little neophobia during this period (Birch 1998). Cashdan has argued that there may be a sensitive period for learning about food that coincides with lower food neophobia (Cashdan 1994, 1998). The rapid rise in food neophobia beginning around age 2 should have a protective function since the older child becomes increasingly independent and able to exert more control over what does, and does not, get consumed. Additional research is needed to determine if age at weaning has an effect (e.g., potentially delaying) on the onset of this rapid rise in food neophobia.

Another factor mitigating the potential impact of food neophobia in infancy is the prior exposure to flavors in utero and in breast milk. Some flavors from a pregnant woman's diet can be carried in the amniotic fluid and swallowed by her fetus (Mennella 1995; Mennella et al. 1995). Human milk also transmits flavors from the maternal diet to the breast fed infant; in contrast, the formula fed infant has a less varied exposure to flavors from food. This exposure via breast milk is believed to lead to better acceptance of novel foods offered during weaning (see Maier et al. 2008; and below). However, the effects may be temporary: a study of food neophobia in 2–5-year old children (Russell and Worsley 2008) found no difference between breast-fed and formula-fed children.

Neophobia may increase again with old age, as reported in a Finnish study (Tuorila et al. 2001). Likewise, Knaapila et al. (2007) found a slight but significant positive correlation between age and FNS scores in both Finnish ($r = 0.23$) and British ($r = 0.21$) samples of adults aged 18–78 and 17–82 years, respectively. The dietary constriction that can result from such increases in neophobia may contribute to the increased incidence of nutritional deficits in the elderly. In addition, there appears to be an interaction of age with type of food, such that people become more willing to try ethnic foods as they age, but less willing to try other kinds of novel foods (cf. Pliner and Salvy 2006).

47.4.2 Sex Differences

Studies of sex differences in food neophobia have reported inconsistent results. Some have described finding greater food neophobia in males and others in females, and others have failed to find a significant difference. Among the studies that have found higher food neophobia in males, Koivisto-Hursti and Sjoden (1997) found that 9-year-old boys were more neophobic than 9-year-old girls, and that fathers had more food neophobia than mothers. Finnish men were also found to be more neophobic than women (Tuorila et al. 2001).

In contrast, Frank and van der Klaauw (1994) found more "won't try" responses by women than by men on the FAS. Additional reports that men have a greater tendency than women to seek unusual and new foods (Logue and Smith 1986; Alley and Burroughs 1991; see section on Gender and Age Correlates below) support the prediction that men are less neophobic.

Reviewing survey and behavioral studies of neophobia separately, Pliner and Salvy (2006) conclude that both types of research usually fail to find gender differences. Some additional research not covered in their review finds no differences, supporting their conclusion. Specifically, Russell and Worsley (2008) found no sex difference in a sample of 2–5-year old Australian children, and Cooke et al. (2003) found no sex difference in a large sample of 2–6-year-old British children. Likewise, Alley et al. (2006) found no sex difference in FNS scores in a sample of 308 university students.

47.4.3 Genetics

Koivisto-Hursti and Sjoden (1997) reported finding some evidence of familial resemblance with respect to both food and general neophobia. While such similarities can result from experience rather than genetic inheritance, there is good evidence for a large genetic component. Recent research (largely based on adult women) examining both family and twin samples indicates that about two thirds of the variation in food neophobia is genetically determined (Knaapila et al. 2007). [Interestingly, this value is very close to the estimates of about 0.54–0.64 for the heritability of sensation seeking (see Zuckerman 2007, pp. 32ff.), which is related to food neophobia, as reviewed below]. A large-scale study (Cooke et al. 2007) of 5,390 twin pairs, aged 8–11 years, gave an even higher estimate of heritability: 0.78 (95% CI = 0.76–0.79).

47.4.4 Information and Social Influences

Pliner, Pelchat, and Grabski (1993) found that both fear of dangerous foods and expectations of unpleasant sensory experiences are significant determinants of the resistance to novel foods. Conversely, healthiness and sensory pleasantness are the motives most often cited when people are asked why they eat the foods they do (e.g., Rappaport et al. 1992). If we are averse to trying new foods in large part because of fear of dangerous or unpleasant substances, then it seems that information that promotes opposite expectations – good taste and safety – should reduce neophobia. In short, the results of pertinent studies (briefly reviewed below) show that such information is sometimes effective. Martins and Pliner (2005) found that resistance to trying new foods is also associated with beliefs about the disgusting properties of these foods. Similarly, Pliner (reported in Pliner et al. 2006) reports finding a strong positive correlation between the FNS and a measure of disgust. Disgust is a powerful block to consumption (Rozin and Fallon 1987) and may prove difficult to overcome so that "disgusting" novel foods will be consumed and, eventually, preferred. In general, foods of animal origin are most likely to provoke disgust.

The effectiveness of experience in increasing preferences for specific foods (see above) is a good, but indirect, indication of the effect of sensory information on responses to foods. Repeated exposure to the sensory properties of a once novel food provides direct specification of these key properties of foods. Likewise, a lack of adverse physiological consequences can provide direct specification of food safety. Nonetheless, the results of a study on 121 adults, Tuorila et al. (1994) showed that sensory information could *decrease* liking for novel foods, even though it increased liking for familiar ones, and a recent study of "sensory education" found only limited and temporary effects on neophobia (Reverdy et al. 2008). Can indirect evidence about foods in the form of verbal information or social influence be more effective?

The results for verbal information are inconsistent and reveal a need for further research. McFarlane and Pliner (1997) tested the willingness to taste six familiar and six unfamiliar foods in 401 volunteers ranging from 10 to 79 years old. Each received no information, taste likeability information, or nutrition information. Their results indicated that nutrition information could be effective for young adults, at least for those for whom nutrition is important. Pelchat and Pliner (1995) found that taste information increased willingness to try novel foods at young ages (10–14 years); a result McFarlane and Pliner (1997) failed to confirm.

Social influence can have powerful effects on diet. It is even capable of countering the strong learned aversions of poisoned rats to food previously containing the poison (Galef 1986). Studies on humans also show significant, if less impressive, effects of social influence on acceptance of, and preferences for, foods (cf. Birch 1990). For instance, Birch (1980) showed that children tend to like and select the same foods as peers. Research on social influence via modeling has found positive, but limited and qualified results: under some circumstances, mothers, teachers, and peers have all been shown to be effective models for consumption of a novel food (cf. Pliner and Salvy 2006). Addessi et al. (2005) demonstrated a reduction in food neophobia in young children for the same type of food as was seen being consumed by others.

Flight, Leppard, and Cox (2003) reasoned that both higher socioeconomic status and dwelling in urban (versus rural) environments may increase exposure to diverse cultures and expand knowledge of foods. Consequently, they expected these to be negatively associated with food neophobia, but found only weak support for this in their sample of over 900 Australian high school students. Nonetheless, other research has supported this perspective: Food neophobia scores collected from 1083 Finns decreased with increasing education and with the degree of urbanization (Tuorila et al. 2001).

47.5 Sensation Seeking and Food Neophobia

Given that food neophobia reflects, in good part, risk avoidance, it should be expected that FN would be correlated with a personality trait associated with risk-taking. *Sensation seeking (SS)* is a personality trait defined by a person's willingness to seek out novel, complex, and intense stimuli while being willing to take risks (physical or social) in order to have such experiences (Zuckerman, 1979, 1994). SS has also been described as "not only a potential for taking risks, but… more generally a quality of seeking intensity and novelty in sensory experience" (Arnett 1994). SS has been fairly well studied for several decades, and it has been repeatedly demonstrated that SS can be influential in determining an individual's behavioral choices. Scholarly considerations of the biological and psychological correlates of this trait are summarized in three books by the pioneer and leading scholar of SS research and theory, Marvin Zuckerman (Zuckerman, 1979, 1994, 2007). Some of the key attributes are highlighted in Table 47.3.

Table 47.3 Sensation seeking summary points

Definition	A personality trait reflecting a person's willingness to seek out novel, complex, and intense stimuli while being willing to take risks (e.g., physical and social) in order to have such experiences
Common measurement instruments	1. Sensation seeking scales (Zuckerman)
	2. Arnett Inventory of Sensation Seeking (AISS)
Selected correlates (cf. Zuckerman 1994, 2007)	Risky behaviors
	• Risky sex (e.g., multiple partners; sex with strangers)
	• High risk sports (e.g., skydiving, hang gliding, mountain climbing)
	• Risky driving (e.g., speeding; driving under the influence)
	Illegal drug use
	Tobacco and alcohol use
	Gambling
	Risky vocations
	Eating habits and food preferences (attraction to unusual, novel and/or stimulating foods)
	Social attitudes (liberal and permissive)

Summarized information about key personality trait Sensation Seeking

47.5.1 Neophobia and Sensation Seeking

The primary tool for measuring SS is Zuckerman's sensation seeking scale (SSS). Zuckerman has created at least six different scales over the years in an attempt to accurately measure one's sensation seeking tendencies (Zuckerman et al. 1964; Zuckerman and Link 1968). Many of these scales are widely accepted and have even been translated and/or adapted by other researchers. SS is associated with risk taking in a wide variety of arenas including driving, sports, drug use, and sexual behavior. As noted above, trying unfamiliar foods is inherently risky, so it would be surprising if there were no discernable effects on food choice.

Zuckerman has recognized that food selection should be related to sensation seeking tendencies. He hypothesized that sensation seekers prefer those foods that are "less bland and more stimulating" (Zuckerman 1994). Therefore, he includes a food choice item on his SSS (Zuckerman et al. 1964; Zuckerman, 1979, 1994) that asks participants to choose between "I order the dishes with which I am familiar, so as to avoid disappointment and unpleasantness" or "I like to try new foods that I have never tasted before."

As predicted, scores on the FNS are correlated with the Experience Seeking subscale of the SSS (Pliner and Hobden 1992). This and other research (e.g., Frank and van der Klaauw 1994; Pliner and Melo 1997; Potts and Wardle 1998; Loewen and Pliner 2000) seem to indicate a definite relationship between neophobia and sensation seeking. Likewise, a Japanese study (Terasaki and Imada 1988) reported a modest correlation between experience eating very unusual foods and the Thrill and Adventure Seeking subscales of the SSS.

While the Zuckerman scales are commonly used, some researchers have attempted to shorten and adapt them or, in several cases, create their own scales (e.g., Hoyle et al. 2002; Madsen et al. 1987; Michel et al. 1999). Arnett (1994) created what is probably the best known alternative scale, the Arnett Inventory of Sensation Seeking (AISS). Arnett felt that when measuring sensation seeking, one should use *novelty* and *intensity* of stimulation as the subscales rather than Zuckerman's *novelty* and *complexity* of stimulation. His reasoning was that the subscale of complexity was difficult to define clearly and, in most cases, was actually a better measure of intensity than complexity. Finally,

Table 47.4 Arnett Inventory of Sensation Seeking (AISS)

  1. I can see how it would be interesting to marry someone from a foreign country
  2. When the water is very cold, I prefer not to swim even if it is a hot day[a]
  3. If I have to wait a long time, I'm usually patient about it[a]
  4. When I listen to music, I like it to be loud
  5. When making a trip, I think it is best to make as few plans as possible and just take it as it comes
  6. I stay away from movies that are said to be frightening or highly suspenseful[a]
  7. I think its fun and exciting to perform or speak before a group
  8. If I were to go to an amusement park, I would prefer to ride the roller coaster or other fast rides
  9. I would like to travel to places that are strange and far away
 10. I would never like to gamble with money, even if I could afford it[a]
 11. I would have enjoyed being one of the first explorers of an unknown land
 12. I like a movie where there are a lot of explosions and car chases
 13. I don't like extremely hot and spicy foods[a]
 14. In general, I work better when I'm under pressure
 15. I often like to have the TV on while I'm doing something else, such as reading or cleaning up
 16. It would be interesting to see a car accident happen
 17. I think it's best to order something familiar when eating in a restaurant[a]
 18. I like the feeling of standing next to the edge on a high place and looking down
 19. If it were possible to visit another planet or the moon for free, I would be among the first to sign up
 20. I can see how it must be exciting to be in a battle during a war

Each item requires a rating on a 4-point Likert scale: 1 = Does not describe me at all, 2 = Does not describe me very well, 3 = Describes me somewhat, and 4 = Describes me very well
[a]Six items on this scale are reverse scored (Arnett 1994)

and perhaps most importantly, the AISS gave more emphasis to the idea of socialization effects on SS behavior rather than purely biological motivation. Hence, Arnett's scale takes into account such external influences as peer pressure and societal practices. The AISS includes 20 statements that are ranked on a 4-point Likert scale (Table 47.4). Like Zuckerman's SSS, the AISS includes an item (ordering "something familiar when eating in a restaurant") that can be seen as assessing food neophobia, and another (about "hot and spicy foods") that may be related to food neophobia. Arnett (1994) has found high internal reliability (0.83–0.86).

As mentioned previously, scores on Zuckerman's SSS were found to be negatively correlated with one's neophobic tendencies (Pliner and Hobden 1992), so it is not surprising that AISS scores also have been shown to be correlated with FNS scores. Alley et al. (2006) found a significant correlation between participants' scores on the FNS and the AISS ($r = -0.42$, $p = 0.0001$) (Fig. 47.2). While such negative correlations indicate that higher sensation seeking is correlated with lower neophobia, one might well take issue with the significance of these correlations because both measures of SS (SSS or AISS) include one or two items that explicitly assess food neophobia. Alley et al. (2006), however, removed these items from the computation of their participants' AISS scores, finding that even without the two food-related items, FNS scores remained correlated with sensation seeking ($r = -0.35$, $p < 0.001$).

47.5.2 Sensation Seeking and Other Food Constructs

In addition to familiarity, SS logically should be associated with some other sensory aspects of food, with high SS associated with more attraction to, and consumption of, foods that are hot (spicy), highly flavored, or unusually textured. However, such tendencies may be masked by other factors that can have a pronounced effect on food choice, particularly genetic differences in taste sensitivity
Fig. 47.2 FNS and AISS correlation College students ($N = 305$) were administered the FNS (M = 29.12, SD = 11.24) and AISS (M = 54.81, SD = 7.41). A significant negative correlation was found between FNS and AISS scores ($r = -0.611$, $p = 0.000$), suggesting that higher SS scores (greater AISS scores) were associated with lower levels of neophobia (i.e., lower FNS score) (Potter and Alley 2009)

and cultural differences in the use of spices and condiments. So, for instance, a person who is a "supertaster" and thereby more sensitive to bitter (among other) tasting substances, may be more adverse to bitter tastes than normal (unless they also are high in the "food adventurousness" aspect of sensation seeking; cf. Ullrich et al. 2004). Nonetheless, research supports these conjectured ties of food preferences and sensation seeking. Studies show that a preference for spicy hot foods is related to sensation seeking or thrill seeking (Rozin and Schiller 1980). This preference may even be driven by sensation seeking, but there is insufficient research to establish this causal connection. Likewise, high sensation seekers, both male and female, apparently have stronger preferences for foods with unusual spices (Logue and Smith 1986) or for foods that are spicy, sour or crunchy (Kish and Donnenwerth 1972; Zuckerman 1979; Terasaki and Imada 1988).

Researchers have also found that a person's arousal level is important when considering the tendency to seek out a new or stimulating situation, as Zuckerman has argued. Pliner and Melo (1997) found a significant interaction between sensation seeking and arousal level that influenced the number of new foods participants ate. This leads to the inference that one's arousal level before being presented with new foods could impact his/her willingness to try them. Several studies show that arousal level can affect the foods that one chooses to eat (Pliner and Melo 1997; Loewen and Pliner 2000; Pliner and Stallberg-White 2000). Similarly, Stallberg-White and Pliner (1999) found that when a food choice is only hypothetical (a nonarousing situation), high sensation seekers make more neophilic choices.

47.5.3 Sensation Seeking: Gender and Age Correlates

Previous research has shown that men tend to have stronger sensation seeking tendencies than women. This sex difference has been seen in American, Canadian, and Australian subjects (Zuckerman 1978; Ridgeway and Russell 1980; Ball et al. 1984). Given that higher sensation seeking is associated with lower food neophobia, the sex difference in sensation seeking suggests that men are more attracted by and willing to try new and unusual foods, whereas women are more likely to seek familiar foods. Researchers, however, have sometimes found no sex differences or even a

reversal of the pattern expected based on greater SS in men (see previous discussion). Such inconsistency demands further research and analysis.

The results from two studies indicate that men tend to have stronger preferences for spicy foods than women (Logue and Smith 1986; Alley and Burroughs 1991). The more recent study had 148 people between 17 and 32 years old complete questionnaires concerning past and current food use and preferences, as well as food and condiment use in one actual meal. Their responses clearly support the prediction that men tend to have a stronger preference for hot foods (e.g., hot peppers) than women. Moreover, men reported a greater previous consumption of unusual foods, and a higher current preference for them. Logue and Smith (1986) reported that their female subjects expressed lower preferences for spicy foods than their male counterparts.

In addition to gender differences, it has also been shown that age can impact one's sensation seeking tendencies. Typically, SS is higher in younger individuals and declines as a person ages. This has been seen in a number of populations, including Australian, German, and English individuals (Zuckerman 1978; Ball et al. 1984; Roth et al. 2005). This trend is largely opposite from that for FN, at least for the period from adolescence to mid-life, showing that SS and FN, while correlated, are separate traits.

47.5.4 Applications to Other Areas of Health and Disease

Understanding the impact of sensation seeking and neophobia on food choice, as well as their potential interactions, is critical to many aspects of human health. Reducing food neophobia may be an effective means of improving dietary quality by increasing the variety of foods consumed. A good example of this has been seen in breast fed versus formula fed infants. Formula fed infants are bound to have less varied exposure early in life to flavors from foods compared to similar breast fed infants. Research suggests that an infant's early experience with flavors in human milk has a positive effect on the transition to, and acceptance of, solid foods. Sullivan and Birch (1994) found that breast-fed infants consumed greater amounts of a novel food (their first vegetable) than formula-fed infants. Human milk-fed infants have been noted to have a faster acceptance of the first transition foods offered. Thus, educating parents about this additional benefit of breast feeding could ultimately increase the quality and variety of diets seen in their children, and might serve to help lessen the prevalence of other medical disorders such as obesity.

According to the US Centers for Disease Control and Prevention (CDC), in the years 2003–2006, 12.4% of children ages 2–5, 17% of children ages 6–11, and 17.6% ages 12–19 were considered obese (CDC.gov 2009). The CDC suggests that parents should work hard to reduce a child's risk of becoming obese, as childhood obesity increases the likelihood of that child staying obese into adulthood, which in turn increases the risk for many other health issues such as high blood pressure and diabetes. Parents who are knowledgeable about food neophobia in children and the advantages of providing a wide variety of healthy foods during childhood should be more likely to promote healthy diets (cf. Skinner et al. 2002; Nicklaus 2009). As discussed above, food neophobia in children is associated with lower variety in diets in general and with particularly low intake of three important food groups: fruits, vegetables, and protein foods. Indeed, Falciglia et al. (2000) found evidence of less healthy eating in neophobic children than for average and neophilic children. A similar finding was reported by Russell and Worsley (2008). Significant contributors to this pattern were less dietary variety and higher consumption of saturated fat in the neophobic children (Falciglia et al. 2000). If, due to exposure or any other reason, high calorie foods have more predictable sensory qualities than lower caloric foods, then high calorie foods may be especially preferred by neophobic eaters.

Given the prevalence of food neophobia in children, particularly for the aforementioned food groups, having a better understanding of the role of food neophobia in the development of eating habits and food preferences is imperative. The design of effective interventions to improve children's diets should incorporate our understanding of neophobia. Furthermore, the impact of food neophobia on long-term food consumption should be considered when attempting to prevent obesity as well as poor nutrition. As Cooke et al. (2003) suggest, "guiding parents in the technique of regular and repeated taste exposure (particularly to vegetables, fruit, meat, and eggs) has the potential to improve the diets of young children at what may be a sensitive period for developing lifelong healthy eating patterns" (p. 206).

Summary Points

- Humans have a wide range of food items available for consumption. Humans and other omnivores must evaluate new foods and decide between rejecting the novel food (and potentially missing out on a good food source) or trying the item (and possibly ingesting something harmful or disagreeable). This choice is referred to as the "omnivore's dilemma".
- Food neophobia is a reluctance/fear of eating food items with which one is unfamiliar. Evolutionarily speaking, this trait is advantageous since being cautious when deciding to eat an unknown item could prevent ingesting dangerous toxins or allergens. However, in modern society (when most foods are safe), this trait can have adverse effects on one's diet when people restrict their diet to familiar items only.
- The most commonly used measure for assessing neophobia is the FNS, developed in 1992 by Pliner and Hobden. Other tools used to measure neophobia include the FNSC and, for older children, the Food Situation Questionnaire (FSQ) developed by Loewen and Pliner (2000). To determine actual neophobic behavioral responses, the willingness to taste novel food (WTNF) and UFST can be used.
- Food neophobia can have a significant impact on an individual's diet, and vice versa. Individuals with higher levels of food neophobia tend to consume less varied diets and consume lesser amounts of vegetables, fruits, and meats. Repeated exposure to novel food items can increase one's propensity to accept (i.e., consume) the item.
- Both the age and sex of an individual can influence food neophobia. In general, food neophobia tends to decline with age, with younger children being more neophobic than older children and children in general being more neophobic than their parents. There are two exceptions to this general trend: (1) there is a period of low neophobia in infants when they are transitioning to solid food, and (2) there is an increase in food neophobia in the elderly. Research on sex differences in food neophobia is inconsistent and may be insignificant, but more research is needed to elucidate the effect of gender on food neophobia.
- Sensation seeking (SS) is a personality trait defined by a person's willingness to seek out novel, complex, and intense stimuli while being willing to take risks (e.g., physical and social) in order to have such experiences. Food selection is related to SS tendencies and scales commonly used to measure SS include at least one food choice question. Higher SS is correlated with lower food neophobia.
- As with food neophobia, the age and sex of an individual can influence SS. Typically, SS is higher in younger individuals and declines as a person ages. Men typically have stronger SS tendencies than women, and given that higher SS is associated with lower food neophobia, it is possible that men are more attracted by and willing to eat new and unusual foods.

Key Terms

Arnett Inventory of Sensation Seeking: Developed by Arnett in 1994 as an alternative to the sensation seeking scale. This scale includes 20 statements that are ranked on a 4-point Likert scale (see Table 47.3).

Food Neophobia: A psychological trait defined by a person's fear (phobia) or unwillingness to consume new (neo) or unknown food items.

Food Neophobia Scale: Developed by Pliner and Hobden in 1992, this is the most commonly used scale to measure food neophobia in adults (see Table 47.1).

Omnivore's Dilemma: Each time a potential but unfamiliar food item is encountered, one must decide to avoid it, and, possibly, miss out on a good food source, or eat it, and, perhaps, ingest something dangerous. This choice is known as the "omnivore's dilemma".

Pickiness: Picky (or "finicky") eaters resist eating many familiar foods (Galloway et al. 2003). Food neophobia is specifically a reluctance to consume a food item that is unfamiliar, while pickiness may be influenced by other variables (e.g., texture).

Sensation Seeking: A personality trait defined by a person's willingness to seek out "novel, complex, and intense" stimuli while being willing to take risks in order to have such experiences (Zuckerman 1994).

Sensation Seeking Scale: Developed and refined by Zuckerman, this is a commonly used scale to measure sensation seeking in adults.

Chapter 48
The Effects of Prior Beliefs and Learning on Consumers' Acceptance of Genetically Modified Foods: Implications for Diet and Behavior*

Wallace E. Huffman, Matthew Rousu, Jason F. Shogren, and Abebayehu Tegene

Abbreviations

GM	Genetic modification
GMO	Genetically modified organism
WTP	Willingness to pay is the maximum amount that an individual is willing to pay for one unit of a good
$U(Y)$	Maximum household indirect utility as a function of household income (Y)
$V(Y - L)$	Maximum household indirect utility as a function of household income (Y) but subject to a lost (L)
$E(U)$	The expected value of household utility (U)
p^i	The probability of a bad outcome under state of the world $i = inf$ (decision maker has informed prior beliefs), *no-I* (decision maker has uninformed prior beliefs), US, USA, United States
\$	US dollar

Classification codes: C91, D12, D82

New food products made from genetically modified crops appeared in US supermarkets starting in 1996 (see Table 48.1). The genetic modification consisted of herbicide tolerance and insect resistance that have been introduced into field crops through the use of techniques in modern biotechnology. Herbicide tolerance and insect resistance are so-called input traits that reduce the expected cost of production to farmers (Fernandez-Cornejo and McBride 2002; FAO 2004), but have no direct benefit to consumers and pose some risks (Chern and Rickertsen 2004; FAO 2004). Consequently, GM products have been subject to much controversy (claims by environmental groups of reducing biodiversity, new food safety concerns due to allergens, and ethical concerns regarding the movement of genes across species), and they have raised important new issues in trade talks especially between the USA and the European Union.

Table 48.1 Some key features of genetically modified foods

Genetic modification: The application of bioengineering using recombinant DNA or gene splicing methods to create new organism, sometimes called biotechnology

First successful GM crops: Starting in 1996, GM cotton, corn, canola, and soybean became available that contain genes from soil bacterial that encoded the ability of plants to be herbicide tolerant or toxic to insects. For example, in cotton, corn, canola, and soybean, the GM crop varieties encoded resistance to a particular herbicide, which generally kills all plants that comes in contract with it. In cotton, GM crop varieties were also encoded to produce a toxic substance that kills key pests in the cotton bud-bollwormcomplex, and in corn, GM crop varieties were encoded with resistance to the Europeancorn borer. One might ask what is the alternative to these, the so-called farmer traits, which area type of biological control of pests? Most likely it would be one or more applications of agricultural chemicals, but might also include the use of a crop rotation containing two or more crops

New potential: New bioengineering methods have been developed to produce fresh vegetables that contain consumer traits of high antioxidants and vitamin C

Current situation: In the US more than 90% of the soybean acreage is planted to herbicide tolerant varieties; 80% of the corn acreage is planted to varieties either herbicide tolerant, insect resistant or both. In cotton, more that 75% of the acreage is either herbicide tolerant, insect resistant or both. In canola, 50% of the acreage is planted to herbicide tolerant varieties. GMOs for consumer traits are about to enter the market

Health concerns: There is no evidence that any individual has been harmed by a GMO organism inserted to commercial crop varieties

This table lists some key facts about genetic modification and biotechnology, including some historical underpinnings of the technology

Huffman et al. (2003) examined the effects of GM-food labels on bidding behavior of participants in an experimental auction, and Rousu et al. (2007) developed a methodology to value the contribution of third-party objective information in a setting with conflicted information. An important question is how decision makers use information when they make decisions about GMOs. For example, individuals generally possess some information about a topic, say GMOs, and they may acquire or be exposed to new information. The issue then becomes what weight is placed on these two types of information. For example, if a decision maker has very strong beliefs he or she may be unaffected by new information. Alternatively, he or she may know nothing about a topic and, hence, place all the weight on new information. More generally we can expect decision makers to use both types of information with weights that sum to one. This type of decision making process can be summarized in Bayes theorem (Grether 1980).

Earlier papers, while interesting, have not focused on the contributions of decision makers beliefs, called subjective prior beliefs, about genetic modification in an experimental auction-market setting. However, other literature applying Bayesian decision making include a discussion of prior beliefs about attributes of goods (Akerlof 1970; Hirshleifer and Riley 1992; Molho 1997; Stigler 1961), new information, and Bayesian learning (DeGroot 1970; Molho 1997, pp. 248–49; Tirole 2003, pp. 373).[1] This paper summarizes new evidence of the role of consumer's prior beliefs about genetic modification and diverse, new information about genetic modification on their WTP for foods that might be genetically modified. The information is of two broad types: subjective prior beliefs that arise from prior investments in information and new information from interested and disinterested parties. In the GM-food debate, the interested parties are classified as the agricultural biotech industry and environmental groups. The agricultural biotech industry consists of the private companies that market GM crop input traits to farmers and distribute probiotech information publically – Monsanto, Syngenta, Pioneer Hi-bred – and the Council for Biotechnology Information, a private trade association. The anti-GM environmental groups include Greenpeace, Friends of the Earth, and Action Aid. Furthermore, Huffman and Tegene (2002) have speculated about the potential value of

---

[1] These beliefs could, however, be uninformative or diffuse (DeGroot 1970)

independent, third-party information in such a conflicted market, and Rousu et al. (2007) have injected independent, third-party information into a set of economic experiments to assess its value.[2] In these food experiments, label types and information treatments were randomly assigned to sessions or trials. In this setting, participants who perceived themselves to be at least somewhat informed about genetic modification bid significantly less for GM-labeled foods than those who considered themselves to be uninformed. An important issue is how prior information affects the interpretation of new information, which this study emphasizes.

If consumers place heavy weight on information from interested parties, including cheap talk or hearsay, their welfare will be lower than if they use objective information (Akerlof 1970; Molho 1997; Morris and Shin 2002). Hence, consumers who have uninformed prior beliefs will have their bidding behavior affected by information from interested parties, but consumers who have informed prior beliefs may be relatively unaffected or place little weight on this type of information (Schultz 1975; Huffman 2001; Tversky and Kahneman 1981; Kahneman 2003). Another possibility is that the presence of third-party information affects the way that consumers use information from interested parties in formulating their bids.

The centerpiece of this research has been a set of experiments conducted in 2001 and which is summarized in Huffman et al. (2003) and Rousu et al. (2007). In these experiments, a hybrid methodology was developed using laboratory auctions that combined the methods of economic experiments, statistical experimental design, and survey design. These auctions are broadly called WTP experiments constructed such that it was in each participant's best interest to bid their true preferences, and furthermore, the winners were expected to "pay" what they "say" or "bid" – they executed winning bids by paying cash for experimental commodities. To add diversity to the set of experimental participants, experiments were conducted at two locations.[3] The model, results, and conclusions follow.

48.1 Methodological Considerations

A simple conceptual framework provides a useful device for helping to understand the observed behavior of consumers. Economists have shown that individuals frequently place less weight on prior beliefs than on new information when bidding on lotteries (e.g., see Grether 1980; Tversky and Kahneman 1974). This work, however, has been extended in two important ways. First, adopt the Bayesian concept of subjective beliefs instead of assuming that prior beliefs are always "fact" or objective beliefs (DeGroot 1970). Second, recognize that prior beliefs and new information from interested and disinterested parties may affect consumer's WTP for a new product that might have some risks, e.g., environmental or human harm.

Consumer utility or satisfaction from consuming genetically modified food products is best represented as depending on prior beliefs about genetic modification. Following Kivi and Shogren (2005), we define state-dependent indirect utility functions for a "good outcome" $U(Y)$ and a "bad outcome" $V(Y – L)$ that are independent of an individuals' prior beliefs or the amount of new information that they have acquired/received. The indirect utility functions give maximum utility for a

---

[2] Independent, third-party information is sometime referred to as verifiable information (Milgrom and Roberts 1986)

[3] An alternative methodology is to use state preference or contingent value surveys. In these surveys a random sample of households are contacted and asked to respond to hypothetical product preference or willingness to pay options. This approach has the advantage of being able to be administered relatively inexpensively to a large sample, which can give precision (for examples see Johnston et al. 2001). However, because responses are hypothetical, they are not bound by a budget constraint. This can lead to hypothetical biases or credibility problems that do not vanish as the sample size increases. For examples, see Diamond and Hausman (1994) and Fox et al. (1998)

given level of income, Y and $Y - L$, and they are weighted by the individuals' subjective probabilities conditioned on their prior beliefs: p^I, probability of a bad outcome, given the participant has informed prior beliefs, and p^{no-I}, probability of bad outcome given the participant has uninformed prior beliefs, to obtain a consumer's expected utility:

$$U\left(Y - WTP^I\right) = EU^I = p^I\left(I, \inf\right)V\left(Y - L\right) + \left(1 - p^I\left(I, \inf\right)\right)U\left(Y\right), \tag{48.1}$$

$$U\left(Y - WTP^{no-I}\right) = EU^{no-I} = p^{no-I}\left(\inf\right)V\left(Y - L\right) + \left(1 - p^{no-I}\left(\inf\right)\right)U\left(Y\right) \tag{48.2}$$

Hence, a consumer's indirect utility is a function of his or her household income, Y, minus his or her WTP for the food products. A consumer is assumed to perceive that the "bad state of nature" will occur with probability p, which differs between those who have informed and uninformed prior beliefs. The posterior probability of a bad (good) outcome or state of nature is determined by a combining together prior beliefs and new information on GM technologies and food, denoted by "*inf.*"

To simplify, it is useful to normalize utility such that U = 1 and V = 0 and, hence, a consumer's expected utility is:

$$EU^I = \left(1 - p^I\left(I, \inf\right)\right), \tag{48.3}$$

$$EU^{no-I} = \left(1 - p^{no-I}\left(\inf\right)\right). \tag{48.4}$$

Next, consider a consumer's determination of the subjective probability of a bad outcome on GM foods, given the following parameterization:

$$p^I = \alpha_0 + \alpha_{\inf}, \tag{48.5}$$

$$p^{no-I} = \alpha_{\inf}. \tag{48.6}$$

Now α_0 is the effect of the informed consumers' prior beliefs about GM on their posterior beliefs about GM, and $\alpha_{\inf}$ is the effect of new information on their posterior beliefs. If prior beliefs are informative, that is, they are not diffuse priors (DeGroot 1970), it is useful to assume $0 < \alpha_0 < p$. Now consumers who have uninformed prior beliefs are expected to place more weight on information from interested parties than participants who have informed prior beliefs. Also it seems plausible (Rousu et al. 2007) that the injection of third-party information affects the way that consumers use information from interested parties in forming their bids. Rearranging (48.5) and (48.6), we obtain the following relationship between posterior probabilities:

$$p^I = p^{no-pI} + \alpha_0 \tag{48.7}$$

Substitute for p^I in (48.3) to obtain

$$EU^I = \left(1 - p^{no-I} - \alpha_0\right) \tag{48.8}$$

and take the difference in expected utility between (48.4) and (48.8) to obtain

$$U\left(Y - WTP^I\right) - U\left(Y - WTP^{no-I}\right) = -\alpha_0 \tag{48.9}$$

Hence, this simple decision framework shows formally that consumers who have the same indirect utility values and receive the same information treatment may have differences in expected utility due only to different *prior beliefs*. More generally, differences in an individual's expected utility are due to differences in prior beliefs and information.

WTP for GM-labeled foods could be higher or lower, depending on the prior beliefs and the content of the new information they obtain/receive. Some evidence has shown that prior beliefs and information that they receive affect WTP. This evidence is summarized below.

48.2 Empirical Considerations

A summary of evidence from food experiments shows how prior beliefs of consumers and new information about genetic modification affect their WTP for standard food products. A few details about this data are presented and more details can be found in the studies by Rousu et al. (2007) and Huffman et al. (2003). Three dissimilar food products were auctioned in a laboratory setting: vegetable oil, tortilla chips, and potatoes. An important feature of the GM food products is that the refining process for vegetable oils, say from soybean oil, all of the amino acids are removed leaving pure lipid or fat, and the resulting oil is chemically indistinguishable irrespective of the use of GM or non-GM soybeans to make the oil. The tortilla chips are a processed product made from yellow corn that might be contaminated by GM-traits for herbicide tolerance or insects resistance, and consumers might have different concerns for GM content here than in russet potatoes that were genetically modified for virus resistance.

Because we are interested in the performance of grocery store and supermarket shoppers, individuals over 18 years of age were chosen for the food experiments.[4] Moreover, they were chosen randomly from two major Midwestern metropolitan areas by a random digital dialing method and contacted by an independent agency to obtain their agreement to participate, given instructions of how to get to the project site, and told that they would be paid $40 for their participation.

To help balance the number of participants in lab sessions and maintain randomness in assignment, arriving participants were alternately assigned to one of two concurrent sessions. Each group/session consisted of 13–16 individuals. After taking a seat in the lab or classroom, participants were asked to complete a questionnaire containing questions about their socioeconomic characteristics and prior beliefs about new technologies, and paid $40. A critical part of the methodology of these experiments is that each session or trial followed exactly the same protocol. Participants were first asked to learn about the auction mechanism. To do this, they engaged in a round of bidding on a candy bar to learn the mechanism of the random nth price auction. In this auction bids are placed and collected by the session monitor, who then arrays them from highest to lowest. Then a random n is drawn from the uniform distribution of 1 to say 13 (when there are 14 participations), suppose it is five, then the four highest bidders pay the fifth highest price. This random nth-price auction mechanism has been shown to be superior to a second-price Vickery auction (where the highest bidder pays the second highest price) for eliciting consumers' entire demand curve for new goods (Shogren et al. 2001). After winners were chosen, they were asked to engage in a second practice round containing a candy bar, box of pens, and a deck of cards to get them familiar with placing three bids on dissimilar goods simultaneously. Winning bids were announced, and participants were given a short quiz on the auction mechanism that was followed by discussion and clarification. This was done to check up on participants' understanding of the auction mechanism.

---

[4]Although several studies have used only college undergraduates in laboratory auctions of food items (including Lusk et al. 2001;Hayes et al. 1995), they are not the best choice for participants when the items being auctioned are ones sold in grocery stores or supermarkets. For example, Katsaras et al. 2001, using a national random sample of grocery store shoppers, showed that the share of college-age (18–24 years) shoppers falls far below their share in the population, 8.5% of shoppers versus 12.8% in the US Census of Population. College students obtain a large share of their food from school cafeterias and a small share from grocery stores and supermarkets compared to older shoppers (Carlson et al. 1998)

Next, one of the six information treatments was randomly assigned and released in each session or trial. These treatments were constructed from the three basic information types defined for these experiments. They were the (1) *industry perspective* – provided by a group of leading biotechnology companies, including Monsanto and Syngenta (Council for Biotechnology Information 2001); (2) *environmental group perspective* – from Greenpeace, a leading environmental group or biotech antagonist (Greenpeace 2001a, b; Friends of the Earth 2001, 2003); and (3) *third-party perspective* – from an independent group of scientists, professionals, religious leaders, and academics, none with a financial stake in GM foods. This third type of information is to be viewed as an informed objective assessment, given the state of science, and without significant direct financial interest in genetic modification. The three information types were packaged into *six information treatments*: (1) the biotech industry perspective; (2) the environmental group perspective; (3) agricultural biotech industry and environmental perspectives; (4) agricultural biotech industry and third-part perspectives; (5) environmental group and third-party perspectives; or (6) all three perspectives. When a trial/session received pro- and antibiotech information, the order was randomized among the participants. Third-party information, however, was always distributed last.

Next, they were asked to go one-by-one in an orderly fashion to the front of the lab/room to view the three experimental products (32 oz. of vegetable oil made from soybeans, 16 oz. tortilla chips made from yellow corn, and 5 lb of russet potatoes) and to place their bids. They were then asked to view another set of these three goods, having different GM-food-label information, and place a new set of bids.[5] In one round participants were bidding on food products that were labeled as genetically modified (GM) and in the other round the food products had a plain-label.[6] Among the two rounds of bidding on experimental goods, one was chosen randomly by the auction monitor to be a binding round in which winners were expected to complete their exchange of money for experimental goods. The actual exchange took place in an adjacent room.[7]

To get a better grasp of the demographic attributes of participants, Table 48.2 provides summary statistics for the sample of participants used in a series of Huffman's GM food papers. Although participants are slightly skewed toward women, Katsaras et al. (2001) showed that women make up a disproportional share of grocery shoppers: 83% of shoppers versus 52% in the US Census of

Table 48.2 Characteristics of auction participants (*N* = 172) variable definition mean St. Dev (Huffman et al. 2007)

Gender	1 if female	0.62	0.49
Age	The participant's age	49.5	17.5
Married	1 if the individual is married	0.67	0.47
Education	Years of schooling	14.54	2.25
Household	Number of people in participant's household	2.78	1.65
Income	The household's income level (in thousands)	57.0	32.6
White	1 if participant is white	0.90	0.30

This table reports on the average value of socio-economic attributes of a sample of individuals used in a number of Huffman's experiments

---

[5] Participants were never told how many total rounds of bidding they would engage in. All participants engaged in a total of four rounds of bidding including the two practice rounds. At the start of the auction of the food products that might be GM, the participants were told that they would be expected to purchase a maximum of one unit of each auctioned commodity. After the second round of bidding on food products that might be GM, the auction part of the experiment ended

[6] The sequence was determined randomly

[7] A strength of this methodology is that each participant engaged in very few rounds of bidding (two rounds on experimental products), which reduces behavior modification associated with the experience of participating in an experiment

Population. Although the demographics of the sample do not perfectly match the population reported by the USA census demographic characteristics for these regions, they are similar and provide a sufficient representation for probing into labeling and information effects on WTP for GM food products.

A key factor for being able to investigate the role of a consumers' prior beliefs is having available preauction information of the type: "Regarding genetically modified foods: How informed do you consider yourself?" The participants were offered the following six options: extremely well informed, well informed, somewhat informed, not very informed, not informed at all, and I don't know. In particular, this information was collected before the start of the lab auction of GM-foods and release of new information.[8] Table 48.3 summarizes these responses and shows that 41.9% of the 172 participants were at least somewhat informed about genetic modification before our auction experiments. The other 58.1% were classified as "uninformed." Hence, a majority of the participants in these experiments were "uninformed about genetic modification." However, a substantial share of them claimed to be informed.

To gain a better understanding of the data from the WTP experiments, sample mean information for average bid prices for GM- and plain-labeled foods for all participants and for participants who had informed and uninformed priors is reported in Table 48.4.[9] Among all participants and commodities, average bids were 14% lower for GM than for plain-labeled commodities (part A). Among participants who had informed prior beliefs about GM foods, the average difference for the bid price of a plain-labeled product less the bid price for GM-labeled counterpart was 18% (part B). Among participants who had uninformed prior beliefs, the average difference for the bid price of a plain-labeled product less the bid price for the GM-labeled counterpart was 11% (part C). Across the two groups, informed and uninformed, the difference is 49%. The difference between these two percentages is not significantly different from zero at the 5% level.

Of central interest is the impact of participants' subjective prior beliefs about genetic modification in a market where information from two types of interested parties is injected. Table 48.4 summarizes the mean differences in bid prices from participants for GM- and plain-labeled food products due to the release of information from interested parties, the agricultural biotech industry or environmental NGOs, given prior beliefs. Part A summarizes the bid prices in a market without third-party information. When participants, both those who had informed and uninformed

Table 48.3 Response of participants to the pre-experiment question of "How informed are you about genetic modification?" (*N* = 172) (Huffman et al. 2007)

Category category	Relative frequency (%)
Extremely well informed	3.5
Well informed	5.8
Somewhat informed	32.6
Not very informed	40.1
Not informed at all	15.7
I don't know total	2.3
	100.0

This table presents the relative frequency of sample participant's response to the survey question of how well they were informed about genetic modification

[8] No effort was made to test participant's beliefs for objectiveness; they are subjective beliefs

[9] Participants who were informed and uninformed did not differ significantly by age, gender, etc

Table 48.4 Mean bids for participants by commodity and type (Huffman et al. 2007)

Part A: Mean bids – all participants and treatments (*N* = 172)

	Mean bid	Standard deviation	Median	Minimum	Maximum
GM OIL	0.91	0.84	0.75	0	3.99
OIL	1.05	0.85	1.00	0	3.79
GM CHIPS	0.93	0.86	0.70	0	3.99
CHIPS	1.08	0.85	0.99	0	4.99
GM POTATOES	0.78	0.67	0.69	0	3
POTATOES	0.91	0.67	0.80	0	3.89

Part B: Mean bids for participants who had informed prior beliefs about genetic modification (*N* = 72)

	Mean bid	Standard deviation	Median	Minimum	Maximum
GM OIL	0.93	0.88	0.77	0	3.99
OIL	1.10	0.89	1.00	0	3.79
GM CHIPS	0.86	0.81	0.75	0	3.50
CHIPS	1.05	0.74	1.00	0	2.99
GM POTATOES	0.73	0.61	0.75	0	2.30
POTATOES	0.92	0.59	0.88	0	2.00

Part C: Mean bids for participants who had uninformed prior beliefs about genetic modification (*N* = 100)

	Mean bid	Standard deviation	Median	Minimum	Maximum
GM OIL	0.90	0.82	0.68	0	3.25
OIL	1.01	0.82	0.99	0	3.29
GM CHIPS	0.97	0.90	0.69	0	3.99
CHIPS	1.10	0.92	0.99	0	4.99
GM POTATOES	0.81	0.72	0.60	0	3.00
POTATOES	0.90	0.73	0.75	0	3.89

This table provides sample mean (average) and median (mid-point observation) value of participant's willingness to pay or bids on six types of food products. Measures of variability include the standard deviation of bid prices and minimum and maximum values

prior beliefs, received only the industry perspective, the mean bid price differences between GM- and plain-labeled products were very small, less than plus or minus 11 cents per product. For participants who had informed prior beliefs about genetic modification and received only the environmental group perspective, the mean bid price differences were 50–60 cents per product, but only the 52 cent difference for potatoes was significantly different from zero at the 5% level. For participants who had uninformed prior beliefs, mean bid price differences were less, 32–37 cents per product, and all are significantly different from zero at the 5% level. For participants who had informed priors and received both the agricultural biotech and environmental group perspectives, the discount for GM products is an average of 29–51 cents per product, but the 40 cent differential for potatoes is the only one of these three differences that is significantly different from zero at the 5% level. In contrast, participants who had uninformed prior beliefs did not discount GM-products.

Part B of Table 48.5 summarizes bids from consumers who received third-party information. When participants, both with informed and uninformed prior beliefs, received only probiotech information followed by third-party information, the mean bid-price difference between GM- and plain-labeled food items was small and similar to those reported in part A. When participants had informed priors and received antibiotech information followed by third-party information, mean bid price differences were 7–20 cents per food item, which is much smaller than the outcome without third-party information

Table 48.5   Mean difference in bid prices of participants for plain-labeled less bid price for GM-labeled food products due to information from interested parties, conditional on prior beliefs (Huffman et al. 2007)

Part A: Participants who did not receive third-party GM-information			
Information treatments	Vegetable oil	Tortilla chips	Potatoes
Received only probiotechnology information, given informed priors ($N = 13$)	−$0.10 $p = 0.63$	$0.11 $p = 0.32$	$0.02 $p = 0.93$
Received only probiotechnology GM-information, given uninformed priors ($N = 17$)	$0.03 $p = 0.68$	$0.00 $p = 0.94$	−$0.08 $p = 0.13$
Received only antibiotechnology GM-information, given informed priors ($N = 8$)	$0.50 $p = 0.12$	$0.61[*] $p = 0.09$	$0.52[**] $p = 0.05$
Received only antibiotechnology GM-information, given uninformed priors ($N = 21$)	$0.34[***] $p < 0.01$	$0.37[***] $p < 0.01$	$0.32[***] $p < 0.01$
Received probiotechnology and antibiotechnology GM-information, given informed priors ($N = 10$)	$0.51 $p = 0.12$	$0.29[*] $p = 0.08$	$0.40[**] $p = 0.05$
Received probiotechnology and antibiotechnology GM-information, given uninformed priors ($N = 18$)	$0.00 $p = 0.97$	$0.01 $p = 0.90$	$0.07 $p = 0.24$
Part B: Participants who received third-party GM-information			
Information treatment	Vegetable oil	Tortilla chips	Potatoes
Received probiotechnology and third-party GM-information, given informed priors ($N =14$)	$0.13 $p = 0.17$	$0.09 $p = 0.52$	$0.07 $p = 0.28$
Received probiotechnology and third-party GM-information, given uninformed priors ($N =14$)	−$0.09 $p = 0.26$	$0.07 $p = 0.43$	−$0.05 $p = 0.38$
Received antibiotechnology and third-party GM-information, given informed priors ($N = 13$)	$0.07 $p = 0.17$	$0.10 $p = 0.55$	$0.20[*] $p = 0.08$
Received antibiotechnology and third-party GM-information, given uninformed priors ($N=16$)	$0.29 $p = 0.21$	$0.33[*] $p = 0.10$	$0.26[*] $p = 0.08$
Received probiotechnology, anti-biotechnology and third-party GM-information, given informed priors ($N = 14$)	$0.16[*] $p = 0.08$	$0.10[*] $p = 0.07$	$0.10 $p = 0.15$
Received probiotechnology, antibiotechnology and third-party GM-information, given uninformed priors ($N = 14$)	$0.03 $p = 0.77$	−$0.08 $p = 0.28$	−$0.06 $p = 0.42$

*Statistically significant at the 10% level using a two-sided t-test

**Statistically significant at the 5% level using a two-sided t-test

***Statistically significant at the 1% level using a two-sided t-test

This table reports on various statistical tests of equality of bid price differences across the three commodities. We are generally looking for differences that are statistically significant. Those are the ones that we have greatest confidence in

(as reported in part A). The most significant of these three outcomes is for potato, but now the bid price difference is only significant at the 10% level. When those who had uninformed priors receive this same set of information treatments, the bid price differences are similar to those in part A in which third-party information was excluded. With third-party information, the differences are at best significant at the 10% level. When participants who had informed priors received all three types of new information, their mean bid price differences were only 10–16 cents per product, which is much lower than the outcome when third-party information was not injected (as reported in part A). Two of these differences are different from zero at only the 10% level. When participants who had uninformed priors received all three types of information, however, their mean price differences were similar to those reported when third-party information was not injected. Hence, the evidence is that bidding behavior was affected by participants' prior beliefs and new information injected into the experiments from interested parties and from a third-party.

Table 48.6 Do the informed and uninformed bid differently? Test of null hypothesis that difference in mean bid price differences for plain-labeled less bid price for GM-labeled food items is zero for participants who had informed and uninformed prior beliefs (Huffman et al. 2007)

Part A: Participants who did not receive third-party information			
Information treatments	Vegetable oil	Tortilla chips	Potatoes
Received probiotechnology GM-information only (N = 30)	t = 0.67 p = 0.51	t = −0.92 p = 0.37	t = −0.55 p = 0.59
Received antibiotechnology GM-information only (N = 29)	t = −0.61 p = 0.54	t = −0.92 p = 0.36	t = −0.99 p = 0.33
Received both probiotechnology and antibiotechnology GM-information (N = 28)	t = −1.83 p = 0.08	t = −1.94 p = 0.06	t = −2.22 p = 0.04
Part B: Participants who received third-party information			
Information treatments	Vegetable oil	Tortilla chips	Potatoes
Received probiotechnology and third-party GM-information (N = 28)	t = −1.85 p = 0.08	t = −0.15 p = 0.89	t = −1.45 p = 0.16
Received antibiotechnology and third-party GM-information (N = 29)	t = 0.87 p = 0.39	t = 0.92 p = 0.36	t = 0.36 p = 0.71
Received probiotechnology, antibiotechnology, and third-party GM-information (N = 28)	t = −0.93 p = 0.36	t = −2.00 p = 0.06	t = −1.66 p = 0.11

This table is testing to see if bid price differences exist by whether the participants have informed prior beliefs about genetic modification or whether they are uninformed conditional on information treatment and commodity. The results are mixed

Table 48.6 summarizes the results for statistical tests of bid price differences for plain and GM-labeled products, conditional on participant's prior beliefs about genetic modification. Part A reports the results for statistical tests for participants who did not receive third-party information. This is a "difference-in-differences" test (see Wooldridge 2002, pp. 283–291, 128–131). It is of interest to test the null hypothesis that the difference-in-mean bid-price difference for plain-labeled and GM-labeled food items is zero across participants who had informed and uninformed prior beliefs. When the participants received only the agricultural biotech industry perspective or the environmental group perspective, no significant difference-in-differences existed at the 5% significance level. If they received the probiotech and antibiotech perspectives, the estimate of the difference-in-differences estimator was significantly different from zero for potatoes (5% level) and tortilla chips (6% level). For vegetable oil, the estimate of difference-in-differences is not significantly different from zero.

Because third-party information is of potentially great social benefit, Part B of Table 48.5 summarizes difference-in-differences results for a situation in which third-party information was injected. The information treatments are (i) probiotech and third-party, (ii) antibiotech and third-party, and (iii) all three types of information. None of the estimates of the difference-in-difference estimator for these tests is significantly different from zero at the 5% level. The third-party information lowers the relative weight placed on information received from interested parties when bids are placed on food items that might be genetically modified. Furthermore, when third-party information is injected into the experiment, prior beliefs about genetic modification have relatively little impact on bidding behavior of participants. Of considerable interest is that both participants who had informed and uninformed prior beliefs behaved in our experiments as if they took the third-party information seriously.

Another dimension of the data is differences in bid prices due to information treatment effects for people who received third-party information, conditional on prior beliefs. Table 48.7 summarizes these results. The null hypothesis is that the difference in mean bid prices for plain- and GM-labeled

Table 48.7 Results for difference-in-differences estimator: Null hypothesis that difference in bid prices for plain-labeled less bid price for GM-labeled food items under different information treatments is zero, given participants' prior beliefs (no third-party information) (Huffman et al. 2007)

Part A: Participants whose prior beliefs were uninformed about genetic modification			
Information treatments	Vegetable oil	Tortilla chips	Potatoes
Received only probiotechnology GM-information versus received only antibiotechnology GM information.	t = 2.11 p = 0.04	t = 2.71 p = 0.01	t = 3.53 p = 0.00
Received only probiotechnology GM-information versus received probiotechnology and antibiotechnology GM-information.	t = 0.20 p = 0.84	t = −0.04 p = 0.97	t = −1.96 p = 0.06
Received only antibiotechnology GM-information versus received probiotechnology and antibiotechnology GM-information	t = 2.03 p = 0.05	t = 2.68 p = 0.01	t = 2.26 p = 0.03
Part B: Participants who had informed prior beliefs about genetic modification			
Information treatments	Vegetable oil	Tortilla chips	Potatoes
Received only probiotechnology GM-information versus received only antibiotechnology GM-information.	t = 1.78 p = 0.09	t = 1.76 p = 0.09	t = 1.72 p = 0.10
Received only probiotechnology GM-information versus received probiotechnology and antibiotechnology GM-information.	t = −1.76 p = 0.09	t = −0.96 p = 0.35	t = −1.45 p = 0.16
Received only antibiotechnology GM-information versus received probiotechnology and antibiotechnology GM-information	t = −0.02 p = 0.98	t = 0.98 p = 0.34	t = 0.43 p = 0.68

This table reports on test of no difference in bid prices of participants due to the type of information treatment that they received, by commodity. The results are mixed

food items under two different information treatments is zero, holding prior beliefs of participants constant. For participants who held uninformed prior beliefs, the estimate of difference-in-differences estimator is significantly different from zero (5% level) for all three food items when participants receive pro- versus antibiotech information. They are also significantly different from zero when participants receive antibiotech information versus pro- and antibiotech information. In fact these two sets of hypotheses produced t-values that look very similar (part A). When participants received pro- versus pro- and antibiotech information the estimate of the difference-in-difference estimator was not significantly different from zero. When participants had informed priors, none of the estimates of the differences-in-differences estimator was significantly different from zero at the 5% level (part B). Hence, a very important result is that participants' prior beliefs affect the relative weight placed on new information from interested parties when third-party information is unavailable.

Another dimension of the data is seen by considering the effects of different combinations of information from interested parties when third-party information is injected, conditional on prior beliefs. For participants who had uninformed priors, three of nine tests shown in Table 48.8, part A, for the estimate of the difference-in-differences estimator are rejected at the 6% level: for potatoes when participants received only probiotech information versus received only antibiotech, and for tortilla chips and potatoes when participants received only antibiotech information versus pro- and antibiotech information. For participants having informed prior beliefs (part B), none of the coefficients of the difference-in-differences estimator is significantly different from zero at the 6% level. With the injection of third-party information, participants who have uninformed prior beliefs about GM bid differently on plain- versus GM-labeled food products than for those who had informed prior beliefs. Those participants who are uninformed behave as if they place greater weight on new information than the informed participants even when it comes from interested parties.

Table 48.8 Results for differences-in-differences estimator when participants received third-party GM-information: Null hypothesis that difference in bid price for plain-labeled less bid price for GM-labeled food items under different information treatments is zero, conditional on participants' prior beliefs (Huffman et al. 2007)

Part A: Participants who had uninformed prior beliefs about genetic modification			
Information treatments	Vegetable oil	Tortilla chips	Potatoes
Bid prices when received probiotechnology and verifiable GM-information versus bids when received antibiotechnology and third-party GM-information.	$t = 1.53$ $p = 0.14$	$t = 1.22$ $p = 0.23$	$t = 1.99$ $p = 0.06$
Bids when received probiotechnology and verifiable GM-information versus bids when received probiotechnology, antibiotechnology, and third-party GM-information.	$t = -0.93$ $p = 0.36$	$t = 1.37$ $p = 0.18$	$t = 0.16$ $p = 0.87$
Bids when received antibiotechnology and verifiable GM-information versus bids when received probiotechnology, anti-biotechnology, and third-party GM-information	$t = 0.99$ $p = 0.33$	$t = 1.95$ $p = 0.06$	$t = 1.98$ $p = 0.06$
Part B: Participants who had informed prior beliefs about genetic modification			
Information treatments	Vegetable oil	Tortilla chips	Potatoes
Bids when received probiotechnology and verifiable GM-information versus bids when received antibiotechnology and third-party GM-information.	$t = -0.55$ $p = 0.58$	$t = 0.03$ $p = 0.97$	$t = 1.13$ $p = 0.27$
Bids when received probiotechnology and verifiable GM-information versus bids when received probiotechnology, antibiotechnology, and third-party GM-information.	$t = -0.25$ $p = 0.80$	$t = -0.03$ $p = 0.98$	$t = -0.42$ $p = 0.68$
Bids when received antibiotechnology and verifiable GM-information versus bids when received probiotechnology, antibiotechnology, and third-party GM-information	$t = -0.89$ $p = 0.38$	$t = 0.02$ $p = 0.98$	$t = 0.78$ $p = 0.44$

This table shows how third-party information affects bid prices. The results are mixed

It is interesting that individuals who had informed prior beliefs about genetic modification coming into our experiments discounted GM-labeled food products more highly than those participants having uninformed prior beliefs. This behavior suggested that their prior information was somewhat negative. Participants who had uninformed prior beliefs about genetic modification before our experiments exhibited the greatest change in bidding behavior due to the injection of new information. Information from interested parties caused a significant change in participants' bidding behavior, and when third-party information was injected their bidding behavior was further modified. Hence, those participants who had informed prior beliefs were relatively unaffected by all types of new information. They may already have made a significant investment in information about genetic modification, and the marginal impact of new information including third-party information was small and not statistically significant.

48.3 Reflections

Our research has shown out that consumers' prior beliefs and new information that they receive while deciding their WTP (both from interested parties and third-party sources) for food products that might be genetically modified. This contradicts findings of Viscusi (1997) and Tversky and Kahneman (1974, 1992) who argued that people frequently ignore base rates. One potential explanation for this

difference of outcome is that instead of measuring prior beliefs as objective knowledge (e.g., monetary lotteries), we asked lab participants to give us information about their prior knowledge about genetic modification. They were asked the following question: "How informed are you about genetic modification?" and they were given five options: extremely well informed, well informed, somewhat informed, not very informed, and not informed at all. This information is subjective, and we use this as their subjective prior belief. Furthermore, we examined their use of prior beliefs and new information to inform decision on willingness to pay for common food items available in grocery stores and supermarkets and not in a lottery.

In additional research, Colson et al. (2009) have assessed consumers' WTP for new food products – fresh potato, tomato, and broccoli – that contain product enhanced consumer attributes of antioxidant and vitamin C levels introduced using genetic modification. The potato is unique in that it has been grown by farmers for 8,000 years under diverse conditions. It has large genetic diversity, but it is very difficult to manipulate the genes by using conventional breeding methods but easy using new bioengineering methods.

These experiments used a new set of data collected from individuals chosen from a random set of telephone numbers in two major metropolitan cities who were contacted by an independent survey group in 2007 to obtain their agreement to participate and willing participants came to a central location or lab. Their WTP was obtained in a series of multiple-round random nth price experimental auctions with randomized food labels and information treatments. Three information types: agro-biotech industry perspective, environmental group perspective, and a third-party perspective are packaged into five information treatments. The three information statement are similar to those of the 2001 experiments reported on above, but the information statements of the agro-biotech industry and third-party in this latter research clearly make a distinction between GM due to moving genes across species, i.e., transgenic, versus moving genes within species, i.e., intragenic. They find that consumers are willing to pay significantly more for bioengineered products from intragenic than transgenic transfers or for conventional products. Supporting earlier research (Rousu et al. 2007), consumers' WTP for these GM food products are affected significantly by the food label and type of information injected into the decision making process.[10] Moreover, these results provide evidence for the first time that consumers are willing to pay a premium for new GM fresh vegetables with enhanced antioxidant and vitamin C levels relative to a similar plain-labeled food product. This information is valuable to consumers, growers, and potential developer of new GM foods. Moreover, a type of GM food product has now been identified where the food industry has an incentive to voluntarily label as GM or more likely to trademark.

48.4 Application to Other Areas of Diet and Behavior

The building evidence from food experiments, including the effects of food labels, information statements, and Bayesian learning, is applicable to adults' decisions on a wide range of choices that affect diet, nutrition, and overall health. In particular, methods in this paper are applicable to lifestyle choices on diet and obesity. The evidence suggests that careful use of food labels and information can affect consumers' choices so that they are more likely to choose new food products that improve their diet and healthy and may reduce their probability of being obese.

---

[10] In these experiments, individuals who claimed to be informed about genetic modification coming into the experiments bid more for intragenic product enhanced fresh vegetables than did the other individuals

Summary Points

- This line of research has shown that experimental economics is a useful tool for analyzing the behavior of consumers as reflected in willingness to pay for foods that may be genetically modified.
- Consumers exhibit Bayesian learning in making decision on how much they are willing to pay for fresh vegetables that might be enhanced with antioxidants and vitamin C, i.e., they in general use information from their prior beliefs and new information injected into the experiment.
- Food labels and information statements affect consumers' willingness to pay for food that may be genetically modified, and these tools may be used to change consumers' diets and health.
- Both skeptics and proponents of new technologies (i.e., interested parties) might try to manage information to achieve private objectives. This is most likely to occur when much is unknown scientifically about the impacts of new technologies or when third-party information is limited or unavailable (Milgrom and Roberts 1986; Huffman and Tegene 2002). Opponents to a new product or technology may try to target people who are relatively uninformed about the technology because the evidence is that they are receptive to new information. Proponents of a new technology can identify consumers who have positive informed prior beliefs about new products or technology because they are easy converts to buying the new product or technology.
- Genetic modification may become an important tool for producing food products with consumer traits of enhanced nutrient value. Genetic modification can also be used to dramatically lowering arcylamide levels in fried potatoes, which have been shown to cause cancer and have been largely banned in French fries sold in California.
- Processor traits can also be enhanced using genetic modification. The latter traits include reduced bruising during the processing of potatoes in food plants, which would reduce waste.
- The key issue, however, is to identify product attributes that consumers value and cannot be introduced by conventional plant breeding. If bioengineering can introduce these traits to food crops, it would improve food quality.

Definition

Genetic modification: The application of bioengineering using recombinant DNA to create new living organism, sometimes called biotechnology

49.1 Introduction

Food craving studies appeared infrequently in the scientific literature until the mid-1980s and important studies on the phenomenology and prevalence of food cravings were conducted in the 1990s. Over the last decade, there has been an increase in food craving research that was likely influenced by the development of new methods to measure food cravings and associated phenomena, such as brain activation. Further, the rise in obesity prevalence led scientists to investigate factors that affect food intake behavior and the association between food cravings and food intake was a logical area of research. The purpose of this chapter is to review the food craving literature and explore the associations between food cravings and food intake, body weight, dieting, and brain activation.

49.2 Food Craving Definition and Etiology

The construct of food craving, as well as its definition, has been influenced by research on drug abuse and addiction. Kozlowski and Wilkinson (1987) reviewed the substance abuse literature and concluded that a proper definition of craving requires that the substance be intensely desired. White

et al. (2002) considered this recommendation and defined a food craving as "an intense desire to consume a particular food that is difficult to resist." Other authors also noted that food cravings represent a strong desire to consume a food (Cepeda-Benito et al. 2000b), and people who report food cravings indicate that it can be difficult to resist eating food in response to cravings. Food cravings differ from hunger by at least one important feature: consumption of a specific food is believed to alleviate food cravings, while consumption of many different types of foods alleviates hunger (Pelchat and Schaefer 2000).

The etiology of food cravings has been the subject of considerable debate. It has been hypothesized that food cravings are elicited by a nutrient deficiency or food restriction (Weingarten and Elston 1990). This hypothesis appears logical, but it is not supported by scientific evidence. If this hypothesis were true, food cravings should increase during weight loss diets, yet they decrease (Harvey et al. 1993; Lappalainen et al. 1990; Martin et al. 2006, 2008a) or are unaffected (Gilhooly et al. 2007) by weight loss diets. Further, restriction of certain types of foods results in a decrease, not an increase, in craving for the restricted foods (Martin et al. 2008a), and food deprivation is not a necessary condition for the occurrence of food cravings (Hill et al. 1991). Lastly, nutritional deficiencies are not associated with food cravings, and people crave foods high in certain nutrients, while failing to crave other foods with higher levels of the same nutrient (Weingarten and Elston 1990). This evidence indicates that the etiology of food cravings is not heavily influenced by nutritional deficiencies or food restriction.

The role of conditioning in the etiology of food cravings, however, has gained empirical support. Food cravings can develop from pairing consumption of certain foods with hunger, suggesting that food cravings are a conditioned expression of hunger (Gibson and Desmond 1999). In the Gibson and Desmond study, individuals assigned to eat chocolate only when hungry developed greater craving for chocolate over a 2-week period, but chocolate cravings decreased among individuals assigned to only eat chocolate when full. Similarly, the biopsychosocial theory of food cravings suggests that food cravings can also develop by pairing food intake with other conditions, such as physical locations (watching a movie) or internal states (emotional arousal or dysphonic mood) (Rogers and Smit 2000). Conversely, conditioning also appears to influence the development of food aversion. Food aversion during pregnancy appears to be the result of pairing consumption of certain foods with nausea (Bayley et al. 2002; Fairburn et al. 1992).

The conditioning model of food cravings is consistent with the above noted finding that food restriction does not increase, and frequently decreases, food cravings (Harvey et al. 1993; Lappalainen et al. 1990, Martin et al. 2006, 2008a). This may occur for a number of reasons. First, when certain foods are restricted during diets, there are limited opportunities to pair consumption of those foods with stimuli that precipitate eating behavior, which limits the development of food cravings. Second, stimuli that once elicited food cravings would no longer be followed by consumption of the craved food, and existing cravings would diminish in frequency or intensity due to extinction. Although the conditioning model of food craving etiology has been supported by experimental evidence (Gibson and Desmond 1999) and the results of trials that involved food restriction (Harvey et al. 1993; Lappalainen et al. 1990; Martin et al. 2006, 2008a), additional research is warranted to further explicate the role of conditioning in food craving etiology.

49.3 Assessment of Food Cravings

Food cravings can be quickly and affordably measured by self-report inventories. Studies prior to 2000 primarily relied on instruments created to measure cravings for specific studies, and the psychometric properties of many of these instruments were not thoroughly examined. In recent years,

Table 49.1 List of self-report inventories designed to quantify food cravings, including the type of cravings measured (general craving vs. cravings for specific types of foods), if the questionnaire measures state or trait cravings, and the reference article

Questionnaire	Type of craving		Trait or state cravings		Reference
	General	Specific	Trait	State	
FCQ-T	x		x		Cepeda-Benito et al. (2000b)
FCQ-S	x			x	Cepeda-Benito et al. (2000b)
FCCQ-T		x	x		Rodriguez et al. (2007)
FCI		x	x		White et al. (2002)
FCI-J		x	x		Komatsu (2008)
QCSRF		x	x		Toll et al. (2008)
OCQ		x	x		Cartwright and Stritzke (2008)

Note. Abbreviations: *FCQ-T* Food Craving Questionnaire – Trait, *FCQ-S* Food Craving Questionnaire – State, *FCCQ-T* Food Chocolate Craving Questionnaire – Trait, *FCI* Food Craving Inventory, *FCI-J* Food Craving Inventory for Japanese, *QCSRF* Questionnaire on Craving for Sweet or Rich Foods, *OCQ* Orientation to Chocolate Questionnaire

however, inventories have been developed and validated to measure many aspects of cravings, including cravings for specific types of foods (White et al. 2002) and state and trait food cravings (Cepeda-Benito et al. 2000b). Furthermore, at least two of these instruments have been modified to measure food cravings in non-English speaking samples (Cepeda-Benito et al. 2000a; Komatsu 2008). The properties of existing self-report instruments to measure food cravings are reviewed here in the order in which the first version of the instrument was published. Additionally, Table 49.1 provides a summary of the characteristics of the inventories.

49.3.1 Food Craving Questionnaire – Trait (FCQ-T) and State (FCQ-S) Versions

The Food Craving Questionnaire has two forms to measure trait (FCQ-T) and state (FCQ-S) food cravings (Cepeda-Benito et al. 2000b). Ratings for the FCQ-T are made on a six-point scale, with "Never" scored as 1 and "Always" scored as 6. Ratings for the FCQ-S are made on a five-point scale, with "Strongly disagree" scored as 1 and "Strongly agree" scored as 5. The FCQ measures the phenomenological aspects of food cravings, and does not measure cravings for specific foods. The FCQ-T includes nine subscales used to measure trait cravings: intention and planning to consume food, positive reinforcement resulting from eating, negative reinforcement resulting from eating, lack of control of eating, preoccupation with foods, craving as a physiological state, emotions caused by cravings, environmentally induced cravings, and guilt-triggered cravings.

The FCQ-S measures state cravings or cravings that are occurring "at this moment." The FCQ-S has five subscales: desire to eat, positive reinforcement from eating, negative reinforcement from eating, lack of control of eating, and craving as a physiological state.

The subscales of the FCQ-T exhibit acceptable test-retest reliability coefficients (0.72–0.88). The FCQ-S has lower test-retest reliability coefficients (0.40–0.63), reflecting the expected instability of state cravings (Cepeda-Benito et al. 2000b). Both the FCQ-T and FCQ-S have adequate internal consistency (coefficient-alpha 0.81–0.94) and discriminant validity (Cepeda-Benito et al. 2000b). The validity of a Spanish language version of the FCQ has also been supported (Cepeda-Benito et al. 2000a).

49.3.2 Food Chocolate Craving Questionnaire-Trait (FCCQ-T)

The Food Chocolate Craving Questionnaire-Trait (FCCQ-T) (Rodriguez et al. 2007) is a modified version of the Food Craving Questionnaire-Trait (FCQ-T) (Cepeda-Benito et al. 2000b). The FCCQ-T utilizes nine subscales similar to the FCQ-T, but the questions within these subscales are specific to chocolate cravings. Both English (coefficient-alpha 0.76–0.92) and Spanish (coefficient-alpha 0.69–0.90) versions of the FCCQ-T have adequate internal consistency, a stable factor structure, and support for their construct validity (Rodriguez et al. 2007).

49.3.3 Food Craving Inventory (FCI)

The FCI measures cravings for specific types of foods by asking respondents to rate the frequency of cravings over the previous month for 28 food items (White et al. 2002). Ratings are made on a five-point scale ranging from "Never," scored as 1, to "Always/almost every day," scored as 5. Higher scores indicate more frequent food cravings. The FCI has four scales that constitute the higher-order construct of food craving, which is represented by the total score. The four scales are: sweets (e.g., brownies, ice cream), high fats (e.g., bacon, fried fish), carbohydrates/starches (e.g., baked potatoes, pasta), and fast-food fats (e.g., pizza, French fries). The FCI has acceptable internal consistency (coefficient-alpha 0.76–0.93) and test–retest reliability coefficients (0.79–0.91), and a stable factor structure (White et al. 2002). Lastly, a state version of the FCI is undergoing validation. This version of the FCI measures cravings for specific types of foods that are occurring "at this moment."

49.3.4 Food Craving Inventory for Japanese (FCI-J)

The FCI was modified to measure food cravings in Japanese females by removing food items unfamiliar to Japanese culture and adding items eaten in Japan. The resulting FCI-J (Komatsu 2008) was validated in samples of Japanese female undergraduate students, and the following five-factor model was supported: sweets, snacks, western foods, sushi, and rice (Komatsu 2008). Support was found for the reliability and validity of the FCI-J and it serves as a valuable tool to quantify culture-specific aspects of food cravings.

49.3.5 Questionnaire on Craving for Sweet or Rich Foods (QCSRF)

The QCSRF measures cravings for sweet or rich foods in smokers. The QCSRF has nine items and a two-factor structure (Toll et al. 2008). The first factor (Relief/Control) assesses the expectation that sweet or rich foods will alleviate negative affect and perceptions of self-control over eating. The second factor (Intensity) measures the intensity of cravings. Higher scores on the Relief/Control factor indicate greater endorsement that the food may relieve negative affect and lower self-control over eating. Higher scores on the Intensity factor indicate more intense cravings. Both factors of the QCSRF show adequate internal consistency (coefficient alpha = 0.87–0.90). The Intensity scale was positively correlated with weight gain from previous attempts to quit smoking (Toll et al. 2008).

49.3.6 *Orientation to Chocolate Questionnaire (OCQ)*

The OCQ is a 14-item self-report inventory that measures three dimensions of chocolate cravings: avoidance of chocolate, approach to chocolate, and guilt related to chocolate consumption. Agreement with each item is rated using a Likert scale (1 = "not at all" to 9 = "very strongly") (Cartwright and Stritzke 2008). When administered to young adults, the three dimensions of the OCQ were found to differentially correlate with frequency and quantity of chocolate consumption, supporting its concurrent validity (Cartwright and Stritzke 2008).

49.4 Food Craving Prevalence

The estimated prevalence of food cravings varies among studies and the discrepant estimates are likely due to the use of different definitions and methods to measure food cravings, as well as demographic differences among the study samples. Nevertheless, there is a consensus that food cravings are common, and occur in 58–97% of adults sampled from industrialized countries (Gendall et al. 1997; Weingarten and Elston 1991). More women report food cravings than men (Weingarten and Elston 1991), and food cravings and food intake increase during the luteal phase of the menstrual cycle (Dye and Blundell 1997; Johnson et al. 1994). The majority of pregnant women report food cravings, primarily for sweet foods (chocolate, fruit, fruit juice, etc.) (Bayley et al. 2002; Fairburn et al. 1992). People report approximately 3–4 food cravings per week (Hill and Heaton-Brown 1994; Hill et al. 1991), with the majority of food cravings occurring in the evening (Hill et al. 1991). Craved foods are frequently high in energy density and fat (Gilhooly et al. 2007), and the most frequently craved food in industrialized countries, particularly among women, is chocolate (Weingarten and Elston 1991). Indeed, the majority (90%) of people who report cravings crave chocolate; further, chocolate cravings comprise 49–60% of food cravings (Hill and Heaton-Brown 1994; Hill et al. 1991).

49.5 The Association Between Food Cravings, Hunger, and Food Intake

Conceptual differences exist between food cravings and hunger (Pelchat and Schaefer 2000), though the two constructs are associated with each other (Cepeda-Benito et al. 2000b; Steel et al. 2006; White et al. 2002). Food cravings are believed to precipitate eating behavior (Weingarten and Elston 1990) and frequently result in consumption of the craved food (Hill and Heaton-Brown 1994; Weingarten and Elston 1991). Among females diagnosed with bulimia nervosa, food cravings can also precipitate binge eating (Waters et al. 2001), which implies that a large amount of food can be ingested in response to food cravings. In other samples and in laboratory settings, however, it appears that food cravings do not always lead to the consumption of a large amount of food (Martin et al. 2008b), though additional research is needed to more thoroughly explore the amount of food eaten in response to food cravings in naturalistic settings.

   In the laboratory, cravings for specific types of foods were associated with consumption of similar foods (Martin et al. 2008b). In this study, the association was examined between the four scales of the FCI and consumption of M&M's® chocolate candies, jelly beans, regular (high-fat) potato chips, and low-fat potato chips. The sweets scale correlated significantly with intake of jelly beans and M&M's®, and the high fats scale correlated with intake of regular potato chips, but not low fat chips (Table 49.2).

Table 49.2 Pearson correlation coefficients between food craving (FCI scales) and consumption (g) of specific foods (Reprinted from Martin et al. (2008b, p. 325). Copyright 2008, with permission from Elsevier)

FCI scales	Grams consumed				
	Baked Lay's®	Jelly beans	Regular Lay's®	M&M's®	Total intake
High fats	−0.04	−0.03	0.27**	0.16	0.13
Sweets	0.01	0.20*	0.13	0.19*	0.20*
Carbohydrates	0.02	0.10	0.14	0.13	0.14

Total score	0.01	0.13	0.23*	0.23*	0.22*

Note. $*p < 0.05$, $**p < 0.01$ (1-tailed)

49.6 The Association Between Food Cravings and Body Mass

The association between food cravings and food intake suggests that food cravings might also be associated with body mass, and evidence suggests that this is the case. Food cravings are associated with body mass index among people diagnosed with type 2 diabetes (Delahanty et al. 2002). Further, obesity is associated with cravings for high fat foods (White et al. 2002), and obesity is associated with sweet cravings among people diagnosed with binge eating disorder (White and Grilo 2005).

Weight loss diets reduce food cravings, but no robust relations have been found between baseline levels of cravings or change in cravings and weight loss (Martin et al. 2006). People who lose more weight during a diet, however, do not indulge in cravings as frequently as those who lose less weight (Gilhooly et al. 2007). Despite the lack of scientific evidence suggesting that food cravings are associated with weight loss treatment outcome, participants most frequently reported food cravings as the reason for failing to adhere to a diet during controlled feeding studies (Hall and Most 2005). Therefore, clinicians are encouraged to explore peoples' beliefs and fears about food cravings before and during weight loss treatment. Research is also warranted to determine the temporal relation between food cravings and food intake or poor adherence to dietary recommendations. This research is possible with the use of ecological momentary assessment (EMA) methodology (Stone and Shiffman 1994), which utilizes communication technology (e.g., cell phones, Smartphones) to collect data from participants in real-time while they reside in their natural environment. EMA data can be used to identify the antecedents and consequences of behavior without relying on retrospective recall, which can introduce bias.

49.7 The Effect of Dietary Restraint, Food Restriction, and Dieting on Food Cravings

The effect of food restriction and dieting on food cravings is an important consideration in the etiology of cravings. Furthermore, anecdotal reports from clinical settings suggest that people frequently believe that food restriction during dieting will increase food cravings, and fear of increased food cravings can affect the likelihood of enrolling in a weight loss program. Research in this area has been complicated by a number of factors, such as the use of different methods to measure food cravings and induce food restriction, and studies appear to produce discrepant findings. The seemingly discrepant findings are not necessarily incompatible, however, as described in this section.

49.7.1 Dietary Restraint and Food Cravings

Dietary restraint is measured with self-report questionnaires and refers to the intent to restrict caloric intake, though people that report high levels of dietary restraint are not necessarily in energy deficit or losing weight (Stice et al. 2007). Dietary restraint has been found to be associated with the development of binge eating pathology (Field et al. 1999) and obesity onset (Stice et al. 2005), particularly among adolescent or college-aged female samples; therefore, dietary restraint is an important construct worthy of investigation.

Cross-sectional studies provide mixed support for an association between self-reported dietary restraint and food cravings. Some (Hill et al. 1991) but not all (Rodin et al. 1991) studies report a significant association between dietary restraint and food cravings.

49.7.2 Short-Term Food Restriction

The effect of short-term food restriction was examined in at least two studies that enrolled samples of college-aged females (Coelho et al. 2006; Polivy et al. 2005). In one study, restrained and unrestrained female participants were assigned to a chocolate deprivation, vanilla deprivation, or no deprivation condition for 1 week (Polivy et al. 2005). Deprivation had no effect on reported food cravings, but restrained participants in the chocolate deprivation condition ate more chocolate than restrained and unrestrained participants in the other groups (Polivy et al. 2005). In another study, female undergraduates were randomly assigned to a carbohydrate restriction, protein restriction, or no restriction control group for 3 days (Coelho et al. 2006). Carbohydrate restriction was associated with more carbohydrate cravings during the study and increased carbohydrate intake during a food intake test. Protein restriction was associated with more cravings for protein-rich foods, but was not associated with increased protein intake during the food intake test (Coelho et al. 2006).

These studies provide important data on short-term restriction of certain types of food and the study designs merit discussion. First, as previously noted, the studies measured changes in cravings that occurred over the short-term (days) in response to food restriction. Second, although neither energy balance nor weight change were measured, it is unlikely that participants would have experienced a significant energy deficit or weight loss if they followed the study instructions. These details and study strengths are important when considering the effects of dieting/weight loss on food cravings, as outlined in the following section.

49.7.3 Food Restriction During Diets Marked by Energy Deficit and Weight Loss

Food restriction and dieting, which is marked by energy deficit and weight loss, decreases food cravings (Harvey et al. 1993; Lappalainen et al. 1990; Martin et al. 2006, 2008a). However, some studies find that dieting increases (Pelchat and Schaefer 2000) or has no effect on food cravings (Gilhooly et al. 2007). More restrictive diets result in larger reductions in food cravings (Harvey et al. 1993; Lappalainen et al. 1990; Martin et al. 2006), as illustrated in Fig. 49.1, and food cravings remain suppressed even after a varied diet is restored following a restrictive monotonous diet (Fig. 49.2). Recent evidence also suggests that the macronutrient content of the diet affects changes in cravings
Fig. 49.1 Change in food cravings (estimated marginal means), measured with the Food Craving Inventory (FCI), from baseline (BL) to week 12 of a food-based low calorie diet (LCD) and very low calorie diet (VLCD) that relied on liquid shakes for the first 12 weeks. The VLCD group demonstrated significantly larger decreases on all craving scores compared to the LCD group ($p < 0.01$) (Reprinted from Martin et al. (2006, p. 119). Copyright 2006, with permission from Nature Publishing Group)

Fig. 49.2 Mean Food Craving Inventory (FCI) scores of VLCD participants who completed an FCI at baseline, VLCD Weeks 6 and 12, and Refeeding Week 6. By Refeeding Week 6, participants had transitioned off of liquid shakes and were consuming a solid food-based diet. All FCI scores decreased significantly between baseline and VLCD Week 6 and did not change significantly thereafter. Additionally, all FCI scores were significantly lower at all three dieting points than at baseline (Reprinted from Martin et al. (2006, p. 119). Copyright 2006, with permission from Nature Publishing Group)
for specific types of foods. Over 2 years, a low-fat diet reduced cravings for high-fat foods, while a low-carbohydrate diet reduced cravings and preferences for foods high in carbohydrate (Martin et al. 2008a). These results indicate that restricting consumption of certain types of foods results in decreased cravings and preferences for the restricted foods.

Although the effect of weight loss on food cravings might appear counterintuitive, it provides some support for the conditioning model of food craving etiology, as previously discussed. The effect of dieting on hunger levels should also be considered in interpreting these findings. Hunger is

unchanged or reduced during dieting (Rosen et al. 1982) and more restrictive diets result in larger decreases in hunger (Wadden et al. 1987). These results suggest that dieting has similar effects on food cravings and hunger, which is not necessarily surprising since hunger and food cravings are associated with each other (Cepeda-Benito et al. 2000b; Steel et al. 2006; White et al. 2002). Moreover, these findings can guide research to identify the mechanism by which food cravings decrease during dieting. For example, it has been hypothesized that change in hunger mediates the relation between dieting and change in food cravings (Martin et al. 2006), but this hypothesis has not been fully tested.

The studies reviewed in this section provide data on the course of food cravings (and hunger) during long-term (weeks to years) food restriction in the context of weight loss diets. It is unclear, however, if similar food craving reductions would be observed when certain types of foods are restricted and weight is maintained. Moreover, change in food cravings over the short-term (days) was not thoroughly assessed in the studies reviewed in this section. The studies reported by Polivy et al. (2005) and Coelho et al. (2006) suggest that short-term food restriction during energy balance might have very different effects on food cravings, and this is an area worthy of future investigation. Moreover, the possibility that change in hunger might mediate the relation between dieting and food craving change requires examination.

49.7.4 Reconciling the Empirical Findings

To summarize, there is mixed support for an association between self-reported dietary restraint and food cravings, and the effect on food cravings of short-term food restriction, which is not likely associated with an energy deficit or weight loss, is inconsistent. Longer-term food restriction that is accompanied by a significant energy deficit and weight loss is associated with a decrease in food cravings. Although these findings appear discrepant, they are not necessarily incompatible when the following issues are considered.

First, the dietary restraint studies, which inconsistently found an association between restraint and food cravings, were primarily cross-sectional and when an association was found the magnitude of the association was modest (Hill et al. 1991). Additionally people who report high levels of dietary restraint are not necessarily in energy deficit or losing weight (Stice et al. 2007). In some samples, dietary restraint is predictive of pathological eating behavior. Therefore, the investigation of food cravings and dietary restraint is warranted, but equating dietary restraint with dieting marked by weight loss is not supported by the research and, similarly, the results from studies on food cravings and dietary restraint will not necessarily be reflective of findings from studies where food cravings were assessed during weight loss.

Second, important differences exist between the studies on short-term food restriction and longer-term food restriction that is also accompanied by weight loss. Participants in the short-term food restriction studies were young college-age females who were presumably not actively losing weight during the study. These samples also appeared to be relatively lean or healthy weight, with a smaller proportion of the samples being overweight or obese. Importantly, these studies measured food cravings in the days following food restriction. The longer-term food restriction studies involved an energy deficit sufficient of promoting significant weight loss and relied on samples of predominantly middle-aged overweight/obese males and females. These studies are limited, however, because they rarely included assessment of craving change after only a few days of food restriction or energy deficit. Consequently, it is possible that food cravings remain stable or increase in the days following the onset of food restriction and energy deficit, and subsequently decrease.

Key Features of Food Cravings

- Food cravings are a common phenomenon whose etiology appears related to conditioning or pairing the consumption of certain foods with hunger, emotional states, physical locations, or activities.
- Dieting and weight loss reduce the frequency of food cravings and more restrictive diets result in larger reductions in food cravings. There is no compelling evidence for potential dieters to fear an increase in food cravings during a diet.
- Randomized controlled trials are warranted to test the efficacy of techniques to manage food cravings and quantify the independent effects of food and calorie restriction on food craving change.

Fig. 49.3 Key features of food cravings

Third, very few studies used the same instrument to measure food cravings, making comparisons among studies problematic. As outlined in this chapter, inventories are available that have good support for their factor structure and psychometric properties. Investigators are encouraged to rely on these or other instruments whose reliability and validity has been supported in future research. Moreover, the cited studies relied on mostly retrospective reports of craving (e.g., questionnaires filled out at weekly sessions). Ecological momentary assessment (EMA) studies should be conducted to more precisely evaluate the temporal course of food craving in the context of ad libitum and restricted food intake.

Although it is difficult to compare the results among some studies due to their differences, these differences demonstrate the importance of each type of study and the how the results can guide future research. For instance, it appears food restriction in the absence of an energy deficit or weight loss has a limited or inconsistent effect on food cravings, while the degree of calorie restriction during weight loss diets appears to be associated with the degree to which food cravings decrease. The findings indicate that future research is needed to quantify the extent to which cravings are affected by: (1) longer-term restriction of specific types of foods during weight maintenance and (2) restriction of specific types of foods during diets that vary in the size of the energy deficit or magnitude of weight loss. Our results suggest that both the degree of energy restriction (Martin et al. 2006) and the macronutrient content of the restricted foods (Martin et al. 2008a) have a direct impact on craving reductions, yet the relative contribution of each manipulation is unknown. Key features of food cravings are summarized in Fig. 49.3.

49.8 Neurobiology of Food Cravings

Exposure to visual and/or olfactory cues associated with preferred foods can elicit craving for those foods. Cues have been shown to drive appetitive behavior (Jansen 1998) and are used to great advantage by advertisers (Halford et al. 2008). Even non-food visual cues (e.g., fast food restaurant logos) can become associated with food reward and promote consumption (Robinson et al. 2007), demonstrating the role of conditioning in appetitive behavior. Recently, neuroimaging studies have demonstrated that exposure to food cues results in activation of a network of brain regions subserving attention, appetitive motivation, and reward (Killgore et al. 2003; LaBar et al. 2001; Simmons et al. 2005; Stoeckel et al. 2008; St-Onge et al. 2005; Wang et al. 2004). At a functional level, this network evaluates information about the potential reward value of environmental cues and initiates behavioral responses aimed at obtaining and consuming food. Specific nodes of this network include the

ventral striatum, which is involved in reward signaling, prefrontal cortex areas involved in the initiation and control of behavior, memory areas including the hippocampus, and regions involved in both stimulus driven and willful attention including the anterior cingulate cortex and fusiform gyrus. Interestingly, exposure to visual cues activates brain regions that are also activated by taste stimuli including the orbitorfrontal cortex and operculum-insula (Rolls 2006). Activation in these regions in response to visual cues (in the absence of taste cues) suggests that visual food information potentially modulates taste and other gustatory information processing.

The specific neural underpinnings of food craving are beginning to be elucidated. In a recent study, brain responses to chocolate taste and visual cues were examined in women who endorsed being cravers or noncravers of chocolate (Rolls and McCabe 2007). Compared to noncravers, cravers exhibited greater activation in response to the sight of chocolate in the orbitorfrontal cortex and ventral striatum, and greater activation to the combined taste and sight of chocolate in the anterior cingulate cortex. In addition to identifying neural correlates of specific food preferences, neuroimaging techniques have been used to examine brain activation during imagining craved foods versus imagining a monotonous diet among subjects who just completed a 2-day bout of a monotonous diet. Compared to individuals who maintained their normal diet, individuals on the monotonous diet exhibited greater activation while imagining liked foods in the hippocampus, insula, and the caudate nucleus (part of the dorsal striatum) (Pelchat et al. 2004).

The studies above provide a first look at the neurobiological basis of food craving. Neuroimaging studies suggest that food cravings appear idiosyncratic and distinct from the subjective experience of hunger. Thus, the findings of the above studies should be considered distinct from those that have examined brain responses to cues depicting foods generally agreed to be appetitive (e.g., donuts, hamburgers) since such foods may not be craved universally (Killgore et al. 2003; Stoeckel et al. 2008). For similar reasons they are distinct from studies which have evaluated the effects of food deprivation and/or overfeeding on brain responses to food cues (Cornier et al. 2007; LaBar et al. 2001; Siep et al. 2009) since these studies manipulate hunger, not necessarily craving.

The extant data thus suggest that exposure to imagined or actual craved foods increases activation in brain regions subserving reward, motivation, and memory. Additional work is necessary to evaluate whether dietary interventions change brain responses to craved foods and whether this modulation can be delineated from those caused by changes in hunger. Asked another way, does the neural circuitry that underlies food craving differ from that underlying hunger and do the two overlap? To the degree that food craving might represent a "liking" of food rather than "wanting," it could be hypothesized that food craving would elicit activation of reward regions (e.g., ventral striatum), whereas hunger would elicit activation of areas subserving compulsive responding (e.g., dorsal striatum). Regions involved in the selection, planning, initiation, and control of behaviors may serve as a final common pathway of both circuits. Additional studies that specifically manipulate both craving and hunger will be necessary to address this question.

49.9 Treatment of Food Cravings

Food cravings are frequently addressed or treated in the context of weight management programs, where techniques are used to reduce the frequency and severity of food cravings and to minimize subsequent food intake. This approach relies on cognitive-behavioral techniques, including distraction and confrontation (Brownell 2000). Patients are also trained to distinguish the difference between food cravings and hunger, and to identify situations or stimuli that elicit food cravings. Once these stimuli are identified, the antecedents and consequences of food cravings and subsequent

food intake can be evaluated and cognitive-behavioral techniques can be used to modify these contingencies. For example, if watching a movie in the evening is associated with a craving for popcorn, patients can prepare and be trained to use relaxation or distraction techniques during the movie to avoid eating popcorn until the food craving diminishes. Assuming the patient successfully avoids eating popcorn during movies, the association between movie watching and cravings will decrease over time. Stimulus control techniques can also be utilized, and stimuli that elicit food cravings can be avoided.

The relation between food cravings and hunger, and the theory that food cravings develop from pairing food intake with external or internal stimuli (e.g., hunger, physical locations, emotions) (Gibson and Desmond 1999; Rogers and Smit 2000) suggest that following a healthy meal plan (three meals per day with planned snacks) and managing hunger will reduce the frequency of food cravings. Other aspects of following a healthy meal plan are also hypothesized to reduce food cravings, such as eating in the same location in the absence of other stimuli, e.g., television or music. The finding that food cravings decrease during weight loss diets, during which participants follow a healthy meal plan (Martin et al. 2006, 2008a), supports this hypothesis, but the effect of meal regulation and hunger management in the absence of weight loss is unclear. Indeed, understanding the independent effects of energy deficit/weight loss and meal regulation/hunger management on food cravings would significantly improve our understanding of the etiology of food cravings and how to most effectively address them.

Acceptance-based approaches (Hayes et al. 1999) can also be used to cope with food cravings. This approach involves cognitive-behavioral principles, but it does not attempt to directly reduce the frequency of food cravings. Rather, the patient is trained to be mindful, and to experience and accept the phenomenon of food cravings with the recognition that the ability to control internal experience is limited.

To our knowledge, there are only two studies that empirically examined the efficacy of specific treatments to manage food cravings. First, an acceptance-based approach was found to help participants who were sensitive to food-rich environments manage food cravings and food intake (Forman et al. 2007). This study also found that cognitive strategies helped participants manage food cravings. Second, acute vagus nerve stimulation in depressed participants was found to change cravings for sweet foods, with approximately half the participants experiencing an increase, and half a decrease, in sweet cravings (Bodenlos et al. 2007).

In reviewing the literature on food cravings, directions for future research are apparent. These directions for future research are outlined in Fig. 49.4.

Directions for future research.

- Further research into the role of conditioning in the etiology and maintenance of food cravings
- Examination of the duration of food cravings that do and do not lead to food intake
- Determination of the amount of food typically consumed in response to food cravings
- Examination of the temporal relation between food cravings and food intake, as well as the antecedents and consequences of food cravings and intake using ecologically valid methodology, such as Ecological Momentary Assessment
- Clarification of the course of food cravings during short- and long-term food restriction while people are in energy balance
- Examination of short-term changes in food cravings during food restriction accompanied by an energy deficit and weight loss
- Examination of differential brain activation associated with hunger and food cravings
- Evaluation of the efficacy of treatments for food cravings in the context of weight loss

Fig. 49.4 Directions for future research

49.10 Applications to Other Areas of Health and Disease

Food cravings are an important construct for patients and clinicians involved in weight management and the treatment of conditions associated with weight gain or obesity (e.g., cardiovascular disease, type 2 diabetes, and hypertension). The food craving literature is also relevant to other conditions, such as renal insufficiency, that require modification and management of the amounts and types of foods eaten. Finally, the role of food cravings in the etiology of overeating or binge eating in certain subsamples is worthy of further investigation.

Summary Points

- In industrialized countries, 58–97% of the population report food cravings (Gendall et al. 1997; Weingarten and Elston 1991).
- Chocolate is the most frequently craved food, particularly among women (Weingarten and Elston 1991).
- Several self-report instruments with acceptable psychometric properties are available to quantify food cravings.
- Overweight and obesity are associated with cravings for high fat foods in individuals with type 2 diabetes (Delahanty et al. 2002) and cravings for sweets in individuals diagnosed with binge eating disorder (White and Grilo 2005).
- In laboratory settings, food cravings are associated with the consumption of similar foods (Martin et al. 2008b).
- Food restriction accompanied by an energy deficit and weight loss reduces food cravings, and more restrictive diets result in larger decreases in food cravings (Harvey et al. 1993; Lappalainen et al. 1990; Martin et al. 2006, 2008a).
- Neuroimaging studies indicate that exposure to imagined or actual craved foods increases activation in brain regions subserving reward, motivation, and memory (Killgore et al. 2003; Simmons et al. 2005; Wang et al. 2004; St-Onge et al. 2005; LaBar et al. 2001; Stoeckel et al. 2008).

Key Terms

Food craving: a desire to consume a specific food or beverage that is difficult to ignore or satisfy with consumption of an alternative food or beverage.

Energy deficit: a state of negative energy balance, where energy expenditure exceeds energy intake.

Dietary restraint: the intent to limit food intake; dietary restraint is not necessarily synonymous with calorie restriction or an energy deficit.

Food restriction: limiting the intake of specific types of foods; food restriction can occur in the presence or the absence of an energy deficit.

Neuroimaging: indirectly or directly measuring the structure and activation of the brain.

Chapter 50
Non-sensory Factors Which Influence Choice Behavior of Foods That Have a Positive Effect on Health

Gastón Ares

50.1 Introduction

Major changes in dietary patterns have occurred during the last decade, mainly due to the acceleration of industrialization, urbanization, economic development, and market globalization (World Health Organization 2003). These changes have led to a replacement of plant-based diets by high fat energy dense diets with an important contribution from animal-based foods, which have caused an increase in the energy density of the diet, with a greater consumption of fat and added sugars in foods, an increase in saturated fat intake, a reduction of the intake of complex carbohydrates and dietary fiber, and a decrease in the consumption of fruits and vegetables (World Health Organization 2002). Such dietary changes, together with a shift in lifestyle toward more sedentary patterns, have had a significant impact on the health and nutritional status of populations and have led to an increase of the occurrence of chronic diseases, causes of disability, and premature death in both developed and developing countries (World Health Organization 2003). These chronic diseases include obesity, diabetes mellitus, cardiovascular disease, hypertension, stroke, and some types of cancer. According to the World Health Organization, in 2001 chronic diseases contributed to approximately 60% of the 56.5 million total reported deaths in the world, and it has been projected that chronic diseases will account for three-quarters of all deaths in 2020 (World Health Organization 2002).

Diet has been identified as one of the main factors that can contribute to the prevention of chronic diseases (World Health Organization 2003). Research has shown that there are certain food components, regarded as nonnutrients, which have biological activities on our body. The consumption of these compounds might be responsible for the beneficial effects connected to some foods and diets, and could help preventing the occurrence of some chronic diseases. These nonnutritive components, which are mainly secondary plant metabolites and dietary fiber, are mostly present in some foods in small quantities and have only limited caloric value. Therefore, the development of foods enriched with these nonnutrients can constitute a way to cope with the chronic disease epidemic.

In this context, the concept of functional foods was developed in Japan in the 1980s and launched in the USA and Europe since the mid-1990s (Menrad 2003). Several definitions have been used but there is consensus on the fact that functional foods can be regarded as foods that beneficially affect

one or more target functions in the body beyond adequate nutritional effects, in a way that is relevant to either an improved state of health and wellbeing or a reduction of risk of disease (Margaret 2002).

Persuading people to make healthier food choices and to consume functional foods could provide important public health effects, such as decreased mortality and increased quality of life (Siró et al. 2008). The success of functional foods depends on consumers' acceptance of these products as part of their daily diet. Therefore, one key aspect to support the development of functional foods is to better understand consumers' perception of this type of food product and to identify the determinants of consumers' acceptance of functional foods (van Kleef et al. 2002).

Consumers do not perceive functional foods as specific products, different from their conventional counterparts (Urala and Lähteenmäki 2003). On the other hand, consumers perceive them as member of the particular food category to which they belong (Urala and Lähteenmäki 2003; Siró et al. 2008). Thus, when shopping for a functional food product within a certain food category, consumers have to choose between functional and conventional foods. For this reason, a large number of factors affect consumers' choice behavior of functional foods. In the present chapter these factors are reviewed, stressing the importance of non-sensory factors.

50.2 Factors Affecting Consumers' Choice Behavior of Functional Foods

Food choice is a very complex process which involves many different interrelating factors. The key facts about food choice behavior are summarized in Table 50.1.

Different food choice models have been developed to understand food choice behavior and to illustrate the factors that influence this process (Sheperd and Sparks 1994). In general, variables influencing food choice could be divided into three main categories: those related to the food, to the person making the choice and to the external economic and social environment within which the choice is made. Figure 50.1 shows an overview of some of the factors that have been extensively reported to be determinants of consumers' food choice behavior.

As has been mentioned before, consumers perceive functional foods as regular food products, similar to their conventional counterparts. Therefore, consumers' choice of this type of product is influenced by the same characteristics, including sensory quality, price, and convenience, as any conventional product. Thus, factors affecting consumers' choice behavior of functional foods could also be divided into the abovementioned categories. Non-sensory factors are the main determinants of consumers' interest in purchasing functional foods. Key features about non-sensory factors affecting consumers' food choice behavior are summarized in Table 50.2. Although the sensory characteristics also play a key role in consumers' interest in functional foods, they are the main determinants

Table 50.1 Key facts of consumers' food choice behaviour. This table lists the key facts of food choice behavior, including its characteristics and the main factors that affect it

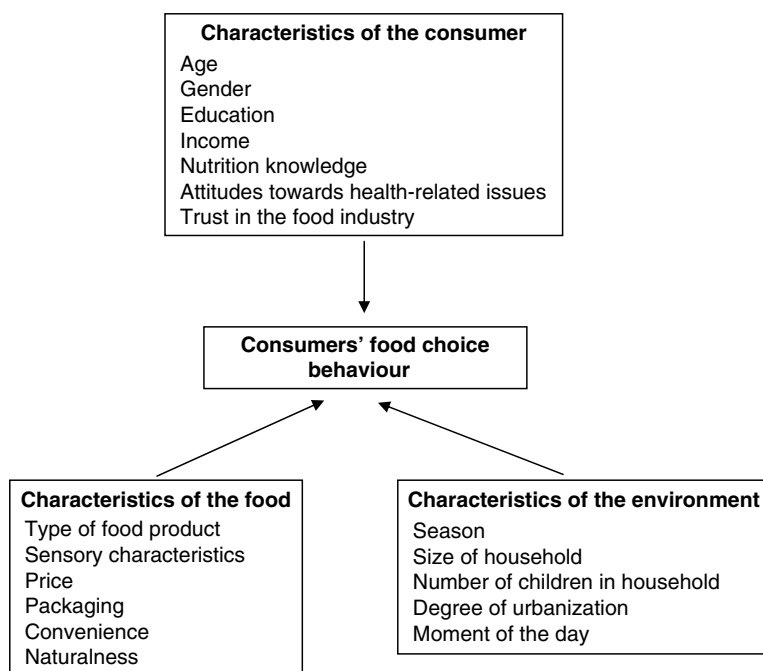
Key facts of food choice behavior
• Food choice behavior could be regarded as consumers' choices regarding the foods they eat everyday.
• Understanding consumers' food choice behavior is important for functional foods development and marketing, and may contribute to the improvement of health by positively influencing food habits.
• Food choice behavior is a complex process, which is affected by many interrelating factors including sensory and non-sensory characteristics.
• Factors affecting consumers' food choice behavior could be grouped in the characteristics of the food, the characteristics of the consumer and finally factors related to the environment in which the consumers make their choices.


Fig. 50.1 Factors affecting consumers' food choice behavior. This figure shows the main factors that have been reported to affect consumers' food choice behavior. These factors could be grouped in those related to the food, those related to the consumer making the choice, and those related to the environment in which the choice is made

Table 50.2   Key facts of non-sensory factors affecting consumers' food choice behaviour. This table lists the key facts of non-sensory factors affecting consumers' food choice behavior

Key facts of non-sensory factors affecting food choice behavior
• Although sensory characteristics of food products have been claimed the most important variables affecting consumers' food choices, non-sensory variables also play a key role.
• Non-sensory factors affecting consumers' food choices could basically be regarded as all the variables that are not related to the sensory characteristics of the product.
• Non-sensory variables include product characteristics such as brand, price, and convenience; characteristics of the consumer, and characteristics of the environment in which consumers decide their choices.
• Non-sensory factors have been reported to be the most important determinants of consumers' interest in functional foods.

of consumers' decision to repeat the purchase of a certain functional food after they have tried it. On the other hand, consumers might be driven by their interest in improving their health status when purchasing a functional food for the first time.

According to several authors, the characteristics of the consumer are the most important in determining attitudes toward functional foods, followed by those related to the food (Lähteenmäki 2003; Verbeke 2005; Urala and Lähteenmäki 2007; Verbeke 2006; Herath et al. 2008; Siró et al. 2008). The key factors affecting consumers' choice behavior of functional foods are listed in Table 50.3. In particular, socio-demographic background, personal motivations, and attitudes toward health-related issues are the key determinants of consumers' acceptance of functional foods (Siró et al. 2008).

Table 50.3 Key features affecting consumers' choice behavior of functional foods. This table lists the key variables that have been reported to affect consumers' choice behavior of functional foods, i.e., consumers' choice of foods that have a positive influence on health

Type of characteristics	Features
Characteristics of the person	– Socio-demographic characteristics (gender, age, educational level, socio-economic class, number of children in household) – Interest in health-related issues – Nutritional knowledge
Characteristics of the product	– Type of product (base product and functional ingredient) – Sensory characteristics – Health claim – Brand – Price

50.3 Characteristics of the Consumer

50.3.1 Socio-demographic Variables

Although the explanatory power of socio-demographic variables in explaining consumers' food behavior has been decreasing (Dagevos 2005), their role in functional foods acceptance cannot be ignored. Socio-demographic variables have been reported to have a great influence on consumer acceptance of functional foods; being gender, age, education, and socioeconomic class the characteristics with the highest influence. Despite the fact that clear gender and age differences have been identified, there is no consensus on how other socio-demographic variables affect functional foods acceptance.

Table 50.4 summarizes the influence of socio-demographic variables in functional food acceptance. As shown, according to most studies, consumers of typical functional foods have been identified as females, well educated, higher socio-economic class, and older than 55 years.

Females have been reported to be more familiar with functional foods, and to more frequently consume these food products than men (Childs and Poryzees 1998; Bogue and Ryan 2000; Herath et al. 2008; Verbeke 2005, 2006; Labrecque et al. 2006; Siró et al. 2008). This has been related to the fact that women are usually more interested in health-related issues (Roininen et al. 1999; Beardsworth et al. 2002). The higher interest of females toward functional foods has important implications considering that they are frequently the person responsible for food selection and shopping in the household and therefore they could affect other peoples' eating patterns (Siró et al. 2008). Thus, women's interest in functional foods could lead to the adoption of this food category by other people in their household, particularly children.

Regarding age, as shown in Table 50.4, middle-aged and elderly people are usually more aware of health-related issues because they are more likely to be diagnosed with a lifestyle-related disease than younger consumers (Verbeke 2006), which may explain the reported higher intention to purchase functional foods (Poulsen 1999; Herath et al. 2008). Moreover, older consumers seem to show different attitudes toward type of functionality than younger ones, preferring functional foods that have short-term effects on health rather than the prevention of diseases. According to Bogue and Ryan (2000) older Irish people were more interested in functional foods that reduce the risk of cancer, while younger consumers were more interested in foods that increase their energy level. Furthermore, Ares et al. (2008a) reported that Uruguayan consumers' interest in preventing cardiovascular diseases seemed to lower with age, whereas interest in lowering cholesterol and blood pressure increased with age. Therefore, age not only influences interest in functional foods but also what types of functional foods consumers are interested in.

Table 50.4 Influence of socio-demographic characteristics on consumers' interest in functional foods. This table summarizes how socio-demographic characteristics such as gender, age, education, and socio-economic class have been reported to affect consumers' interest in functional foods. The table lists the most positive group toward functional foods for each socio-demographic characteristic, together with the source from which the information was extracted.

Socio-demographic characteristic	Group more interested in functional foods	Source
Gender	Females	Childs and Poryzees (1998)
		Poulsen (1999)
		Bogue and Ryan (2000)
		Beardsworth et al. (2002)
Age	Older than 35	Childs and Poryzees (1998)
	Between 34 and 54 years old	Herath et al. (2008)
	Older than 55	Poulsen (1999)
		Anttolainen et al. (2001)
Education	Well educated	Childs (1997)
	Higher-educated	Anttolainen et al. (2001)
	Less formal educated	Herath et al. (2008)
Socio-economic class	Higher income	de Jong et al. (2003)
	Higher socio-economic class	Hilliam (1996)
	Lower income	Herath et al. (2008)

As shown in Table 50.4, several authors have reported that higher income and higher education contribute to consumers' willingness to consume functional foods; which has been attributed to higher awareness about this type of foods and to a higher ability to pay a premium price for them. On the other hand, Herath et al. (2008) reported that Canadian consumers more receptive toward functional foods tend to have received less formal education and be in lower income households, which have been attributed to the fact that they might face more health problems and they could not have a healthy diet through the foods they usually afford to consume.

It is important to remark that the influence of socio-demographic variables could not be analyzed without taking into account the type of functional food and its health claim, since there are clear differences in the influence of socio-demographic variables between different functional food products (Poulsen 1999; de Jong et al. 2003).

50.3.2 Attitudes Toward Health

Consumers can only be expected to choose functional foods over conventional ones if the former are perceived as healthier. Consumers must be interested in achieving or preserving a good health status, and they must think of functional foods as important in helping them staying healthy (Krystallis et al. 2008). Besides, consumers have to be informed about their beneficial health effect, they must trust in the health claim, perceive it as safe, and they must have a perceived need for using the product (Lähteenmäki 2003). Therefore, attitudes toward health are central in determining consumers' acceptance of functional foods.

In general, consumers think they are responsible for their own health status (Ares et al. 2008a,b,c) and are aware of the relationship between diet and health. This suggests that, generally speaking, consumers are aware of the fact that certain foods could have a positive influence on their health. However, according to Verbeke (2005) consumers' perception of the role of diet on health did not affect functional foods acceptance.

Apart from being aware of the influence of their food choices on health, consumers need to be interested in improving their wellbeing, staying healthy, and preventing disease. Several studies have

reported that consumers more interested in preserving their health condition or preventing disease have a more positive attitude toward functional foods (Ares et al. 2008c, 2010).

Thus, in order to consume functional foods, consumers should think that these food products will have a relevant positive effect on their health status. Perceived reward was reported to be the strongest single predictor for willingness to use functional foods by Urala and Lähteenmäki (2007), whereas Cox et al. (2004) found that self-efficacy was the best predictor of the intention to consume a functional food with a stated memory improvement claim. Furthermore, Herath et al. (2008) stated that a key driver of functional foods acceptance is perceived disease threat. According to several authors, the interest in functional foods is affected by the health condition of the consumers and their family (van Kleef et al. 2005; Verbeke 2005). Personal experiences with illness and the existence of a family member with a specific health problem increase the probability of accepting functional foods. Verbeke (2005) reported that the existence of a family member with a health problem increased the acceptance of functional foods by Belgian consumers.

However, although consumers' interest in health-related issues is central in determining their choice behavior of functional foods, it is not enough to support the consumption of functional foods (Krystallis et al. 2008). For example, de Jong et al. (2004) reported that only 11% of the consumers with high cholesterol levels reported being users of cholesterol-lowering spreads.

50.3.3 Influence of Nutritional Knowledge

According to Labrecque et al. (2006) high knowledge on the health benefits of functional foods is also relevant for the acceptance of these products, together with health and product-related benefits, beliefs, and credibility of information.

Nutritional knowledge has been claimed to have a great influence on dietary behavior (Patterson et al. 1995; Wardle et al. 2000). Several studies have reported that increasing nutritional knowledge is associated with higher intake of fruits and vegetables (Wardle et al. 2000; Patterson et al. 1995). However, according to several authors the influence of nutritional knowledge on food preferences and selection is rather small (Räsänen et al. 2003). Crites and Aikman (2005) suggested that increasing nutrition knowledge makes health a more important determinant of attitudes but that overall attitudes and behavior change less due to the fact that other evaluative bases are not affected by nutritional knowledge.

However, nutritional knowledge has been reported to affect consumers' choice behavior of functional foods. Ares et al. (2008b) reported that nutritional knowledge significantly affected consumers' perceived healthiness and willingness to try functional foods concepts which consisted of combinations of base products and nutritional modifications. According to these authors, consumers with low nutritional knowledge were not interested in the addition of fiber or antioxidants to healthy products such as bread, yogurt, or milk desserts, decreasing their willingness to buy scores. On the other hand, consumers with high nutritional knowledge increased their willingness to purchase scores, and were interested in functional foods which consisted of healthy products enriched with fiber and antioxidants.

Moreover, Wansink et al. (2005) reported that consumers who had both attribute-related knowledge and consequence-related knowledge of functional foods were more willing to consume these products than those who had only one type of information. As shown in Table 50.5, whereas only 11% of the consumers who had no knowledge about soy consumed this product, 68% of consumers who had both knowledge about the healthy characteristics of soy and their consequences on health, consumed it. Thus, in order to accept functional foods, consumers should know that the food contains

Table 50.5 Influence of nutritional knowledge on soy consumption (Wansink et al. 2005). This table summarizes results reported by Wansink et al. (2005) about the relationship of nutritional knowledge and soy consumption. Consumers were segmented according to their type of knowledge about soy in four groups: those who had no knowledge about soy (comprising 143 consumers), those who had knowledge about the attributes of soy (composed of 277 consumers); those who had knowledge about the consequences on health of soy consumption (composed of 122 consumers), and those who had knowledge about both soy attributes and the consequences on health of soy consumption (comprising 63 consumers). For each of these segments percentage of consumers who consume soy is reported. As shown, soy consumption was higher for the group who had both attribute and consequence knowledge

Type of knowledge	Percentage of consumers who consume soy (%)
No knowledge of soy ($n = 143$)	11
Attribute knowledge only ($n = 277$)	15
Consequence knowledge only ($n = 122$)	24
Attribute and consequence knowledge ($n = 63$)	68
Fig. 50.2 Percentage of consumers aware of the health effect of different functional ingredients (Bech-Larsen et al. 2001). This figure shows the percentage of consumers who are aware of the health effect derived from the consumption of different ingredients commonly used in functional foods formulation, in three different countries: USA, Finland, and Denmark, as reported by Bech-Larsen et al. (2001)

a certain functional ingredient and which are the consequences related to the consumption of that particular functional ingredient.

Furthermore, consumers have a limited knowledge of the health effects of functional ingredients. As shown in Fig. 50.2, a low percentage of consumers is aware of the health effect of several functional ingredients. For example, only 6–14% of the consumers in Denmark, Finland, and USA is aware of the health effect of flavonoids and oligosaccharides, whereas between 20% and 40% of the consumers is aware of the health effects of other widely spread functional ingredients such as omega-3 and antioxidants. Therefore, there is a strong need for information and communication activities to consumers in order to encourage functional foods consumption (Menrad 2003). Therefore, the use of health claims might be necessary for assuring that consumers are aware of the health benefits of the product and therefore consider substituting conventional foods by their functional alternatives.

50.3.4   Trust in Functional Foods

Trust in functional foods also plays an important role since consumers do not directly and immediately experience the health benefits of these products (Siegrist et al. 2008; Verbeke 2005). Consumers

have to trust in the claimed health benefits of functional foods in order to consume them. For example, Niva et al. (2003) reported that trust was determinant of the frequency of use of cholesterol-lowering spread. According to these authors 32% of Finish consumers were doubtful about functional foods. Moreover, Labrecque et al. (2006) reported that credibility of information about functional foods was an important determinant of the acceptance of functional foods.

Trust in the food industry also affects consumers' acceptance of functional foods. As reported by Siegrist et al. (2008), consumers who trust in the food industry are more likely to buy functional foods compared to those who do not trust in it.

Moreover, the production of functional foods requires the use of novel technologies in order to incorporate functional ingredients. Therefore, consumers might perceive this type of products as less natural than their conventional counterparts and therefore might not be chosen by consumers who perceive naturalness as an important attribute underlying their food choices. According to Jonas and Beckman (1998) Danes consumers perceived functional foods as unnatural and impure, which decreased their interest and willingness to buy these food products.

According to Urala and Lähteenmäki (2007) consumers' confidence in functional foods is related to both trust in the health claims and to perceived safety. A segment of consumers might be suspicious about the possible harmful effects of functional foods. Besides, O' Connor and White (2010) reported that risk associated with functional foods was also a determinant of consumers' willingness to use this type of product.

Therefore, functional food consumers might be those who are interested in taking care of their health status, who receive, understand, and trust the 'message' of functional foods and who feel in control of their health condition.

50.4 Characteristics of the Product

50.4.1 Type of Functional Food

Functional foods can basically be regarded as a carrier product enriched with a functional ingredient with a positive effect on health. Consumers' acceptance of functional foods depends on the carrier product, the consumer, and the health claim attached to it (Lähteenmäki 2003).

The perceived healthiness of the base product has a great influence on consumers' perception of functional foods. Carrier products with a healthy image have been reported to be more attractive than carriers with an unhealthy image (van Kleef et al. 2005; Ares et al. 2008a; Siegrist et al. 2008). Consumers' attitudes toward functional foods are more positive when intrinsically healthy products, such as yogurt, cereals, bread, and juice are considered (Siró et al. 2008). However, the opposite trend has been reported by Bech-Larsen et al. (2001). These authors stated that consumers considered the enrichment of "non healthy" foods more justified than enrichment of foods which are perceived as healthy per se.

Consumers' perception of the functional ingredient is also important in determining functional foods acceptance. Familiar functional ingredients (e.g., vitamins, fiber, minerals) are usually preferred to novel functional ingredients (e.g., polyphenols, selenium, flavonoids) due to the fact that consumers are not aware of the health benefits of the latter group of ingredients (Bech-Larsen et al. 2001; Siró et al. 2008). Regarding the health effect of the functional ingredient, van Kleef et al. (2005) and Siegrist et al. (2008) reported that consumers rated physiological health claims as more

attractive than psychological health claims; whereas van Trijp and van der Lans (2007) reported that yogurts with the added benefits of reducing the negative impact of stress or improving concentration had lower consumer appeal than products strengthening the body's natural defense system. However, consumers do not perceive functional ingredients independently from the carrier product (van Trijp and van der Lans 2007; Siegrist et al. 2008). Poulsen (1999) stated that consumers prefer functional ingredients that are already contained in the base product.

Moreover, van Kleef et al. (2005) explored carrier product and health claim compatibility for 100 hypothetical products. In their study they did not find a significant interaction between health claim and carrier. This result implies considerable flexibility in the design of functional foods, since the attractiveness of the health claim is not affected by the carrier.

Therefore, consumers' prior thoughts about the healthiness of the base product and the functional ingredient are key determinants of their attitudes toward functional foods and sometimes might override the influence of health claims (Siró et al. 2008).

50.4.2   Influence of Information

Functional foods are usually characterized using different types of claims. There are basically three types of health claims, as shown in Table 50.6 (ILSI Europe 1999). Considering the low level of awareness of the health effect of functional ingredients, food companies usually use "enhanced function" or "reduced disease risk" health claims to efficiently communicate the health effect of functional foods to consumers. The extent to which consumers find health claims appealing and trusty depends on the content and format of the message (Mazis and Raymond 1997).

Basically, message of health effects could be formulated to provide a potential benefit (e.g., "enhanced function") or to prevent a negative situation (e.g., "reduced disease risk"). The use of one type of claim depends on which has the greater persuasive impact on consumers (van Kleef et al. 2005). According to Krishnamurthy et al. (2001), in the context of attribute framing, people react more positively to positive than negative messages. Therefore, it has been stated that health claims that emphasize the positive influence of functional foods are preferred over health claims that emphasize the prevention of diseases (Krishnamurthy et al. 2001). In this context, enhanced function claims might be more appealing to consumers than reduced disease risk claims, because the former evoke positive associations from memory (van Kleef et al. 2005). 'Reduced disease risk' might confront consumers with illness and problems they might suffer in the future. However, little research has been carried out on this topic and results in literature regarding the effect of claims are rather contradictory. While van Kleef et al. (2005) reported that Dutch consumers reacted more favorably to

Table 50.6 Type and description of claims used in functional foods. This table lists and describes the different types of claims that are used on the labels of functional foods to assure that consumers are aware of the presence of the functional ingredient and of the relationship between the consumption of that ingredient and its positive effect on health

Type of claim	Description
Nutrient content	Characterize the level of a nutrient in a food (e.g., high in fiber)
Enhanced function	Relationship between the consumption of a food or food ingredient that contributes beneficially to one or more target functions in the body (e.g., reduce cholesterol level)
Reduced disease risk	Relationship between the consumption of a food or food ingredient and reduction of the risk of a specific disease or an undesirable health condition (e.g., reduce the risk of cancer)

"disease reduced risk" claims than to "enhanced function" framed health claims; Bech-Larsen et al. (2001) reported the opposite trend. van Kleef et al. (2005) have reported that consumers preferred health claims that stress the prevention of physiologically based illnesses. This could be explained considering that in many cases negative information is more informative, attracts more attention, and stimulates deeper processing than positive information.

50.4.3 Influence of Brand and Price on Consumers' Acceptance of Functional Foods

Today's consumers have to trade several factors against each other in order to select which food they buy or eat. In the case of functional foods, consumers might have to trade health, sensory, and other non-sensory factors, such as brand, price, and convenience, when deciding to buy a certain functional food. Research about consumer perception of functional foods has been focused on their health and sensory characteristics. However, the influence of non-sensory factors such as brand and price, on consumer perception of functional foods has not received much attention.

The importance of brand in consumers' perception of food products has been extensively reported (Jaeger 2006). According to Keller (1998) brand consists of a promise, a guarantee or contract with the manufacturer and a symbolic means and sign of quality.

On the other hand, price could influence consumer purchase intention in two different ways: it could lower purchase intention due to a greater monetary sacrifice, or it could have a positive impact on purchase impact because of an increase in perceived product quality (Jaeger 2006). Functional foods might be more expensive than their conventional counterparts and might affect consumers' acceptance. According to several authors there is a group of consumers who are not affected by a price increase, and are willing to pay premium price for functional foods (Poulsen 1999; Bogue and Ryan 2000). However, consumers seem to be only willing to accept limited price increase for functional foods (Menrad 2003), such as 30–50% when compared to their conventional counterparts (Siró et al. 2008). Thus, price increase should be taken into account for encouraging functional foods consumption.

According to a study carried out by Ares et al. (2010), brand is a key attribute influencing consumers' choice behavior of functional yogurts. In this study, consumers were asked to choose among different yogurt concepts differing in functionality (regular yogurt, enriched with fiber and antioxidants), brand (national familiar, national unfamiliar, and foreign familiar), price (low, regular, and high), and health claims (with and without "reduced disease risk" health claim). Results showed that non-sensory product factors, such as brand and price, have an important impact on consumer decision to buy functional foods. As shown in Table 50.7, the importance attributed to brand was similar to that of the type of yogurt when deciding which type of yogurt they would buy, regardless of consumers' interest in health-related issues. Price showed a relative importance close to 20%, suggesting that it could also affect consumer decisions regarding the purchase and consumption of functional foods. There was a small tendency that consumers more interested in health issues were less sensitive to an increase in price (Table 50.7). Results suggested that consumer choice of functional yogurts might be highly affected by their brand since, the influence of type of yogurt was similar to the influence of brand for both clusters. Therefore, the development of functional foods could be regarded as an alternative for small companies to differentiate their products and make them more attractive for consumers. However, considering the influence of brand, large food companies have more chances to develop functional foods that are appealing for consumers.

Table 50.7 Relative importance of different non-sensory factors in consumers' choice behavior of functional yogurts, for consumers with high and low interest in health-related issues (Ares et al. 2009). This table summarizes results reported by Ares et al. (2009) about the influence of different non-sensory factors on consumers' choice of functional and regular yogurts. Consumers were segmented into two groups according to their interest in health-related issues: 55 consumers with high interest in health-related issues and 48 consumers with low interest. Consumers had to choose between regular and functional yogurt concepts differing in brand, price, and the presence of health claims. From consumers' choices, the relative importance of each of the evaluated non-sensory variables was calculated for each consumer segment. As shown, brand and type of yogurt had the highest relative importance, regardless of consumers' interest in health-related issues

Consumer segment	Relative importance (%)			
	Type of yogurt	Brand	Price	Health claim
High interest in health-related issues ($n = 55$)	38.3	37.3	17.8	6.6
Low interest in health-related issues ($n = 48$)	37.3	28.9	24.1	8.0

50.5 Other Non-sensory Characteristics

Apart from brand and price, there are other non-sensory factors related to the product which could influence consumers' choice behavior of functional foods. However, these factors, which include convenience and packaging, have not been much studied.

Convenience can be regarded as measure of a food product's ease of preparation. Considering consumers' time constraint in today's world, convenience has become an important non-sensory factor influencing consumers' food choice (Jaeger 2006). According to Urala and Lähteenmäki (2003), convenience is also an important factor in determining consumers' choice of functional foods. Consumers would probably not be willing to compromise convenience for health-related issues and therefore functional foods should be developed maintaining the convenience of their conventional counterparts.

Packaging plays a major role in attracting consumer attention and influencing consumer purchase decisions. In the current self-service economy, packaging provides food companies the last chance to persuade consumers to buy the product before brand selection. Therefore, packaging might consist on a relevant factor for affecting consumers' purchase decisions of functional foods. However, no studies have been found reporting the influence of this non-sensory attribute in functional foods acceptance.

50.6 Influence of Sensory Characteristics

Despite the aim of the present chapter was to review the influence of non-sensory variables on consumer perception of functional foods, the importance of sensory characteristics could not be left unmentioned. In order to gain the health benefits derive from functional foods consumption, consumers need to include them as part of their usual diet for a relatively long period of time, and consequently the sensory properties of functional foods should not discourage sustained consumption. Negative changes in the sensory characteristics of foods due to the addition of functional ingredients might cause potential aversive consumer reactions (Siró et al. 2008). The addition of many functional ingredients results in the appearance of off flavors that decreases the sensory quality of the product. Several authors have reported consumers are hardly willing to consume functional foods they do not like (Tuorila and Cardello 2002; Cox et al.; 2004; Verbeke 2006). These findings suggest that consumers expect functional foods to have good sensory properties that provide them hedonic pleasure, apart from having a positive influence on their health, being not willing to compromise on the taste of functional foods for eventual health benefits. Thus, the development of functional foods

with bad sensory characteristics is a risky option since consumers might not be willing to repeatedly consume them (Verbeke 2006).

50.7 Applications to Other Areas of Health and Disease

Understanding consumers' choice behavior of functional foods could provide valuable information for improving their acceptance of this type of food product. Knowing what consumers take into account when deciding to buy or to reject a certain functional food product could lead to the design of products that successfully address consumers unfulfilled needs and could avoid the development of products that are destined to fail in the market. Moreover, information about what consumers take into account when selecting functional food products could be useful in the design of marketing strategies to encourage their consumption. This could increase consumers' awareness and interest in functional foods, improving the health status of the population and helping chronic disease prevention.

Summary Points

- Consumers do not perceive foods with a positive effect on health (i.e., functional foods) as a separate food category, different from their conventional counterparts.
- Consumer willingness to purchase functional foods is not unconditional, being influenced by several sensory and non-sensory factors.
- Health-related issues are central in determining consumers' acceptance of functional foods.
- Consumers' awareness of the health effect of different functional ingredients is limited, which indicates the necessity of using health claims to appropriately communicate these benefits to consumers and encourage functional foods consumption.
- Product characteristics such as brand, price, packaging, and convenience should be taken into account when developing functional foods since they play an important role in consumers' perception.
- Despite the influence of non-sensory characteristics, sensory characteristics of functional foods should be considered since consumers are hardly willing to compromise on the taste of functional foods for eventual health benefits.

Definitions and Explanations of Key Terms or Words Used in the Chapter

Choice behavior: is the act of making a selection among two or more alternatives, usually after a period of deliberation or consideration of the characteristics of each alternative.
Functional foods: are foods that have a positive effect on health beyond adequate nutritional effects, resulting in an improved state of health and wellbeing or a reduction of disease risk.
Non-sensory factors: are variables that are not related to the product's sensory characteristics and affect consumers' choice behavior.
Attitude: is a construct that represents an individual's disposition to respond favorably or unfavorably to an item.
Chronic diseases: are diseases of long duration and generally slow progression, such as cancer or cardiovascular diseases.

Chapter 51
The Concept of Chronotype in Eating Behaviors

Christoph Randler

Abbreviations

CSM   Composite scale of morningness
EDI-2   Eating disorder inventory-2
MCTQ   Munich chronotype questionnaire
MEQ   Morningness–eveningness questionnaire
SCN   Suprachiasmatic nucleus
TFEQ   Three-factor eating questionnaire

51.1 Introduction: The Concept of Chronotype

Human individuals organize their lives in an approximately 24-h rhythm. This rhythm is innate and it is based on an endogenous pacemaker (Dunlap 2004; Koukkari and Sothern 2006). This innate biological rhythm exists, even when environmental inputs, such as sunlight or clocks, are absent (Burgess and Eastman 2008; Czeisler et al. 1999). The endogenous pacemaker is directed by the suprachiasmatic nucleus (SCN) in the brain (Dunlap 2004).

The underlying mechanism of this circadian preference is the variability of a set of psychological, behavioral, and biological variables which have roughly a 24-h oscillation (i.e., a circadian rhythm; Burgess and Eastman 2008). Diurnal changes have been found in both biological (e.g., body temperature and levels of hormone secretion) and psychological variables (e.g., mood and performance; Tankova et al. 1994).

However, there are large interindividual differences in humans. Some are morning "Larks" or early risers, mostly active early in the morning, achieving their maximum of mental and physical activity in the morning and becoming tired early in the evening. In contrast, "Owls" usually have difficulties getting out of bed, and need a longer time to have their senses recovered in the morning, but "Owls" are able to work till late evening and they often achieve their physical and mental daily height during late afternoon and evening hours.

These individual differences in chronotype, timing of sleeping or biological rhythms are viewed as an interesting facet of personality (Matthews 1988). Although these differences were often viewed

Table 51.1 Key features of chronotype. Table gives a short overview over the concept of chronotype or morningness–eveningness which is different from sleep length because it is related to the timing of sleeping

People differ in their individual sleep–wake cycle

Chronotype reflects these individual differences in sleep–wake cycles

Early chronotypes get up and go to bed early

Late chronotypes get up and go to bed late

Chronotype is not linked with sleep length

Chronotype reflects the timing of sleeping (wake time, sleep onset)

Chronotype focuses on the question "When do you sleep?" rather than "How long do you sleep?"

Chronotype is heritable, but environmental and social factors contribute

Women are earlier chronotypes than men

The sleep–wake cycle changes during the lifespan

Table 51.2 Questionnaires used in chronobiological/chronopsychological research. The table depicts the most relevant questionnaires used in chronobiological research as means of paper–pencil tests. Other instruments might include hormone secretion or body temperature but questionnaires are useful to screen large samples

Measurement	Acronym	No. of questions	Type	Measure	Original
Morningness–eveningness questionnaire	MEQ	19	Mixed format questions	Preference, clock times	Horne and Östberg (1976)
Composite scale of morningness	CSM	13	Likert type	Preference, clock times	Smith et al. (1989)
Basic language morningness scale (based on CSM, but easier wording)	BALM	13	Likert type	Preference, clock times	Brown (1993)
Preference scale (based on the CSM)	PS	12	Likert type	Preference compared to others	Smith et al. (2002)
Circadian type inventory (some refinements; especially for shift workers)	CTI	30 (18; 11)	Likert type	Flexibility/ amplitude of rhythms	Folkard (1987), Di Milia et al. (2005)
MEQ short form	rMEQ	5	Mixed format questions	Preference, clock times	Adan and Almirall (1991)
CSM short form	rCSM	7	Likert type	Preference, clock times	Randler (2009), Di Milia (2009)
BALM short form	–	7	Likert type	Preference, clock times	Pornpitakpan (2000)
Munich chronotype questionnaire	MCTQ		Mixed-format questions	Clock-based	Roenneberg et al. (2004)

in some kind of dichotomous manner ("Larks" and "Owls"), they also reflect a continuum between both extremes (Natale and Cicogna 2002). There are different terms to define the concept, such as chronotype, morningness–eveningness, circadian preference/typology, or diurnal preference (see Tables 51.1 and 51.2).

51.2 What Determines Chronotype?

Chronotype is seen and understood as an individuals' innate or intrinsic component of the body (biological rhythm). This indicates that the biological rhythm of every individual is based on some intrinsic (endogenous) component of the body that can be influenced – at least partially – by social and environmental factors (Randler 2008c,2008d). At first, some genes have been identified that were associated with the variability in the circadian clock (e.g., Archer et al. 2003; Carpen et al. 2005).

Further, chronotype is heritable, and there were correlations between twins (Hur et al. 1998), and parents and children (Leonhard and Randler 2009). Heritability estimates suggest that between 12% and 29% (Klei et al. 1998), and up to 54% of the variance in circadian preference is determined by genes (Hur et al. 1998). One may assume that chronotype genes are the genetic and heritable basis, but the real expression of chronotype reflects some kind of social, cultural, and environmental factors, leading individuals with identical genotype to different "real" or lived chronotypes. As in other animals, it has been suggested that sunrise may act as an important zeitgeber to entrain the circadian clock (Natale et al. 2009; Randler 2008c; Roenneberg et al. 2007). These studies found that people living in more easterly regions within the same time zone are more morning oriented than the people living in the westerly regions (Randler 2008d). However, other environmental or sociocultural aspects have rarely been studied (Caci et al. 2005; Randler and Díaz-Morales 2007), but it seems that the interplay between these factors is needed to determine an individual's chronotype. Also, it seems that chronotype is unrelated to the social economic status (Paine et al. 2006).

51.3 Changes in Chronotype During the Lifespan

There are significant changes in morningness–eveningness during the lifespan from childhood to retirement. We have only very limited evidence of the age groups of very young children, but at the primary school level (6–10 years), young children often are morning orientated. During the age of puberty, adolescents shift from morningness to eveningness. This shift typically occurs at the age of 12–14 years in many countries and cultures (Díaz-Morales et al. 2007; Randler 2008a, 2008c). At the age of 19–21 years, humans again experience a shift back toward morningness (Roenneberg et al. 2004; Tonetti et al. 2008). This shift is currently supposed to be a marker for the end of adolescence (Roenneberg et al. 2004). From then on, people become more and more morning orientated until retirement, and, again, after retirement there is a paucity of data. People therefore experience a shift toward eveningness during puberty, then back to morningness at the end of adolescence and become progressively more morning oriented parallel with an increasing age. During puberty and adolescence, young people show a delay of rise/wake and bed/sleep times during the weekend (Fig. 51.1).
Fig. 51.1 Rise times, bed times, and evening meal times of adolescents during 35 days (based on sleep log data). The figure shows the weekend delay in bed times and rise times. Adolescents go to bed later on Friday and Saturday, and get up later on Saturdays and Sundays. However, evening meal times remain more or less stable. Based on Becht & Randler (unpublished data)

At the weekend, rise times were about 2 h later, and bed times were shifted accordingly. However, meal times (with the exception of breakfast) remain more or less stable (see below).

The changes might be caused by sex hormones as well as by psychosocial aspects (Carskadon et al. 1993). It has been suggested that these changes are in accordance with pubertal development (Carskadon et al. 1993), and hence, linked with the increase of sex hormones. Correlational analyses provide evidence that adolescents scoring higher on eveningness are also in a higher pubertal developmental stage (Carskadon and Acebo 1993; Randler et al. 2009). Supporting evidence for the hypothesis that sex hormones are linked with changes in morningness–eveningness comes also from a study on menopause in women. During menopause, sex hormones rapidly decrease, which is linked with a change toward a higher morning orientation (Randler and Bausback 2010).

51.4 Sex/Gender Differences in Chronotype

Sex differences in chronotype have been found in some studies that compared biological (physiological) measurements between men and women (see Tankova et al. 1994). However, most survey studies using questionnaires did not reveal differences between the sexes in chronotype, e.g., because of a missing age-adjustment or because of small sample sizes. Boys and men are more evening oriented than girls and women given a similar age range (Tonetti et al. 2008). These results have been confirmed by a meta-analysis (Randler 2007). Interestingly, women had a more significantly advanced sleep phase than males, that is, they were earlier chronotypes or more morning orientated only during the years when sex hormones were present (Tonetti et al. 2008). This gives supporting evidence for the function of sex hormones. The differences between the sexes may result from receptors for sex hormones in the SCN which is the location of the circadian pacemaker (Kruijver and Swaab 2002).

51.5 Psychological Correlates of Chronotype

Chronotype has been found to correlate with psychological constructs which makes it interesting for psychological aspects of eating behaviors. For example, eveningness was associated with Eysenck's personality dimension of extraversion (Tankova et al. 1994; Cavallera and Giudici 2008), and morningness was associated with the conscientiousness scale of the Big Five Inventory (Randler 2008b; Tonetti et al. 2009). Also, higher or better academic performance was related to morningness (Wolfson and Carskadon 2003; Randler and Frech 2006).

Eveningness was associated with a number of psychological and psychosomatic disturbances, such as depression (Chelminski et al. 1999; Drennan et al. 1991), or seasonal affective disorder (Natale et al. 2005), while morningness was related to satisfaction with life (Randler 2008f).

51.6 How to Measure Chronotype

Chronotype can be measured by a variety of methods. From a biological viewpoint, physiological measurements can be used to assess the chronotype of humans, e.g., by measuring the daily rhythm of body temperature. Morning types or larks have their lowest body temperature during the early parts of the night, while evening types have their lowest temperature in the early morning. Similarly,

the hormone melatonin, peaks some hours earlier in "Larks" than in "Owls". Also, the cortisol awakening response is higher and more pronounced in morning types (Kudielka et al. 2006).

However, these immediate or direct assessments of chronotype are costly and often time consuming, preventing us from large-scale studies or rendering them impossible. To this end, a set of questionnaires have been developed to assess an individuals' chronotype. The most widely used measurements are depicted in Tables 51.2 and 51.3. Some of these questionnaires are also available as a short or reduced version. The correlations between the scales are usually high because nearly all these questionnaires measure a more or less similar construct (e.g., Randler 2009). Therefore, one should use the questionnaire adequate to the study situation, e.g., when time is a constraint it may be possible to use only the short form of the CSM or the Morningness–Eveningness Questionnaire (MEQ). However, in studies where more resources are available, it might be helpful to combine measurements.

In recent times, the scales were improved from a psychometric point of view. The factor structure of the questionnaires is still not fully resolved (Caci et al. 2009). However, this is to be expected in measurements that are more or less newly developed, but many characteristics, such as wake/rise time, bed time, and physical or mental peak performance correlate with the scores on the respective scales. Also, the MEQ has been validated by hormonal measures, such as cortisol (Kudielka et al. 2006) or by melatonin. There is some evidence for the validity of these scales both from a psychometric point of view (reliability, factor structure), and from external validation (by assessment of alertness or hormonal profiles).

The lark–owl continuum has metric scale level. In addition, it is possible to group individuals by using cut-off scores (e.g., extreme lark, moderate lark, intermediate, moderate owl, extreme owl).

51.7 Chronotype and Eating Behaviors

Only very few studies have assessed the relationship between chronotype and eating behaviors. Schubert and Randler (2008) used the CSM in combination with the German version of the Three-Factor Eating Questionnaire (TFEQ) (Pudel and Westenhöfer 1990). The questionnaire is based on three basic constructs of eating behavior: cognitive restraint, disinhibition, and perceived hunger. Schubert and Randler (2008) found a positive correlation between "Larks" (high CSM scores) and cognitive restraint, and negative relationships between CSM scores and disinhibition, and between CSM scores and perceived hunger (Fig. 51.2). Their results indicate that chronotype is linked with eating behavior and that individuals skewed toward eveningness experience more disinhibited eating and perceive more hunger.

The cognitive restraint scale can be divided into two subscales, flexible and rigid control of eating behavior (Westenhöfer et al. 1999). In their study there was an association between morningness and flexible control, with morning oriented individuals scoring higher on the flexible control scale, but there was no association between CSM scores and rigid control (Schubert and Randler 2008).

51.8 Chronotype and Food Intake

As morningness–eveningness was associated with the psychological constructs of eating behaviors, further studies explored the relationship between food intake and chronotype; two studies focused on this specific aspect. In one, a proxy of midpoint of sleep was used (Fleig and Randler 2009), in

Fig. 51.2 Relationship between the perceived hunger scale from the Three-Factor Eating Questionnaire and scores on the composite scale of morningness (*CSM*). High CSM scores reflect morningness, and low CSM scores reflect eveningness. The data were obtained from the perceived hunger scale from the Three-Factor Eating Questionnaire. High scores represent higher expression of perceived hunger. The negative relationship indicates that evening oriented persons perceive more hunger (data based on Schubert and Randler 2008)
another one the CSM. The first study was based on food logs reporting food intake in adolescents, while the second used a food–frequency list to assess food intake. Fleig and Randler (2009) analyzed different groups of food. Food logs were distributed among adolescent school pupils to asses their food intake. The caloric value was calculated for each pupil, and the calories were assigned to different food types. In a regression analysis, the authors revealed a positive correlation between chronotype and fast food consumption (standardized $\beta = 0.260$), between chronotype and cola and caffeinated drinks (standardized $\beta = 0.163$), and a negative correlation between chronotype and dairy products (standardized $\beta = -0.177$). No relationship was found between chronotype and either sweets, or vegetables and salad, or meat. These results indicate that earlier chronotypes (or individuals skewed toward morningness) consumed less fast food, less caffeinated drinks but more dairy products. In general, this suggests a healthier lifestyle in morning oriented adolescents. Using a food–frequency list based on a Likert-type format in adolescents, there were negative correlations between CSM scores and fast food, meat, coffee, and caffeinated drinks, suggesting that adolescents oriented toward eveningness consumed more of these food items (unpublished data). In some aspects, both studies are in agreement (fast food and coffee are consumed more in evening types), but in some they disagree which may be a result of the sample size (the food log study had less participants), or in the format of the questions: While the Likert-type scale measures food intake frequency in retrospect (e.g., over the past four weeks), the food logs measure the real intake rate, but usually over a shorter period. Further research is therefore needed to investigate the relationship between food intake and chronotype.

51.9 Chronotype and Eating Disorders

Few studies examined the relationship between eating disorders and chronotype. For example, nocturnal eating was associated with eating disorders such as binge eating (Greeno et al. 1995) and bulimia nervosa patients had a sleep onset about 1 h later than healthy individuals (Latzer et al. 1999).

Fig. 51.3 Relationship between eating disorders and chronotype in adolescent girls. High CSM scores reflect morningness, and low CSM scores reflect evening-ness. The mean of the three scales of the eating disorder inventory-2 (*EDI-2*) is based on three scales: bulimia, drive for thinness, and body dissatisfaction. High scores represent higher expression of eating disorders. Thus the negative relationship indicates that evening orientated persons suffer more from eating disorders (Data based on Schmidt and Randler 2010)
Kasof (2001) found correlational evidence between eveningness and bulimic behavior in University students of both sexes, suggesting that evening types are higher at risk. In adolescent girls, Schmidt and Randler (2010) reported correlations between three scales of the Eating Disorder Inventory-2 (EDI-2) and the CSM (Fig. 51.3). Individuals scoring higher on eveningness reported higher scores on the drive for thinness, the bulimic, and the body dissatisfaction scale. Natale et al. (2008) compared women around the age of 30 in a clinic for eating disorders with a control group of healthy women of similar age. These authors also found that women suffering from eating disorders were later chronotypes, and they suggest that the disorder leads to a later chronotype. However, the data on adolescents suggest that eveningness is an unspecific risk factor for eating disorders. It seems clear that eating disorders and chronotype are linked with each other, but the correct direction seems not yet fully resolved.

51.10 Chronotype and Meal Times

Meal times differed between weekdays and weekends in many persons, and the largest differences are found in breakfast time. In adolescents, breakfast times differed significantly between weekdays (mean 6:36) and weekends (9:15), while meal times of lunch and dinner were similar (lunch: 13:15 versus 13:10; dinner: 18:51 versus 18:56). A look at the variance (SD) shows that at all three meal times, the variance was higher on weekends (Fleig and Randler 2009). Caloric intake at breakfast was higher on the weekend compared to week days, while intake at lunch and dinner did not differ (Fig. 51.4). In adults, results were similar and lunch and dinner times remained rather stable when comparing weekends with weekdays, but adults also showed a delay in breakfast times (7:27 on weekdays versus 8:32 on weekend days, Costa et al. 1987).

   Also, chronotype influences the timing of meals in adolescents. Mean breakfast time at the weekend was later in late chronotypes which was a result of later rise times of late chronotypes. As rise times in late chronotypes differ more between weekdays and weekends, this suggests a more regular
Fig. 51.4 Caloric intake in adolescents according to meal time. Caloric intake was measured using food logs in adolescent school pupils. Statistical comparisons show significant differences in intake at breakfast. Pupils ate more at weekend breakfast (from unpublished data, Fleig and Randler). Data are means and 95% confidence intervals

lifestyle in earlier chronotypes. Dinich (2003) asked people about their most preferred meal during the day. Evening oriented persons showed a preference for evening dinner, and morning types preferred the breakfast.

51.11 Chronotype and Drug Abuse

Chronotype was found to be linked with addiction, e.g., with alcohol and cigarette consumption, i.e., evening oriented people smoked more cigarettes (Wittmann et al. 2006) or were more often habituated smokers (Randler 2008e). Cigarette smoking has been associated with delayed sleep onset and with a shorter sleep duration, i.e., smokers tend to go to bed later than nonsmokers and they sleep shorter. Adan et al. (2004) found differences in mood and activation between high- and low-dependent smokers and nonsmokers. Wittmann et al. (2006) found that people living against their own biological clock are more often smokers which might be a consequence of "social jetlag." People of later chronotypes who would like to go to bed and get up later than their normal daily schedule might tend more to cigarette smoking to compensate for their distortion of their daily rhythm.

51.12 Chronotype and Obesity

Recent studies showed a significant relationship between sleep duration and obesity, suggesting that short sleepers acquire a higher Body Mass Index (review: Cappuccio et al. 2008) However,

Table 51.3   Key features of the morningness–eveningness questionnaire. The table gives an overview over the key concepts that have the different questionnaires in common

The questionnaires are based on Likert-type questions and on clock times
The questionnaire often asks for preferences ("When would you like to get up if you are entirely free to plan your day?")
A total score is obtained by adding the scores for each items
The total score can be used for correlational analyses
Groups (Owls or Larks) can be defined by cut-off scores
The questionnaires differ in length

Table 51.4   Correlation between body mass index (BMI; z-transformed) and sleep–wake variables in adolescents, based on unpublished data from Randler and Hammer

	BMI z-scores
Average sleep duration	−0.185**
Sleep length on weekdays	−0.176**
Sleep length on free days	−0.108 ns
Rise time week day	0.155**
Rise time weekend	0.145*
Bed time week day	0.278***
Bed time free days	0.269***

***Denotes $p < 0.001$, ** $p < 0.01$, *$p < 0.05$; *ns* not significant. Please note that the sleep length was calculated from rise times and bed times (which means time in bed). The data indicate that bed times seem to have the most relevant influence on BMI

the influence of chronotype has not been assessed in any previous study, but it might indeed be the timing of sleeping rather than the sleep duration itself (see Table 51.4). In a study based on adolescents, there were significant relationships between sleep–wake variables and BMI (Hammer and Randler, unpublished data, see Table 51.4, Fig. 51.5). The data further suggest that it is the timing of sleeping (or chronotype), rather than the sleep length itself with later chronotypes having a higher BMI. Here, further studies are needed to find the optimal predictor for this relationship.

51.13 Applications to Other Areas of Health and Disease

A very interesting facet of the study of health and disease might be the application of chronotype questionnaires and to look at these relationships in more detail in further studies. One question, e.g., emerging in the study of eating disorders is whether an eveningness orientation is a risk factor or a premorbid trait for eating disorders (Schmidt and Randler 2010), or whether eating disorders themselves influence and modulate the circadian preference and shift individuals to an evening orientation (Natale et al. 2008). Another interesting aspect is whether problematic eating behavior is a result of disruption of the circadian timing or whether it is a prerequisite.

Further, we do not know much about the relations of different hormones that influence the sleep–wake cycle and hormones that affect eating behavior in humans.
Fig. 51.5 BMI (z-scores) according to midpoint of time in bed, which is the midpoint between bed time and rise time on free days. Z-scores were obtained for each gender and age class separately. Midtime in bed measure as the clock time between going to bed and rising based on 284 adolescents. Early chronotypes have an early midtime in bed, late chronotypes have a late midtime. Body mass index was obtained by self-report. Late chronotypes had a higher body mass index when controlling for age and gender. Data are means and one standard error

Summary Points

- Individuals skewed to eveningness (or late chronotypes) have a more problematic eating behavior, scoring higher on disinhibition and perceived hunger of the TFEQ.
- Individuals skewed to morningness (or early chronotypes) score higher on the cognitive restraint scale and the flexible control subscale.
- Individuals skewed to eveningness (or late chronotypes) showed higher incidence of eating disorders, and scored higher on the scales drive for thinness, bulimic behavior, and body dissatisfaction.
- Evening oriented adolescents ate more fast food, and consumed more cola and caffeinated drinks.
- Meal times between weekend and weekdays differ at breakfast but not at lunch and dinner with later meal times at the weekend.
- Evening oriented persons exhibit a less regular lifestyle (e.g., in meal times).
- Eveningness (or late chronotype) was related to higher consumption of alcohol and cigarettes.

Key Terms

Circadian preference/typology: is a description of the preference of an individual for a specific time of day, e.g., whether an individual prefers morning or evening hours for physical and mental activity.
Chronotype: some kind of classification of people into different classes, e.g., into larks and owls. However, chronotype is usually measured on a metric or continuous scale, and can also be

grouped into three, five, or seven groups. Late chronotypes have a late midpoint of sleep and a low score in the psychological questionnaires (MEQ, CSM), and early chronotypes have an early midpoint of sleep and high scores on the psychological questionnaires.

Eveningness: the orientation toward evening hours. This is measured by a questionnaire (Table 51.2). Individuals scoring high on eveningness were often called Owls.

Lark: In a European context, this considers an early awakening bird, the skylark (*Alauda arvensis*), and it is used as a synonym for early rising people.

Midpoint of Sleep: the midpoint between two clock times, the timing of sleep onset when an individual starts sleeping, and the timing of awakening. Somebody with a sleep onset at 0:00 and a wake time of 6:00 has his/her midpoint of sleep at 3:00. This midpoint can be calculated for workdays and for free days. In most persons, the midpoint of sleep on free days is later than on work days.

Morningness: the orientation toward morning hours. This is measured by a questionnaire (Table 51.2). Individuals scoring high on eveningness were often called Larks.

Owl: this is a synonym for persons staying out late and going to bed late.

Chapter 52
Feeding and Sleep Behavior

Chin Moi Chow and Christopher Paul Herrera

Abbreviations

SWS	Slow wave sleep
BMI	Body mass index
CHO	Carbohydrates
GI	Glycemic index
HFLC	High fat–low carbohydrate
LFHC	Low fat–high carbohydrate
MSLT	Multiple sleep latency test
EEG	Electroencephalography
REMS	Rapid eye movement sleep
NREM	Nonrapid eye movement
TRP	Tryptophan
5HT	5-Hydroxy-tryptamine (serotonin)
LNAA	Large neutral amino acids
CCK	Cholecystokinin
PS	Paradoxical sleep

52.1 Introduction

Feeding is associated with a rise in body temperature resulting from an increased metabolic rate. Its influence on sleep is mediated not through the ingestion process but by the by-products of macronutrients. Because feeding occurs during the wake period, feeding and sleeping are mutually exclusive. On the other hand, wakefulness and feeding are mutually inclusive. Hypocretin, a neuropeptide which stimulates both food ingestion and wakefulness in humans and in rats, shows stable levels in the wake period (Fujiki et al. 2001; Nishino et al. 2000). Melatonin, which is released at dark onset, depresses food intake and increases sleep propensity (Bermudez et al. 1983).

e-mail: chin-moi.chow@sydney.edu.au

Normal feeding behavior usually consists of three regular meals, with the majority of the meals taken in the light phase of the light–dark cycle. However, regular feeding behavior is evolving in view of food abundance, availability of fast foods, and a busy lifestyle resulting in irregular meals and feeding on-the-go being more prevalent. Dieting with food restriction is commonly practiced in those who are concerned with weight gain, while fasting is observed as part of religious beliefs (Ramadan), and in the animal kingdom during hibernation (bears, ground-squirrels, reptiles), egg incubation (ducks, geese), breeding and molting (penguins), and when food becomes sparse. Whilst feeding is often associated with lethargy and subjective sleepiness, not sleeping enough has been shown to impact directly on feeding behavior. Objectively measured electroencephalographic (EEG) changes offer a dimension not attainable in subjective sleep measures. EEG measures reveal that sleep is usually entered through Stage 1 drowsy sleep, followed by "true" sleep characterized by the sleep EEG spindle structure (Stage 2) and deep sleep (Stage 3 or slow wave sleep, SWS), then rapid eye movement sleep (REMS). Stages 1–3 do not exhibit rapid eye movements and are collectively known as nonrapid eye movement (NREM) sleep. This chapter covers three areas of interest: macronutrient effects on sleep, feeding behavior and sleep patterns, and sleep duration and appetitive behavior.

52.2 Diet and Sleep

There is considerable scientific evidence detailing the effects of dietary intake on sleep. The main dietary constituents that can readily influence sleepiness are the macronutrients of carbohydrates (CHO) and fat, with opposing effects from protein. Whilst sleepiness is increased after CHO– or fat-based meals, macronutrient ingestion per se does not promote sleepiness. Postprandial sleepiness is primarily influenced by the circadian timing (time of day) of the meals and the macronutrient content via neurochemical changes. Secondary factors include patterns of habitual feeding and gender. Because feeding can alter sleep patterns, it will become vital for dietitians, nutritionists, and other allied health practitioners to understand the relationship between diet and sleep, since poor sleep (seen in shift workers and in those with insomnia and depression) has implications for poor health outcomes. Figure 52.1 depicts the factors influencing postprandial sleepiness; the most significant factors are those at the base levels of the pyramid.

Fig. 52.1 Factors impacting postprandial sleepiness. The factors influencing postprandial sleepiness are presented on the pyramid. The most significant factors are those at the base levels of the pyramid. Note it is possible that these factors may interact with each other at any level
52.2.1 Circadian Timing of Meals

Sleep and metabolism are tightly regulated by the circadian clock that is located in the suprachiasmatic nucleus of the hypothalamus (Kovac et al. 2009). The body clock keeps time of all biological rhythms. Circadian rhythms are those with an oscillation of approximately 24 h. These rhythms not only display peaks and troughs of activity at different times of the day, but show phase relationships. For an example, the peak core temperature that occurs at around 1600–1800 h is linked to alertness, whereas the temperature nadir occurring at around 0400–0600 h is linked to sleepiness. Not surprisingly, the time of day that meals are eaten exerts an influence on postprandial sleepiness. A biphasic response was observed after a high-fat–low-carbohydrate (HFLC) or a low-fat–high-carbohydrate (LFHC) meal provided at breakfast or lunch. The response showed an increase in alertness that lasted for up to 30 min followed by a shift toward sleepiness that was greatest between 1100–1400 h independent of the meal type (Wells and Read 1996; Wells et al. 1998). The initial increase in alertness may be explained by the thermic effect of the meal, while the postprandial sleepiness coincides with the postlunch dip, a circadian phenomenon (Monk 2005). This phenomenon has been examined in a study where a 3 h sleep opportunity was allowed after either a CHO liquid lunch meal or a no food condition. Sleep occurred in both conditions suggestive of a strong postlunch circadian dip, however, sleep duration was markedly increased following food intake (Zammit et al. 1995), suggesting that in addition to the circadian effect, the meal itself impacted sleep.

Harnish and colleagues queried if postprandial sleepiness was due to the ingestion process related to gustatory, olfactory, and/or visual cues associated with a meal (Harnish et al. 1998). They explored this question using the Multiple Sleep Latency Test (MSLT) with four nap opportunities tested at 1700 h and terminating at 2100 h. They offered participants a mixed macronutrient meal (energy from fat 46% and from carbohydrates 42%) or a sham meal (chewed and expectorated) in a crossover study, where the meal allocation was randomized and counter-balanced. There was only a small difference in the postprandial sleep between the feeding and sham feeding conditions at 2 h postprandially. However, sleepiness was delayed with progression of the remaining nap studies, which likely reflects an increased state of alertness linked to the circadian temperature peak as well as the thermic effects of the meal.

52.2.2 Macronutrients and Sleep

Meals high in CHO and fats are more effective in promoting sleep compared to protein meals. An increase in sleepiness has been reported at breakfast after high CHO meals compared to high protein meals (Leathwood and Pollet 1983). Postprandial sleepiness after HFLC and HCLF meals may be present for up to 4 h depending on the measurement tool used. In several studies, subjective measures of sleepiness were present at 60 min following meal consumption (Lloyd et al. 1994, 1996; Spring et al. 1982/1983; Wells et al. 1998; Wells and Read 1996; Leathwood and Pollet 1983), whereas objective measures of sleepiness (MSLT and Akerstedt EEG analysis) were present between 1.5 and 4 h, respectively (Wells et al. 1998).

It is apparent that macronutrients impact on nocturnal sleep. Early evidence showed that SWS is immediately increased after intravenous administration at bedtime of either pure glucose or of an amino acid mixture, whereas increases in REMS occurred after glucose administration only (Lacey et al. 1977). Dietary intake of CHO similarly shows this trend in REMS. A dose–response effect for

increased REMS was present after iso-caloric diets with low, medium, and high CHO content (100, 300, and 600 g, respectively) (Phillips et al. 1975). Further, an increase in REMS was evident after a low calorie CHO snack given 45 min before the usual bedtime (Porter and Horne 1981). In accordance with these results, a reduction in CHO intake (e.g. 50 g/day or completely eliminated as in a very low carbohydrate diet), resulted in a reduction in REMS (Afaghi et al. 2008; Kwan et al. 1986), total sleep time (Kwan et al. 1986), and increased SWS (Afaghi et al. 2008).

Afaghi et al. 2007 tested the efficacy of a high versus a low glycemic index (GI) CHO meal and the timing of the high GI meal (4 h versus 1 h before the usual bedtime) on the sleep patterns of healthy adults. The subjects took significantly less time to fall asleep after the high GI compared to the low GI isocaloric meal eaten 4 h before their usual bedtime (Afaghi et al. 2007). They also took less time to fall asleep after the high GI meal ingested 4 h before bedtime than after that ingested 1 h before bedtime. Remarkably, there were no differences to other stages of sleep. In a separate study, when a cereal-type bedtime snack was given just prior to bedtime, there was a reduction in sleep latency and a more restful sleep reported in healthy subjects (Brezinova and Oswald 1972).

52.2.3 Macronutrients and Neurochemicals

Carbohydrates may positively influence sleep, given that the glycemic level of a meal importantly dictates the availability of tryptophan (TRP) to the brain. TRP is a crucial amino acid that links diet and sleep, as it is the biological precursor to serotonin (5HT), which is an intermediary to the synthesis of melatonin, a sleep-inducing agent. The availability of TRP depends on its concentration in relation to the other large neutral amino acids (LNAA), since each competes for a single transport protein across the blood–brain barrier (Wurtman 1988). Postprandial sleepiness may therefore be linked to the nutrient-specific macronutrient ingestion and changes to the ratio of TRP/LNAA. Figure 52.2 illustrates the postprandial changes in the ratio of TRP/LNAA after two carbohydrate-based meals (sucrose, high GI; raw starch, medium GI) and one fat and protein meal. There is a clear GI dose-dependent increase in the TRP/LNAA ratio after CHO-based meals, and a decreased ratio after a protein and fat meal (Lyons and Truswell 1988). The time required for digestion and absorption
Fig. 52.2 Postprandial change in TRP/LNAA after carbohydrate and fat + protein meals. The mean change in plasma TRP/LNAA ratio in 13 subjects after sucrose (high GI), raw starch (medium GI), or fat+protein evening meals is shown. Vertical bars represent SEM. Values after sucrose were significantly different from corresponding raw-starch ($p < 0.05$, Neuman–Keul's test). Values after fat+protein were significantly different from both corresponding carbohydrate meals ($p < 0.001$) *TRP* tryptophan, *LNAA* large neutral amino acids, *GI* glycemic index (Data are from Lyons and Truswell 1988. With permission from the Publishers)

Fig. 52.3 Meal composition leads to changes in serotonin (*5HT*). Percent change observed in platelet-poor plasma 5HT levels after the administration of test meals: meal 1, carbohydrate; meal 2, protein-rich; meal 3, fat-rich. *5HT* 5-hydroxytryptamine or serotonin (Data are from Blum et al. 1992. With permission of the Publishers)
of the macronutrients relates to the plasma appearance of TRP, since the TRP/LNAA ratio peaks between 2 and 4 h after ingestion of a high-CHO meal. This peak rise in the TRP/LNAA ratio has been replicated for evening meals (Lyons and Truswell 1988) providing evidence for a mechanistic role of high GI meals for sleep improvement.

High GI meals, through hastened entry of glucose into the blood, facilitate a greater insulin response that mediates the selective uptake of LNAA into skeletal muscle, leaving TRP that is largely bound to plasma albumin free to cross into the brain for conversion into serotonin (5HT) (Wurtman 1988). This cascade of events has been shown to lead to an increase in 5HT production. Figure 52.3 shows the postprandial levels of platelet-poor plasma (PPP)-5HT after a CHO-, fat-, or protein-rich meal (Blum et al. 1992). As can be seen the level of PPP-5HT was significantly increased from baseline after the CHO-rich meal (4.47-fold) compared to after the fat-rich meal (1.66-fold) (Fig. 52.3), reflecting a reduction in the glycemic response when fat is added to a meal. Increased PPP-5HT is likely responsible for the increase in REMS after CHO intake, since increased levels of plasma tryptophan correlate positively with REMS in normal individuals (Chen et al. 1974).

The increase in postprandial sleepiness after fat-based meals may be explained by the release of the neuropeptide cholecystokinin (CCK) in response to the delivery of fatty acids and protein-rich chyme to the duodenum. It has been shown that increased levels of CCK are present at approximately 3 h after digestion of HFLC meals or after intraduodenal infusion of lipids (Wells et al. 1995). Postprandial sleepiness was present after both conditions compared to saline infusion. The authors suggested that postprandial sleepiness after ingestion of fat may be explained by an increased CCK level that is mediated by vagal afferent signals to the brain (Schwartz et al. 1993). Evidence in the animal model corroborates these findings (Fara et al. 1969; Murray et al. 1993). Despite the soporific effects of high fat meals, increased fat intake may lead to positive energy balance and may contribute to weight gain.

52.2.4 Impact of Habitual Feeding Behaviors and Gender

It is apparent that habitual food choices (Lloyd et al. 1996) and gender both greatly influence subjective sleepiness (Wells et al. 1998). Meals that deviate from habitual intake with respect to the time of day, volume, or macronutrient content may cause a decline in subjective mood state and increased

sleepiness (Lloyd et al. 1994, 1996). It is unclear if the carbohydrate feeding behavior and choice of foods at breakfast have a physiological basis, however, it is possible that this behavior is signaled by a low blood glucose level following an overnight fast (Robertson et al. 2002) and may be synchronized with the sleep–wake cycle (Krauchi et al. 2002). In fact, mood has been shown to improve after an LFHC breakfast meal, showing a decrease in fatigue when compared to an HFLC meal, a mixed macronutrient meal, and when no breakfast meal was provided (Lloyd et al. 1996). However, subjective alertness declined after big lunches compared to small lunches irrespective of habitual lunch size (Craig and Richardson 1989). Additionally, solid meals but not liquid meals increase sleepiness compared to an equal volume of water (Orr et al. 1997). Gender may also modify the dietary effects on sleepiness. In females, a decline in alertness is more prominent for those eating larger-sized meals compared with their usual sized lunch-time meals (Smith et al. 1991). In another study, females tended to report greater postprandial sleepiness than males (Wells and Read 1996); however, other subjective mood states such as feelings of lethargy, boredom, and mental slowness have been reported across genders independent of meal type (Smith et al. 1988).

52.3 Fasting and Sleep Patterns

It could be said that nutritional sufficiency is marked by a normal sleep pattern. However, fasting or overfeeding, on either end of a continuum from insufficiency to over-sufficiency, induces an altered pattern of sleep. Sleep is severely disturbed in patients with anorexia nervosa (Lacey et al. 1975) and in obesity (Dixon et al. 2005). The sleep of both groups is characterized by an increased wake time, decreased SWS, and REMS. Re-feeding in anorexia (Lacey et al. 1975) brings about normalization of sleep patterns. The changes in sleep pattern with food restriction (acute or chronic fasting) present a paradoxical picture in that acute fasting of several days increases SWS, whereas chronic fasting decreases SWS. Attention is drawn to SWS, a sleep stage marked by low frequency, high amplitude activity on the EEG. SWS, the deepest stage of sleep, is usually intense and present in large amounts in the first of 4–6 sleep cycles that occur during nocturnal sleep. SWS is determined by prior sleep and waking and represents a marker of the sleep homeostatic process (Borbely 2001). Importantly, SWS has the lowest metabolic rate of all sleep stages and lowest brain glucose metabolism (Heiss et al. 1985), which is 10–15% lower than when lying quietly awake (Dewasmes et al. 1989). Thus, changes to SWS with acute or chronic fasting take on metabolic significance. Additionally, the onset of SWS coincides with the release of growth hormone (Sassin et al. 1969), which plays a key role in glucose homeostasis, particularly in brain glucose levels during the nocturnal fast. Growth hormone spares glucose for the brain by increasing blood glucose through antagonism of insulin release, and increasing hepatic glycogen storage through gluconeogenesis, as well as stimulation of fat oxidation and suppression of protein oxidation. Thus, increases in SWS appear metabolically apt where lipid store is adequate and fat oxidation sustains energy supply (acute stages of fasting), whereas diminished SWS is favored where lipid reserve is low or depleted (chronic fasting). The relationship between SWS and acute and chronic fasting and re-feeding is depicted in Fig. 52.4 and preempts the supporting literature (cross-sectional and longitudinal) that follows.
Fig. 52.4 Paradoxical relationship between SWS, food restriction, and re-feeding. Acute fasting of several days increases SWS, whereas chronic fasting decreases SWS. When re-feeding occurs, SWS is restored. *SWS* slow wave sleep

Acute fasting of 3–4 days promotes an increase in SWS in man (MacFadyen et al. 1973; Karacan et al. 1973), geese (Dewasmes et al. 1984), emperor penguins (Dewasmes et al. 1989), and pigeons (Rashotte et al. 1998), although not in the rat (Dewasmes et al. 1989). Changes in REMS or paradoxical sleep (PS, equivalent to human REMS) were variable, showing decreases (Dewasmes et al. 1989; MacFadyen et al. 1973), increases (Dewasmes et al. 1984), and no change (Rashotte et al. 1998; Karacan et al. 1973). In these species, starvation mediates falls in metabolic rate and energy expenditure. SWS appearance is apt given a low metabolic state and low brain glucose metabolism during this sleep state (Heiss et al. 1985). Further, the paralleled growth hormone release mobilizes lipids to yield energy substrates while sparing glucose for the brain. Thus, increases in SWS present a survival strategy that sustains energy supply through a lowered metabolic state and increased fat mobilization. Karacan et al. (1973) noted considerable variability in the individual growth hormone response to fasting during the sleep period. They noted that those who typically did not exhibit a peak response (5 ng/mL) during the baseline, non-fasting night showed the strongest sleep growth hormone response to fasting, although the peak level was reached by all subjects on the fasting night.

As fasting continues into a chronic nature, adipose store progressively becomes depleted. The timing of depletion depends on body size and types (ecto-, meso-, and endomorphs). Depletion signals the beginning of increased protein utilization and a critical period during which death may occur should fasting continue. Chronic fasting, contrasting acute fasting, is associated with a reduction in SWS duration, REMS, and increased wakefulness. These findings have been observed in anorexia nervosa (Lacey et al. 1975) and in geese (Dewasmes et al. 1984). Dewasmes and colleagues proposed that sleep changes may be linked to changes in body fuels (Fig. 52.5). They demonstrated three periods of fasting in animals that hibernate and also in those that do not (e.g. the rat). Period I corresponds to acute fasting of 3–5 days, with reduction in metabolic rate, but high rate of fat mobilization; Period II corresponds to chronic fasting, where lipids contribute to 94% and protein to 6% of energy expenditure; and Period III, the critical period that marks the beginning of increased protein utilization and potential death. In the case of the geese, the authors showed a progressive increase in SWS and PS through Periods I and II, and a downward direction for these sleep parameters in Period III (Fig. 52.5). The reduction in both SWS and PS was observed in parallel with an increased wake period.

In premenopausal women, restricted energy intake over 4 weeks led to a delay in sleep onset but notably a reduction in SWS (Karklin et al. 1994). Their sleep findings resemble those seen in chronic starvation. Although their dietary strategy did not involve total food restriction, the women exhibited a

Fig. 52.5 SWS and fasting in geese. Percentages of slow wave sleep per 24 h in fed geese and their change over course of long-term fasting. Fasting begins at 0 time. The solid line represents least-square regression equations for relations of proportions of SWS to time of fasting, within limits of the three periods *SWS* slow wave sleep (Data are from Dewasmes et al. 1984. With permission from the Publishers)
hypometabolic state, as indicated by a significant decrease in plasma triiodothyronine (T_3) (Karklin et al. 1994). Furthermore, they lost around 8% of their initial body mass (baseline mean body mass being 71.2 ± 8.0 kg) (Karklin et al. 1994), and it may be inferred that they lost substantial amount of fat mass.

In two studies of young, growing rats, total food restriction over 4 days saw a reduction in SWS coincident with an increased wake time and decreased PS (Guesdon et al. 2005; Minet-Ringuet et al. 2004). Both studies noted that food restriction induced a reduction of fat mass and only half of the adipose tissue store remained at the end of the 4-day food restriction, given the low reserve in these young animals. These studies are more in line with the chronic starvation state, where substantial fat mass reduction is linked to a decrease in SWS. Similar sleep data have been reported in very lean rats (Danguir and Nicolaidis 1979).

52.4 Sleep Deprivation and Appetitive Behavior

Humans are sleeping less, averaging 7 h compared to 9 h a century ago. Emerging evidence demonstrates an important relationship between short sleep, appetite regulation and body mass, and energy metabolism. Short sleep refers to duration of less than 6 h, whereas long sleep refers to more than 9 h on a typical night. Short or long sleep is linked to an increase in body mass index (BMI), demonstrating a U-shaped relationship in children and adolescents (Taheri 2006), and in adults (Fig. 52.6) (Taheri et al. 2004; Chaput et al. 2007). A meta-analysis of cross-sectional data of 30 studies showed a consistent picture of short sleep duration, predicting an increased body mass in adults (Cappuccio et al. 2008), but these findings may not directly translate to longitudinal outcomes. In the Whitehall II study, an association at baseline was found but there was no evidence that sleep duration influenced body mass change over 5 years (Stranges et al. 2008).

Although causality for the U-shaped association has not been proven, there are physiological data implicating a mechanistic link between sleep duration and BMI. For example, in short sleepers (Taheri et al. 2004) and in those who were sleep deprived with only 4 h of sleep per night for two nights (Spiegel et al. 2004), increases in appetite with potential weight gain have been implicated with demonstrable decreases in the appetite suppression hormone, leptin (secreted by adipocytes), and
Fig. 52.6 The relationship between BMI and average nightly sleep. Mean BMI and standard errors for 45-min intervals of average nightly sleep after adjustment for age and sex. Average nightly sleep values predicting lowest mean BMI are presented by the central group. Average nightly sleep values outside the lowest and highest intervals are included in those categories. The number of visits is indicated below the standard error bars. Standard errors are adjusted for within subject correlation (Data are from Taheri et al. 2004. With permission from the Publishers)

increases in the appetite-stimulating hormone, ghrelin (secreted by the stomach). Short sleep duration is associated with increased fat intake (Shi et al. 2008). Under conditions of ad libitum food intake, healthy individuals who were sleep restricted (5.5 h for 14 d) favored food of higher CHO content from snacks (65% versus 61%) compared with nonrestricted conditions (8.5 h for 14 days) (Nedeltcheva et al. 2009b). However, there were insignificant differences in serum leptin and ghrelin between the two sleep conditions (Nedeltcheva et al. 2009a). Sleep fragmentation showed a significant, albeit small increase in overnight energy expenditure (Bonnet et al. 1991), arguing against the connection between short sleep and increases in body mass. Nonetheless, a body of evidence showed that sleep restriction alters glucose metabolism by significantly decreasing glucose tolerance (Nedeltcheva et al. 2009a; Spiegel et al. 2004). Further, both short and long sleep times are associated with an increased risk of impaired glucose intolerance and type 2 diabetes (Chaput et al. 2007). Thus, it appears that sleeping less than the optimal amount needed for an individual holds a link to increased body mass and impaired glucose metabolism. However, its causal relationship to increased weight gain and risk of obesity or diabetes remains to be further explored. Certain predisposing conditions such as an increased opportunity to eat, food availability and selection, and physical inactivity may be additive effects that potentiate weight gain and obesity (Fig. 52.7), as suggested by Taheri (2006).

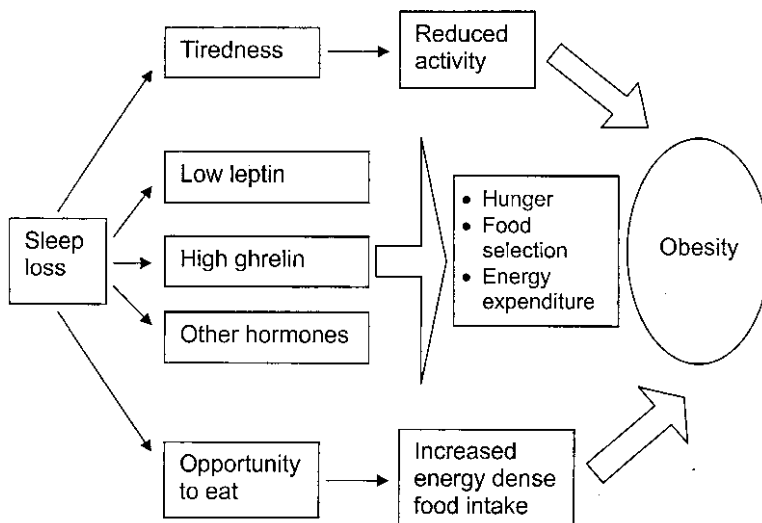
In contrast to human findings, the laboratory rat exhibits characteristic behavior of hyperphagia and demonstrable weight loss following sleep deprivation, in particular PS deprivation. Many studies performed PS deprivation by taking advantage of muscle atonia that characteristically occurs during this sleep stage in a classic flower pot or platform technique (Martins et al. 2006). The experimental rat is placed on a platform (6.5–7 cm in diameter) surrounded by water in a container. When muscle atonia occurs, the rat touches or makes facial contact with or falls into the water, and wakes up. Food ingestion in sleep-deprived animals shows variable patterns. In the acute 24 h of PS deprivation, both reduction (Martins et al. 2008; Hanlon et al. 2005) and increases (Suchecki et al. 2003) have been reported, whereas an early study described no change in overall food intake, although there was a reduction in meal size that was compensated by an increase in meal frequency during the period of sleep deprivation (Elomaa 1981). After 4–5 days of PS deprivation, increased free-feeding behavior


Fig. 52.7 The potential mechanisms through which short sleep duration could result in obesity. Short sleep duration can affect both energy intake and energy expenditure. It results in tiredness that may hamper physical activity, and alters metabolic hormones to increase appetite and affect food selection. Additionally, extra time awake provides increased opportunity for food intake. Other potential mechanisms include effects of sleep on basal metabolic rate, thermic effect of food, and nonexercise activity thermogenesis (Data are from Taheri 2006. With permission from the Publishers)

was consistently observed (Bergmann et al. 1989; Hanlon et al. 2005). In addition, a universal finding in the rat, following sleep deprivation, was the negative energy balance that was explained by increased energy expenditure (Elomaa 1981; Suchecki et al. 2003; Hanlon et al. 2005; Martins et al. 2008; Galvao Mde et al. 2009) and activation of brown fat thermogenesis (Koban and Swinson 2005). In sleep-deprived rats, increased energy metabolism was evidenced by an increased nonspecific motor activity such as eating, drinking, climbing (Suchecki et al. 2002), and gnawing (Martins et al. 2008).

Uniquely, sleep restriction induces a preference for CHO-rich foods in humans (Nedeltcheva et al. 2009b; Spiegel et al. 2004) and in rats (Bhanot et al. 1989; Suchecki et al. 2003). Shift workers who remain awake for periods up to 24 h demonstrate an increased CHO craving (Wurtman and Wurtman 1995). Sleep deprivation is a form of stress, which may mediate changes in appetitive behavior. Healthy females under experimentally induced stress responded with greater food consumption and preference for more sweet food, and these subjects showed high levels of cortisol (Epel et al. 2001). The appetitive behavior may represent a coping strategy for stress, since a high CHO diet decreases cortisol level and alleviates feelings of depression in humans (Markus et al. 2000). Indeed, following sleep deprivation, increased stress corresponds with an increased sympathetic and hypothalamic–pituitary–adrenal (HPA) axis activity (Fadda and Fratta 1997; Suchecki et al. 1998), increased level of cortisol (Galvao Mde et al. 2009; Spiegel et al. 1999) and adrenocorticotropic hormone (Galvao Mde et al. 2009; Suchecki et al. 2003).

52.5 Food Deprivation, Sleep Deprivation, and Brain Glycogen

SWS is increased with food deprivation (acute fasting of 3–4 days). Its appearance may be metabolically beneficial in that brain glycogen accumulation occurs during sleep, whereas it is mobilized on waking (reviewed comprehensively in (Brown 2004)). Brown cited that depletion of glycogen of 40% occurred after sleep deprivation for 12–24 h and complete repletion took place after recovery sleep. Upon SWS initiation, brain glycogen content increased by 70% above waking levels. Although brain glycogen store is low (0.5–1.5 g, 0.1% of total brain weight) relative to the well-fed liver (100 g, 6–8% of the weight of the liver) and skeletal muscle (400 g, 1–2% of the weight of skeletal muscle), its accumulation following sleep deprivation was a slow process and reached its baseline level only after 9 h of recovery sleep. More rapid repletion has been observed. Whilst these data were based on rat studies, nuclear magnetic resonance detection of ^{13}C glucose labeling of glycogen in human brain has been obtained. Sleep deprivation in humans and rats stimulates an increase in food intake with particular preference for CHO and energy dense foods (see earlier section). Thus, elevated blood glucose increases insulin release and facilitates brain glucose uptake via insulin-insensitive GLUT1 and insulin-sensitive GLUT4 glucose transporters and glycogen storage (Brown 2004). A synthesis of these findings proposes that (1) food and sleep deprivation leads to a state of brain glycogen deficit and (2) recovery SWS and the appetitive behavior (preference for carbohydrate intake) function to replete glycogen in both conditions as depicted in Fig. 52.8.

52.5.1 Application to Health and Disease

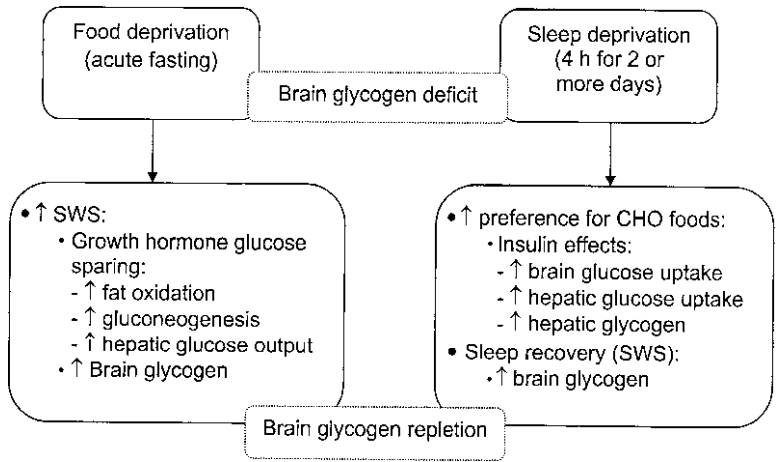
Altered feeding and sleeping behaviors are common amongst dieters, shift workers, and those leading a busy life style. Both the meal timing and its macronutrients have direct impact on sleep, while sleeping less than an individual's requirement stimulates appetite and influences food choices. Short sleep is


Fig. 52.8 Proposed relationship between food deprivation, sleep deprivation, and brain glycogen stores. Brain glycogen deficit occurs following either food or sleep deprivation. Acute fasting of several days promotes an increase in SWS. Sleep deprivation (sleeping a maximum 4 h per night) for 2 or more days increases preference for CHO foods and is followed by sleep recovery with increases in SWS. This appetitive behavior and increased SWS in both conditions function to replete glycogen stores. *SWS* slow wave sleep, *CHO* carbohydrates

Table 52.1 Key factors for managing sleep. This table reflects the key factors used in the management of sleep difficulties. CHO: carbohydrate difficulties

1. Practice sleep hygiene
   - Follow a regular sleep and wake time 7 days a week
   - Sleep in a quiet, dark, and cool environment
   - Avoid excessive caffeine, nicotine, and alcohol prior to bedtime
   - Avoid daytime napping, except in circumstances such a shift work or certain sleep disorders when napping can be beneficial
2. Macronutrients
   - Use natural foods rich in tryptophan (milk, yoghurt, cheese, soybean, sesame seeds, spinach, or turkey) in combination with CHO-based meals
   - Use moderately high GI CHO for evening meals. Use low GI foods for daytime meals to sustain energy
   - Keep evening meal 3–4 h before usual bedtime
   - Use a light CHO snack at bedtime if needed
3. Exercise
   - Exercise 20–40 min 3–4 times per week at least 5–6 h before usual bedtime
   - Avoid strenuous exercise closer to bedtime
4. Seek professional guidance
   - Consult general practitioner or sleep specialist if sleep difficulties continue

associated with poor health outcomes and is becoming the norm, as healthy people self-select to sleep less adding to those who have sleeping difficulties due to shift work, insomnia, depression, the normal aging process, sleep disorders, underlying pathology, the effects of medications, or being menopausal. Thus, the use of macronutrients as an adjunct to exercise may have health and sleep benefits when practiced several hours before the usual bedtime and in coordination with the appropriate sleep hygiene practices (described in Table 52.1). For example, an evening meal that consists of moderately high GI foods may promote sleep onset for those with difficulty sleeping. Meanwhile, low GI foods are recommended for daytime meals and especially for those who are overweight, obese, or with diabetes.

Macronutrients may also be used to an advantage for managing sleep difficulties in shift workers and those with insomnia and depression. Sleep initiation and duration may improve by using

moderately high GI foods after their night shift (or when sleep is planned). Given that the efficacy of high GI foods on sleep is founded on tryptophan, natural foods rich in tryptophan (milk, yoghurt, spinach) are particularly suitable in combination with a CHO-based meal. Choosing a light meal low in GI with a portion of protein during the shift (or when alertness is desired) may circumvent post-prandial sleepiness and lethargy as sleep propensity increases. Similarly, avoiding high fat and large meals prior to or during a night shift may reduce postprandial sleepiness.

Summary Points

- Food ingestion has a direct influence on sleep through its macronutrients, largely carbohydrate and fat.
- Carbohydrates, in particular those with a high glycemic index, shorten sleep onset by increasing tryptophan availability to the brain.
- High-fat meals promote sleep through cholescystokinin released by the small intestine.
- Postprandial sleepiness, following a lunch meal, depends on the thermic effects of food and coincides with the circadian phenomenon of postlunch dip.
- Increased prior wakefulness or sleep deprivation intensifies postprandial sleepiness.
- Under-feeding alters sleep patterns: in many species, acute fasting of 3–4 days increases SWS with variable REMS, whereas chronic fasting decreases SWS and REMS with paralleled increased wakefulness.
- The sleep changes associated with fasting may be linked to changes in the fuel stores of protein and fat. The two extreme conditions of a feeding continuum, anorexia nervosa, and obesity show marked sleep disturbances.
- SWS, occupying 20% of total sleep time, is time-locked to growth hormone release and brain glycogen accumulation.
- Greater SWS appearance during fasting may reflect brain glucose sparing effects via fat mobilization mediated through the action of growth hormone.
- SWS diminishes as lipid stores become depleted in chronic fasting.
- Sleep duration affects appetitive behavior: in humans short sleep stimulates an increased appetite and risk of weight gain, although causality has not been established for the association between short sleep and BMI.
- In rats, short sleep stimulates hyperphagia and weight loss that may be explained by brown adipose tissue thermogenesis.

Definitions

Light–dark cycle: Alternating period of light and dark over 24 h
Circadian rhythm: Endogenous 24 h rhythms of behavior and physiological function (e.g. core body temperature, sleep–wake) linked to the light–dark cycle
Glycemic Index: A number scale (0–100) used to rank carbohydrates on their ability to increase blood glucose levels compared to an equal amount of pure glucose (GI = 100). High GI foods (GI ≥ 70) promote a greater surge in blood glucose compared to moderate or low GI foods (GI ≤ 55)
Cholecystokinin: A neuropeptide released by the duodenum of the small intestine, in response to fatty acids and protein chyme from the stomach
Postprandial: Following a meal

Thermogenesis: The production of heat

Postlunch dip: A naturally occurring, daily period of increased fatigue or lethargy usually present between 1400 and 1600 h

MSLT: An EEG test of daytime sleepiness consisting of four nap opportunities at 2-h intervals

Akerstedt EEG Test: An EEG test consisting of a static 5 min period with eyes open in which the EEG is analyzed by spectral power analysis

Stage 1 (sleep): A state of drowsiness marked by a decrease in the EEG alpha rhythm, and low voltage mixed frequency waves

Stage 2 (sleep): Commonly used to identify the onset of sleep, this sleep stage is characterized by specific morphology in the EEG; namely the sleep spindle (12–14 Hz EEG burst) and the k-complex (sharp negative–positive deflection)

Stage 3 (sleep): A state of deep sleep characterized by high-voltage, low-frequency (0.5–3.9 Hz) EEG waves accompanied with a low threshold in skeletal muscle tone

Slow wave sleep: A term used to identify deep sleep (Stage 3 sleep)

Rapid eye movement sleep: A period of sleep characterized by low voltage mixed frequency waves, bursts of rapid eye movements or quiescence, and associated with skeletal muscle atonia

Nonrapid eye movement sleep: A term used to group sleep stages 1, 2, and 3

Gluconeogenesis: Formation of glucose from noncarbohydrate sources

Paradoxical sleep: Equivalent to rapid eye movement sleep; used to describe the period of sleep in animals characterized by muscle atonia and low-voltage, mixed-frequency EEG

Chapter 53
Healthy Choices? The Implications of Direct and Indirect Stimuli for Product Perception and Food Consumption

Vivianne H.M. Visschers and Thomas A. Brunner

Abbreviation

FOP   Front-of-package label

53.1 Introduction

Consumers are exposed to many environmental stimuli as they make their daily food choices. External stimuli can influence their food choice and, ultimately, their diet and health. For example, many people take the price of food products into account when deciding what to eat. Others may be affected by what people around them eat, even though they are not aware of this influence.

External stimuli are defined in this chapter as all cues in the environment or context that may affect people's food consumption. We divide them in direct and indirect stimuli. *Direct stimuli* are those that are meant to help people to make an informed food choice, e.g., a nutrition table helps consumers to determine the healthfulness of a food product. People will consciously notice this type of stimulus as being relevant to their product perception and food choice.

On the other hand, people are unaware that they use *indirect stimuli* in their food choices. Although they may observe these types of stimuli and their outcomes, the influence of the stimulus itself on their food perception, choice, or consumption goes unnoticed. For example, people appear to eat more when they eat in a group, simply because more people around the table make the meal last longer than when eating alone (Pliner et al. 2006). People then have a longer opportunity to eat, although they do not notice this happening.

We rely on Bargh's (1990) description of *unconscious processing* in our explanation of how direct and indirect stimuli influence food perception, choice, and consumption. In his auto-motive model of unconscious motivations, Bargh proposed that stimuli from the environment can automatically trigger decisions through experience. He suggested that people do not need a conscious intent to start a behavior; indeed, they may not even be able to access this intent or motive. Some scholars assume that unconscious or automatic processes primarily determine behavior, and that in the case of food choice, people scarcely notice how environmental stimuli affect their food consumption (e.g., Dijksterhuis et al. 2005). Based on this assumption, we can also argue that people do not always process direct

information consciously. In other words, consumers may not be aware of the decision process; i.e., how they process the direct information in their minds, or how they come to a decision or behavior. An example would be someone who reads a magazine article about vitamins in fruit. Reading is, of course, a relatively *conscious process*. This person then makes his weekly grocery list, but now lists more fruits than he would usually do, although he did not consciously make a decision to eat more fruit.

In this chapter, we will discuss how direct and indirect stimuli can affect people's food consumption and other related factors, such as their perception of food. First, we discuss how direct stimuli related to food products can influence consumers. These stimuli are presented on and around food products and are intended to inform consumers; examples would be nutrition tables or nutrition claims. Second, we examine how indirect stimuli can affect people's food consumption. More specifically, we examine how stimuli that are present in the food environment can determine how much people eat. The relationship between these two types of stimuli is then discussed. Last, we suggest possible applications of our findings to other areas of health and disease.

53.2 Direct Stimuli

In the following section, *nutrition information* on food products is taken as an important example of direct information, because nutrition information is intended to act as a decision aid to help consumers make healthy food choices. Because of the complexity of nutrition information, such as nutrition tables, its full understanding often requires extensive cognitive elaboration. Other examples of direct stimuli related to food are advertisements around foods, and information in the media or from the social environment.

Many food products present nutrition information in the form of a table or a claim on their package. Nutrition tables include the amounts of energy and of at least three nutrients (i.e., protein, carbohydrate, and fat) per 100 g or milliliters in a product. Several studies have indicated that people pay little attention overall to this type of information, although they often say they do (see Higginson et al. 2002; Cowburn and Stockley 2005 for an overview). A recent study showed a more refined finding; namely, that visual attention to nutrition information depends on people's motivation and the product's design (Visschers et al. 2010, see Fig. 53.1). This implies that nutrition information should be conspicuously and attractively designed, as well as being easily understandable.

53.2.1 Direct Information as Reference

Although a number of previous studies examined the effect of different presentation formats of nutrition information on food products on their use and understanding, these studies did not provide clear results about effectiveness of this information itself on understanding (e.g., Feunekes et al. 2008; Geiger et al. 1991; Lewis and Yetley 1992; Van Kleef et al. 2007). Other studies in consumer psychology showed that when people evaluate a product, the presence of *reference information* and the type of reference information seem to affect their evaluation of this product (i.e., the evaluability principle, Hsee 1996).

For example, people were asked to compare two products on two attributes. One was easy to evaluate (e.g., the degree of under- or overfilling of an ice cream cup), while the other was more difficult to evaluate on its own, but was more important for product perception (e.g., the size of the ice cream cup). When people received information about the two attributes, based on only one product,

Product x Type of Motivation
Fig. 53.1 Effect of type of motivation on respondents' attention to nutrition tables, and front-of-package labels on different products. This bar graph presents the number of respondents that looked at least once at the nutrition table or front-of-package label (*FOP*) (Visschers et al. 2010, with permission from the authors). The frequency numbers are presented per product and per type of motivation. Half of the 32 respondents were motivated to choose a healthy product and the other half were motivated to look for a tasteful product. While they were doing this, their visual attention was recorded by an eye tracker, an instrument to measure people's eye movements. The results presented in this bar graph show that the majority of the respondents paid attention to the nutrition table on each product. This did not differ between the two types of motivation or the products (χ^2s < 6.23, ps > 0.18). The type of product did influence whether people noticed the FOP on the five products ($\chi^2(3) = 13.05$, $p = 0.005$); most respondents noticed the FOP on the Naturaplan Bioflakes but most respondents did not notice the FOP on the other products. Note that the package of Prix Garantie Cornflakes did not present an FOP

they evaluated the product on the easy-to-evaluate attribute and neglected the hard-to-evaluate attribute (Hsee 1996, 1998). As a result, they valued a small cup of ice cream that was overfilled more highly than a larger, underfilled cup containing more ice cream. When they could evaluate the two ice creams on both attributes, they compared the products on the hard-to-evaluate attribute so that this attribute determined their evaluation. Now they preferred the larger, underfilled ice cup containing more ice cream.

Thus, to use the hard-to-evaluate attribute, a comparison with another product was needed: the content of the underfilled cup was related to the content of overfilled cup. People make better choices when they can refer the values of an attribute that lacks clear boundaries to those of another product. In line with this finding, reference information related to nutritional value may help people choosing healthy food products.

Examples of reference information in nutrition tables could be the average level of fat in similar products or the average number of kilocalories in a healthy alternative of this type of food. Four studies by Viswanathan and Hastak (2002) tested reference stimuli presented either as the *average amount* of a nutrient in the product category (i.e., in all chocolates) or as the *range* of the nutrient in the product category. Adding one of these two reference formats to the standard nutrition table improved respondents' understanding of the product's nutritional value, compared to the percentage daily value information.

Feunekes et al. (2008, Study 1) also indicated the importance of reference information about a product's nutritional value. They examined people's understanding of six different nutrition labels

on food products, e.g., a multiple traffic light, a healthier choice tick, or a health protection factor. The labels indicated the overall nutritional value of the product. Participants least understood, liked, and trusted the Health Protection Factor (i.e., a pictogram in which the healthiness was presented by a number, such as is seen on sunscreen lotions). A possible explanation for this finding may be that the Health Protection Factor did not include any reference information; consumers were not informed about the meaning of the presented number or about its maximum score.

In another experiment, various nutrition tables, which differed on reference information, were examined using a hedonic product and a product with a healthy image: chocolate and yogurt (Study 1, Visschers and Siegrist 2009). Respondents received one of six nutrition tables and rated the presented product on its attractiveness and perceived healthiness. Except for the standard nutrition table, all other five tables included reference information, such as a nutrition table with a bar that presented the summarized nutrition quality of the product together with the average nutrition quality of the product category (see Fig. 53.2). The findings indicated that reference information in the nutrition tables affected participants' product perception. The respondents evaluated the chocolate presented in the nutrition table with reference information as less attractive than when it was presented with the standard nutrition table (see Fig. 53.3). Thus, people's perception of the chocolate seemed to be more in line with its actual nutritional value after seeing the reference information than it was after reading the standard information.

Nutrition tables with or without reference information did not affect the product perception of the healthy-image product (i.e., the yogurt) in this study. The authors suggested that this was due to the high nutritional value of the presented yogurt so that reference information could not increase respondents' healthiness perception. Visschers and Siegrist (2009) therefore conducted a second study with a similar design, but which presented a low-nutritional value yogurt and a high-nutritional value yogurt. This time, reference information in nutrition tables appeared to affect people's healthiness perception of a product with a healthy image, if it had a low nutritional value (see Fig. 53.4). Moreover, this effect was influenced by people's nutrition–health awareness. The reference information did not change either the product's attractiveness or the product perception of the high-nutritional yogurt.

In sum, the effect of nutrition tables with reference information on product perception appears to depend on two conditions (Visschers and Siegrist 2009). First, the nutritional value of the product-at-hand determines whether reference information can change people's perception of the product. Nutrition tables with reference information can change consumers' perception of food products with

Fig. 53.2 The NDI plus product category nutrition table. In this nutrition table, the NDI score of a chocolate is compared to the average NDI score of all chocolates. The table is an example of one of the six tables presented to participants in Visschers and Siegrist (2009, Study 1) (Reprinted from Appetite. 52: 505–512. Copyright (2009), with permission from Elsevier)

Nutrition Information BonChoc

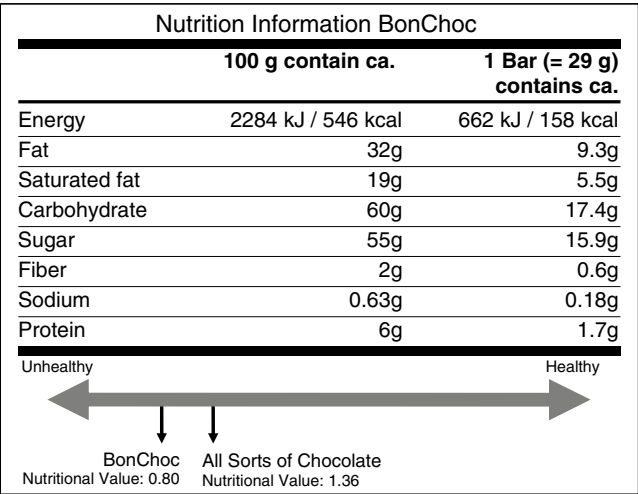
Nutritional Value: 1.36


Fig. 53.3 Respondents' mean attractiveness rating for chocolate for each nutrition table.
This bar graph shows respondents' mean attractiveness rating of chocolate after seeing one of six nutrition tables (Study 1, Visschers and Siegrist 2009, with permission from the authors). The respondents who had seen the Control nutrition table (see *) rated the chocolate as more attractive than the respondents who had seen one of the other nutrition tables, $F(5, 143) = 3.97$, $p = .002$. The Control nutrition table was the standard nutrition table, which only included the values of eight nutrients. The NDI Score nutrition table consisted of the nutrition density score (*NDI*) of the product, together with five stars in which the corresponding NDI score was colored black. The NDI plus Product Category nutrition table included alongside the NDI score of the product at hand, the average NDI score of the product category on a bar (Fig. 53.2). The NDI plus Orange nutrition table was a bar with the NDI score of the product and the NDI score of a very healthy product, namely an orange. The percentage daily value (%DV) nutrition table presented the standard table plus the %DV for each nutrient. Last, the Smiley's nutrition table included the standard information plus a positive, negative, or neutral smiley for each nutrient. Except for the Control nutrition table, all other tables included reference information

low nutritional value, compared to the standard nutrition table; whereas these tables do not seem to affect the perception of products with high nutritional value. Second, the type of product that is presented in the nutrition table determines what kind of perception is changed within the individual. Reference information in nutrition tables can only influence the primary association with a product (e.g., chocolate = tasty and yogurt = healthy) and only when this is not in line with the actual nutritional value of the product.

Moreover, direct information should be mentioned very explicitly, such as in graphical comparisons of a food's healthiness to that of other products. For example, in four studies, Raghunathan et al. (2006) showed that if consumers receive only nutritional information about the product-at-hand (similar to the standard nutrition table), information that a product is healthy results in less perceived tastiness than does information that a product is unhealthy. People therefore seem to apply the rule: unhealthy = tasty if they can only evaluate one product. In contrast, when they can compare the same product based on reference information, their tastiness perception is more in agreement with the product's actual nutritional value.

Direct nutrition information was also presented explicitly for comparison in a study about the effect of fat reduction in foods (Visschers and Siegrist in press). Respondents could compare the fat contents of two products presented in nutrition tables and were asked to choose one of two products
Fig. 53.4 Mean perceived healthiness ratings of low-nutritional value and high-nutritional value yogurts per nutrition table. In this graphic, the mean perceived healthiness of yogurts is presented per nutrition table (Study 2, Visschers and Siegrist 2009, with permission from the authors). Respondents rated the healthiness of either a low-nutritional value (low NV) yogurt or a high-nutritional value (high NV) yogurt, presented with one of three nutrition tables. The three nutrition tables were selected from Study 1 (see Legend to Fig. 53.3 for a description). Results showed that the type of nutrition table affected the perceived healthiness of the yogurts, $F(2, 172) = 3.04$, $p = .05$. Respondents who evaluated the NDI plus Product Category nutrition table rated the low NV yogurt as less healthy than the high NV yogurt, $t(58) = -1.76$, $p = .04$ (see *). The perceived healthiness did not differ between the low-NV yogurt and high-NV yogurts in the Control nutrition table or in the NDI plus Orange table, $-1.09 < ts < .14$, $ps > .28$

or none. The fat content of these two products was reduced in two following steps. Crisps A always contained less fat (reduced-fat product) than Crisps B (full-fat product). At the last step, respondents compared a zero-fat product (Crisps A) with a reduced-fat product (Crisps B). Although most respondents at first favored the reduced-fat product over the full-fat product, after a considerable fat reduction, most preferred the product with some fat over the zero-fat product (see Table 53.1).

Therefore, two standard nutrition tables can also function as references, if they are explicitly presented side-by-side. These direct stimuli can steer people in their food choice. The type of reference offered seems to determine which criterion people use for their choice. If two products appear similarly tasteful, they choose the healthiest product (i.e., reduced fat). If both products are already low in fat, they look for the tastier alternative (i.e., some fat rather than no fat).

53.2.2 Direct Information as Qualitative Translator

Another way in which direct information can influence product perception and food choice is as a translator of quantitative information. For example, health labels on products translate the quantitative information of the nutrition table into a qualitative interpretation. A chocolate bar that contains 546 kcal and 32 g of fat per 100 g, of which 19 g are saturated fat, may be presented with a red traffic light label for fat on its package so that the consumer can easily see that this is not a very healthy product.

Table 53.1 Percentage of respondents choosing Crisps A, Crisps B, or none of the products, at each fat reduction step. In this table, the percentage of respondents that chose Crisps A, Crisps B, or none of the two products is presented per fat reduction step. Crisps A always contained less fat than Crisps B. Crisps A contained almost zero fat at Step 2, and zero fat at Step 3. The random sample of this study contained 80 adults. More respondents chose Crisps A, the reduced fat product, at Step 1. This percentage significantly decreased after a substantial fat reduction: more respondents then chose Crisps B ($\chi^2_F(2) = 15.03$, $p = .001$) (Data are from Visschers and Siegrist in press. With permission from the authors)

Fat reduction step	Choice		
	Crisps A	Crisps B	None
Step 1: 15 vs. 27 g	63.75	10	26.25
Step 2: 1 vs. 23 g	50	25	25
Step 3: 0 vs. 22 g	42.5	31.25	26.25

Table 53.2 Key facts for direct and indirect stimuli related to food consumption. This table presents the key facts of direct and indirect stimuli related to food consumption. The key facts include the presentation, mental processing, functioning, and the kind of effects of direct and indirect stimuli

1. Direct stimuli are information about food products that are intended to influence consumers; for example, through their liking, health perception, or consumption.
2. Consumers can consciously notice direct stimuli and can process them elaboratively, but this need not be the case.
3. Indirect stimuli are not consciously processed by consumers.
4. Indirect stimuli affect consumers' food consumption through priming: indirect stimuli initiate an association that is related to food consumption, e.g., body weight.
5. Direct stimuli first affect people's product perception and food choice before they influence food consumption. Direct stimuli can evoke automatic responses related to food consumption, if they are more familiar.
6. Indirect stimuli can only determine food consumption; that is, they can increase or decrease the consumption volume if one is already eating.
7. Consumers' motivation plays a role in the effects of both direct and indirect stimuli. People should be motivated to pay attention to, and to mentally process, direct stimuli in order for these to affect food perception. People should only be somewhat motivated so that the indirect stimuli can influence their food consumption. The motivation should be related to the indirect stimuli.

A nutrition *claim* that communicates a product's low-fat content seems to affect consumer preference for it. Several studies found that consumers rated products with low-fat claims as less tasty than the same products without this claim or than similar products with more fat (Solheim and Lawless 1996; Kähkönen and Tuorila 1998; Stubenitsky et al. 1999). Solheim and Lawless (1996) asked consumers first to taste a reduced-fat product and to report their taste evaluation. The consumers then saw a low-fat claim, together with this product, while they again tasted the product. Consumers found the taste of the product to be better before seeing the low-fat claim than after. When presented the other way around, when people first estimated the expected pleasantness of a food, only based on a low-fat claim, and then rated the product's pleasantness on its actual taste, they expected a bad taste at first but corrected this rating after tasting the product (Kähkönen and Tuorila 1998). Nutrition claims about fat content thus affect people's taste perception.

Nutrition *labels* can also function as translators of nutrition information, such as the healthy choice label or a front-of-package label. Products with a nutrition label appear to be perceived as healthier than the same products without a label. Feunekes et al. (2008) used various labeling formats to investigate their effects on the perceived healthiness of healthier and less healthy food

products. Respondents had to evaluate the products before and after the labels were presented to them. The presence of the labels primarily increased the perceived healthiness of the healthier products (see Fig. 53.5). A nutrition label on unhealthier products slightly decreased the perceived healthiness, compared to the same products without a label.

Nutrition information formats that include *verbal descriptors* of the nutrition values (e.g., "fat: high, carbohydrates: medium" etc.) seem to increase consumers' understanding of the individual nutrient levels (Levy et al. 1996; see Cowburn and Stockley 2005 for a review; British Market Research Bureau 2009). However, the studies showed varying effects of verbal descriptors on people's health estimates of the products. Verbal descriptors per nutrient in front-of-package labels (FOPs) caused better health estimations of the presented products than did FOPs lacking this information (British Market Research Bureau 2009). In contrast, Levy et al. (1996) examined verbal descriptors for each nutrient in nutrition tables. Participants were asked to make health ratings of products, based on one of various nutrition table formats. The verbal descriptors in the nutrition table resulted in health ratings that differed much more from the products' actual healthiness than other formats, such as the standard nutrition table.
Fig. 53.5 Mean differences in perceived healthiness ratings for healthier and less healthy products per nutrition label, when respondents compared a product pair (**a**), or chose a product from a shopping basket (**b**). These bar graphs present respondents' mean difference in perceived healthiness ratings of healthier and less healthy products before and after doing one of two tasks. Figure 53.5a shows the mean differences in perceived healthiness ratings when respondents had compared two products. Figure 53.5b presents these when respondents had to choose one product from a shopping basket. The products were labeled with one of four nutrition labels: the Healthier Choice Tick, the Multiple Choice Tick, Stars, or the GDA scores (Guideline Daily Amounts). The presence of one of the four labels appeared to increase respondents' perceived healthiness of the healthier products and slightly decreased the perceived healthiness of the less healthy products. Note: Means that do not share letters in the same category differ at $p < .01$. Data are from Feunekes et al. (2008) (Reprinted from Appetite. 50: 57–70. Copyright (2009), with permission from Elsevier)

Overall, various qualitative translators have been investigated. It appears that a general qualitative translator, such as a nutrition label, can influence people's health perception of the product. A fat-reduction claim can change people's taste perception. Similarly, as specific products are primarily associated with specific perceptions, a specific qualifier only appears to affect people's primary association (i.e., with fat). The effects of verbal descriptors per nutrient on healthiness perception do not appear to be very consistent.

53.3 Indirect Stimuli

Much information exists in the food and eating environment that consumers do not directly relate with the food they perceive or consume. These stimuli are processed without awareness and indirectly affect how much people eat. Simply seeing a food product can stimulate consumption (Boon et al. 1998; Painter et al. 2002), making stockpiling a trigger for higher food intake (Chandon and Wansink 2002). Perceived variety is another factor that increases consumption (Rolls et al. 1981), even if the taste of the food items is identical; for example, when food items are colored differently (Khan et al. 2005). The effect of package size (Wansink 1996) and size of portion servings on food intake is well supported (Edelman et al. 1986; Rolls et al. 2007). People will eat more of even a less-favored food if it is offered from a large container compared to a smaller one (Wansink and Kim 2005). Besides package size, the form of packaging and the form of the utensil used for eating also affects consumption volume (Wansink and van Ittersum 2003). For example, people drink more from short and wide glasses than from tall and narrow ones that hold the same volume, as shown in Fig. 53.6.

53.3.1 Seemingly Unrelated Indirect Stimuli

However, there are other factors that are not that closely related with food that also have an influence on how much people consume. Pleasant lighting, decor, or music make the eating experience more comfortable and enjoyable, and therefore lead people to spend more time eating (Lyman 1989; Stevenson et al. 1999; Caldwell and Hibbert 2002). Effort related to food, i.e., the ease of reaching food, access to food, or convenience with which food can be consumed, is one of the strongest influences on consumption (Schachter et al. 1974; Engell et al. 1996; Levitsky 2002; Painter et al. 2002).

Fig. 53.6 An example of short and wide glasses and tall and narrow glasses. People drink more from short and wide glasses (*left*) than from tall and narrow ones

Distracters, such as reading or watching television, can also increase food intake by initiating, obscuring, or extending consumption (Bellisle and Dalix 2001; Wansink and Park 2001). Finally, the number of other people present while eating increases food intake in a linear manner (De Castro and Brewer 1992; Pliner et al. 2006).

Another explanation, besides the longer duration of the meal mentioned in the introduction, for higher food intake when in the company of others comes from the literature on modeling eating behavior. These experiments usually include a naïve participant who eats in the presence of a confederate of the experimenter. The confederate is instructed to eat a lot in half of the sessions and only little in the other half of the sessions. The main conclusion from the research on modeling is that people eat more when their eating companions eat more and people eat less when their eating companions eat less (Nisbett and Storms 1974; Polivy et al. 1979; Rosenthal and Marx 1979; Conger et al. 1980). Individual differences, such as hunger, obesity, dieting, or social desirability, do not affect this companion effect (Rosenthal and Marx 1979; Goldman et al. 1991; Herman and Polivy 2005). To explain why people eat more when accompanied, Herman et al. (2003) suggest that in most eating situations, people unconsciously look at other people for guidance as to how much is appropriate to eat. Thereby, the person who eats the most sets an upper limit for food intake. Of course, the larger the group, the more likely it will include a person who eats a lot.

Another factor influencing how much people eat, without being aware of it, was found by running an extended version of the standard modeling experiment. Johnston (2002) used an ice cream tasting task and instructed a confederate to eat a lot of ice cream in half of the sessions and only little ice cream in the other half of the sessions. Besides varying food intake, the physical appearance of the confederate was varied as well: in half of the sessions, the confederate was of normal weight and in the other half the confederate was obese. With the normal-weight confederate, the well-known modeling effect was found. Participants ate a lot of ice cream when the confederate ate a lot and participants ate only little ice cream when the confederate ate little. However, with the obese confederate, participants ate little ice cream, no matter how much the confederate ate; i.e., the modeling effect was inhibited. It seems that the obese confederate somehow caused participants to reduce their food intake to a minimum.

Recently, Brunner and Siegrist (2009) replicated and extended the study by Johnston (2002). Instead of an obese confederate, they used bathroom scales that they placed in the experimental room in half of the sessions. The confederate in their study was always of normal weight. Participants were instructed to taste and rate chocolate. The authors found that in the sessions with the scales present, participants did not model the confederate's eating behavior; i.e., they ate little, even if the confederate ate a lot of chocolate. Without the scales, the modeling effect could be replicated (see Fig. 53.7). Put another way, relatively unobtrusive scales that were placed a few meters away from the person had a dramatic influence on that person's consumption volume, even if an eating companion was present who set the upper limit of food intake much higher.

In a second study, Brunner and Siegrist (2009) used a verbal statement rather than scales. The experimenter remarked at the beginning of every other session that chocolate makes people fat but also happy. She said this in a rather humorous way, making participants think that it was a joke that was not related to the experiment. The verbal statement exerted the same influence as the scales. Without the statement, participants modeled the behavior of the confederate; whereas, when the statement was given, participants ate little chocolate even if the confederate ate a lot of it (see Fig. 53.8).

Finally in a third study, Brunner and Siegrist (2009) ran an experiment without a confederate. Participants were again invited to take part in a chocolate tasting. Half of them filled in questions about gender, age, size, and particularly weight before the tasting, the other half of participants started directly with the tasting and filled out their demographics and weight at the end of the study. Results showed that merely reminding participants of their weight by letting them declare how much
Fig. 53.7 Consumption frequencies of chocolate in the presence or absence of bathroom scales, when the confederate had a high versus a low consumption. This line graph shows the effects of a bathroom scales prime in combination with the consumption behavior of a confederate on people's consumption volume (Study 1, Brunner and Siegrist 2009, with permission from the authors). When the bathroom scales were not present, respondents who were accompanied by a confederate who consumed a lot of chocolate also consumed a lot of chocolate, and they consumed more than respondents who were accompanied by a confederate who consumed a small amount of chocolate. When the bathroom scales were present, the consumption volume of the confederate did not influence the consumption of the respondents; respondents ate a small amount of chocolate, whether the confederate consumed a large amount or a small amount (interaction effect: $F(1, 50) = 4.26$, $p < .05$)
Fig. 53.8 Consumption frequencies of chocolate in the presence or absence of a statement that chocolate makes people fat, when the confederate had a high versus a low consumption. This line graph shows the effects of a remark by the experimenter that chocolate makes people fat, in combination with the consumption behavior of a confederate on people's consumption volume (Study 2, Brunner and Siegrist 2009, with permission from the authors). When the experimenter did not make this remark, respondents who were accompanied by a confederate who consumed a lot of chocolate also consumed a lot of chocolate and more than respondents who were accompanied by a confederate who consumed a small amount of chocolate. When the experimenter made this remark, the consumption volume of the confederate did not influence the consumption of the respondents; respondents ate a small amount of chocolate, whether the confederate consumed a large amount or a small amount (interaction effect: $F(1, 42) = 3.15$, $p < .10$)

they weigh reduced food intake in the following chocolate tasting. In addition, there was an interesting interaction between the *priming* condition and the degree to which participants monitored their body weight. Only for the primed participants, i.e., for participants who declared their weight before tasting the chocolate, was monitoring body weight negatively related with consumption volume. No correlation was found for participants who directly started with the tasting; i.e., it did not matter how strongly they monitored their weight.

It is important to mention that none of the participants was aware of the influence that resulted from the scales, the experimenter's remark, or the declaration of body weight in any of the three studies. Therefore, the three studies show very clearly that eating behavior, and particularly consumption volume, is affected by unobtrusive external information that is processed unconsciously. The factor that was found to influence food intake was a priming of body weight related cognitions. Whenever participants were primed with weight cognitions, they reduced their food intake.

53.3.2 Subliminal Priming

The findings of Brunner and Siegrist (2009) can be related to *subliminal* priming. In experiments using subliminal priming, information is presented just below the normal limits of human perception. These cues are unrecognized by the conscious mind but might affect thoughts and behavior on an unconscious level. In 1957, James Vicary received much media attention by claiming to have significantly increased sales of Coca Cola and popcorn in a movie theatre by subliminally flashing the message "drink Coca Cola" and "eat popcorn" onto the movie screen (Henderson 1957). Vicary himself admitted later on in an interview that his data were not very meaningful – the whole story was a hoax (Danzig 1962). Fifty years later, Vicary's dream partly came true. Subliminally priming thirst resulted in participants drinking more than unprimed participants, but only when participants were thirsty (Strahan et al. 2002). It appeared possible to even prime a specific brand of drink. Subliminally priming "Lipton Ice" increased participants' preference for that brand, but again only for thirsty participants (Karremans et al. 2006; see also Veltkamp et al. 2008).

The question is raised as to why subliminal priming only works for thirsty participants in these studies. Strahan et al. (2002) refer to Higgins' (1996) notion that priming mainly affects behavior in situations in which the intended behavior is applicable. Therefore, priming thirst only results in drinking behavior if participants have the opportunity to drink and if they want to drink because they are thirsty. Hence, priming can only exert its power when people are already motivated to pursue the related goal.

53.3.3 Comparing Subliminal and Supraliminal Priming

The same reasoning that holds for subliminal priming may also hold for *supraliminal* priming (i.e., stimuli above the threshold of human perception), as long as the information is processed without awareness. Most people are motivated, at least to some degree, to monitor their body weight. Therefore, Johnston's (2002) as well as Brunner and Siegrist's (2009) studies show that the behavior of eating less was applicable. Participants had the opportunity to eat, but priming the concept "body weight" increased the motivation to eat little. Brunner and Siegrist's (2009) third study shows very

clearly that two conditions are needed to reduce food intake effectively: both a priming of body weight cognitions and the motivation to monitor body weight. Recall that the degree of monitoring body weight did not influence consumption volume in the unprimed participants. However, primed individuals decreased their consumption volume quite strongly if they were motivated to monitor their body weight.

Brunner and Siegrist (2009) suggested that most people were motivated to some extent to monitor their body weight. Consequently, they found significant results in the other two studies in which they did not directly control for body weight monitoring. Without the motive to monitor body weight, priming alone would hardly be adequate to decrease food intake. From an ethical point of view, this is somewhat of a relief, as it indicates that priming alone will not be sufficient to impose just any behavior upon someone. People need to have at least some degree of motivation before they can be directed toward a specific behavior.

To conclude, there is a good deal of evidence to support the idea that eating behavior – and consumption volume in particular – is heavily affected by external stimuli that are processed without awareness. These indirect cues can be closely related to food, such as portion size, but they can also be more distant, such as lighting or any cue that subconsciously activates cognitions about body weight.

53.4 Discussion

This chapter focused on the influence of direct and indirect stimuli on food perception and consumption. The take-home message might be that indirect and direct stimuli affect consumers under different conditions. Dual process theories of information processing essentially posit that people can process information both elaborately and consciously (also called central, systematic, or analytical processing), as well as intuitively and more automatically (i.e. peripheral, heuristic, or experiential processing, see Petty and Cacioppo 1986; Chaiken et al. 1989; Fazio and Towles-Schwen 1999). Which of these two processing modes is more prominent in a certain situation appears to depend on people's motivation for deliberate processing and their opportunity to do so, such as their available time and cognitive abilities (Fazio and Towles-Schwen 1999). Figure 53.9 shows how indirect and direct stimuli affect food choices, following dual process theories.

As people mostly do not consider indirect stimuli as important for their food choice or consumption, they are not motivated to process these elaborately, but do so rather automatically. If participants in a priming study recognize a cue as a prime, its effect on behavior is lost as they switch to conscious processing (see Bargh and Chartrand 2000). The indirect stimulus should instead be familiar to the observer so that it is automatically associated with the appropriate behavior. Furthermore, unconsciously processed information can only affect behavior that a person has already planned to carry out and that fits the situation. Related to food, a prime can therefore only increase or decrease food consumption or direct a food choice if the person is already in a choice situation. In other words, a prime cannot initiate food consumption without the underlying motivation to do so. Thus, the presence of the scales in the studies by Brunner and Siegrist (2009) could only influence how much of the offered chocolate participants ate. If they had not offered food to the participants, but instead had examined participants' behavior in general after seeing the prime, they probably would not have found any effect of the prime, as people would have had to initiate a new behavior on their own.

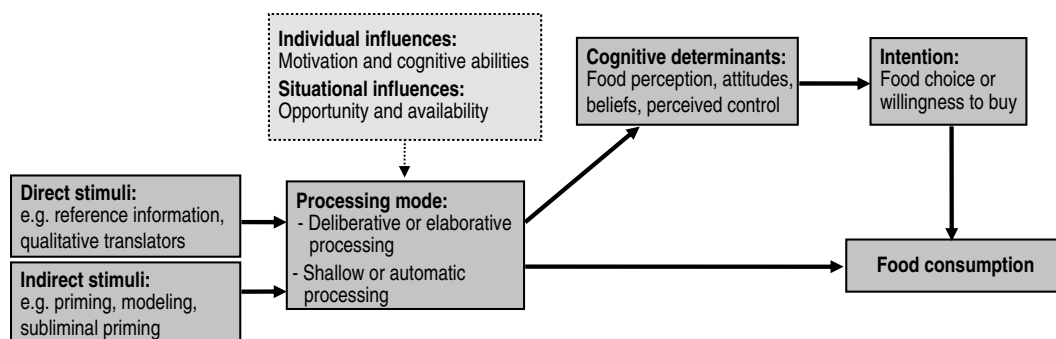
Direct stimuli are more likely to be processed deliberately, as consumers generally consider these to represent important information for a food choice and are therefore motivated to understand them.


Fig. 53.9 Schematic presentation of the influence of direct and indirect stimuli on food consumption and its prede-termining factors, based on dual process theories. The model presented in this figure explains how direct and indirect stimuli affect people's food perception, choice, and consumption. The processing mode of these two types of informa-tion (i.e., how they are processed) mainly determines the effect of the information on consumers. Processing modes are derived from dual process theories of information processing (see Petty and Cacioppo 1986; Chaiken et al. 1989; Fazio and Towles-Schwen 1999), which posit that people will process information deliberatively if they are motivated, if they have the cognitive abilities, and if given an opportunity to do so, as well as when the necessary information is available; otherwise, they will use shallow or automatic processing. Deliberative processing affects food consumption indirectly; it first influences the cognitive determinants related to the food and then people's intention before they change food consumption. Shallow or automatic processing determines food consumption directly

As a result, direct stimuli can affect not only people's behavior, but also several factors that underlie this behavior, such as the perception of the product or the intention to buy it.

Besides the different ways of processing direct and indirect information, these two types of information may seem dissimilar in two other respects. First, they have different presentation modes; direct stimuli are mostly intended to influence consumers and thus are explicitly presented on the food-at-hand, whereas indirect stimuli are not explicitly indicated to people, as they are mostly not related to the food itself. Second, direct and indirect stimuli differ in the kind of effects they can have on consumers. The studies reviewed in this chapter mainly examined consumers' product perception and product choice, after receiving direct information. The effect of indirect stimuli, on the other hand, was investigated with respect to consumption volume. This latter depen-dent variable could also be measured in studies that examine the influence of direct information on people. However, based on cognitive behavior change theories (e.g., Ajzen 1991), many researchers assume that direct information first has to change people's product perception (i.e., attitude), and the intention to buy this product, before the actual consumption behavior can be altered. It is there-fore commonly accepted to study direct stimuli related to these two predetermining factors of behavior.

Nevertheless, direct information does not always have to be processed consciously. As mentioned in the introduction of this chapter, consumers seem to respond to most external cues (including direct information) automatically (Dijksterhuis et al. 2005). For example, a parent may be inclined to grab the mini chocolate bars that are put up at the checkout because they are presented with a picture of happy children, which reminds him of his children, without considering whether the children even like these chocolate bars. Moreover, previous research has shown that cognitive behavior change theories are not the only predictors of food consumption behavior. Factors that are not included in these models, such as habit strength, sometimes play a greater role in behavior (e.g., De Bruijn et al. 2007). Inclusion of a behavior measure is therefore recommended when investigating the influence of direct stimuli on consumers.

Furthermore, this overview implies that direct and indirect stimuli are not as unrelated as the reviewed studies in this chapter may have suggested. For example, consumers may automatically associate an established health label on food products with a high level of healthiness, so that they will choose to consume a product that is presented with this type of label, without paying attention to the type of product or to the nutrition table. However, some health labels are assigned per product category, e.g., fat-free ice cream and regular ice cream are both snacks – the former can be assigned with a health label, whereas the latter cannot. However, both contain more fat and sugar than a regular yogurt, which cannot be presented with a health label in its category. The health label on a food product may automatically trigger the idea that it is healthy and people might therefore choose this product, without consciously considering the product's actual content. In this situation, direct information is used as a simple decision rule or heuristic, namely "health label implies healthy food."

Our review also showed that for both direct and indirect stimuli, people need to have some kind of motivation so that the stimuli can influence their perception or behavior. Brunner and Siegrist (2009) showed that people who are motivated to monitor their body weight are, to a greater extent, affected by a body weight prime than are those who do not have this motivation. However, too much motivation may hurt the priming effect. The priming of cognitions about body weight probably does not make a difference for people who are consciously and constantly monitoring their body weight. It then results in a ceiling effect and additional priming of this behavior no longer matters. On the other hand, priming alone also does not work. Motivation is necessary, but sometimes is not sufficient to activate behavior. In these cases, priming can prod people into action (see Herman and Polivy 1984).

Motivation also plays a role in the effect of direct stimuli on food perception and choice. In the second study by Visschers and Siegrist (2009), the effect of the various nutrition tables, with and without reference information, was affected by people's nutrition–health awareness. Additionally, in another study, these same authors revealed that people's visual attention to food packages could be directed more at nutrition information if they had a health goal than if they had a hedonic goal in their product choice (Visschers et al. 2010).

To conclude, the influence of direct and indirect stimuli depends on the individual's motivation and the situation. People who are highly health-motivated are interested in health and nutrition information and, consequently, will pay attention to nutrition information that is directly displayed. New or unfamiliar situations and important decisions will also stimulate people to consider the information offered deliberately. Indirect stimuli will mostly affect people when they have a moderate motivation level and the situation does not allow or does not stimulate a deep level of processing of the information and cues that are present. Over time, direct stimuli can function as indirect stimuli, once people are very familiar with them and no longer see the need to contemplate their meaning. The food environment thus includes direct and indirect stimuli, which sometimes initiate healthy choices. Consumers are exposed to a large amount of information when dealing with food; luckily, some of the cues are indirect so that the consumers are not constantly overwhelmed.

53.5 Applications to Other Areas of Health and Disease

The knowledge of how direct and indirect stimuli can influence food perception, choice, and consumption can be very well applied into the field of health communication. Doctors and counselors provide patients with information for making informed decisions; for example, about, a

treatment plan. Much research has investigated how the format and the content of this information can influence patients (i.e., direct stimuli). However, little attention has been paid to investigating, for example, how the communication situation (e.g., the doctor's conversational technique), which may convey indirect information, affects patients' decisions. Patient information leaflets or other developments of medication instructions could be regarded as another application field. Lastly, the findings reported in this review may be interesting in terms of the development of health interventions, especially those that promote healthy eating. Health interventions today are mostly theory- and evidence-based. The information that is communicated to the relevant population and the methods applied in a health campaign could profit from more knowledge of direct and indirect stimuli.

Summary Points

- When people only receive information about two attributes of one product, they base their evaluation on the easier-to-evaluate attribute and neglect the harder-to-evaluate attribute, although the latter may be more important for the evaluation (i.e., evaluability principle).
- People make better product choices or product evaluations when they can directly compare products on relevant characteristics.
- Direct nutrition information mainly changes people's primary association with a food product (e.g., chocolate = tasty).
- Direct nutrition information can only change people's product perception if this perception was not in line with the product's actual nutritional value.
- People can process information in two ways: one is a more deliberate and elaborate process; the other is based on intuition and automaticity.
- External stimuli that are processed without awareness affect human behavior. For eating behavior, these cues can be closely related with food (e.g., salience, package size) or more distant (e.g., music, distracters such as reading).
- In modeling experiments, participants' consumption volume is influenced by a confederate who either eats a lot or only little. The modeling effect has been demonstrated various times and has been regarded as a very robust phenomenon.
- Priming cognitions about "body weight" is strong enough to inhibit the modeling effect. These cognitions reduced food intake of participants, even in the absence of an eating companion. The motivation to monitor body weight is a significant covariate for primed participants.
- Subliminal priming has also been shown to influence eating behavior. Participants drink more when primed with thirst, but only when they are thirsty.
- Priming only works when the resulting behavior is applicable, i.e., there must be an opportunity to show the behavior, and the behavior must be motivated to some extent. The underlying motive is essential (e.g., thirsty participants, participants who are eager to monitor their body weight).
- Supraliminal priming works in the same way as does subliminal priming, as long as the stimuli are processed without awareness. If participants recognize the cue as a prime, its effect on behavior is lost.

> **Definitions of Key Terms**
>
> **Conscious information processing**: Any mental elaboration of information that is under some deliberate control.
>
> **Direct stimuli**: Cues or information that are presented to people with the intention of affecting their perception, choice, or behavior. People can process direct stimuli elaborately, which does not ascertain that they process them fully consciously.
>
> **External information**: All stimuli that are present in the decision context and that may affect people's thoughts and behavior.
>
> **Indirect stimuli**: Cues or information that unconsciously affect people's behavior, although people do not notice them as relevant for their current behavior or do not even consciously perceive them.
>
> **Nutrition information**: Information on and around a food product that informs consumers about the nutritional value of the product.
>
> **Priming**: The influence of an earlier presented stimulus on the response to a current stimulus.
>
> **Reference information**: Information about an attribute of a product or a range of products that functions as a comparison in the evaluation of another product.
>
> **Subliminal**: Presentation of a stimulus below the normal limits of human perception.
>
> **Supraliminal**: Presentation of a stimulus above the normal limits of human perception.
>
> **Unconscious information processing**: The mental elaboration of information or cues from the environment without being aware of doing so, although one may be aware of the information/cue and of its outcome (a thought or behavior).

Abbreviations

BMI	Body mass index
CART	Cocaine- and amphetamine-regulated transcript
CCK	Cholecystokinin
DMV	Dorsal motor nucleus of the vagus nerve
ERK	1/2 extracellular signal-regulated kinase 1/2
GES	Gastric electrical stimulation
$GHS\text{-}R_{1a}$	Growth hormone secretagogue receptor type 1a
GLP-1	Glucagon-like peptide-1
5-HT	Serotonin
IP	Intraperitoneal
IV	Intravenous
MCH	Melanin-concentrating hormone
MCH_1	Melanin-concentrating hormone receptor 1
N	Number
NO	Nitric oxide
NTS	Nucleus of the solitary tract
PYY	Peptide YY
RYGB	Roux-en-Y gastric bypass
SP	Substance P
TRH	Thyrotropin-releasing hormone
Ucn 2	Urocortin 2

54.1 Introduction

Brain sites regulating food intake receive an impressive range of peripheral signals from the gastrointestinal tract, endocrine pancreas, liver, and adipocytes that are integrated from the brainstem to the forebrain to maintain appropriate meal size and energy homeostasis. These peripheral signals

reach the brain either directly via the bloodstream and by crossing or bypassing the blood–brain barrier or via receptors located on afferent neurons of which the vagus nerve has been the most important and extensively studied (Cummings and Overduin 2007). This chapter will describe the role of the vagus nerve and affiliated brainstem nuclei in the control of food intake with a major focus on circulating gut peptides. In addition, in the light of the rising incidence of obesity in developed countries (James 2008), modulation of vagal activity as possible strategy in the treatment of adiposity and associated diseases will also be discussed.

54.2 Vagally Mediated Sensing in Stomach, Small Intestine, and Pancreas

Endogenous factors that influence vagal afferent activity encompass mechanoreceptors stimulated by gut distention along with gut peptides released from enteroendocrine cells (Dockray 2004; Chaudhri et al. 2008). In the stomach, the afferent fibers of the vagus nerve located in the external muscle layers are sensitive to stretch and tension, and encode changes in volume and luminal pressure resulting from ingested food (Phillips and Powley 2000). However, vagal afferent fibers are also located in the gastric mucosa (Berthoud 2008). Since the gastric oxyntic mucosa contains a variety of endocrine cells (Bordi et al. 2000), vagal fibers are strategically positioned to detect released gastric hormones. Ghrelin is the only peripherally produced food intake stimulating hormone and its major site of synthesis are X/A-like cells of the gastric corpus (Date et al. 2000). Ghrelin levels rise before a meal and are suppressed upon meal ingestion and convergent evidence supports an initial mediation through vagal pathways (Cummings et al. 2001). The ghrelin receptor, the growth hormone secretagogue receptor type 1a (GHS-R$_{1a}$), is expressed on vagal afferent fibers and in neurons of the nodose ganglion that contains cell bodies of vagal afferents in rats and humans (Table 54.1) (Date et al. 2002a; Burdyga et al. 2006). The stimulation of food intake following intravenous (IV) injection of ghrelin in rats was abolished by subdiaphragmatic vagotomy or after capsaicin pretreatment which selectively ablates small diameter afferents (Date et al. 2002a). Ghrelin also failed to stimulate food intake in human subjects that underwent surgical procedures resulting in complete truncal vagotomy (Le Roux et al. 2005). However, a vagal-independent action on food intake has also been reported when ghrelin was administered intraperitoneally (IP) in rats (Arnold et al. 2006). As ghrelin is released from X/A-like cells into the circulation, it is likely that vagal mechanisms reported to play a role upon systemic injection of the peptide are the main physiological relevant gut–brain pathway. Leptin is a 16-kDa protein expressed in the gastric mucosa (Bado et al. 1998) besides being one of the important adipose tissue-derived food-intake decreasing hormones

Table 54.1 Gastrointestinal peptide and protein hormones regulating food intake that involve vagal pathways

Hormones	Production sites	Receptors
Ghrelin	Gastric X/A-like cells	GHS-R$_{1a}$
Leptin[a]	Gastric chief and P cells	Leptin
CCK	Intestinal I cells	CCK$_1$
GLP-1	Intestinal L cells	GLP-1
PYY$_{3-36}$	Intestinal L cells	Y$_2$
Glucagon	Pancreatic α cells	Glucagon[b]

This table lists peptide and protein hormones derived from the gastrointestinal tract and their receptors, most of which have been identified on vagal afferent fibers

[a]Also largely produced by adipocytes

[b]Not been identified on vagal afferents

(Friedman and Halaas 1998). The presence of the leptin receptor in nodose ganglia (Buyse et al. 2001) (Table 54.1) and activation of gastric vagal afferent fibers by leptin (Wang et al. 1997) indicate that leptin action may involve, in addition to a direct central action, a vagal component that was established particularly in the context of its synergistic interaction with cholecystokinin (CCK) (Barrachina et al. 1997). Therefore, gastric vagal afferents encode inputs from mechanical changes in luminal pressure and volume as well as chemoreceptors activated by specific gastric peptide and protein hormones which are transmitted to the hindbrain through ascending vagal projections.

In the small intestine, vagal afferents are present in the lamina propria but not the epithelium (Berthoud et al. 1995). CCK is produced in intestinal I cells (Cummings and Overduin 2007) which are in close proximity to vagal afferent fibers (Berthoud 2008). The afferent vagus nerve expresses both CCK_1 and CCK_2 receptors (Wren and Bloom 2007), and CCK-induced early satiation is mediated via the CCK_1 receptor (Table 54.1) (Wren and Bloom 2007). Vagal afferents are activated by CCK which is released in response to ingestion of fatty acids and proteins (Berthoud 2008). Glucagon-like peptide-1 (GLP-1) is produced in intestinal L cells (Cummings and Overduin 2007) and displays food intake-reducing properties (Chelikani et al. 2005). Converging evidence established that peripherally released GLP-1 mediates its effects via the vagus nerve. This is supported by the gene expression of the GLP-1 receptor on vagal afferent fibers (Cummings and Overduin 2007) (Table 54.1), the increase in vagal afferent fiber activity upon IV injection of GLP-1 reaching physiological concentrations (Bucinskaite et al. 2009), the activation of nodose ganglia neurons in vitro by GLP-1 (Kakei et al. 2002), and the suppression of IP injection of GLP-1-induced reduction of meal size by subdiaphragmatic vagal deafferentation (Rüttimann et al. 2009). Peptide YY (PYY) is also produced in intestinal L cells (Cummings and Overduin 2007) and circulates in two molecular forms, PYY_{1-36} which binds to Y_1, Y_2, and Y_5 receptors, and PYY_{3-36} which selectively binds to Y_2 and Y_5 receptors (Keire et al. 2002). Consistent reports indicate that the anorexigenic effect of PYY_{3-36} (Batterham et al. 2002; Chelikani et al. 2006) is mediated via the Y_2 receptor (Cummings and Overduin 2007). The Y_2 receptor is expressed on vagal afferents (Cummings and Overduin 2007) and vagotomy abolishes the anorexigenic effect of PYY_{3-36} (Table 54.1) (Koda et al. 2005). Therefore, although there is a direct effect of circulating PYY_{3-36} at hypothalamic and medullary sites receptive for humoral factors regulating feeding (Batterham et al. 2002), the vagus nerve also seems to play an important role in mediating PYY's food intake inhibition.

Glucagon produced in pancreatic α cells (Date et al. 2002b) decreases food intake (Moran 2006), an effect which is also mediated by vagal afferents (Berthoud 2008), although glucagon receptors have not been identified on vagal afferents (Table 54.1) (Woods et al. 2006). In contrast, the pancreatic hormones amylin and insulin seem to signal humorally to other peripheral organs such as the liver and brain areas outside of the blood–brain barrier namely the area postrema which has been identified as neurophysiological substrate of amylin's satiety effect (Berthoud 2008). Taken together vagal afferent fibers sense mechanical information. In addition, peptides released from several enteroendocrine cells lining the lumen of the gastrointestinal tract, act on cognate receptors expressed on vagal afferents (Dockray 2009) and activate vagal ascending pathways projecting to the brainstem influencing neuronal activity of specific nuclei and those of interconnected brain structures.

54.3 Interactions Between Gut Peptides Signaling to the Brain

As described above gut peptides play an important role in modulating the activity of vagal afferents and thereby mediating information to the brain. As during feeding and fasting, the release of gut peptides is not singly but simultaneously affected, a number of studies have evaluated their possible

interactions. A synergistic effect between the short-term modulator of food intake CCK-8 and the long-term signal of energy balance leptin has been well characterized (Wang et al. 2000). Leptin-injected IP at subthreshold doses did not influence food intake alone but decreased food intake when coinjected with a subthreshold dose of CCK-8 (Barrachina et al. 1997). This was linked with an increased gastric vagal afferent discharge and Fos expression, a marker for neuronal activation, in brain nuclei regulating food intake (Barrachina et al. 1997). Also, coinfusion of CCK and GLP-1 reduces caloric intake with a greater magnitude than an additive effect suggesting a synergistic interaction between these two peptides (Gutzwiller et al. 2004). Furthermore, urocortin 2 (Ucn 2) coinjected with CCK-8 suppressed food intake and delayed gastric emptying, under conditions when the two peptides alone had no effect (Gourcerol et al. 2007). This synergistic interaction takes place directly on gastric vagal afferent fibers as demonstrated at the electrophysiological level in an isolated gastric vagus preparation using infusion of subthreshold doses of Ucn 2 and CCK-8 and molecular level with the expression of receptors for both peptides in the nodose ganglia (Gourcerol et al. 2007). Another study showed that IP injection of ghrelin-induced increase in food intake and Fos expression in specific hypothalamic nuclei regulating food intake was completely abolished by coinjection with CCK-8 (Kobelt et al. 2005). Likewise, peripheral injection of bombesin abolishes ghrelin's orexigenic effect (Kobelt et al. 2006). These examples highlight the importance of the interaction between gut peptides influencing vagal activity and their impact to regulate food intake and digestive functions.

Feeding status also differentially influences the expression of receptors in the nodose ganglia providing additional control mechanisms of vagal sensory information to the brain (Dockray 2009). For instance, the expression of the cannabinoid receptor CB_1 and the melanin-concentrating hormone receptor 1 (MCH_1), both mediating food intake-stimulating effects, is increased after fasting, whereas the expression of the Y_2 receptor mediating PYY's anorexigenic effect is decreased (Dockray 2009). Conversely, re-feeding decreases the expression of CB_1 and MCH_1, through CCK_1-dependent mechanisms (Dockray 2009). In contrast, CCK stimulates the expression of the Y_2 receptor (Burdyga et al. 2008). Besides regulating the expression levels of receptors, CCK increased the expression of the anorexigenic cocaine- and amphetamine-regulated transcript (CART) and decreased the expression of the orexigenic melanin-concentrating hormone (MCH) (Dockray 2009). The stimulatory effect of CCK on CART expression can be blocked by exogenous ghrelin (Dockray 2009). Taken together, these data indicate a complex interplay between gut peptides and the regulation of receptor and ligand expression depending upon the metabolic status and thereby vagal-dependent signaling regulating food intake.

54.4 Brainstem Integration of Vagal Input

The gut signals sent to the brain via ascending vagal afferent fibers are first transmitted to the nucleus of the solitary tract (NTS) located in the dorsal medulla. The coding from vagal afferent terminals in the NTS involves the release of glutamate and the activation of catecholaminergic neurons (Rinaman et al. 1995). Glutamate receptors are present on NTS neurons, and treatment with glutamatergic N-methyl-d-aspartate (NMDA) receptor antagonists blocks peripheral CCK-induced reduction of food intake (Schwartz 2006). CCK also activates the extracellular signal-regulated kinase (ERK) 1/2 and cAMP responsive element-binding protein (Sutton et al. 2004). The ERK pathway seems to be necessary for CCK's action as shown by an attenuated food intake-suppressive effect after treatment with U0126 to block ERK signaling (Sutton et al. 2004). The molecular mechanisms involved in the integration of various satiety signals within the NTS represent a novel field of investigations that require further studies particularly the relationship between glutamatergic transmission of gut negative-feedback signals and the control of food intake.

From the NTS, information is further transmitted to interconnected forebrain structures such as the hypothalamus, amygdala, and cortex. In turn, the NTS also receives information from hypothalamic nuclei such as the paraventricular nucleus of the hypothalamus and limbic structures like the central nucleus of the amygdala through descending projections (Schwartz 2006). Therefore, the NTS integrates central as well as peripheral signals in order to regulate food intake (Schwartz 2006). Moreover, hindbrain nuclei such as NTS and ventrolateral medulla (VLM) directly influence energy expenditure. These brainstem nuclei affect fat mobilization from white adipose tissue (Shi and Bartness 2001) and signal to brown adipose tissue through descending projections from the nucleus raphe pallidus (Morrison 2001) which plays an important role in body weight regulation (van Marken Lichtenbelt et al. 2009). However, the brainstem is also able to control food intake independently without input to or from forebrain structures. Brainstem transected rats (chronically decerebrated rats) are able to control meal size similarly as intact controls (Grill and Kaplan 2002) suggesting that the caudal brainstem is able to integrate peripheral signals in order to induce meal termination.

54.5 Vagal Efferent Function

The efferent vagus nerve innervates the gastrointestinal tract up to the last third of the transverse colon (Cannon–Boehm point) and is involved in the regulation of digestion, absorption, and propulsion of nutrients. Acute vagotomy increases fundic tone and decreases antral motility resulting in impaired reservoir function of the stomach (Travagli et al. 2006). Most of the neurons of the dorsal motor nucleus of the vagus nerve (DMV) are cholinergic (Travagli et al. 2006), whereas only few neurons express nitric oxide (NO) synthase (Krowicki et al. 1997) or catecholamines (Kalia et al. 1984) which could be involved in gastric relaxation (Travagli et al. 2006). Most vagal preganglionic fibers activate cholinergic nicotinic receptors (Schemann and Grundy 1992) resulting in the activation of gastric myenteric cholinergic neurons (Miampamba et al. 2001) which coordinates the stimulation of gastric acid and pepsin secretion and propulsive motor function (Taché et al. 2006).

Neurons of the DMV are activated by thyrotropin-releasing hormone (TRH) positive nerve fibers which originate from TRH neurons in the raphe pallidus, raphe obscurus, and the parapyramidal regions resulting in a stimulation of gastric secretion, motor function, and blood flow (Taché 2009). Serotonin (5-HT) and substance P (SP) that are colocalized in TRH-synthesizing neurons and also released in response to activation of these neurons potentiate the action of exogenous and endogenous TRH on gastric acid secretion and motility (Taché 2009). In contrast, SP coreleased with TRH reduces the excitatory action of TRH (Taché 2009), thereby modulating the TRH effect. Injection of TRH analog into the medulla increases food intake via a vagus-dependent increase of circulating ghrelin levels (Ao et al. 2006). Moreover, sham feeding (exteroceptive olfactory and visual sensory inputs without ingestion of food and associated oropharyngeal stimulation) activates the brainstem TRH signaling pathway and contributes to the vagal-dependent cephalic phase of gastric acid secretion (Taché 2009). Collectively these data strongly support a physiological role for brainstem TRH in the vagal regulation of gastric function associated with digestive processes and food intake.

Like preganglionic neurons, excitatory postganglionic neurons mediate their actions mostly via acetylcholine release resulting in an increase of gastrointestinal peristalsis and tone (Miampamba et al. 2001; Travagli et al. 2006). In contrast, inhibitory postganglionic neurons mediate their effects possibly through NO and vasoactive intestinal polypeptide (Goyal et al. 1980; Desai et al. 1991) resulting in relaxation for instance at the pyloric level allowing emptying of the stomach. Taken together, medullary TRH controls food intake through activation of gastric vagal efferent activity thereby modulating the release of the orexigenic ghrelin and gastric functions to coordinate the various

components linked with food ingestion such as accommodation, mixing with gastric acid and pepsin secretion, and propulsion into the intestine (Taché 2009).

The efferent vagus nerve also plays an important role in the homeostasis of blood glucose levels through its effect on the liver and pancreas. Medullary TRH induces vagal-dependent insulin release from pancreatic ß cells in rats (Taché 2009) resulting in an enhanced glucose tolerance. Moreover, vagal activation inhibits enzymes involved in glucose production and stimulates enzymes for glycogen synthesis in the liver (Shimazu 1971).

54.6 Applications to Other Areas of Health and Disease – Clinical Implications

Overweight, obesity (body mass index, BMI > 30, Table 54.2), and associated diseases are a major health issue both in the USA (Ogden et al. 2006) and worldwide (James 2008) mainly contributing to morbidity and mortality in industrialized countries (Flegal et al. 2007). Two-thirds of the adult US American population are either overweight or obese (Flegal et al. 1998; Marx 2003) and the prevalence is still rising (Table 54.3) (Flegal et al. 1998). Therefore, the World Health Organization has declared obesity as the greatest threat to human health (Wynne et al. 2004). Public health initiatives have failed to reverse the rising incidence of obesity (Wren and Bloom 2007) and the drug treatment options are very limited so far (Gura 2003). Other treatment options involve targeted alterations of vagal nerve functions such as gastric electrical stimulation (GES) and bariatric surgery.

GES devices have been advocated early on, besides pharmacologic, surgical, and cognitive approaches to reduce food intake and treat obesity (Abell et al. 2006). GES involves electrodes placement on the outer lining of the stomach along the lesser curvature which are connected to a subcutaneously implanted pacemaker-like device allowing the delivery of low-level electrical stimulation on the stomach wall (Abell et al. 2006; Zhang and Chen 2006). Animal studies have shown that electrical stimulation near the lesser gastric curvature decreases food intake (Cigaina et al. 1996; Zhang et al. 2009). Also, 1 year long GES studies performed so far in morbidly obese subjects

Table 54.2 Classification of the BMI (kg/m²)

Category	BMI range (kg/m²)
Underweight	16.5–18.4
Normal	18.5–24.9
Overweight	25.0–29.9
Obese	30.0–39.9
Morbidly obese	40.0–49.9
Super obese	>50

This table shows the BMI (calculated from a person's weight and height) ranges used as a diagnostic tool to identify weight problems within a population such as underweight, overweight, and different grades of obesity

Table 54.3 Key facts highlighting the rising prevalence of worldwide overweight and obese population (Adapted from James 2008)

	2002	2007	2015 (estimation)
At least overweight (BMI >25)	1.4 billion	1.5 billion	2.3 billion
Obese (BMI >30)	356 million	523 million	704 million

This table shows the worldwide rising prevalence of overweight and obesity since 2002 and projection to 2015

Table 54.4 Non placebo-controlled clinical trials with a duration >1 year investigating the effects of gastric electrical stimulation on body weight in patients with morbid obesity

1,025	28% after 10 years	Sugerman et al. (2003)
34	25% after 10 years	Sjostrom et al. (2004)

This table shows the weight reducing effect of RYGB bypass in longitudinal 3–10 years studies in obese patients

N indicates the number of patients enrolled in each clinical study

(BMI > 40) showed a decrease in body weight (Cigaina 2002; De Luca et al. 2004; Shikora 2004; Zhang and Chen 2006; Bohdjalian et al. 2006), whereas one study failed to show an improvement in patients that had previously failed to lose weight after adjustable gastric banding (Table 54.4) (Hoeller et al. 2006). Several reports on mechanisms involved in GES action indicate that reduced appetite and increased satiety linked with alterations of gut hormones regulating food intake may be part of decrease in body weight (Hasler 2009). Experimental studies also showed alterations in responsiveness of brain circuitries involved in food intake (Zhang and Chen 2006). There is evidence that GES enhances vagal afferent signaling (Peles et al. 2003) and reduces vagal parasympathetic efferent activity (Hasler 2009) which may contribute to these changes.

Bariatric surgery is the most effective treatment for long-term weight loss in morbidly obese patients so far with Roux-en-Y gastric bypass (RYGB) being the most commonly performed (Table 54.5) (Tanner and Allen 2009). This procedure consists of opening the stomach 2–3 cm distal from the angle of His, forming a small gastric pouch, dividing the small bowel 20 cm distal of the ligament of Treitz, performing a gastro-jejunostomy and re-anastomosis of the small intestine by entero-enterostomy (Fig. 54.1) (Tanner and Allen 2009). The underlying mechanisms causing the sustained weight loss are still poorly understood. Reduction of ghrelin levels has been discussed as a possible contributing mechanism. One study showed very low circulating ghrelin levels and loss of meal-related ghrelin changes after RYGB (Cummings et al. 2002). This procedure may damage ventral as well as dorsal gastric branches of the vagus nerve (Fig. 54.1) which seems to be involved in ghrelin regulation as shown in human studies where atropine reduced ghrelin levels (Maier et al. 2004). Also, vagotomized rats do not show the fasting-induced increase of ghrelin (Simonian et al. 2005) and central vagal stimulation by medullary TRH increases circulating ghrelin in rats (Ao et al. 2006). Furthermore, exogenous ghrelin failed to stimulate food intake in patients that had undergone surgical procedures involving vagotomy (Le Roux et al. 2005). Therefore, altered vagal-dependent ghrelin

Fig. 54.1 Graphic representation of procedure and vagal innervation before and after Roux-en-Y gastric bypass (RYGB). The physiological situation is shown in (**a**), gastric bypass using Roux-en-Y anastomosis consists of cutting stomach and jejunum, forming a small gastric pouch and re-anastomose stomach and jejunum and duodenum and jejunum respectively (**b**). Ventral and dorsal gastric branches of the vagus nerve can be damaged during this procedure (**b**)
release and related orexigenic signaling might contribute to the surgery-induced weight loss. Moreover, even when the vagus nerve is left intact the threshold for stimulation of vagal afferents by nutrients could be lowered leading to increased afferent signaling which can give rise to increased perception of fullness and nausea (Powley et al. 2005). As the stomach size is reduced by 90%, patients ingest just a small amount of food and the stretching of the wall of the stomach pouch conveys the sensation of fullness through vagal afferents, similar to that eaten by a large meal. However, more studies, especially in animal models using targeted selective vagotomy, are needed to increase the understanding of mechanisms underlying the weight loss after RYGB.

54.7 Conclusion

The vagus efferent nerve innervates the gastrointestinal tract including adjacent organs such as the pancreas and liver and is involved in the regulation of food intake, gastrointestinal digestive function, and glucose control. Afferent vagal fibers encode mechano- and chemo-sensory stimuli originating from the gut and adipose tissues and relay this information to brainstem nuclei connected with circuitries regulating food intake and associated digestive processes. In light of the rapidly rising prevalence of obesity and associated fatal diseases, efficient treatments are urgently needed. The most effective treatment of morbid obesity, the bariatric surgery technique RYGB, may involve alterations of vagal afferents and efferents in regulating food intake contributing to the observed weight loss. Further experimental studies will enhance our understanding of vagal signaling under those conditions and the possible targeted surgical modification. This may lead to a more effective and highly targeted antiobesity treatment.

Summary Points

- Vagal afferents respond to mechanical and chemical signals, such as gut peptides, protein hormones, and neurotransmitters by increased activity which is transmitted first to the brainstem and interconnected forebrain circuits regulating food intake.
- The afferent vagus nerve sends signals first to the nucleus of the solitary tract (NTS) through ascending projections from the nodose ganglion.
- The caudal brainstem circuitry is able to integrate peripheral signals in order to induce meal termination autonomously.
- The efferent vagus nerve controls gastric motility and integrates gastric accommodation to ingested food and propulsive motor activity to empty the stomach content and is involved in glucose homeostasis.
- The incidence of obesity is rapidly rising in industrialized countries and treatment options are very limited so far.
- Gastric electrical stimulation (GES) is a procedure used in patients with morbid obesity which showed 20–25% efficiency to decrease excess body weight in a number of non-placebo-controlled clinical studies. The underlying mechanism may involve alterations of vagal activity.
- Roux-en-Y gastric (RYGB) bypass is the most effective (25–35% body weight loss) treatment for patients with morbid obesity (BMI >40). Vagal denervation-induced decrease of circulating ghrelin levels, along with increased vagal sensory signaling through activation of mechanoreceptors, may be contributing mechanisms causing sustained weight loss.

Definition and Explanation of Key Terms Used in This Article

The parasympathetic **vagus nerve** is the cranial nerve X originating from the brainstem providing innervation of the viscera in the thoracic and abdominal cavity up to the last third of the transverse colon.

Ghrelin is the only peptide hormone peripherally produced and centrally acting known to stimulate food intake. The main source of ghrelin is X/A-like cells of the stomach.

The **nodose ganglion** contains cell bodies with peripheral processes forming the afferent fibers of the vagus nerve with ascending projections to the brain medulla and descending projections innervating the gut.

Capsaicin is a neurotoxin isolated from red pepper that is an important tool to selectively ablate afferent fibers.

The **nucleus of the solitary tract (NTS)** is located in the brainstem and receives input from the facial (VII), glossopharyngeal (IX), and vagus afferent nerve and regulates visceral functions including gastrointestinal functions.

The **dorsal motor nucleus of the vagus nerve (DMV)** located in the brainstem ventral to the NTS is part of the dorsal vagal complex and contains cell bodies of which axons constitute the efferent vagus innervating the gut.

Gastric electrical stimulation is a treatment approach for morbid obesity involving stimulation of electrodes placed next to the lesser curvature of the stomach. Short pulse stimulation is used to reduce food intake and decrease body weight.

Roux-en-Y gastric bypass (RYGB) is the most effective treatment option for long-term weight loss in patients with morbid obesity and therefore the most common technique among bariatric surgery approaches.

Key Facts of Vagal Stimulation

1. Vagal afferent fibers send signals from the stomach, small intestine, and the first two-thirds of the transverse colon to the hindbrain in response to mechano- and chemo-stimulation resulting from changes in luminal pressure and volume and specific peptide and protein hormone release from enteroendocrine cells and adipose tissue.
2. The efferent vagus nerve controls gastric and intestinal motility to coordinate the various components of food ingestion linked first with the accommodation of food and second its propulsion after mixing with gastric acid and pepsin secretion.

Key Features of the Brainstem

1. The signals sent to the brainstem via the afferent ascending vagal fibers are first transmitted to neurons in the nucleus of the solitary tract (NTS) located in the dorsal medulla.
2. The caudal brainstem is able to integrate peripheral signals and induce a reflex signal leading to meal termination.
3. The molecular mechanisms involved in the integration of satiety signals in the NTS and the consecutive regulation of food intake represent a novel field of investigations.

Chapter 55
Anticipatory Physiological Regulation in Feeding Biology

Michael L. Power and Jay Schulkin

Abbreviations

AgRP	Agouti-related protein
CCK	Cholecystokinin
CNS	Central nervous system
GHS receptor	Growth hormone secretory receptor
mRNA	Messenger ribonucleic acid
NPY	Neuropeptide Y
Ob-Rb	Short, soluble form of the leptin receptor
POMC	Proopiomelanocortin

55.1 Introduction

Behavior, physiology, and metabolism are not merely reactive. Animals anticipate. Sometimes the anticipation is driven by acute events. The senses convey information about the external environment to the central nervous system, which interprets the information within the constraints of experience, and intrinsic, evolved tendencies. The central nervous system sends messages to the appropriate peripheral organs to begin the physiological cascades that prepare the organism to respond to the anticipated challenge. In other instances these anticipatory changes reflect internal, clock-like rhythms. For example, the secretion of many hormones (e.g., cortisol, leptin, ghrelin) becomes entrained in light of longer term, repeated conditions. These circadian rhythms allow an animal to be in the most appropriate physiological state at different time points. Animals change state driven by their own internal clocks. In all of these cases, the changes in physiological state can be in advance of the potential need.

Anticipatory responses are associated with central nervous system coordination of physiology. Some authors (e.g., Schulkin 2003) have emphasized how the central coordination of physiology, anticipatory

Table 55.1 Key features of anticipatory physiological responses in feeding biology

1. Cephalic phase responses increase the efficiency of absorption and metabolism of nutrients from ingested food by stimulating multiple organ systems in anticipation of feeding

2. For example, the hormone insulin is secreted from the pancreas and acts to regulate circulating glucose concentration; insulin has a cephalic phase response in which the pancreas secretes insulin in anticipation of eating, before any actual change in circulating glucose. Loss of this anticipatory response compromises glucose control

3. Gastric secretion of leptin appears to have a cephalic phase; leptin pairs synergistically with CCK to decrease feelings of hunger and to reduce food intake

4. Ghrelin secretion is hypothesized to be part of the cephalic phase response and either stimulates feelings of hunger or is stimulated by these feelings

5. Learned associations can affect cephalic phase responses, either increasing or decreasing the magnitude of the response. Also, making food available at consistent times can modify the circadian rhythms of some cephalic phase responses (e.g., ghrelin)

6. Cephalic phase responses serve to keep peripheral physiology in synchrony with behavior and motivation

This table lists key features of anticipatory physiological responses in feeding biology, otherwise known as cephalic phase responses

physiological responses, and the interplay of physiology and behavior appear not to be fully incorporated into the classic homeostatic paradigm of physiological regulation. The concept of allostasis, defined as the "…process by which an organism achieves internal viability through bodily changes of state," has been proposed as an alternative (Schulkin 2003). Many of the examples of allostatic regulation provided by Schulkin (2003) involve the concept that the hormones that regulate peripheral physiology in response to a challenge are also involved in changing central motive states of the brain, and thus induce behaviors that aid the animal to meet the challenge.

The regulation of food intake is a paradigmatic example of the linkage of peripheral physiology with central motive states, and the concept that behavior and physiology act together to preserve viability (Table 55.1). The hormones insulin and ghrelin are excellent examples of this concept. Both act to influence and regulate peripheral physiology and metabolism in response to immediate cues and also to long-term learning. Both also act in the brain, and are signaling molecules in neural circuits important to the regulation of food ingestion (Clegg et al. 2003; Cowley et al. 2003). Both also have cephalic phase responses that are important in feeding biology.

55.2 Importance of Anticipatory Responses in Feeding Biology

Because we feed in discrete meals, food enters our bodies in pulses. Meals result in perturbations of the internal milieu that must be accommodated (Woods 1991). Our internal milieu cannot be strictly constant. The digestive system and numerous other organ systems (e.g., liver, kidney, adipose tissue) constantly change to accommodate conditions of nutrient excess (feeding) followed by potential nutrient deficits (between meals). The secretory responses that regulate absorption, storage, and mobilization of nutrients change over the day, sometimes favoring a net deposit into storage pools and sometimes favoring a net mobilization into extracellular fluid.

These changes take time. Cephalic phase responses, anticipatory digestive and metabolic responses to cues that feeding is imminent, allow organisms to get "ahead of the curve." They improve the efficiency with which animals digest food, and absorb and metabolize the liberated nutrients. They also prime the organism to meet the resulting homeostatic challenges presented by the influx of nutrients (Woods 1991).

55.2.1 *Cephalic Phase Responses*

The term cephalic phase response generally refers to digestive and metabolic responses to food cues generated by the central nervous system that act to prepare the organism to ingest, digest, absorb, and metabolize food (Pavlov 1902; Powley 1977). These anticipatory physiological responses increase the efficiency with which an organism incorporates food into its tissue (Woods 2006).

The concept of cephalic phase response was first introduced by Pavlov in his work on the alimentary tract and its secretions. The original term proposed by Pavlov was "psychic secretions" (see Powley 1977). The change in terminology to cephalic phase responses was both to distance the concept from the mystical notions associated with the word psychic, and to reflect the fact that there are relevant anticipatory responses that are not secretions (e.g., gastric motility, thermogenesis).

For Pavlov, salivary secretions were digestive secretions, serving the same intrinsic function as gastric and intestinal secretions – enabling the animal to utilize food for bodily needs (Pavlov 1902). He demonstrated in dogs that salivation varied with the food ingested. For example ingesting dry food stimulated greater salivation than ingesting wet food. He also, famously, demonstrated that salivation can occur in anticipation of feeding (Pavlov 1902). He extended the work to gastric secretions, and showed that they too could be stimulated by the sight, smell, and taste of food. Anticipatory secretion of other digestive fluids has been demonstrated as well. Digestive secretions are anticipatory as well as reactive.

The concept of cephalic phase responses has changed little since the original demonstrations. It was revitalized by Powley (1977), with special emphasis on the cephalic phase insulin response, extending the concept from digestion to metabolism. In functional terms cephalic phase responses are anticipatory changes in physiology and metabolism that serve to prepare the digestive tract to digest food and absorb nutrients, and to prepare other organ systems (e.g., liver, adipose tissue) to metabolize and store the absorbed nutrients. The gut and brain work together to acquire and utilize the nutrients necessary for life. Recent evidence suggests that cephalic phase responses not only prepare an animal to eat, but they may also play a role in appetite and satiety, and thus in the beginning and ending of a meal. For example, both ghrelin and leptin secreted by the stomach appear to exhibit a cephalic phase. Thus, by the first bite of food, or even before, physiological processes have been set in motion that will influence the duration of the meal and the amount of food eaten.

55.2.1.1 Evidence for Cephalic Phase Responses

There is a considerable literature on cephalic phase responses. Cephalic phase responses have been demonstrated in a wide range of mammals, including humans, nonhuman primates, dogs, cats, sheep, rabbits, and rats (Powley 1977); but cephalic phase responses have been demonstrated in other vertebrate taxa as well. Their evolutionary origin would appear to be quite ancient; for example striped bass display cephalic phase insulin and glucagon responses (Papatryphon et al. 2001). Some of these cephalic phase responses are general, and some appear to be specific to the taste of the food, i.e., responses to sweet substances differ from those to bitter substances. Even the sight of food within sealed plastic containers stimulated gastric secretions in humans (Feldman and Richardson 1986). Adding smell and taste to the sensory experience increased the response (Feldman and Richardson 1986). In humans, dogs, and rats, palatability of the offered food is positively correlated with the extent and magnitude of the cephalic salivary and gastric secretions (reviewed in Powley 1977). Thus appetite, or the psychological state of wanting food, directly affects the physiological processes of digestion and metabolism (Pavlov 1902; Powley 1977).

Fig. 55.1 Plasma insulin
concentration following a
sham feeding. The sham-fed
subjects (*filled circles*) show
a cephalic phase insulin
response occurring minutes
after tasting food. The
subjects who fasted (*open
circles*) show a continuously
stable concentration of
insulin in the plasma (Data
from Teff 2000)
Cephalic phase responses can be demonstrated using the technique of sham feeding. In humans, this consists of masticating the test diet or tastant, but not swallowing it. In animal models, the use of fistulas at different parts of the GI tract allows an animal to masticate and swallow, but keeps the food from the GI tract below the fistula. Thus food sensory cues can be restricted to sections of the alimentary canal. Sham feeding stimulates a number of changes in the gastrointestinal tract, the circulatory system, and in behavior. Sham feeding induces the secretion of peptides from the pancreas, resulting in an anticipatory rise in circulating insulin concentration (Fig. 55.1).

Pavlov (1902) demonstrated that food placed directly into the stomach of dogs was poorly digested; however, if sham feeding preceded the intragastric intubation, then digestion was enhanced. Several clinicians in the 1800s and early 1900s independently discovered that patients with fistulas who needed to be fed by gastric intubation fared much better if they were allowed to chew and taste food prior to the delivery of the meal to their stomach. Appetite increased, and patients were better able to maintain body weight. One patient insisted on swallowing the masticated food, even though it was shortly regurgitated from his esophogeal pouch (reviewed in Powley 1977).

But cephalic phase responses do more than just enhance digestion; they enhance metabolism as well. Glucose is a prime example of a nutrient whose blood concentration is actively regulated by both reactive and anticipatory physiology. If blood glucose falls below a critical concentration it can lead to rapid brain damage and then death. High concentrations of blood glucose are potentially toxic, and are associated with macular degeneration, brain cell death, and higher mortality after stroke (Williams et al. 2002; Gentile et al. 2006). A number of mechanisms have evolved to resist changes in blood glucose concentration, and keep it within safe levels. Glucose is constantly being shuttled among different pools, or perhaps more precisely, the energy contained in glucose is shuttled among these pools.

Insulin is the primary peptide regulating glucose metabolism. Insulin increases glucose storage (in the form of glycogen) in liver and muscle, decreases lipolysis and gluconeogenesis, and increases fatty acid synthesis by adipose tissue (Porte et al. 2005). The net result is to lower blood glucose concentration by increasing the conversion of glucose to other energy storage molecules (glycogen and fat) and decreasing the production of glucose from the liver. An increase in blood glucose is met with an increase in insulin secretion from the pancreas. However, circulating insulin can increase even in the absence of a blood glucose change in anticipation of feeding.

In humans and rats there is a robust cephalic phase insulin response (reviewed in Powley 1977; Powley and Berthoud 1985; Teff 2000). If food is masticated and tasted, the pancreas rapidly begins

Fig. 55.2 Plasma insulin concentration following ingestion of a mixed nutrient sandwich. The data shows an initial pulse of insulin secretion between 0 and 10 min after ingestion followed by a larger, more sustained secretion in response to the absorption of digested nutrients (Data from Teff 2000)
Fig. 55.3 Plasma insulin concentration following ingestion of a standard meal. The cephalic phase insulin response to a meal was partially blocked by the infusion of trimethaphan (*filled circles*) relative to saline infusion (*open circles*). In the saline infused women a small increase in insulin was observed at 5, 7, and 10 min after beginning a meal, although blood glucose did not show a significant increase until 15 min. Insulin levels were higher in the saline infused women compared to the trimethaphan infused women at 3, 7, and 15 min after beginning the meal (Data from Ahren and Holst 2001)

to secrete insulin, as well as other peptides. This initial pulse of insulin secretion is followed by a larger, more sustained insulin secretion in response to the absorption of digested nutrients (Fig. 55.2). The cephalic phase insulin response thus anticipates and mimics, at an attenuated level, the postabsorptive insulin response to changes in blood glucose concentration (Teff 2000).

Although the magnitude of the cephalic phase insulin response is small compared to the postprandial response, it has significant physiological effects (e.g., Ahren and Holst 2001). Preventing the cephalic phase response, for example, through infusion of trimethaphan, results in both significantly higher peak blood glucose concentration and impaired reduction of glucose within the first hour postprandial (Figs. 55.3 and 55.4). Thus the absence of a cephalic phase insulin response compromises glucose control

Fig. 55.4 Blood glucose concentrations following ingestion of a standard meal. There were no significant differences in blood glucose between saline (*open circles*) and trimethaphan (*filled circles*) infused women for the first 25 min after beginning the meal. In both groups blood glucose was not significantly different from baseline until 15 min. At 45 and 60 min saline infused women had significantly lower blood glucose concentrations (Data from Ahren and Holst 2001)
and can lead to hyperinsulinemia (Berthoud et al. 1980). Administration of insulin immediately prior to or at the beginning of a meal, i.e., during the preabsorptive period, improves glucose control in obese humans (Teff and Townsend 1999) and in type 2 diabetics (Bruttomesso et al. 1999).

55.2.1.2 Evidence for Central Nervous System Contribution

Conditioned taste preferences and conditioned taste aversions provide strong proof that responses to food cues can be learned and modified (Booth 1972; Rozin 1976). Most animals readily learn to avoid food sources that render them ill; a special visceral learning linked to food ingestion (Garcia et al. 1974; Rozin 1976). Bait shyness linked to poison is an important adaptation (Richter 1953).

Rats, and many other animals, generally like sweet tasting substances. However, rats can be conditioned to react aversively to sweet solutions by rendering them ill after ingestion. They will decrease their intake of the sweet solutions when they are exposed to them again; they also emit species specific oral/facial rejection responses as opposed to the normal positive oral/facial responses associated with desired foods (Berridge et al. 1981). Importantly, the cephalic insulin response is now decreased to orally infused sweet solution (Fig. 55.5; Berridge et al. 1981).

Cephalic phase responses can also be stimulated by operant conditioning; i.e., animals can learn to associate arbitrary sensory stimuli with the availability of food, and then will react as if the food itself has been perceived. Animals have been conditioned to time of day (Woods et al. 1970), sounds, tastes in water, and visual cues (e.g., Pavlov 1902; Woods et al. 1977) among others. For example, rats fed at a certain time everyday begin to secrete insulin (Woods et al. 1970) and ghrelin (Drazen et al. 2006) in a circadian pattern in anticipation of feeding.

55.2.2 The Paradox of Feeding

Cephalic phase responses are not just about digestion. They serve postabsorptive metabolism and physiology as well as digestion. They prepare the organism to assimilate the ingested nutrients. This is a key adaptation, as although feeding is necessary for survival, it also presents a significant challenge to homeostasis, in what has been termed the paradox of feeding (Woods 1991).

Fig. 55.5 Plasma insulin concentration following an oral infusion of various solutions. The cephalic phase insulin response to an orally infused sugar solution was significantly attenuated in rats that had been conditioned by pairing the sugar solution with a poison that caused gastrointestinal upset. There was no consistent insulin response to a sodium chloride solution (Data from Berridge et al. 1981)
The homeostatic paradigm has guided thought and research on physiology for over 100 years. Starting from the work of Claude Bernard (1865) to Walter Cannon (1935), the concept that stability of the internal milieu is required for health and survival has been a central tenet. Woods (1991) eloquently presented the fundamental paradox of feeding from this physiological perspective. Organisms must consume food in order to survive; however, the act of consumption results in an influx of bioactive substances into the body, and presents a challenge to the stability of the internal milieu. Nutrients are required, but many nutrients are also toxic; they have maximal as well as minimal levels for concentration in the blood. Feeding can have negative as well as positive effects and requires metabolic adaptations to return the intercellular fluid to its homeostatic set points.

Although both of us have questioned the primacy of the homeostatic paradigm (Schulkin 2003; Power 2004), neither of us denies the importance of homeostasis in understanding functional and adaptive aspects of physiology. We have merely argued that homeostasis does not represent all of physiological regulation, and that often animals are required to abandon homeostasis to serve the goal of being a viable organism (defined in the evolutionary sense as capable of passing on its genetics to future generations). Viability, not stability, is the parameter of evolutionary importance (see Power 2004). In the case of the challenges presented by digesting, absorbing, and metabolizing nutrients, however, the homeostatic paradigm provides insight into the selective pressures driving the evolution of complementary digestive and metabolic adaptations. In particular, it highlights the inherent contradictions between adaptive changes that enhance the efficiency of digestion and absorption of nutrients with the necessity of maintaining the blood stream within critical parameters for many of the absorbed nutrients.

Anticipatory digestive responses to food cues increase the rapidity and efficiency with which food is transformed into nutrients, and thus can be absorbed through the intestinal walls. This increased efficiency in absorption presents both advantages and challenges to the organism. The main advantage is obvious; the digestive tract can process a greater amount of food per unit time, and thus the rate of nutrient transfer from the environment to the animal is greater. This allows, among other possible effects, greater total food intake, shorter latency time between meals, shorter total feeding/foraging time to meet requirements, an increased ability to meet requirements on foods of lower quality or that are scarce in the environment, or combinations of these effects. However, the more quickly and efficiently an organism can digest and absorb ingested food, the greater the potential

disruption to the homeostatic conditions of the internal milieu. This requires correspondingly rapid and efficient metabolic responses in order to accommodate the pulse of nutrients entering the blood stream, keep the concentrations within tolerable limits, and eventually return the intercellular fluid to the "normal" range. This is the third phase of feeding; regulation of the absorption and metabolism of digested nutrients. Anticipatory metabolic responses to sensory contact with food or food cues that aid this phase of feeding have been demonstrated, most notably the cephalic phase insulin response (e.g., Powley and Berthoud 1985), previously discussed.

Digestive and metabolic cephalic phase responses likely would have evolved in concert. The advantages of rapid and efficient digestion and assimilation of nutrients are tempered by the subsequent greater perturbation of homeostasis due to the rapid influx of these efficiently acquired nutrients. Anticipatory, cephalic phase metabolic responses serve to ameliorate the challenge to homeostasis, and thus allow increases in digestive and absorptive efficiency. The net effect of the coordination of these processes establishes many of the constraints on feeding, such as maximal meal size and frequency, types of foods that can be eaten, the efficiency with which nutrients can be incorporated into the body, and so forth. Thus one adaptive function of satiety is to restrain feeding in defense of homeostasis (Woods 1991).

55.2.3 Cephalic Phase Responses in Appetite and Satiety

Cephalic phase responses have been suggested to play a role in appetite and satiety (Powley 1977; Woods 1991, 2006). Palatable foods generally result in more robust cephalic phase responses than do less preferred foods. Preventing cephalic phase responses results in animals and humans eating smaller meals (reviewed in Woods 1991). Cephalic phase responses would appear to allow larger meals, presumably due to their ability both to stimulate digestive processes and to address the challenge to homeostasis of the subsequent absorbed nutrients. It has also been suggested that cephalic phase responses are linked to motivation to feed, and thus may actually play a more direct role in determining meal size and total daily food intake beyond the permissive one of ameliorating negative consequences of feeding.

Insulin and leptin are important signaling molecules relevant to feeding biology. Basal circulating concentrations of insulin and leptin are in proportion to fat mass. Both insulin and leptin are transported across the blood–brain barrier, and act centrally to regulate appetite, reduce food intake, and possibly increase energy metabolism (Woods et al. 2003). Leptin is primarily produced by adipose tissue. Insulin is produced by the pancreas, but insulin signaling is affected by adipose tissue and has potent effects on adipose tissue.

Circulating levels of both insulin and leptin are regulated. Insulin secretion responds to changes in blood glucose or amino acid concentration. At basal levels, leptin generally reflects total adipose tissue; however, leptin synthesis and secretion are regulated by a number of factors. Insulin, glucocorticoids, and estrogens, among others, increase leptin secretion; androgens, free fatty acids, and growth hormone, among others, decrease leptin secretion (Kershaw and Flier 2004). Leptin secretion also varies by the type or location of the fat; i.e., subcutaneous fat generally has higher leptin secretion compared to visceral fat (Fain et al. 2004; Kershaw and Flier 2004). Fasting reduces circulating leptin far out of proportion of any fat loss, and refeeding will rapidly return circulating leptin to previous levels. In very lean populations of humans (Kuzawa et al. 2007) and nonhuman primates (Banks et al. 2001) circulating leptin generally is very low and is a poor indicator of total fat mass.

Leptin and insulin differ in important ways; circulating levels of leptin and insulin appear to reflect different fat depots. Leptin concentration is more reflective of subcutaneous fat, and insulin is

more reflective of visceral fat. Visceral fat also is more sensitive to insulin than is subcutaneous fat. Because of the differences between men and women in the proportion of visceral to subcutaneous fat, in general leptin is better correlated with total adipose mass in women, and insulin is more highly correlated to total adipose mass in men (Woods et al. 2003).

Men and women differ in the responses to central insulin and leptin. Men are more sensitive to central insulin, and women are more sensitive to central leptin. For example, intranasal insulin reduced feelings of hunger in men but not in women (Hallschmid et al. 2004). In men, intranasal administration of insulin led to weight loss, and specifically fat loss; it resulted in weight gain, primarily extracellular water, in women. Similar results have been obtained in rats. Central insulin was more effective in reducing food intake in male rats, while female rats were more sensitive to central leptin (Clegg et al. 2003).

Leptin also is a gut peptide. It is synthesized and secreted by the gastric mucosa, and appears to be secreted during meals (Bado et al. 1998). Vagal stimulation results in gastric mucosal leptin secretion, but no increase in plasma leptin concentration (Sobhani et al. 2002), suggesting that gastric leptin is secreted during the cephalic phase of gastric secretions, and acts in a paracrine fashion. Leptin receptor mRNA is present in vagal afferent neurons that innervate the gastric fundus, suggesting that leptin may have direct stimulatory effects on vagal afferents (Peters et al. 2005). Infusions of leptin into the celiac artery, but not the jugular vein, significantly reduced intake of a sucrose solution by rats (Peters et al. 2005).

Some of the leptin secreted by the gastric mucosa appears to survive the gastric acid and travels intact to the intestine where it is thought to perform multiple functions regulating the absorption of lipid, carbohydrate, and protein (reviewed in Picó et al. 2003). The functional form of the leptin receptor (Ob-Rb) is expressed in human jejunum and ileum (Morton et al. 1998). Leptin has been shown to inhibit d-galactose absorption (Lostao et al. 1998) and increase the intestinal absorption of small peptides (Morton et al. 1998). Leptin also stimulates cholecystokinin (CCK) secretion (Guilmeau et al. 2003). Leptin and CCK form a positive feedback loop; plasma CCK stimulates gastric leptin secretion (Bado et al. 1998) and duodenal infusion of leptin in rats increased plasma CCK comparable to the effects of feeding (Guilmeau et al. 2003). Leptin and CCK appear to act synergistically to activate vagal afferent neurons (Peters et al. 2004).

CCK has direct effects on meal size. Giving exogenous CCK to rats resulted in meals that were shorter on average than the meal duration of control rats. However, the treated rats ate a greater number of meals per day, and total daily food intake did not differ between treated and control rats (West et al. 1984). In rats without expression of CCK receptor type A, meals were of greater duration and consisted of greater amounts ingested. The number of meals per day decreased; however, the net effect was an overall greater daily food intake, and eventual obesity (Moran and Kinzig 2004).

Thus, in addition to its role in long-term energy balance, leptin has been suggested to play a role in short-term satiety signals, either directly via vagal afferents or indirectly through stimulation of CCK secretion. Indeed, leptin and CCK appear to act synergistically to reduce both long- and short-term food intake (Barrachina et al. 1997; Matson and Ritter 1999). The short-term regulation of food intake may function more as a defense of homeostasis than as a means of achieving neutral energy balance.

55.2.4 Ghrelin

Ghrelin is the only gut peptide known so far to stimulate food intake. Ghrelin is secreted into the bloodstream by the stomach and intestines. Exogenous ghrelin rapidly increases food intake in rats (Wren et al. 2001b) and humans (Wren et al. 2001a). Indeed, ghrelin is as potent at stimulating feeding

as neuropeptide Y (NPY). Starvation increases ghrelin plasma concentration and refeeding rapidly decreases circulating ghrelin (Ariyasu et al. 2001).

Ghrelin has been suggested to act to initiate feeding (Cummings et al. 2001, 2004). However, it is uncertain whether under natural conditions ghrelin truly serves to initiate feeding or whether its main function is to prepare the body for an expected meal (Frecka and Mattes 2008). Ghrelin has effects on peripheral organs that would serve to prepare the digestive tract for food. For example, ghrelin stimulates gastric acid secretion (Date et al. 2001), gastric emptying (Levin et al. 2006), gastrointestinal motility (Trudel et al. 2002), and pancreatic secretions (Sato et al. 2003). Of course these are not mutually exclusive functions. Indeed they are complementary; an example of a hormone serving to coordinate peripheral physiology with central motive states.

Ghrelin is an ancient regulatory molecule; it has been detected in chickens, fish, and bullfrogs (Tritos and Kokkotou 2006). In addition to its functions regulating appetite, ghrelin is a potent secretagogue of growth hormone from the pituitary through binding to the growth hormone secretory (GHS) receptor (Takaya et al. 2000). Circulating ghrelin exists in both an acylated and nonacylated form. The nonacylated form does not activate the GHS receptor, but does appear to have effects on glucose homeostasis, lipolysis, adipogenesis, cell apoptosis, and cardiovascular function, suggesting that another receptor might exist (Tritos and Kokkotou 2006). Ghrelin is produced by the post-translational cleavage of a prepropeptide of 117 residues; an alternative cleavage of this prepropeptide produces obestatin (Zhang et al. 2005). Intriguingly, obestatin has been shown to suppress food intake (Zhang et al. 2005), though the effect has not been reliably replicated. Thus the ghrelin gene appears to produce two distinct peptide hormones with opposing actions. These facts highlight the importance of post-translational mechanisms in understanding gene effects.

The processes that affect evolutionary change are limited in that they can only work on existing variation. There are many examples of ancient regulatory molecules, like ghrelin, which, over time, became adapted and co-opted to serve multiple, diverse functions. These regulatory molecules serve as "information molecules," transmitting information among organ systems and coordinating the responses of peripheral organs and the central nervous system to external and internal challenges to an organism's viability. An evolutionary perspective predicts that these molecules will have multiple and diverse functions. Ghrelin is an important gut peptide that is also a neuropeptide. Based on its known functions, ghrelin serves to coordinate peripheral physiology with appetite.

55.2.4.1 Ghrelin and Cephalic Phase Responses

When human volunteers were provided meals on a fixed schedule, plasma ghrelin concentration displayed a consistent pattern of being low immediately after a meal, slowly increasing, and then displaying a pronounced increase in concentration immediately prior to the next meal followed by an equally dramatic decline immediately after the meal (Cummings et al. 2001; Fig. 55.6). The pattern of ghrelin concentration was roughly opposite to the pattern of insulin concentration, but in phase with the circadian cycle of leptin concentration, though much more variable than leptin concentration. Because the meals were provided at fixed times, this evidence supports the hypothesis that the surge in ghrelin secretion prior to meals is a cephalic phase response that serves to initiate feeding and/or to prepare the person to digest and metabolize food.

Frecka and Mattes (2008) investigated the pattern of circulating ghrelin in 21 human subjects with either a habitual long or short interval between breakfast and lunch. The patterns of circulating ghrelin differed between these two groups exactly as their feeding habits would predict. Ghrelin increased prior to the anticipated meal time, and then declined after the meal was eaten. There was no difference between groups in the nadir of circulating ghrelin after breakfast or in the amount of time postbreakfast the nadir occurred. The time interval between the postbreakfast nadir and the prelunch

Fig. 55.6 Mean plasma ghrelin concentration over a 24-h period with three set meals. Mean plasma ghrelin in 10 human subjects (9 women and 1 man) over a 24-h period consuming breakfast (B), lunch (L), and dinner (D) at set times (8:00, 12:00, and 17:30). Subjects were aware of when meals were to be provided and the time (Data from Cummings et al. 2001)
ghrelin peak was significantly longer for the habitual long interval group; but the peak ghrelin levels did not differ. In both groups the ghrelin peak occurred about 20–30 min prior to lunch. Circulating ghrelin concentration was associated with the subjects' reports of feeling hungry; however, changes in hunger appeared to precede changes in ghrelin concentration, leading Frecka and Mattes (2008) to suggest that the primary role of ghrelin was to prepare the gut in anticipation of feeding as opposed to directly increasing motivation to feed. The pattern of circulating insulin was opposite to that of ghrelin, and was consistent with a role for insulin in regulating ghrelin secretion, a finding in concordance with previous research (e.g., Cummings et al. 2004).

Further evidence for a cephalic phase component to ghrelin secretion patterns comes from a study involving rats fed either ad lib or at a fixed time. Freely feeding rats had a peak of ghrelin secretion just before the dark phase of their light cycle. The meal-trained rats had a significantly higher peak of ghrelin secretion just before the time they had become accustomed to have access to food (Drazen et al. 2006), even though that was during the light phase of their day, during which rats usually are less likely to feed.

Ghrelin secretion appears to have a cephalic phase for both the anticipatory rise before a meal and the decline with the initiation of feeding. In a study of real and sham feeding in human volunteers, serum ghrelin concentration always increased just prior to the meal. Whether the volunteers actually ate or performed a sham feeding, serum ghrelin concentration initially declined (Arosio et al. 2004). These results are consistent with the pattern of plasma ghrelin in six humans (three men and three women) accustomed to eating three meals per day who fasted over a 33-h period. Plasma ghrelin increased on both mornings (around 8:00), the middle of the day (12:00–13:00) and in the early evening (17:00–19:00). These increases were followed by a spontaneous decline in plasma ghrelin despite the fact that the subjects were fasting (Fig. 55.7; Natalucci et al. 2005). Thus the pattern of circulating ghrelin appeared entrained, and eating food was not required for the decline in circulating ghrelin postmeal time.

These results in rats and humans suggest that appetite can be entrained to a circadian clock. It suggests that hunger can occur in anticipation of food being available, but if the food is not delivered, then the system reverts to a "nonfeeding" state. Perhaps the readers are familiar with the phenomenon of being hungry, but not able to eat; after several hours the feelings of hunger recede. Of course the scent and sight of food can bring them back intensified, but otherwise, a person will no longer be "hungry" despite having not fed.
Fig. 55.7 Blood ghrelin concentration during a 32-h period of fasting. Men and women (three and three) were accustomed to eating breakfast, lunch, and dinner at approximately 8:00, 12:30, and 18:30; they then fasted for approximately 32 h, starting at midnight. Blood was collected via catheter every 20 min starting at 8:00 for 25 h when they were fed breakfast. The pattern of circulating ghrelin concentration showed a consistent pattern of rising before the expected meal time, and declining afterward, even when no food was ingested (Data from Natalucci et al. 2005)

Ghrelin is associated with hunger (Cummings et al. 2001, 2004; Levin et al. 2006; Frecka and Mattes 2008), though whether ghrelin expression stimulates hunger or is stimulated by hunger is debated. Ghrelin is expressed in the brain, especially in many areas of the hypothalamus, but also in the amygdala, bed nucleus of the stria terminalis, and cortex (Cowley et al. 2003). In the hypothalamus ghrelin frequently colocalized with NPY and stimulated activity of NPY and agouti-related protein (AgRP) neurons (Cowley et al. 2003). The effects of ghrelin in the arcuate nucleus are especially intriguing; ghrelin increased the activity of NPY neurons and inhibited POMC neurons (Cowley et al. 2003). The GHS receptor is expressed in most NPY neurons (Willesen et al. 1999). Ghrelin increases gene expression of both NPY and AgRP (Goto et al. 2006). The orexigenic effects of ghrelin are abolished in NPY and AgRP null mice (Chen et al. 2004).

Although the hypothalamus and especially the arcuate nucleus has garnered much recent attention, brain circuits relevant to feeding behavior are widely distributed in the brain. Ghrelin expression and effects in other brain regions, both forebrain and brainstem, deserve attention. For example, ghrelin administration in caudal brainstem has potent orexigenic effects (Faulconbridge et al. 2003, 2005). These effects are mediated by GHS receptors and NPY, as in the hypothalamus, but appear to represent a distinct neural circuit from the hypothalamic circuit and to rely on different NPY receptors (Faulconbridge et al. 2005).

55.3 Conclusions

Physiological and metabolic systems serve the survival and reproductive capabilities of the organism (fitness). In real-world situations animals are constantly balancing competing imperatives. It can be argued that the resolution and prioritization of those competing imperatives is a principal function of

the central nervous system. Another principal function of the CNS is the coordination of responses to and in anticipation of challenges. The central nervous system is intimately involved in physiological regulation.

Anticipatory, feedforward systems are vital to regulatory physiology. Physiology is not merely reactive. Cephalic phase responses are a fundamental concept in regulatory physiology; a paradigmatic example of anticipatory physiological responses. They need to be integrated across the diverse regulatory information molecules that are being discovered. They need to be viewed in an adaptive, evolutionary perspective. They represent, in our opinion, the results of feedforward evolutionary pressures; an "arms race," if you will, between the imperatives of increasing the rate of nutrient acquisition and of defending the internal milieu.

Some cephalic phase responses (e.g., ghrelin and insulin) appear to affect appetite (central motive states) as well as peripheral physiology, and thus are involved in coordinating physiology and behavior. Cephalic phase responses serve to increase meal size/duration (efficiency of digestive and metabolic responses) and thus increase food intake per meal. They also begin endocrine cascades to terminate a meal. There are multiple reasons, in addition to energy balance and adipose tissue homeostasis, to terminate a meal. Defense of homeostasis (sensu Woods 1991) is an important consideration.

Another simple, and perhaps little considered factor, is that animals have many necessary functions to perform to be viable. There are strong incentives and redundant neural circuits reinforcing feeding behavior. There have to be equally strong mechanisms to stop feeding in the presence of available food or animals would be constantly feeding, regardless of other imperatives. There are many constraints on animals, but time is a universal one. Animals, to be viable, must apportion their time among the various activities necessary for survival and reproduction. Motivation should vary over the circadian cycle, and peripheral physiology should be in synchrony with behavior. Cephalic phase responses are adaptive mechanisms to achieve these purposes for feeding biology.

Summary Points

- Anticipatory feeding responses prepare organisms for physiological imbalances due to the ingestion of nutrients.
- These anticipatory feeding responses, termed cephalic phase responses, improve the efficiency of food digestion, absorption, and metabolism.
- The central nervous system is intimately involved in cephalic phase responses; organisms can learn when to expect food. Some cephalic phase responses can become entrained to a circadian rhythm.
- Insulin has a cephalic phase response and circulating insulin increases in anticipation of feeding; loss or attenuation of this response compromises the ability to regulate circulating glucose levels.
- Ghrelin is a gut peptide that acts in the brain to stimulate food intake. It also acts on peripheral organs to prepare for a meal.
- In humans and rats fed at consistent times over many days, ghrelin has been shown to have a circadian rhythm that matches the expected meal times. This circadian rhythm is evident even if the human subjects are fasting.
- One function of the circadian rhythm of ghrelin may be to align motivation and peripheral physiology, such that feeding behavior and the preparatory physiological changes to enhance digestion and metabolism occur at the times of expected food availability.

Key Terms

Homeostasis: A term popularized by the American physiologist W.B. Cannon in the 1920s to describe the physiological processes that serve to maintain the stability of the internal milieu, a concept originally proposed by Claude Bernard in the late 1800s. A modern definition is the physiological processes that serve to protect the viability of the organism by resisting changes to its internal states. An example relevant to this essay is the secretion of insulin from the pancreas to maintain circulating blood glucose within certain boundaries.

Allostasis: The physiological processes that serve to protect the viability of an organism by changing its internal states. This concept has been proposed in recognition of the fact that not all adaptive physiological regulation is homeostatic (resisting change). Many regulatory processes serve to change an animal's state in response to external or internal conditions. The distinction between homeostatic and allostatic processes can often be difficult, and can depend on the time frame perspective. Both concepts can be incorporated into the concept of regulatory physiology as the total of processes that act to adjust an organism's internal state in response to challenges in order to enhance the organism's evolutionary fitness.

Cephalic phase response: An anticipatory physiology response to either the sensing of food or to the expectation that food will become available that serves to prepare the body to digest, absorb, and metabolize nutrients.

Insulin: A peptide hormone secreted by the pancreas. Insulin serves to regulate circulating glucose concentration by regulating aspects of glucose and lipid metabolism primarily in muscle, liver, and adipose tissue.

Ghrelin: A peptide hormone secreted by the stomach. Ghrelin acts in the brain to stimulate appetite and food ingestion, and acts in the periphery to prepare the gut to digest food.

Leptin: A peptide hormone primarily secreted by adipose tissue; but also by the stomach. Leptin acts in the brain to suppress appetite.

Circadian rhythm: Cyclical changes to an organism's physiology and metabolism that usually occur over a roughly 24-h cycle. In this essay the circadian rhythm of circulating ghrelin is discussed in the context of expected meal times.

Chapter 56
Food Intake and Heart Rate Variability: Toward a Momentary Biopsychosocial Understanding of Eating Behavior

Hiroe Kikuchi, Kazuhiro Yoshiuchi, Ken Ohashi, Fumiyo Sato, Yoshiyuki Takimoto, Akira Akabayashi, and Yoshiharu Yamamoto

Keywords Heart rate variability • Ecological momentary assessment

Abbreviations

AN	Anorexia nervosa
BED	Binge eating disorder
BMI	Body mass index
BN	Bulimia nervosa
BPV	Blood pressure variability
BRS	Baroreflex sensitivity
cEMA	Computerized ecological momentary assessment
ECG	Electrocardiography
EMA	Ecological momentary assessment
HF	High frequency
HRV	Heart rate variability
LF	Low frequency
PDA	Personal digital assistant
RSA	Respiratory sinus arrhythmia
SBP	Systolic blood pressure

56.1 Introduction

Heart rate variability (HRV) is a term which refers to variations of heartbeat intervals of sinus rhythm (Task Force of the European Society of Cardiology the North American Society of Pacing Electrophysiology 1996). Heart rate is under the control of the cardiac autonomic nervous system. HRV is analyzed by various methods such as time domain analysis, frequency domain analysis, and nonlinear analysis (Table 56.1). Frequency domain analysis provides a power spectrum, which shows the power distribution along the frequency of the variation. Based on physiological studies on the

Table 56.1 Key facts of autonomic nervous system and heart rate variability

1. The autonomic nervous system (ANS) is the part of the peripheral nervous system that acts as a control system.
2. The ANS controls visceral functions such as heart rate, digestion, respiration rate, salivation, perspiration, diameter of the pupils, urination, and sexual function.
3. The ANS is divided into two parts: the sympathetic nervous system (SNS) and parasympathetic nervous system (PNS).
4. Functionally, the SNS and PNS are complementary in maintaining a balance in the tonic activities of many visceral structures and organs.
5. The SNS is concerned primarily with organ responses during rage and fright, such as increase of heart rate and blood pressure.
6. The PNS is concerned primarily with conservation of energy and maintenance of organ function during periods of minimal activity such as decrease of heart rate and blood pressure.
7. Heart rate variability (HRV) usually indicates variations of instantaneous RR intervals.
8. HRV is used for noninvasive investigation of the cardiovascular ANS function.

This table lists the key facts of the autonomic nervous system (ANS) including the function of the ANS, the complementary functions of the sympathetic nervous system and parasympathetic nervous system, and the association between the ANS and heart rate variability

transmission frequency properties of sympathetic and parasympathetic controls and those involving autonomic blockades, the power of the high frequency (HF) component (0.15–0.40 Hz) is considered to reflect cardiac parasympathetic activity and the power of the low frequency (LF) component is considered to reflect both cardiac sympathetic and parasympathetic activities. Therefore, HRV is used for the noninvasive investigation of cardiovascular autonomic functions. HRV is also known to have a prognostic value in life-threatening cardiac diseases.

In this chapter, HRV in two extreme states of food intake will be discussed first. One is obesity as a consequence of excess food intake, and the other is anorexia nervosa as an example of extremely low body weight resulting from insufficient food intake. Then, the need for a momentary biopsychosocial understanding of the interplay between eating behavior and the underlying physiology, and how this can be achieved, will be addressed.

56.2 Obesity and Heart Rate Variability

The autonomic nervous system is involved in the regulation of energy expenditure and is assumed to contribute to the pathophysiology of obesity. In addition, obese subjects suffer from an increased risk of cardiovascular diseases, and it has been speculated that the cardiac autonomic function may in part explain this risk. Reduced heart rate variability itself is also known to predispose patients with life-threatening cardiac diseases to sudden cardiac death (Goldberger et al. 2008). Therefore, the autonomic nervous system is thought to play a role in obesity and related complications, and HRV in obesity has been investigated (Table 56.2).

Previous studies on HRV in obese subjects have almost consistently showed that parasympathetic nervous activity indexed by HF power of HRV is more significantly decreased in obese subjects than in nonobese controls (Piccirillo et al. 1998; Karason et al. 1999; Skrapari et al. 2007). Although sympathetic activity has been suggested to increase in obesity in studies using other indexes like plasma norepinephrine levels, conclusions concerning sympathetic nervous activity from previous studies are rather inconsistent. One reason is that no frequency component of HRV is affected solely by sympathetic activity, which makes the interpretation of the results difficult. The ratio of LF power to HF power (LF/HF) of HRV is sometimes used as an index of cardiac sympathetic function. However, the results of LF/HF are still inconsistent (Piccirillo et al. 1998; Skrapari et al. 2007).

Table 56.2 Studies on obesity and heart rate variability

First author, Country, year	Sample size, description, baseline age (mean or range)	Measurement and analysis	Variables of HRV	Major results
Cross sectional study				
Chen, Taiwan, 2008	77 Obese (BMI > 28)/CON (BMI < 23) Without HT 29.6/ 28.1	512 beats Power spectral analysis (FFT)	VLF(0.01–0.04 Hz), LF(0.04–0.15 Hz), HF(0.15–0.40 Hz), TP(0.01–0.40 Hz), nLF, nHF	nLF, nHF: obese < CON. In obese subjects, waist and waist–hip ratio were positively correlated with nLF, LF/HF, and negatively correlated with nHF.
Skrapari, Greece, 2007	60 Obese (BMI > 30)/CON (BMI < 25) Without HT 42.7/42.8	5 min, supine Power spectral analysis (CGSA)	HF (0.15–0.5 Hz), LF (0.05–0.15 Hz), TP (0.003–0.50 Hz), LF/HF	LF: obese < CON, HF: obese < CON, LF/HF: obese > CON
Piccirillo, Italy, 1998	43 Moderately obese(BMI < 40)/massively obese (BMI > 40)/CON (BMI <26) Without HT 47.0/ 52.0/ 48.1	10 min, supine & HUT Power spectral analysis (autoregressive)	TP, HF (0.15–0.40 Hz), LF (0.04–0.15 Hz), VLF (–0.04 Hz), nHF, nLF, LF/HF	nLF at rest and HUT: massively obese < moderately obese, CON (decreased LF may reflect the inability to respond to the neurotransmitter of SNS)
Longitudinal study				
Poirier, USA, 2003	8 Obese (BMI >= 40) Without uncontrollable HT 18–50 (inclusion criteria)	24 h Time domain analysis, power spectral analysis (details NA)	SDNN, SDANN, rMSSD, pNN50, VLF (0.0033–0.04 Hz), LF (0.04–0.15 Hz), HF (0.15–0.40 Hz), LF/HF	After weight loss, LF, HF, SDNN, and SDANN increased during both diets. rMSSD and pNN50 increased only during high carb diet.
	Weight loss by diet (3 mm) followed by weight maintenance by high fat diet and high carb diet (3 mm)			
Laaksonen, Finland, 2003	41 Obese with metabolic s yndrome (BMI 30–45, waist >=102 in M and >= 90 in W) 49.2	5 min, paced breathing (0.2 Hz) Power spectral analysis (modified covariance autoregressive model)	TP (0–0.40 Hz), LF (0.04–0.15 Hz), HF (0.15–0.40 Hz)	After weight loss, TP, LF increased. These changes gradually attenuated during weight maintenance.
	Weight loss by VLCD (9 weeks) followed by weight mainte- nance by either orlistat or placebo with a mildly hypocaloric diet			

(continued)

Table 56.2 (continued)

First author, Country, year	Sample size, description, baseline age (mean or range)	Measurement and analysis	Variables of HRV	Major results
Emdin, Italy, 2001	Weight loss by hypocaloric diet (8 mm) Obese(BMI > 30.5 in men, 27.3 in women)/lean Without HT 39/34	24 h Power spectral analysis (autoregressive) for every 256 beats	VLF (0.003–0.03 Hz), LF (0.03–0.15 Hz), HF (0.15–0.40 Hz)	LF: obese < lean. LF/HF was positively associated with fasting plasma insulin (after adjustment for sex, age, HR and BMI). After weight loss, LF was increased.
Karason, Sweden, 1999	Weight loss by either gastric surgery or diet (1 year follow up) Obese (BMI 31–52)/ CON (BMI 17–27) 7 obese took antihypertensive medication 49/49	24 h Time domain analysis, power spectral analysis (FFT) for every 5 min	SDNN, SDANN, SDNN index, LF (0.05–0.15 Hz), HF (0.15–0.40 Hz)	SDNN, SDANN, SDNN index, HF: obese < CON Both LF and HF were negatively associated with BW after adjustment for age, sex, smoking, and antihypertensive treatment. Weight decreased only in those treated with surgery and not in those treated with diet. After weight loss, SDNN index and HF increased. Changes in both daytime HF and daytime LF were negatively associated with BW after adjustment for age, sex, smoking, and antihypertensive treatment.
Hirsch, USA, 1991	Weight gain & loss by fluid formula Normal-obese (BMI 23.4–49.9) Without HT 20–48	256 s, supine & standing Power spectral analysis (FFT)	LF (0.04–0.10 Hz), resp.F (respiratory freq. +/- 0.06 Hz), LF/resp.F	With 10% increase in BW, resp.F declined and HR rose.

This table lists studies on obesity and heart rate variability. *VLCD* very low calorie diets, *BMI* body mass index, *CON* control, *HT* hypertension, *HUT* head-up tilt, *CGSA* coarse-graining spectral analysis, *FFT* fast Fourier transform, *NA* not available, *TP* total power, *VLF* power of very low frequency component, *LF* power of low frequency component, *HF* power of high frequency component, *nLF* normalized power of low frequency component (LF/(TP-VLF)), *nHF* normalized power of high frequency component (HF/(TP-VLF)), *resp.F* power of respiratory frequency component, *SNS* sympathetic nervous system, *BW* body weight, *HR* heart rate. Refer to definition and explanation of key terms for SDNN, SDANN, SDNN index, rMSSD, and pNN50

Some researchers have speculated that no apparent activation of sympathetic nervous activity indexed by HRV has been due to a postreceptor downregulation process or heterogeneous sympathetic nervous activation among organs.

Decreased parasympathetic nervous activity has not only been observed in a cross-sectional study but also in a longitudinal study. Hirsch et al. (1991) reported that a 10% increase in body weight due to increased caloric intake is associated with a decline in parasympathetic activity indexed by the power of the respiratory frequency component. Furthermore, several studies have shown that cardiac parasympathetic activity mainly indexed by the HF power of HRV is increased with body weight reduction regardless of the method used for reduction (e.g., gastric surgery, diet therapy) (Karason et al. 1999; Laaksonen et al. 2003; Poirier et al. 2003), and a change in HF power is negatively correlated with a change in body weight (Karason et al. 1999). It is sometimes discussed whether altered cardiac autonomic function is a cause of obesity or a result of obesity. These longitudinal studies suggest that obesity causes changes in cardiac autonomic function.

The mechanism of autonomic nervous system change in obesity is still unknown. Recently, Chen et al. (2008) reported that in obese subjects, HF power was negatively correlated with waist circumference and waist to hip ratio, but not with the body mass index (BMI), and suggested that central rather than general obesity is related to the change in the cardiac autonomic function. In relation to central obesity, leptin, insulin, and the resistance of leptin and insulin seen in obese subjects may also play a role in linking obesity with the sympathetic nervous function, as increased leptin and insulin levels are thought to increase sympathetic nervous activity (Paolisso et al. 2000; Emdin et al. 2001). However, their relationships to parasympathetic nervous activity as reflected by the decreased HF power of HRV are less clear.

Some researchers claim that caloric restriction itself may affect HRV because their study with a 1-year follow-up after gastric surgery showed that an improvement of HRV was apparent in the acute body weight reduction phase but was attenuated in the later follow-up period, and the improvement of HRV was correlated with caloric intake but not with BMI or insulin resistance (Bobbioni-Harsch et al. 2008).

56.3 Anorexia Nervosa and Heart Rate Variability

Anorexia nervosa (AN) is a major subtype of eating disorder characterized by a refusal to maintain minimally normal body weight, intense fear of obesity, and body image disturbances. From the nutritional viewpoint, AN is a state of severely low body weight due to decreased and limited food intake.

Since AN has a high mortality rate and its major cause of death is cardiac complications such as cardiac sudden death, HRV in AN patients has been investigated (Table 56.3). However, the results of the studies have been inconsistent. Some have reported that sympathetic nervous activity was decreased while parasympathetic nervous activity did not change (Kreipe et al. 1994; Rechlin et al. 1998), while others have reported that parasympathetic activity was increased with or without a decrease in sympathetic activity (Petretta et al. 1997; Galetta et al. 2003). One report showed that both sympathetic and parasympathetic activities were decreased (Melanson et al. 2004).

Recently, Ishizawa et al. investigated HRV in AN by using frequency domain analysis and fractal analysis, together with blood pressure variability (BPV) and baroreflex sensitivity (BRS) in order to evaluate cardiac autonomic function more reliably and to evaluate cardiovascular risk (Ishizawa et al. 2008). A total of 32 AN patients and 37 healthy normal weight controls underwent 10-min beat-to-beat recording of heartbeat interval and systolic blood pressure (SBP). Spectral analysis was performed for heartbeat interval and SBP time series. Detrended fluctuation analysis (Peng et al. 1995),

Table 56.3 Studies on anorexia nervosa and heart rate variability

First author, country, year	Sample size, description, baseline age (mean or range)	Measurement and analysis	Variables of HRV	Major results

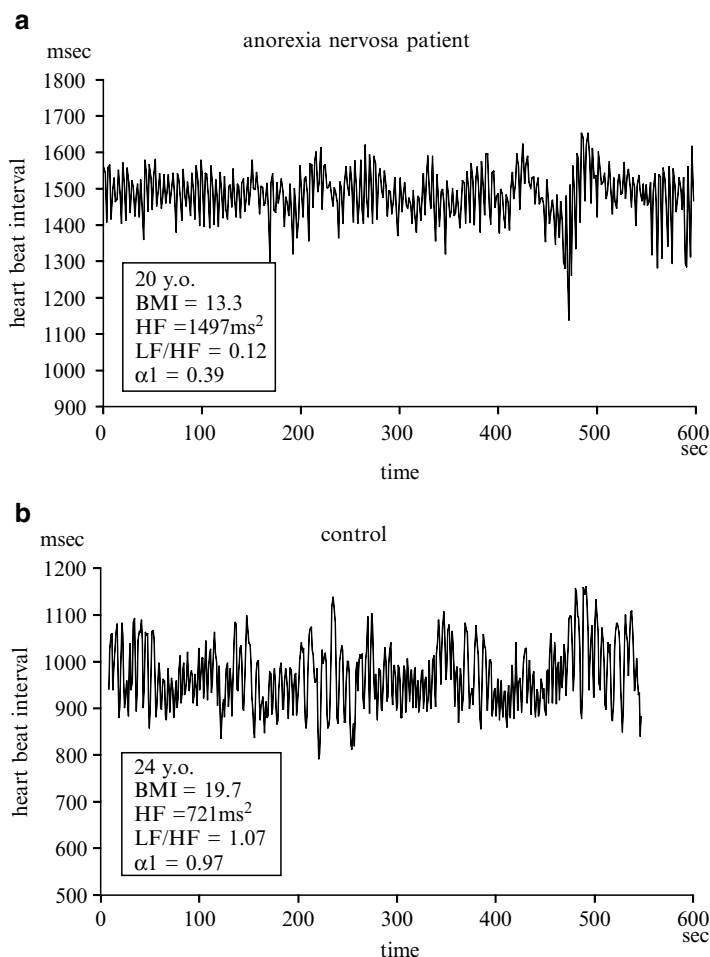
Fig. 56.1 Heartbeat intervals of an anorexia nervosa patient and a healthy control. Representative data of heartbeat intervals for both groups are shown. (**a**) An anorexia nervosa patient. (**b**) A healthy control. Insets show HF power of HRV, power ratio of LF to HF of HRV, and scaling exponent α1 for the respective data. *y.o.* years old, *BMI* body mass index, *HF* power in the low frequency range, *LF/HF* ratio of power in the low frequency range to that in the high frequency range


which has been used for risk stratification in cardiac patients (Huikuri et al. 2000; Mäkikallio et al. 2001b), was also conducted for quantifying the fractal correlation of HRV and the short-term scaling exponent α1 was calculated. Representative data of heartbeat interval variability for AN patients and controls are shown in Fig. 56.1.

In AN compared with healthy controls, HF power of HRV, total power of HRV, and BRS were significantly higher, and LF power of BPV, LF/HF of HRV, and the scaling exponent α1 of HRV were significantly lower. These results suggested increased parasympathetic nervous responsiveness in AN, which could be considered as an adaptive response to caloric deprivation, although it may be contrary to the increased risk of cardiac complication because decreased, rather than increased, parasympathetic nervous activity is usually related to death in cardiac patients. The results also suggested that, despite decreased sympathetic nervous responsiveness which may lead to a decreased risk of cardiac sudden death, there was a decrease in the scaling exponent α1, known to be associated with higher mortality (Huikuri et al. 2000; Mäkikallio et al. 2001b).

Although it is rational that responses of HRV in AN are in the opposite direction compared to obese subjects, the mechanism which causes such responses and the relationship with restricted food intake is still unclear and needs to be further investigated.

56.4 Bulimia Nervosa and Heart Rate Variability

Obesity and AN are thought to be conditions where excess or restricted food intake and resultant increased or decreased body weight or fat may affect the cardiac autonomic nervous function probed by HRV. However, there is another condition where the change of HRV mimics that in AN, while food intake and body weight are not severely reduced. That is bulimia nervosa (BN).

BN is another type of eating disorder, characterized by regularly repeated binge eating episodes with compensational behavior, which may be purging, such as vomiting and overuse of laxative, or something other than purging, such as overactivity and fasting. BN patients usually show normal body weight or slightly increased body weight.

BN is also known to cause cardiac complications, as does AN. In addition, some studies (Faris et al. 2008) have suggested that the ability to feel satiety in BN patients is compromised, and vagal function, although it is a visceral afferent function, might be involved in this. The natural course of BN is more benign than that of AN, and HRV in BN has attracted less attention than that in AN. Still, there have been a few studies on BN and HRV.

Kennedy et al. (1989) reported that vagal tone measured by respiratory sinus arrhythmia (RSA), which usually corresponds to HF power of HRV, increased in BN as well as in AN. Rissanen et al. (1998) reported that vagal tone measured by RSA was higher in BN than in healthy controls and, after 8 weeks of treatment by fluoxetine combined with cognitive behavior therapy, vagal tone was decreased to the level of healthy controls. Although the pharmacological effect of SSRI is not negligible when interpreting the changes after treatment, BN patients have been consistently reported to have elevated cardiac parasympathetic nervous activity without a significant change in body weight or fat, which is reversible with treatment.

These changes of HRV in BN cannot be explained by changes in body weight and fat or caloric restriction. Possible factors that may affect HRV are psychological symptoms and behaviors (e.g., eating patterns which cannot be measured by caloric intake, repeated binging, and purging), and further investigation is necessary.

56.5 Binge Eating Disorder and Heart Rate Variability

Another example which suggests that HRV change can be explained not only by body weight and fat or food intake but also by eating behavior or psychological factors is the study of cardiac parasympathetic regulation in obese women with or without binge eating disorder (BED).

BED is categorized as an eating disorder, though it is not treated as discriminated disease entity yet. BED is characterized by repeated binge eating which is similar to BN, but not accompanied by compensatory behaviors, which usually leads to overweight or severe obesity.

Friederich et al. (2006) compared cardiac parasympathetic activity of obese subjects with BED and those without BED. HF power of HRV during rest was not different between obese subjects with and without BED. The decrease in HF power of HRV during mental stress (a standard Stroop Color-Word Interference Test and a delayed auditory feedback task) was more pronounced in obese subjects with BED than those without BED. Hunger score and binge eating frequency were negatively correlated with the change of HF power of HRV during mental stress (i.e., more hunger and more frequent binge eating were related to a greater reduction in HF power of HRV). They pointed out that the hyper-responsiveness of HF power of HRV may be related to the psychopathology of BED.

In BN, it is argued that an increased baseline parasympathetic activity is related to binge eating, while this is not true in obese BED because there are no significant differences in HF power of HRV

at rest between obese subjects with and without BED. However there still is a difference in HF power change during mental stress between obese patients with and without binge eating. Again, further investigation is necessary to clarify the relationships between body weight, food intake, binge eating, psychopathology, and HRV at rest and its response to stress.

56.6 Need for a Biopsychosocial Understanding

As previous studies of obese subjects and AN patients have shown, HRV is thought to be related to food intake or body weight. However, as shown in cases of BN and obese BED, HRV cannot be explained only by the amount of digested and absorbed food, nor by body weight and fat. Behavior (e.g., binge eating and purging) itself is considered to affect HRV. Thus, the frequency and timing of such behavior (e.g., How often does a patient binge? When was the last binge eating before the electrocardiography (ECG) was recorded?) may have to be accurately assessed. Coexistent psychological pathology is also thought to affect HRV because it is well known that the heart rate is under the strong influence of emotional as well as affective factors. Therefore, in order to understand the relationship between HRV and food intake in more detail, it should be investigated and interpreted together with behavioral and psychological factors.

Furthermore, food intake itself is also known to be associated with psychological and even social factors. It should be investigated not only from the physiological viewpoint (energy balance as physiological homeostasis) but in the context of interactions with biological (autonomic nervous system activity, energy expenditure, etc.), psychological (psychological stress, mood states, etc.), behavioral (binging, purging, etc.), and social (companion, situation, etc.) factors. This is called the "biopsychosocial" point of view.

Eating disorders are extreme but good examples of disorders which involve biological, behavioral, and psychological/psychiatric pathology, and especially require a biopsychosocial approach. The importance of such an approach, however, is not limited to eating disorders but it may also be applicable to other conditions such as obesity, and even to healthy subjects when promoting healthy eating.

56.7 What Is Ecological Momentary Assessment and Why Is It Important?

What kind of methods would enable us to conduct a biopsychosocial investigation of eating behavior? First, an appropriate method for evaluating psychosocial factors in real daily life is required. Laboratory tests have the advantage that they can provide detailed data. However, the ecological validity of them is compromised. To date recalled self-reports, such as questionnaires filled in based on the subjects' recalled self-report, have often been used for evaluating subjective symptoms or experience in daily life settings, such as psychological stress, mood states, pain, and so on. It is pointed out that there is the disadvantage of recall bias in such evaluations based on recalled self-reports.

Therefore, in 1994, ecological momentary assessment (EMA) was proposed as a more appropriate method to record and evaluate mainly subjective symptoms (Stone and Shiffman 1994). EMA is a method in which subjects record their symptoms and phenomena precisely when and where they occur. Formerly, it was carried out by using paper-and-pencil diaries, but faked compliance due to hoarding and so on was inevitable when using paper-and-pencil diaries. Computerized EMA (cEMA), in which subjects use portable computers or personal digital assistants (PDA) as electronic diaries, is able to overcome the faked compliance by recording time of data inputs and is being used more

often. The accuracy in time is advantageous, especially when investigating temporal relationships between factors.

Actually, EMA has already been applied to BN and BED, after Smyth et al. (2001) pointed out the usefulness of EMA in eating disorder studies. Stein et al. (2007) conducted a study using EMA in 33 BED patients and reported that negative mood was significantly higher at prebinge than at nonbinge times and was also higher at postbinge times than at prebinge times in BED patients. Hilbert et al. (2007) conducted a study using EMA in 20 BED and 20 BN patients and 20 controls, and also reported that negative mood was significantly higher at prebinge times than prior to regular eating in BN and BED. They also found that negative mood increased after binge eating compared with those at prebinge times and during binge eating. Engel et al. (2007) conducted a study using EMA in 133 BN patients and reported that anger, which was one aspect of negative mood, was related to binge eating in BN patients. They found that the preceding anger level and the variability of the preceding anger predicted binge eating.

Most previous studies utilizing EMA in BED and BN have focused on binge eating as an event and on its correlates such as mood states. Food intake as an amount of energy or nutrition has rarely been measured, though self-reported binge eating episodes had to be confirmed to be large enough to qualify as binge eating. The measurement of energy intake could also be important when investigating other conditions without binge eating, such as obesity. In order to achieve a biopsychosocial investigation of eating behavior, data concerning energy intake, as well as physiological data such as physical activity and heart rate, should also be collected in the context of EMA, as mentioned above.

56.8 Concept of "Mobile Nurse"

Recently, Struzik et al. (2007) proposed the concept of the so-called "Mobile Nurse." Mobile Nurse is a system consisting of PDA which can communicate, through a bidirectional wireless network, with various wireless sensors for monitoring physiological variables such as ECG and physical locomotor activity, and software which works on PDA. As it is able not only to collect various kinds of symptoms and signs concurrently but also to combine, analyze, and integrate them on site, Mobile Nurse is primarily intended to enable on-site diagnoses and treatment prescriptions. It is also a powerful tool to give us a comprehensive understanding of human behavior, including eating behavior, from biopsychosocial aspects.

In order to integrate recording and evaluation of food intake into the above system, a PDA-based food recording system making an accurate food intake evaluation for a prolonged time in a daily setting is necessary.

56.9 Development of PDA-based Food Recording System

Self-monitoring of food intake is clinically important in body weight reduction and hitherto it has been applied to patients with obesity. However, previously used food recording systems are mostly based on paper-and-pencil diaries. It has been pointed out that food recording systems using paper-and-pencil diaries have shortcomings similar to those mentioned above in the case of EMA, i.e., faked compliance. It is also said that the inconvenience or burden for subjects is substantial if they have to calculate the energy and nutrients consumed by looking up the meals they have had in a calorie chart themselves. This is not practical, especially if recording goes on for a long time.

To overcome these problems, PDA-based systems have been developed for food recording systems, too. Actually this can be considered as the application of cEMA to food recording. As mentioned in connection with cEMA, PDA-based food recording systems can prevent faked compliance because PDA can record the time when data are input and therefore this may possibly even improve the reliability. Furthermore, it may reduce the inconvenience to the subjects, having a food database within it and making the recording and calculating process easier.

There have been several studies using PDA-based food recording systems. However, the reliability of the systems has rarely been confirmed. In one previous study investigating the accuracy of the PDA-based food recording system, although data recorded by the PDA-based system were significantly correlated with the data acquired by 24-h dietary recall, it was also reported that a major cause of errors in consumed energy estimated by the PDA-based system was errors in estimated portion sizes (Beasley et al. 2005).

Recently, it has been suggested that photos of menus may be helpful to reduce errors in estimated portion sizes. Fukuo et al. (2009) developed a PDA-based food recording system with a calorie database including photos of menus (Fig. 56.2), and studied its reliability and practicability in 44 healthy adults and 16 adult patients with type 2 diabetes mellitus. Subjects recorded their food intake and the times of starting meals as soon as possible after finishing meals for seven consecutive days. On the eighth day, they were interviewed by dietitians and food intake on the seventh day was evaluated by a 24-h dietary recall method, which at the time was regarded as a standard.

Daily intake of energy, proteins, carbohydrates, and fats was not different between PDA-based systems and a 24-h dietary recall method in either healthy adults or diabetes patients. In an analysis of the Pearson correlation and intraclass correlation coefficient of absolute agreement, there were significant correlations between daily intake of energy and respective nutrients estimated by the PDA-based system and those estimated by a 24-h recall method in both subject groups (Figs. 56.3 and 56.4).

The compliance rate was 0.98 ± 0.06 (mean ± SD) in healthy adults and 0.98 ± 0.03 (mean ± SD) in diabetic patients. The adherence rate, which was a proportion of inputs made within a predefined time

Fig. 56.2 Captured screen of PDA-based food recording system. After selecting menus, photos of menus are displayed on the screen. Subjects can estimate the portion sizes by reference to these photos. *PDA* personal digital assistant

Fig. 56.3 Consistency of daily total energy intake estimated by PDA-based food recording system and 24-h dietary recall method in healthy adults. Abscissa is for 24-h dietary recall method and ordinate is for PDA-based food recording system. Each dot stands for one subject. If estimations by the two methods agree, the dot is on the diagonal line shown in the plot. Pearson correlation coefficient is 0.854 ($P <$ 0.001) for these data, supporting the accuracy of this food recording system. *PDA* personal digital assistant

healthy controls
Fig. 56.4 Consistency of daily total energy intake estimated by PDA-based food recording system and 24-h dietary recall method in patients with type 2 diabetes mellitus. Abscissa is for 24-h dietary recall method and ordinate is for PDA-based food recording system. Each dot stands for one subject. If estimations by the two methods agree, the dot is on diagonal line shown in plot. Pearson correlation coefficient is 0.808 ($P <$ 0.001) for these data, supporting the accuracy of this food recording system. *PDA* personal digital assistant

diabetes mellitus
after the meal, was 0.41 ± 0.17 within 1 h, 0.53 ± 0.16 within 2 h, 0.73 ± 0.17 within 6 h in healthy adults and 0.59 ± 0.31, 0.66 ± 0.27, and 0.79 ± 0.21, respectively, in diabetic patients. This newly developed PDA-based food recording system was shown to have a good accuracy and a high compliance rate.

56.10 Application in Healthy Subjects

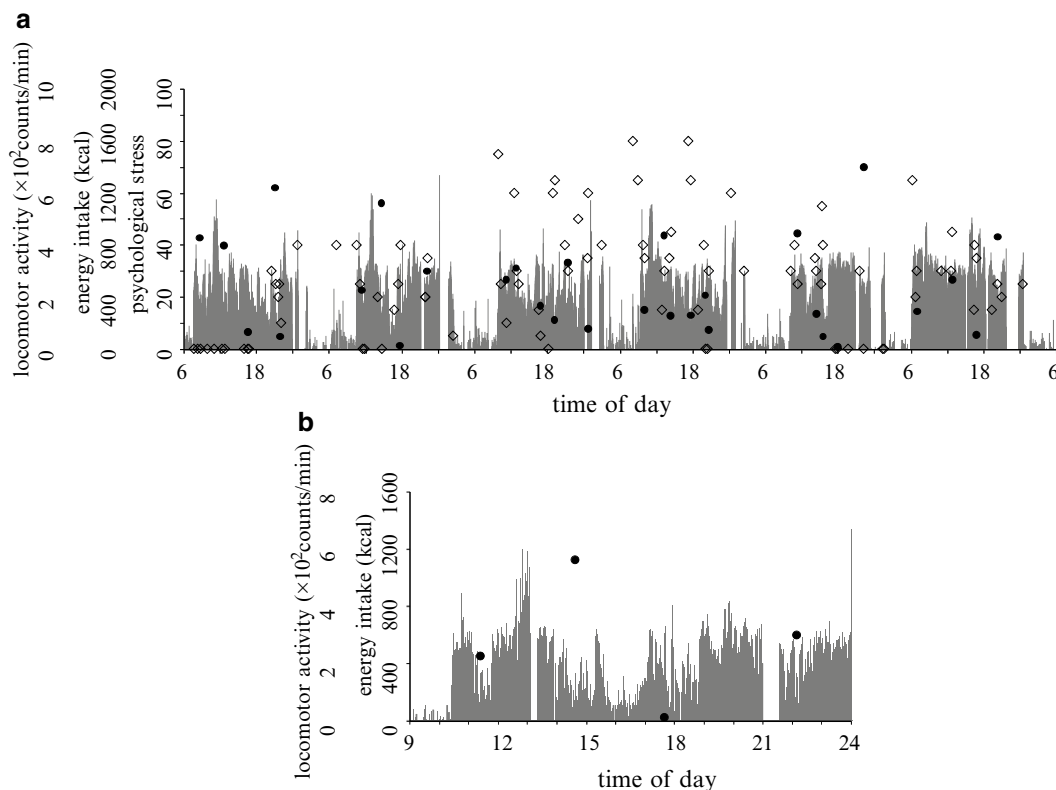
The "Mobile Nurse" system combined with the PDA-based food recording system described above could be a promising tool for a comprehensive understanding of human eating behavior. Preliminary results of a pilot study utilizing these systems in healthy adults are shown below.


Fig. 56.5 Data example of locomotor activity, momentary psychological stress, and energy intake from one healthy graduate student. (**a**) Bar chart shows locomotor activity. *Filled circles* show energy intake. *Open diamonds* show momentary psychological stress. (**b**) A part of (**a**) is magnified. It seems that increased locomotor activity was followed by increased energy intake and decreased locomotor activity was followed by decreased energy intake

Healthy undergraduate and graduate students wore watch-type computers for seven consecutive days. They recorded psychological stress, mood states, appetite, and circumstances (whom they were with and where they were) using the computers as electronic diaries just before and after meals and snacks, as well as at random prompts, when waking up and when going to bed. They also recorded food intake by the PDA-based food recording system just after meals and snacks. Locomotor activity was also recorded continuously by an actigraph installed inside the watch-type computer (Kikuchi et al. 2007).

A total of 20 subjects made 509 recordings of food intake and 1,628 recordings of other factors such as psychological stress and mood states. Representative data are shown in Fig. 56.5. Locomotor activity was continuously recorded and shows diurnal cycles (high in the daytime and low at night). When data were considered in more detail (Fig. 56.5b), it seemed that increased locomotor activity (12:00–14:30) was followed by increased energy intake (14:30) and decreased locomotor activity (19:00–22:00) was followed by decreased energy intake (22:00). The relationship between the psychological factor and energy intake can also be considered. Figure 56.6 is a scatter plot of energy intake and the momentary depression score of one student just before eating. In this student, the momentary depression score before eating is significantly and negatively correlated with energy intake, suggesting that energy intake was smaller in more depressive mood states.

In order to investigate the relationship between locomotor activity and food intake, the total amount of locomotor activity since the last eating was calculated for each meal and snack, and multilevel

Fig. 56.6 Data example of momentary depression score before eating and energy intake from one subject. In this student, the momentary depression score before eating was negatively correlated with energy intake ($r = -0.417$, $p = 0.030$). The linear regression line is shown in the plot
Table 56.4 Energy intake and accumulated locomotor activity. This table shows the results of the pilot study utilizing the newly developed PDA-based food recording system and actigraph (509 recordings made by 20 subjects). Multilevel modeling was used to test the effect of accumulated locomotor activity since last eating on energy intake with control for meal types. The effect of accumulated locomotor activity was significantly positive, suggesting that greater locomotor activity was followed by increased energy intake. Accumulated locomotor activity was dealt with in units of 10^3 counts per minute. Estimated parameters shown in this table are based of the following model:

Level 1:

$Energy_{ij} = \pi_{0i} + \pi_{1i} Activity_{ij} + \pi_{2i} Mealtype(B)_{ij} + \pi_{3i} Mealtype(L)_{ij} + \pi_{4i} Mealtype(D)_{ij} + \varepsilon_{ij}$

Level 2:

$\pi_{0i} = \gamma_{00} + \zeta_{0i}$
$\pi_{1i} = \gamma_{10}$
$\pi_{2i} = \gamma_{20}$
$\pi_{3i} = \gamma_{30}$
$\pi_{4i} = \gamma_{40}$

$Energy_{ij} = (\gamma_{00} + \zeta_{0i}) + \gamma_{10}Activity_{ij} + \gamma_{20}Mealtype(B)_{ij} + \gamma_{30}Mealtype(L)_{ij} + \gamma_{40}Mealtype(D)_{ij} + \varepsilon_{ij}$

	Coefficient (S.E.)	*F* value	*p* value
Intercept (kcal)	264.5 (70.6)		
Effect of accumulated locomotor activity	2.17 (0.86)	$F(1, 232) = 6.34$	$p = 0.013$
Effect of meal types		$F(3, 45) = 48.9$	$p < 0.0001$

$Energy_{ij}$ is energy intake of ith subject's jth eating and $activity_{ij}$ is corresponding accumulated locomotor activity. Meal types are controlled by incorporating them into the model using dummy variables: $Mealtype(B)_{ij}$, $Mealtype(L)_{ij}$, and $Mealtype(D)_{ij}$. Mealtype(B) takes one when the meal type is breakfast and otherwise equals zero. Mealtype(L) is for lunch, Mealtype(D) is for dinner, and a snack is the reference. Intercept (energy intake when the accumulated locomotor activity is zero and the meal type is a snack) is modeled as a random effect by including a residual ζ_{0i}, and estimated value of the average of individual true intercept (γ_{00}) is shown in the table. γ_{10} is the slope representing the effect of accumulated locomotor activity and γ_{20}, γ_{30}, and γ_{40} are the difference in energy intake between respective meal types and snacks. S.E.: standard estimation

modeling (Schwartz and Stone 1998) was used to test the effect of the accumulated amount of locomotor activity on energy intake. There was a significantly positive association between energy intake and the accumulated amount of locomotor activity since the last eating (Table 56.4). An example of data from one subject is plotted in Fig. 56.7 to show the relationship between accumulated locomotor activity and energy intake. The result is intuitive because it means that a greater amount of accumulated locomotor activity was followed by more food intake. What is remarkable with the results,
Fig. 56.7 Data example of accumulated amount of locomotor activity and energy intake from one subject. Abscissa is for accumulated amount of locomotor activity since the last eating and ordinate is for energy intake. Accumulated locomotor activity was positively associated with energy intake after controlling for meal types. *Filled circle* breakfast, *filled diamond* lunch, *open circle* dinner, *open diamond* snack

however, is that the fact is confirmed in usual daily settings, not in a laboratory, by using an objective measurement of locomotor activity as a biological factor and a newly developed, accurate, and onsite PDA-based food recording system. It is important in further research to evaluate how such relationships between biological and (eating) behavioral factors could be altered in pathological cases with abnormal food intakes.

Although an example using locomotor activity as the biological factor is introduced here, the same kind of investigation can also be applied to heart rate and heart rate variability with an appropriate sensor. If food intake and heart rate variability are analyzed together with other biological, psychological, and social factors captured in daily settings, a more comprehensive understanding of food intake from a biopsychosocial viewpoint will be achieved.

56.11 Applications to Other Areas of Health and Disease

HRV is used as a predictor for prognosis of cardiac diseases. Decreased SDNN from 24-h Holter ECG has been shown as a predictor for all-cause mortality after acute myocardial infarction (Kleiger et al. 1987; La Rover et al. 1998) and in chronic heart failure patients (Nolan et al. 1998; Bilchick et al. 2002; Cygankiewicz et al. 2009). Scaling exponent α1 from DFA has also been reported to be a predictor for all-cause and cardiac mortality in patients with acute myocardial infarction (Huikuri et al. 2000) and chronic heart failure (Mäkikallio et al. 2001a). More powerful predictors have recently been proposed (Schmidt et al. 1999; Bauer et al. 2006; Kiyono et al. 2008) for risk stratification of cardiac patients, and the analyses of HRV constitute modern data analyzers for Holter ECG.

EMA has been applied to conditions other than BN and BED which were introduced here (Yoshiuchi et al. 2008). With the advantage of greater reliability when assessing subjective symptoms than conventional methods, EMA has hitherto often been used to investigate pain-related diseases such as arthritis and headache, and fatigue in conditions such as cancer and chronic fatigue syndrome so far.

In this chapter, locomotor activity has been analyzed in relation to energy intake. Recently, it has been suggested that an analysis of locomotor activity to know how active and resting periods are

interwoven throughout daily lives can reveal an alteration in behavior in major depressive disorder (Nakamura et al. 2007) and the putative animal model (Nakamura et al. 2008). With the development of appropriate analysis methods, locomotor activity could thus be a psychological as well as a physiological indicator.

Summary Points

- Heart rate variability is used for the noninvasive investigation of cardiovascular autonomic function.
- In obese subjects, HF power of HRV, which reflects parasympathetic nervous activity, is reported to be decreased. Some longitudinal studies have also reported that decreased HF power in obese subjects is ameliorated by body weight reduction.
- In anorexia nervosa patients, though reports on HRV are rather inconsistent, some studies suggest that cardiac parasympathetic nervous activity indexed by HF power is increased, which is a change in the opposite direction to that in obese subjects.
- Because HRV as well as food intake can be affected not only by biological factors but also by psychosocial factors such as emotional and/or mood states and behavior, a biopsychosocial perspective is needed to achieve a comprehensive understanding of HRV and food intake.
- The recently developed PDA-based food recording system combined with electronic diaries and sensors collecting physiological information is a promising tool for a biopsychosocial understanding of food intake.

Definition or Explanations of Key Terms

Heart rate variability (HRV): The variation in the interval between consecutive heartbeats. HRV is regarded as an indicator of cardiac autonomic nervous activity and is also known to have a predictive value of mortality in certain cardiac diseases. HRV is analyzed by various methods such as time domain analysis, frequency domain analysis, and nonlinear and fractal analysis.

SDNN: Standard deviation of normal-to-normal (NN) intervals (intervals between adjacent QRS complexes of sinus rhythm). Either 5-min recordings or 24-h recordings are recommended.

SDANN: Standard deviation of the average NN intervals calculated over 5 min. This estimates the variation due to cycles longer than 5 min.

SDNN index: Mean of the 5-min standard deviations of NN intervals calculated over 24 h. This estimates the variation due to cycles shorter than 5 min.

pNN50: Percentage of differences of successive NN intervals which are longer than 50 ms.

RMSSD: Square root of the mean squared differences of successive NN intervals.

ULF: Power in the ultra low frequency range (≤ 0.003 Hz).

VLF: Power in the very low frequency range (0.003–0.04 Hz).

LF: Power in the low frequency range (0.04–0.15 Hz).

HF: Power in the high frequency range (0.15–0.40 Hz).

LF/HF: Ratio of LF power to HF power.

Ecological momentary assessment (EMA): An assessment method mainly used for recording subjective experiences such as symptoms and behavior. In EMA, subjects record phenomena at the moment when it occurs and at the place where it occurs, usually by using portable computers or personal digital assistants as electronic diaries. This can maximize ecological validity by avoiding recall bias.

Chapter 57
Branched-Chain Amino Acids and Central Fatigue: Implications for Diet and Behavior

Eva Blomstrand

Abbreviations

BCAA	Branched-chain amino acids
CR10	The Borg CR10 scale®
DA	Dopamine
FFA	Free fatty acids
LNAA	Large neutral amino acids
NE	Norepinephrine
5-HT	5-Hydroxytryptamine
5-HIAA	5-Hydroxyindole acetic acid
VO_{2max}	Maximal pulmonary oxygen uptake

57.1 Introduction

The branched-chain amino acids (BCAA: leucine, isoleucine, and valine), which are essential components of our diet, share a similar chemical structure (Table 57.1; Fig. 57.1 depicts the structure of leucine). In contrast to most other amino acids, which are metabolized primarily in the liver, the BCAA are metabolized mainly in skeletal muscle. However, their less extensive metabolism in other tissues has several important functions, e.g., in the case of the brain, supplying energy, providing nitrogen for synthesis of the neurotransmitter glutamate, and modulating the synthesis of the mono-amines dopamine (DA), norepinephrine (NE), and 5-hydroxytryptamine (5-HT). It is this latter process, and in particular, the role of BCAA in regulating the synthesis of 5-HT, which will be discussed here.

The rate-limiting step in the synthesis of the monoamines is the transport of their precursors tyrosine (DA and NE) or tryptophan (5-HT), across the blood–brain barrier (Newsholme and Leech 1983; Young 1986). The transport protein involved is common for the large neutral amino acids (LNAA; tyrosine, phenylalanine, tryptophan, and BCAA) and since this transporter is almost saturated at normal plasma levels of LNAA, competition for entry occurs (Fernstrom 2005;

e-mail: eva.blomstrand@gih.se

Table 57.1 Key features of branched-chain amino acids

1. Leucine, isoleucine, and valine are known as the branched-chain amino acids (BCAA) because of their similar structure; Fig. 57.1 depicts the structure of leucine
2. The BCAA are essential amino acids, i.e., they must be provided in the diet
3. Dietary proteins such as meat, poultry, fish, egg, milk, and cheese contain 15–20 g BCAA/100 g protein
4. The BCAA are primarily metabolized in skeletal muscle, i.e., they escape the liver and ingestion of BCAA therefore leads to a rapid rise in their concentration in peripheral blood
5. BCAA, in particular leucine, stimulate protein synthesis

Notes: This table lists the key facts of the branched-chain amino acids including dietary sources, metabolism, and regulatory functions

$$CH_3 \diagdown \atop CH_3 \diagup CH - CH_2 - \overset{\overset{\displaystyle NH_2}{|}}{CH} - COOH$$
Leucine

Fig. 57.1 Chemical structure of leucine. The branched-chain structure is common for leucine, isoleucine, and valine; only minor differences exist in their chemical structure

Pardridge 1998). Accordingly, elevating or lowering plasma concentrations of BCAA can reduce or enhance, respectively, the transport of tyrosine and tryptophan into the brain and thereby the synthesis of DA and NE and of 5-HT, respectively (Fernstrom 2005; Choi et al. 2009). Dietary intake of protein and carbohydrates, as well as ingestion of BCAA, results in pronounced alterations in plasma ratios of tyrosine and tryptophan in relation to the other LNAA, alterations associated with changes in central fatigue and cognitive function (Blomstrand et al. 1997; Gijsman et al. 2002; Portier et al. 2008).

57.2 Central Fatigue During Physical Exercise

57.2.1 Causes of Fatigue

Fatigue during physical exercise can be described as the inability to maintain a certain force or rate of work, depending on the nature of the exercise. Such fatigue may be related to central and peripheral factors, both of which are influenced by the intensity and duration of the exercise, environmental conditions, nutritional intake, and the physical condition of the individual involved. Peripheral fatigue reflects, by definition, changes in the exercising muscles, whereas central fatigue is an outcome of dysfunction or limitations within the central nervous system.

Extensive investigation of peripheral fatigue has revealed several causative metabolic changes, e.g., depletion of substrates for the production of energy or accumulation of products which impair muscle contraction (see Sahlin 2006). Central fatigue is more difficult to quantitate, particularly in connection with dynamic exercise such as cycling or running. Consequently, less is presently known about what causes this latter form of fatigue, although several mechanisms have been proposed, including (1) elevation of the plasma level of ammonia, due primarily to its enhanced rate of production by the exercising muscle; (2) a reduction in the blood level of glucose due to the depletion of hepatic glycogen stores; (3) elevated circulating levels of cytokines released from muscle; and (4) increased release of neurotransmitters, especially 5-hydroxytryptamine (5-HT) in the brain.

57.2.2 Synthesis of 5-HT and Its Role in Fatigue

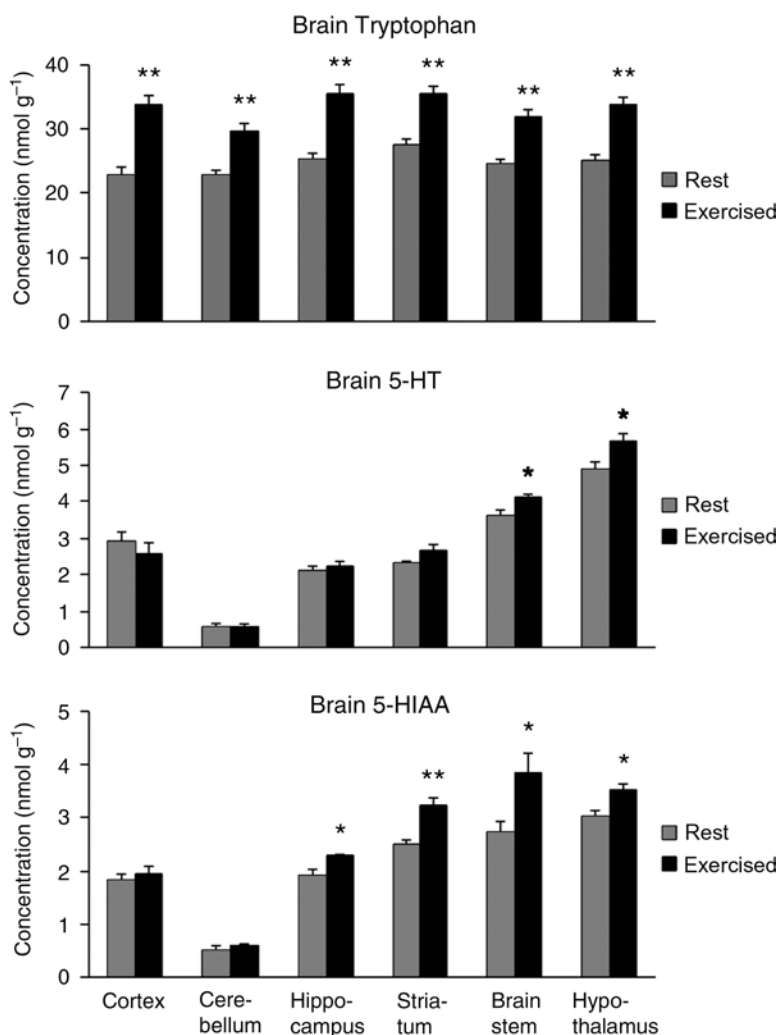
In 1963, Barchas and Freedman (1963) reported for the first time that the level of 5-HT in the brain was elevated after rats had swum until becoming exhausted. Later, Romanowski and Grabiec (1974) proposed that this increase could be related to central fatigue, although the underlying mechanism was not known. Subsequently, a number of confirmatory investigations have also demonstrated that sustained exercise results in an increase in the release and turnover of 5-HT in certain parts of the brain of experimental animals (see Chaouloff 1997; Meeusen et al. 2006). Figure 57.2 illustrates the various responses to sustained exercise in different brain regions. Tryptophan is similarly elevated in all areas measured, whereas 5-HT levels are increased only in brain stem and hypothalamus (Blomstrand et al. 1989).


Fig. 57.2 The effects of sustained running on concentrations of tryptophan, 5-hydroxytryptamine (5-HT), and 5-hydroxyindole acetic acid (5-HIAA) in different regions of the rat brain. Tryptophan is similarly elevated in all areas measured after sustained running, but the effect on 5-HT and 5-HIAA levels vary between different regions. The values are presented as means $\pm$ SE for 8–10 animals. $^{*}P < 0.05$ and $^{**}P < 0.01$ for rest in comparison to postexercise (Reprinted from Blomstrand et al. 1989. With permission)

The potential involvement of 5-HT in central fatigue was first examined in more detail employing pharmacological manipulation of rodents. For instance, administration of an agonist of 5-HT to rats impairs running performance in a dose-related manner (Bailey et al. 1992, 1993) and administration of a 5-HT antagonist improves running performance (Bailey et al. 1993). In another approach to evaluating the role of 5-HT in connection with fatigue, Caperuto et al. (2009) subjected rats to a 5-week exhaustive exercise training program and found that the hypothalamic level of 5-HT remained elevated 24 h after the last exercise session. At this same time-point the endurance performance of these animals was 35% lower than that of rats trained moderately and with no elevation in their hypothalamic concentration of 5-HT.

While the results on rodents clearly indicate a role of 5-HT in fatigue, studies on human subjects are less conclusive. Studies employing drugs selectively inhibiting the 5-HT reuptake have provided various results in connection with endurance exercise; some support (Wilson and Maughan 1992; Struder at al. 1998), while others argue against the involvement of 5-HT in fatigue (Meeusen et al. 2001; Strachan et al. 2004). Furthermore, oral administration of a $5-HT_{1A}$ agonist was found to reduce time to fatigue (Marvin et al. 1997), whereas 5-HT antagonists did not influence performance (Pannier et al. 1995; Meeusen et al. 1997). The complexity of the 5-HT system as well as the use of different drugs, in some cases acting on both 5-HT and DA receptors complicates interpretation of these findings especially since exercise itself influences the metabolism of DA, which may also be involved in the development of fatigue, either directly or through inhibition of 5-HT synthesis in certain regions of the brain. The effect of pharmacological alteration of neurotransmission during exercise has been comprehensively reviewed by Meeusen et al. (2006).

When an elevated level of 5-HT was first proposed to cause central fatigue, the underlying mechanism was unknown. In the mid-1980s the following hypothesis was put forward (Newsholme et al. 1987): The first reaction in the synthesis of 5-HT is catalyzed by the enzyme tryptophan hydroxylase. Because this enzyme is not saturated with its substrate under physiological conditions, the rate of 5-HT synthesis is sensitive to alterations in brain levels of tryptophan, which are regulated not only by the plasma concentration of tryptophan, but also by the plasma levels of the other large neutral amino acids (LNAA), including the BCAA, which compete for the same carrier system (see above). "Therefore, increases in the plasma concentration ratio of tryptophan/BCAA could lead to an increase in the rate of entry of tryptophan into the brain and hence in the concentration of 5-HT. Such changes can occur in sustained exercise" (Newsholme et al. 1987), see Fig. 57.3.

57.2.3 Changes in the Ratio of Tryptophan/BCAA Concentrations in Plasma

The contribution of protein to energy metabolism in the form of amino acids during physical exercise has been estimated to be only 3–6%, much less than the contributions made by carbohydrates and fats, which are the major fuels for skeletal muscle. Regardless of this relatively minor contribution to energy production, the metabolism and plasma levels of amino acids are affected in pronounced ways that depend primarily on the intensity and duration of the physical exercise. During prolonged exercise of low- to moderate intensity, BCAA are taken up by muscle, which is consistent with an increased rate of oxidation, which eventually reduces their plasma concentrations (Ahlborg et al. 1974; Blomstrand et al. 2005). The aromatic amino acids are primarily taken up by the liver and their plasma concentrations, including tryptophan, either increase or remain unchanged during prolonged exercise of moderate intensity (Ahlborg et al. 1974; Blomstrand et al. 2005).

Of importance in this connection is the fact that tryptophan is the only amino acid that binds to albumin in the plasma, to an extent of as much as 90% and thus only 10% of the total plasma tryptophan is in the free form (Curzon et al. 1973). Since, free fatty acids (FFA) and tryptophan compete for
Fig. 57.3 Metabolic changes which may cause central fatigue. During prolonged exercise, BCAA are taken up by the muscle and the plasma concentration decreases. Exercise also elevates the plasma level of FFA due to their enhanced release from adipose tissue as a consequence of sympathetic nervous activity, which should displace tryptophan (Trp) from albumin and thereby increase the concentration of free tryptophan. An increase in the plasma ratio of free tryptophan/BCAA favors the transport of tryptophan into the brain and increases the synthesis and release of 5-HT from some neurons, which could lead to central fatigue

the same binding sites on albumin (Curzon et al. 1973), the elevated plasma levels of FFA associated with exercise (due to their enhanced release from adipose tissue, as a consequence of sympathetic nervous activity) should displace tryptophan from albumin and thereby elevate the concentration of unbound tryptophan (Curzon et al. 1973). As expected, there is a positive correlation between the plasma levels of free tryptophan and FFA in human subjects (Blomstrand et al. 1997). Several investigations have documented an increase in plasma levels of free tryptophan and, consequently, a marked elevation in the plasma ratio of free tryptophan/BCAA both during and, especially, after prolonged exercise, as well as during intermittent types of exercise such as soccer and tennis (Blomstrand et al. 1991a; Davis et al. 1992; Lehmann et al. 1995; Strüder and Weicker 2001). Only minor changes in the plasma ratio of total tryptophan/BCAA were observed during exercise, which leads into the discussion around whether it is the level of free or total tryptophan that governs uptake by the brain.

57.2.4 Regulation of Tryptophan Uptake by the Brain

57.2.4.1 Studies on Rodents

A number of studies have been conducted on experimental animals regarding the regulation of tryptophan transport into the brain and varying results have been reported in different situations. Certain studies on food deprived or immobilized animals have indicated that it is the free level that regulates this uptake, whereas dietary investigations on experimental animals have provided evidence that this is not the case (see Fernstrom and Fernstrom 2006). This conclusion receives additional support from the recent demonstration that dietary intake of carbohydrates and/or proteins with varying amino acid

contents results in an approximately eightfold variation in the cortical content of tryptophan that is clearly related to the ratio of total tryptophan/other LNAA in plasma (Choi et al. 2009).

In contrast, in exercising animals a pronounced elevation of the plasma concentration of free tryptophan is associated with a nearly proportional rise in the brain level of tryptophan, with no such relationship to the total concentration of tryptophan (Chaouloff et al. 1985, 1986). In an attempt to distinguish the effect of exercise from that of the elevated levels of free tryptophan, Chaouloff et al. (1985) injected nicotinic acid into rats prior to their running on a treadmill for 1 h, which totally blocked the release of fatty acids from adipose tissue, but, surprisingly, the concentration of free tryptophan increased as did the brain level of tryptophan. A comprehensive review and discussion of the importance of free *versus* total tryptophan in plasma for the uptake into the brain in relation to the complex activation of the 5-HT system in brain neurons has been provided by Fernstrom and Fernstrom (2006).

57.2.4.2 Studies on Human Subjects

Measurements of tryptophan and 5-HT levels are not possible to perform on the human brain; nonetheless, brain exchange of tryptophan may give some indication of changes in brain 5-HT synthesis following exercise or nutritional supply. During a 3-h session of ergometer cycling at 60% of maximal oxygen uptake (VO_{2max}), the arterial concentration of free tryptophan rises continuously, whereas the total concentration remains unchanged. Since brain blood flow was not altered during exercise, the arterial-jugular venous concentration difference may be employed as an indicator of the net uptake of amino acids into the brain. At the same time as the arterial concentration of free tryptophan rises, net uptake of tryptophan by the brain (measured as the difference in concentrations in the artery and the jugular vein) occurs (Table 57.2). In addition, ingestion of carbohydrates during this exercise attenuated the elevation of plasma levels of free tryptophan and prevented the uptake of this amino acid into the brain (Blomstrand et al. 2005). Altogether, the results indicate that the free tryptophan level plays a major role for the uptake of tryptophan by the brain during prolonged exercise.

In the same experiment, there was an uptake of BCAA by the brain during exercise despite a reduction in their plasma concentrations as well as the plasma ratio of BCAA/other LNAA (Blomstrand et al. 2005). This observation was unexpected, but may suggest that the activity of the transport system is enhanced during physical exercise. There is some evidence from studies on rodents that stimulation of β-adrenergic receptors located at the blood–brain barrier increases the amino acids transport into brain (Eriksson and Carlsson 1988; Takao et al. 1992). The exercise-induced increase in plasma

Table 57.2 Arterial concentration (μmol L^{-1}) and the arterial-jugular venous (a-jv) concentration difference (μmol L^{-1}) of aromatic and branched-chain amino acids (BCAA) at rest and after 180 min ergometer cycling at 60% of VO_{2max}

Amino acid	Rest		Exercise 180 min	
	Arterial concentration	(a-jv) difference	Arterial concentration	(a-jv) difference
Tyrosine	55 ± 3	–1.4 ± 1.0	78 ± 4[*]	0.8 ± 0.5
Phenylalanine	65 ± 2	–0.7 ± 0.9	81 ± 1[*]	1.8 ± 0.6[**]
Tryptophan				
Free	12 ± 1	–0.4 ± 0.2	20 ± 2[*]	–0.4 ± 0.3
Total	61 ± 2	–0.3 ± 1.1	55 ± 5	1.7 ± 0.5[**]
ΣBCAA	505 ± 12	8 ± 9	470 ± 25[*]	18 ± 2[**]

Notes: The arterial concentration of free tryptophan rises during sustained exercise, whereas the total concentration remains unchanged. At the same time, net uptake of tryptophan by the brain (measured as the difference in concentration in the artery and the jugular vein) occurs. The values presented are the means ± SE for five subjects. ΣBCAA is the sum of valine, leucine, and isoleucine. [*]$P < 0.05$ vs. rest and [**]$P < 0.05$ different from zero (Reprinted from Blomstrand et al. 2005. With permission)

levels of E and NE, which stimulate the β-adrenergic receptors, may therefore facilitate transport of LNAA over the blood–brain barrier. The significance of the enhanced uptake of BCAA during exercise remains unclear, although leucine may act as a regulator of the excitatory neurotransmitter glutamate (Hutson et al. 2001), thereby playing another role in neurotransmission in addition to affecting the synthesis and release of 5-HT.

Whether ingestion of BCAA during exercise, which raises their plasma concentrations, would influence the uptake of tryptophan by the brain has not yet been examined, but two observations suggest that this may be the case. First, intravenous infusion of ~5 g BCAA during 150 min (arterial concentration rose from 353 to 770 μmol L^{-1}) under resting conditions does enhance uptake of these amino acids by the human brain and, in addition, the brain uptake of the aromatic amino acid tyrosine was diminished (tryptophan was not analyzed) (Sato et al. 1981). Secondly, administration of valine to rats prevents the exercise-induced increase in tryptophan uptake as well as the release of 5-HT (Chaouloff et al. 1985; Gomez-Merino et al. 2001; Smriga et al. 2006).

57.2.5 Supplementation of BCAA During Exercise

57.2.5.1 Studies on Human Subjects

In line with the considerations discussed above, raising the plasma level of BCAA and thereby counterbalancing the increase in free tryptophan that occurs both during and after sustained or intermittent exercise should reduce transport of tryptophan into the brain, decrease the rate of 5-HT synthesis, and delay mental fatigue. Ingestion of BCAA has exerted positive effects on both mental performance and perceived exertion in both field studies and controlled laboratory experiments, as illustrated by the following experiments. When subjects were supplied with 6–9 g of a mixture of BCAA (plasma level increased from 450 to 1,150 μmol L^{-1}) during ergometer cycling

Fig. 57.4 The category-ratio scale CR10. The Borg CR10 scale can be used for measuring most kinds of perceptions and experiences, including pain and perceived exertion as well as changes in mood and emotions (Reprinted from Borg 2004, 2008. With permission)

Fig. 57.5 Ratings of mental fatigue (CR10) during exercise. The subjects were supplied a mixture of the three BCAA in aqueous solution or a placebo consisting of flavored water during 60 min ergometer cycling at 70% of VO_{2max} followed by 20 min of maximal exercise. When subjects ingested BCAA their ratings of mental fatigue was lower than during ingestion of placebo. The values presented are means ± SE for 7 subjects. *$P < 0.05$ between the trials during the 0–60-min period of exercise when the rate of work was the same (Reprinted from Blomstrand et al. 1997. With permission)
at 70% of VO_{2max}, their ratings of perceived exertion and mental fatigue Figure 57.4 were reduced (Fig. 57.5) and their cognitive performance after the exercise improved (Blomstrand et al. 1997). Similarly, during an off-shore race lasting 32 h, ratings of fatigue were lowered and a decline in short-term memory prevented by ingestion of a high-protein supplement and large amounts of BCAA (Portier et al. 2008).

In addition, physical performance improved in a warm environment (evaluated as time to exhaustion at 40% of VO_{2max}) from 137 to 153 min when BCAA (9–16 g) were ingested (Mittelman et al. 1998). However, the performance was not significantly affected in temperate conditions (Blomstrand et al. 1997), raising the possibility that central fatigue is more pronounced during exercise in the heat than at cooler temperatures. Support for this proposal has been presented by Pitsiladis et al. (2002), who observed higher serum levels of prolactin (an indicator of central 5-HT activation) during exercise at 30°C than at 10°C. In contrast, administration of paroxetine, an inhibitor of 5-HT reuptake, to human subjects during exercise in the heat had no influence on either performance or the endocrine response (Strachan et al. 2004). Two additional studies were thereafter conducted in the heat and both failed to detect an effect of BCAA supplementation on physical performance (Cheuvront et al. 2004; Watson et al. 2004). However, in the former study, subjects were supplied with BCAA together with *carbohydrates*, a supplementation protocol which has been employed in several other studies and which likely reduces the development of fatigue (see below).

Ingestion of carbohydrates is known to improve physical performance during sustained exercise; therefore many studies have investigated the effect of drinks containing both BCAA and carbohydrates as described in the following experiments. An improvement in the subjects´ mental agility (evaluated as performance on various psychological tests) was observed following sustained competitive exercise (i.e., a soccer match or a 30-km cross-country race) (Blomstrand et al. 1991a; Hassmén et al. 1994), but not after exercise in the heat under controlled laboratory conditions in comparison to intake of carbohydrates alone (Cheuvront et al. 2004). Similarly, during exercise under controlled laboratory conditions no additional benefit to physical performance was provided

by addition of BCAA to a solution of carbohydrates (Blomstrand et al. 1995; Van Hall et al. 1995; Davis et al. 1999; Cheuvront et al. 2004). However, the fact that inclusion of carbohydrates attenuates the increase in plasma level of free tryptophan (Davis et al. 1992), as well as in the uptake of tryptophan by the brain (Blomstrand et al. 2005), may explain the absence of any effect by BCAA in these experiments. In contrast, ingestion of 16 g BCAA together with carbohydrates during a marathon race improved running performance in a subgroup of "slower" runners (Blomstrand et al. 1991b). This experimental protocol has both advantages and disadvantages: the advantage is the competitive situation as such and that a large number of subjects can be studied; however, the weakness is the difficulty in controlling the experimental conditions.

The divergent reports regarding the influence of supplementation with BCAA on physical performance may relate not only to differences in the type, intensity, and duration of the exercise employed, but also to the *fitness level* of the subjects. Regularly training, which is associated with enhanced synthesis of 5-HT, may lead to adaptive changes in neurotransmission involving 5-HT that may delay fatigue. Such changes are likely to attenuate the possible beneficial effects of BCAA with respect to central fatigue. Some evidence suggests that well-trained athletes exhibit a reduced neurosensitivity to 5-HT (i.e., downregulation of the sensitivity of the 5-HT receptor as measured by a smaller increase in serum levels of prolactin following a challenge with buspiron, a 5-HT_{1A} agonist or a 5-HT_{2c} agonist) in comparison to sedentary individuals (Jakeman et al. 1994; Broocks et al. 1999). Although nine weeks of endurance training was insufficient to produce any change in neuroendocrine response to buspirone (Dwyer and Flynn 2002), this training period may have been too short to cause alterations which may result from years of training. In contrast, Strachan and Maughan (1999) could not detect any difference in prolactin release by trained and untrained individuals treated with d-fenfluramine, an inhibitor of the release and reuptake of 5-HT; however, the dose of d-fenfluramine may have been insufficient to induce a response (Strachan and Maughan 1999).

57.2.5.2 Studies on Rodents

Supplementation of BCAA to experimental animals seems to give a clear response with regard to physical performance. Intraperitoneal injection of BCAA to rodents before running on a treadmill improved their exercise capacity (run time to exhaustion was 30–35% longer than after saline infusion; the BCAA level rose from 522 to 1,497 µmol L^{-1} and from 426 to 751 µmol L^{-1}, respectively) in two studies (Calders et al. 1997, 1999). Moreover, voluntary intake of BCAA positively correlated with the volume of exercise in freely moving rats (Smriga et al. 2006). Only in one study, when rats were fed BCAA or water before prolonged treadmill running no difference in time to fatigue was detected (Verger et al. 1994). Similar to the situation in human subjects, supplementation of carbohydrates (glucose) to rats improved running performance but addition of BCAA gave no further improvement in exercise capacity (Calders et al. 1999).

Also in experimental animals, exercise training affects the central 5-HT sensitivity; a significant reduction in the sensitivity of the 5-HT_{1A} receptor occurs as rapidly as after 5 or 6 weeks of exercise training (Dwyer and Browning 2000). Furthermore, another exercise-induced adaptation which may influence the central 5-HT activity involves the rate of 5-HT synthesis in neurons. The protein level of the rate-limiting enzyme in this process, tryptophan hydroxylase, was reported to be reduced in rats following 6 weeks of endurance training and, furthermore, decreased levels of tryptophan and 5-HT were observed in certain regions of the brains of trained animals following nonexhaustive exercise in comparison to sedentary controls (Langfort et al. 2006).

57.2.6 Possible Adverse Effects of BCAA

In light of the effects which acute intake of BCAA might have on neurotransmission, it is necessary to discuss possible adverse effects of such intake as well. Ingestion of 5–10 g BCAA in connection with (before, during, and after) physical exercise elevates the plasma levels of these amino acids for 3–4 h, a relatively short period of time. The accompanying temporary reduction in the uptake of other LNAA into the brain is thus unlikely to have negative effects on sleep or cause changes in mood. Furthermore, it is unlikely that the rate of protein synthesis in the brain is reduced as a result of decreased uptake of other LNAA. Long-term use of BCAA, i.e., ingestion of 30–50 g/day (in addition to the dietary consumption) for 2 years is tolerated well, with no adverse effects being reported (Fernstrom 2005).

On the other hand, ingestion of large amounts of BCAA in connection with exercise may be detrimental to performance by enhancing the production of ammonia, which can be toxic to the brain. When 20–30 g is ingested as a bolus prior to or during exercise, a rise in plasma levels of ammonia has been observed in certain studies, but not others (see Blomstrand 2006); whereas smaller amounts (7–10 g or 100 mg/kg body weight) taken repeatedly during exercise and recovery do not result in any increase in the release of ammonia from muscles (Blomstrand and Saltin 2001). With such relatively small amounts of BCAA, which are sufficient to counterbalance the elevated concentration of free tryptophan during and after exercise (Blomstrand et al. 1997), there is no indication that this fatigue will occur earlier due to elevated levels of ammonia in the blood.

57.3 Applications to Other Areas of Health and Disease

BCAA have been employed to treat or improve the condition of several groups of patients, including those with hepatic encephalopathy, amyotrophic lateral sclerosis (ALS), phenylkenonuria (PKU), bipolar illness (periods of mania), schizophrenia (tardive dyskinesi), spinocerebellar degeneration, and cancer (see Fernstrom 2005). The specific effects of BCAA on central fatigue and cognitive performance may be beneficial in connection with some conditions.

Postoperative fatigue experienced by patients following major surgery can persist for many days. Pronounced increases in serum levels of free tryptophan have been observed in such patients, and, moreover, their rating of fatigue is correlated to both the concentration of free tryptophan and the ratio of free tryptophan/BCAA in plasma (McGuire et al. 2003). According to the hypothesis concerning central fatigue presented above, the rate of 5-HT synthesis should be elevated in these patients, which may contribute to their feeling of fatigue. The authors suggest that provision of BCAA may help to overcome fatigue under these conditions by elevating plasma levels of BCAA, thereby counterbalancing the rise in free tryptophan and consequently slowing down the synthesis of 5-HT.

Other groups of patients who may benefit from ingestion of BCAA are those with psychiatric disorders, including mania and schizophrenia, which are associated with overactivity of dopaminergic pathways. Some evidence indicates that ingestion of BCAA can reduce dopamine function in healthy individuals, as well as the clinical ratings of mania in patients (Gijsman et al. 2002; Scarna et al. 2003).

Summary Points

- Physical exercise results in elevated synthesis and release of 5-HT in the brain of experimental animals.
- In human subjects, endurance exercise is associated with changes in the ratio of free tryptophan/other LNAA in the plasma which promote transport of tryptophan into the brain and possibly also the synthesis of 5-HT.
- There is a net uptake of both tryptophan and BCAA by the brain during sustained endurance exercise, suggesting that the activity of the transport system is enhanced.
- Ingestion of BCAA, which raises their concentrations in plasma, counterbalances the increase in free tryptophan during sustained exercise, reduces fatigue, and improves cognitive performance.
- Under certain conditions, BCAA can also improve physical performance, but this is dependent on the type of exercise, the amount and composition of the supplement administered and the fitness level of the subjects.
- The mechanisms underlying the influence of BCAA on central fatigue may not only involve a reduction in tryptophan uptake, but also a direct effect on metabolism and/or neurotransmission in the brain.

Definitions of Key Terms

Blood–brain barrier: The capillary network surrounding brain cells which is impermeable to, e.g., amino acids, so that specific transporters are required for uptake.
Branched-chain amino acids: Essential amino acids metabolized primarily in skeletal muscle.
Central fatigue: Fatigue caused by failure or limitations within the central nervous system.
Cognitive performance: Performance in standardized psychological tests.
Endurance exercise: For example, running or cycling.
Fatigue: The inability to maintain a given power output or rate of work.
Large neutral amino acids: Tyrosine, phenylalanine, tryptophan, and branched-chain amino acids.
Low-intensity exercise: 30–50% of VO_{2max}.
Moderate-intensity exercise: 60–75% of VO_{2max}.
Physical performance: Often measured as time to exhaustion at a given rate of work or time to complete a given distance (time trial).
5-hydroxytryptamine: A neurotransmitter involved in the regulation of mood, sleep, and arousal.

58.1 Introduction

The occurrence of menses (menstruation) during the female cycle indicates the functionality of the menstrual cycle, which starts at menarche (onset of first menses at puberty) and dissipates at menopause (time period of cessation of last menses). Although numerous factors can affect the functioning of this cycle, the timing of menarche appears to be genetically determined (van den Akker et al. 1987) and related to height and nutritional (or energy) factors (Nichols et al. 2006). Menopause occurs when women run out of oocytes, which may be related to smoking and parity, although genetic factors, social, hormonal, and environmental exposures/interactions could also be relevant (Nichols et al. 2006). Body mass index does not appear to be associated with menopause (Kalichman et al. 2007). The menstrual cycle is also complex because it incorporates hormonal, neuroendocrine, physical, and psychological changes which recur regularly (cyclically) throughout a woman's reproductive life span. Some changes experienced during the menstrual and premenstrual phases of the cycle can cause problems. For example, it has been suggested that menstrual cycle irregularities or cycle length (linked to metabolic and hormonal abnormalities, insulin resistance, and imbalances in hyperestrogens and hyperandrogens) could potentially increase the incidence/occurrence of cardiovascular disease (Rubba et al. 2008). In infertile women with polycystic ovarian syndrome, the clinical

Table 58.1 Key facts of the menstrual cycle

The menstrual cycle provides an environment fit for reproductive functioning
The cyclic rhythm depends on the synchronized functioning of a number of coordinated systems — particularly the endocrine system
The premenstrual dysphoric syndromes are characteristic of menstrual cycle dysfunctions
Premenstrual dysphoria includes physiological, psychological, and behavioral symptoms
Specific food cravings during premenstrual dysphoric states have led to the hypothesis that nutritional factors may explain some of the etiology of premenstrual distress
To date, no effective treatment for premenstrual dysphoria exists

Note: This table lists the key facts of the human female menstrual cycle, endocrine control, premenstrual dysphoria, problems of defining and treating premenstrual dysphoria

characteristics are irregular menses and high insulin levels (Hyperinsulinemia) (Myer et al. 2005). Similarly, links between nutrition (such as carbohydrate cravings) and enhanced mood (through a tryptophan-mediated increase in brain serotonin) have been reported (Corsica and Spring 2008). Physiological and psychological (including mood or dysphoric) disturbances of the menstrual cycle have been studied by researchers from many disciplines and orientations, but interrelationships between the various processes identified have not been unambiguously demonstrated. However, there is no doubt that internal (e.g., hormonal) and external (e.g., nutritional) factors influence the experience of the menstrual cycle. The focus of this chapter is on nutrition and its possible link to mood disturbances during the premenstrual phase of the menstrual cycle. The summary points are detailed in Table 58.1.

58.2 Hormonal Control of the Menstrual Cycle

The cerebral control of the menstrual cycle, through the involvement of the hypothalamus, which is seated deep within the brain, is to produce hormones that control numerous essential functions such as hunger, thirst, sleep, sex drive, body temperature, and mood (see Table 58.2). Many of these are also closely linked to nutritional and behavioral factors. In fact, all cells in the body (including the brain) have hormone receptors, and any deficiencies in the tight control of hormonal functioning can cause a whole series of other problems, one having a knock-on effect on yet another (e.g., diabetes and stunted growth in children). Specifically, cyclic changes in appetite, overeating, or food cravings have been identified as one of several criteria for premenstrual dysphoric mood disorders (Braverman 2007). Similarly, deficiencies in nutritional input (when people have lost too much body weight) as in anorexia nervosa or famine can lead to amenorrhea (the cessation of menses), whereas too much food intake over long periods of time, as in obesity, can lead to infertility.

The hypothalamus also influences the release of hormones from glands such as the pituitary gland through neural and hormonal loops. The pituitary is located relatively near the hypothalamus and this gland produces hormones that control the activity of endocrine glands and is therefore also called the "master gland" (Coll et al. 2007). For example, the pituitary gland secretes growth hormone, thyroid-stimulating hormone, antidiuretic hormones, and prolactin, which stimulates breast development and later milk production in women.

The menstrual cycle is controlled by the endocrine system as shown in Fig. 58.1, which shows how the hypothalamus controls much of the positive and negative feedback mechanisms, initiating the release and inhibition of hormones and other endocrine substances. The onset of puberty is triggered by an increase in initial gonadotropin-releasing hormone (GnRH) from the hypothalamus.

Table 58.2   Hormonal control of functions

The menstrual cycle	Hunger	Kidney function
Ovulation	Digestion	Blood pressure
Pregnancy	Energy	Blood cell production
Fertility	Sugar and fat metabolism	Immune system functioning/ wound healing
Sleep	Salt and water balance	Libido
Growth	Hair/bones	Moods

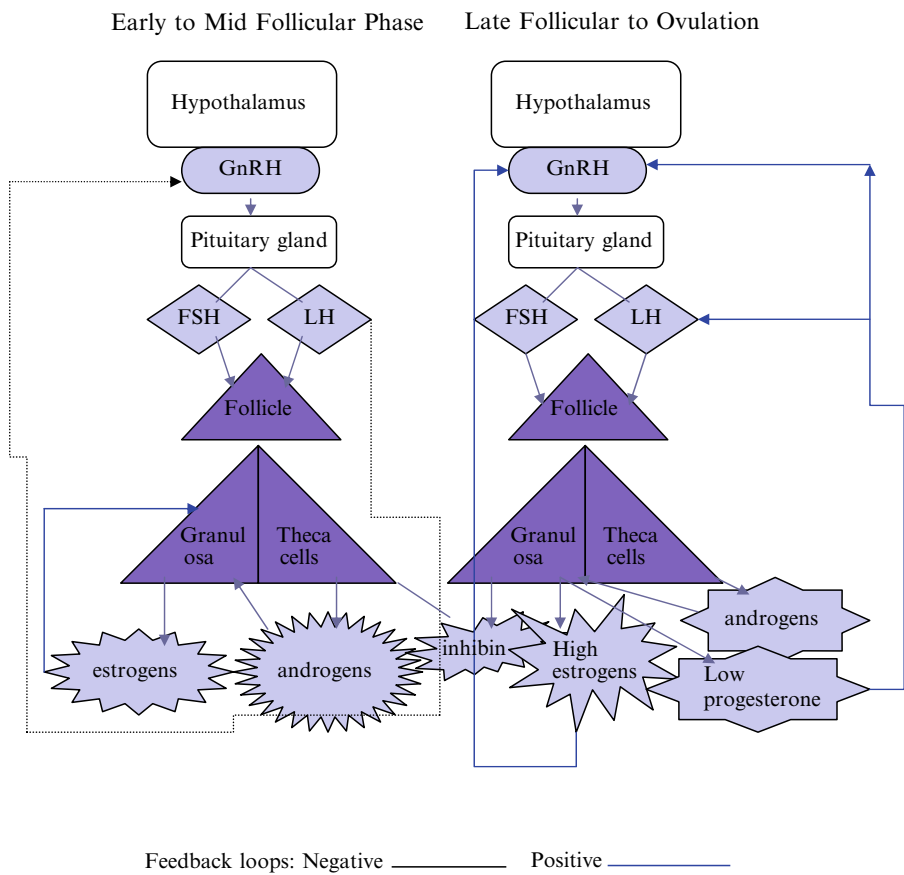
Note: This table lists the hormonal control of a number of physiological and behavioral functions


Fig. 58.1 Endocrine control of the menstrual cycle. The hypothalamus controls much of the positive and negative feedback mechanisms initiating the release and inhibition of hormones and other endocrine substances. Positive and negative feedback loops inform hormone-releasing glands (pituitary and other endocrine glands such as the ovaries), during the mid-to-early follicular phase of the cycle on the left, and the late follicular to ovulatory phase on the right

This leads to an increase in pituitary luteinizing hormone (LH), which triggers the pubertal events of the female menstrual cycle. Following puberty, during the cyclic menstrual phase, the hypothalamus responds to low levels of estrogen by producing a hormone to stimulate GnRH secretion from the anterior pituitary. The pituitary gland acts in unison with the hypothalamus, as do the hormones estrogen and androgen secreted as a result of follicular development. This is called the follicular phase. With continued growth of the follicles, estrogen production within the follicle maintains

sensitivity to LH and follicle-stimulating hormone (FSH). These activities in turn increase the number of LH receptors, allowing luteinization and ovulation to occur (the ovulatory phase). Circulating estradiol levels trigger ovulation, which then triggers a rise in progesterone along with a second rise in estrogen – the luteal phase. The latter part of the luteal phase is what is often referred to as the premenstrual phase, which is associated with a fall in hormone levels, allowing gonadotropins to increase again, initiating a new cycle.

The organs producing the hormones are the pituitary, adrenals, thyroid, ovaries, and testes. Hormones (specific proteins produced by human endocrine organs) contribute to the maintenance of cellular functions and homeostasis, or maintaining an effective balance, pending diurnal, environmental variation (place as well as toxins medications and pollutants), psychological functioning, including changes in stress levels, dietary function, and food intake. Aging processes cause hormone levels to decrease and health maintenance problems tend to increase. Although a naturally occurring and well-tuned cyclic event incorporating the timely integration and interactions of many different systems, menstrual cycle functioning can be accompanied by a number of uncomfortable or distressing disorders, one of which occurs just before the onset of menses, or in the premenstrual phase of the menstrual cycle.

58.3 Premenstrual Dysphoric Syndrome

The premenstrual syndrome is a combined psychological, behavioral, and physiological problem characterized by mood swings, depression, anxiety, irritability, crying, impaired concentration/memory, anger, aggression, insomnia, bloating, cramping, breast tenderness, acne, food cravings, weight gain, hot flushes, and palpitations. Premenstrual symptoms are reported by huge numbers of women across the globe, recently estimated to occur in between 70–90% of women who have menstrual cycles, with an estimated 20–40% describing these as problematic, affecting their daily functioning (termed as the Premenstrual Syndrome or PMS) and 3–8% reporting impairment in quality of life as a result of severe PMS symptoms – termed as Premenstrual Dysphoric Disorder (PMDD; Mishell 2005). Despite reports of the significant social, psychological, and economic effects of PMS/PMDD, the syndromes have been relatively under-recognized in large-scale epidemiological studies (Ussher and Perz 2006) or in research determining the relative health burden of PMS (Halbreigh et al. 2003). Theoretical research exploring etiological factors of PMS/PMDD has failed to reach consensus (Bancroft 1993; van den Akker et al. 1995a–c; Ussher 1996), and treatment effectiveness and appropriateness remain uncertain (Gold 1994; Halbreigh et al. 2003). In addition to medical treatment, consisting largely of antidepressant medication (Bose et al. 2008), behavioral treatments have also been shown to have some effect on improving the occurrence of symptoms during the premenstruum, and this is likely to be the result of learning to cope with the symptoms (Estes 1993; Hunter et al. 2002). Educational and informational packages for the treatment of PMS symptoms have also been offered with some successes reported (Bancroft 1993; Huston and Fujitsubo 2002). Changes in dietary behavior have been reported to occur in a self-help study, which qualitatively reported changes in the perception of the impact of PMS/PMDD (Ussher and Perz 2006).

However, the variation in symptoms from slight to moderate and severe necessitates accurate diagnosis and *targeted* treatment. The lack of etiology and resultant lack of effective treatments are likely to be the result of the lack of unity of the expression of PMS/PMDD, with the possibility that separate conditions with separate etiologies exist. In addition to the etiological elusiveness of the problem, the numerous interactive systems of the menstrual cycle, and the unreliability of diagnosis, the cycle is likely to be influenced by nutritional needs. For example, absorption and expulsion or

repulsion of certain foods or nutrients are likely to be influenced by variations in behaviors and variations in fluctuating hormone levels. This chapter reviews the evidence presented by research on the link between PMS and nutrition. Media reports of cures and potions reported to help the population in its cyclic suffering are prolific, although there is little evidence of their efficacy (Yonkers et al. 2008). It should be noted that because of the wide ranging effects of PMS, the willingness of sufferer's partners and employers of sufferers as well as those afflicted themselves to try and believe in these self-help remedies is huge. Businesses have latched onto the magnitude of the need for a miracle cure for this prolific curse and have also extolled the virtues of substances and lifestyles of unproven utility.

First, a definition of PMS is warranted because an accurate diagnosis is essential in research attempting to delineate the causes and treatment effects of PMS. Following years of debates and research which has failed to accurately define the study populations, undeniably hampered progress in the area. The National Institutes of Health consensus conference on PMS in 1980 put forward a rigorous set of criteria for defining this previously loosely defined syndrome. The Diagnostic and Statistical Manual III (DSM III) adopted the criteria to define the severe form of PMS. They termed it the Late Luteal Phase Dysphoric Disorder, but was subsequently termed Premenstrual Dysphoric Disorder (PMDD). The criteria for fulfillment of a diagnosis of PMDD are shown in Table 58.3.

DSM IV, the revised classification system, describes the research criteria for PMDD, which includes a prospective evaluation and confirmation of at least two consecutive menstrual cycles, focusing on the timing of the symptoms as shown in Table 58.4. A 30% increase in symptoms from the follicular to late luteal phase is a necessary criterion (NIMH 1983). The diagnostic PMDD criteria are for severe and disruptive PMS, and therefore do not include many women across populations suffering from milder though also debilitating or impairing symptoms. It is also important to note that the specificity of the diagnosis includes all symptoms, which may limit the opportunity to unravel subsyndromes, for example, those primarily psychological in nature versus those driven by water retention. It is possible that seeking a unified etiology is not realistic, but we will move on with those reservations in mind. The cumbersome daily monitoring of symptoms to ensure an accurate

Table 58.3 Diagnostic criteria for PMDD

Symptom	Timing
Presence of at least 5 luteal phase symptoms	Timing of symptoms must be confirmed using daily charting/diaries over a minimum of 2 cycles
At least one symptom must be a mood symptom	
Evidence of functional impairment is necessary	

Note: The table shows the diagnostic criteria which must be met by a woman presenting with premenstrual dysphoric disorder

Table 58.4 Revised diagnostic criteria for PMDD – American Psychiatric Association (2000)

Symptom	Timing
Presence of at least 5 luteal phase (primary) symptoms in most cycles	Timing of symptoms must be confirmed using daily charting/diaries over a minimum of 2 cycles
At least one symptom must be a mood symptom (primary symptom)	Symptoms must be present most of the time 1 week before menses remitting within a few days of menstrual onset
Evidence of functional impairment is necessary in work, school, other usual activities and/or relationships	
Symptoms must not be an exacerbation of another condition	

Note: The table shows the revised diagnostic criteria which must be met by a woman presenting with premenstrual dysphoric disorder

diagnosis is essential as reports of prospective and retrospective ratings of symptoms do not always correlate (van den Akker and Steptoe 1985; ACOG 2000; Wyatt et al. 2002; Steiner et al. 2006).

There are popular reports (Hope-Riedesel 2008) detailing specific types of PMS (e.g., Guy Abraham, -UCLA), ranging from Type A (Anxiety), C (Carbohydrate Cravings), D (Depression), H (Hyperhydration and water imbalance), and P (Pain). These predominant types of PMS are purportedly caused by high estrogen levels coupled with vitamin, calcium, magnesium, and zinc deficiencies (for Type A); sensitivity to insulin (Type C); higher levels of progesterone (Type D); sodium sensitivity (Type H); and eating the right fats and avoidance of wrong fats (Type P).

However, although altered mood is a significant symptom of severe PMS, it is important to differentiate clinical affective disorders (clinical depression) from cyclic mood swings such as PMS. People with clinical affective depression may also have PMS, in which case their symptoms may worsen during the premenstrual phase of the cycle. However, women with PMS are not usually also diagnosed with clinical affective disorders, so treatments for them should be differentiated.

58.4 Nutritional Factors and the Menstrual Cycle

Because of its cyclic nature, endocrine hormones have been held responsible, as have changes in serotonin and tryptophan neurotransmitter levels. It has also been suggested that nutritional/dietary factors can influence the chemical changes and severity of PMS experienced. For example, Table 58.5 shows the relationships observed between nutritional factors and biochemical changes affecting psychological functions.

It stands to reason therefore that nutritional replacement of these dietary deficiencies is necessary to restore the balances of organ and reproductive functioning and hence do away with aggravating factors, excesses, and toxicities. However, research demonstrating the exact mechanisms of dietary deficiencies is not conclusive, as will be shown below.

Nutrition is in part guided by neuroendocrine and hormonal control systems, and is also under the control of psychological and behavioral factors. Some conditions associated with the menstrual cycle have been targeted with nutritional therapies where biochemistry and nutrition are combined into a therapeutic substance or dosage for the alleviation of unpleasant symptoms or dysfunctioning. Nutritional therapy is usually associated with naturopathy, or drug-free medicine to treat people with malaise. It is therefore considered a holistic approach, because it attempts to treat the body as a whole curing causes of symptoms, not just masking the symptoms. A nutritional approach to menstrual cycle-related conditions such as PMS is to consider PMS the result of extra nutritional demands not being met, or for example, sugar levels behaving erratically. Nutritional therapy is actually a really old form of therapy, practiced widely before modern drugs became household therapies. It is

Table 58.5 Relationships between nutrition, biochemical, and psychological factors

Vitamin B6 is related to an imbalance of estrogen, which can lead to impaired mood
Deficiencies in fatty acids (e.g., evening primrose oil) needed to produce prostaglandins
An excess in calcium from too much dairy produce forces depletion of magnesium because they compete for absorption, leading to a deficiency of one and toxicity of other
Deficiencies of vitamins A, C, E, and other B vitamins and iron and zinc are also contributory factors
Excesses of dietary salt, alcohol, caffeine, smoking, and animal fats can aggravate symptoms

Note: This table shows a number of the relationships which have been identified between nutritional, biochemical, and psychological variables

based on whole body health and well-being, detecting deficiencies and supplementing through nutritional advice or supplements. Previous research has explored the effect of carbohydrates on depression in general and PMS in particular. If PMS low mood is treated with medications such as SSRIs (selective serotonin reuptake inhibitors), they may mask any nutritional deficiency underlying the root cause of PMS.

There are links between biochemical states and nutrition, for example, the neurotransmitter serotonin is involved with appetite regulation and mood. Low serotonin levels in the brain can cause depression directly, and can lead to carbohydrate cravings (such as sweets and salty snacks), commonly reported in the luteal phase in women reporting PMS. Studies of the effects of carbohydrate intake have suggested mood-related benefits, possibly through an enhanced transport of tryptophan to the brain, which in turn might lead to an increase in the synthesis of tryptophan (Freeman et al. 2002). Murphy and Wagner's (2008) review of mood disorders and vitamin D indicates that there may be a biochemical mechanism between vitamin D and PMS, seasonal affective disorders, non-specific mood disorder, and major depression affecting women. The media has produced several reports of the advantages of taking vitamin D and calcium to alleviate PMS (e.g., BBC News 2005), but no underlying theoretical model demonstrating the pathways for these relationships have been documented. Other correlational but not causal research has demonstrated a decreased premenstrual regional cerebral blood flow in the temporal lobes in women with PMS – compared using scans taken post menstruation – and no such changes were observed in non-PMS sufferers (Buchpiguel et al. 2000).

Increased cravings for particular food types in conjunction with impaired mood have been reported decades ago (e.g., Morton et al. 1953; Smith and Saunder 1969; Wurtman et al. 1989; Brzezinski et al. 1990). More recent research also reported a significant increase in caloric (mainly fat) intake and a modest increase in alcohol craving in women with PMDD in the luteal phase compared to the follicular phase (Reed et al. 2008). These cyclic changes were not present for their control group, suggesting that the dysphoria may be related to the altered food consumption and desire. However, other research failed to find these effects for PMS or cycle phase (Bryant et al. 2006). Nevertheless, interactions between (mood-enhancing) drugs and nutrition intake have also been reported (e.g., Haney et al. 1997; 2008) suggesting that pharmacological treatment targeting depressive symptoms may exacerbate nutritional changes in women suffering from premenstrual mood disorders. Studies reporting nutritional effects for cycle-related dysphoria are likely to have contributed to the increased interest in herbal and homeopathic remedies instead of the less agreeable pharmaceutical treatments (Bramwell and Dye 2006).

In a recent systematic review of the literature, Canning et al. (2006) evaluated the efficacy of alternative nutritional and herbal treatments in studies using randomized research designs. Although the gold standard suggests that diagnosis using daily monitoring is clearly desirable, their review included retrospective determination of PMS/PMDD status (both definitions were used) to ensure that a comprehensive number was included in their evaluation. The review also incorporated studies of oral contraceptive pill users. Canning et al. included vitamin B6, magnesium, calcium, vitex agnus castus, evening primrose oil, St John's Wort and Ginkgo Biloba. Of the 113 articles identified, 26 studies were included in the review. Table 58.6 shows the positive and negative outcomes of the nutritional supplements/treatments reported in the review.

The study clearly shows a positive effect of calcium, and a relatively positive outcome for half the studies assessing the effectiveness of vitamin B6. The authors note that the efficacy of magnesium and evening primrose oil were not confirmed and that insufficient quality research has been carried out on Vitex agnus castus, St John's Wort and Ginko Biloba. They also point out that unfortunately, accurate comparisons cannot be made in the absence of some uniformity of diagnosis and assessment of improvement.

Table 58.6 Efficacy of treatments reported in a systematic review of nutritional supplements/treatments for PMS/PMDD by Canning et al. (2006)

Treatment	Studies reporting an Improvement in PMS/PMDD	Studies reporting no Improvement in PMS/PMDD
Calcium	Thys-Jacobs et al. (1989, 1998)	–
Magnesium	Facchinetti et al. (1991) Walker et al. (1998)	De Souza et al. (2000) Walker et al. (2002)
Vitamin B6	Abraham and Hargrove (1980) Barr (1984) Doll et al. (1989) Kendall and Schnurr (1987) Williams et al. (1985)	Diegoli et al. (1998) Hagen et al. (1985) Malmgren (1987) Smallwood et al. (1986) Stokes and Mendels (1972)
Evening Primrose Oil	Ockerman et al. (1986) Puolakka et al. (1985)	Collins et al. (1993) Khoo et al. (1990)
Vitex agnus castus	Atmaca et al. (2003) Halaska et al. (1998) Schellenberg (2001)	Turner and Mills (1993)
St John's Wort	–	Hicks et al. (2004)
Ginko Biloba	Tamborini and Taurelle (1993)	–

Note: This table shows the studies supporting improvements in premenstrual dysphoric symptoms and nutritional supplement

58.5 Conclusion/Summary

Nutritional effects on the menstrual cycle have been studied increasingly over the last couple of decades, rapidly matching the interest previously generated by the pharmacological effects of menstrual cycle functions and disorders. To date, it is impossible to extrapolate clear pathways within the research of menstrual cycle dysphoric mood such as premenstrual distress, although there is less doubt about the effects of nutritional variables on menarche and fertility. It is possible that effective theoretical pathways of nutrition on cyclic dysphoric mood have been so elusive because of the difficulty in accurate diagnosis of mild, moderate, and severe premenstrual dysphoria. Nevertheless, more research is warranted on the specific effects of nutrition on menstrual cycle disorders such as premenstrual dysphoria.

58.6 Applications to Other Areas of Health and Disease

Women reporting discomfort of distress for menstrual cycle-related symptoms are in a majority. Considering the complex nature of the human female reproductive system it is unsurprising that many other conditions in relation to women's reproductive health also defy ready explanations of etiology and consequently elude effective targeted treatment. It is advisable that regular monitoring of impairments in behaviors, such as concentration and alterations in mood states, such as irritability, anxiety, and depression are given due consideration by health care professionals and researchers. Behavioral and nutritional interventions may have positive effects on well-being in a number of ways, even if such interventions do not target proven etiological factors.

Summary Points

- The main function of the menstrual cycle is to secure an environment fit for reproductive functioning.
- The menstrual cycle depends on the adequate functioning of a number of coordinated systems, particularly the endocrine system.

- Menstrual cycle dysfunctions include premenstrual dysphoric syndromes.
- Premenstrual dysphoria is difficult to define and nutritional effects on premenstrual dysphoria have been variously studied.
- Etiological factors and treatment efficacy of premenstrual dysphoria are uncertain.

Definitions of Key Terms

The menstrual cycle: A regularly recurring 28-day cycle occurring in females.

Premenstrual syndrome/premenstrual dysphoric disorder: A psychological and physiological disorder of unknown etiology.

Dietary supplements: Some dietary supplements such as homeopathic medicines, vitamin B6, calcium, or magnesium may be useful in reducing some symptoms of PMS.

Menses: The overt blood flow from the uterus to the vagina during the monthly menstrual cycle.

Menarche: One of the later stages of puberty marked by the first occurrence of menses starting around the age of 12 in girls.

Menopause: One of the early stages of menopause marked by the cessation of the last occurrence of menses averaging around the age of 52 in women.

Nutrition: The materials necessary to support life.

Endocrine system: The endocrine system controls some of the hormone-releasing mechanisms in the body.

Hormones: Small amounts of chemicals released by cells affecting other parts of the body or organs.

Abbreviations

BE	Binge eating
BED	Binge eating disorder
BMI	Body mass index
BW	Body weight
CR	Cognitive restraint
DIS	Disinhibition
EE	Energy expenditure
NE	Night eating

59.1 Introduction

The human body is a machine that obtains energy from the environment through food and uses energy for functioning, for moving, for modifying the environment, and for obtaining other food. According to the first principle of thermodynamics, energy cannot be dissipated, and therefore when energy intake exceeds energy expenditure (EE), the surplus is stored in the adipose tissue and then body weight (BW) increases. When energy intake however is inadequate to meet requirements, energy derived from adipose tissue breakdown is used as fuel, and then BW reduces. Consequently, any factor causing weight change, whether psychological, behavioral, pharmacological, endocrinal, or anything else, must ultimately act on energy intake, or output, or some combination of these (Garrow 1988).

Because under physiological conditions BW remains substantially stable over time, a very complex regulatory mechanism must be postulated which exactly matches the effects of unpredictable factors, such as physical activity and food intake, which are affected by individual behavior and by the individual–environmental relationship, and with biological processes that remain completely independent of the environment and the subject's willpower.

Human body EE is accounted for both by the energy required for the body's biological functioning as well as by the energy employed during physical activity. Usually, the former represents more than two-thirds of the total. In developed industrialized countries, strenuous exercises for long amounts

of time are not required, and only a very few individuals (usually only the top agonistic athletes) are engaged in strenuous physical activity for many hours a day over long periods. Therefore, nearly all subjects living in the western world must be regarded as practically sedentary. EE due to physical activity, which accounts for no more than 20% of total EE, is substantially similar in all individuals. Consequently, BW regulation is closely and directly dependent on food intake.

59.2 Food Intake and Body Weight

59.2.1 *Weight Gain and Weight Loss*

When food intake permanently increases, EE remaining constant, a corresponding increase in BW develops. The increase in BW consists in energy-consuming lean body mass as well as the metabolically nearly inert adipose tissue (Fig. 59.1). In a normal subject, the former represents two-thirds of the accumulated weight. Therefore, considering for lean and fat tissue an overall EE of 40 kcal/kg/day and 5 kcal/kg/day, respectively, a one kilogram increase in BW corresponds to an increase in total EE of about 17–20 kcal/day (Forbes 1987; Nelson et al. 1992). Weight gain stops when the increase in EE alone, because of the weight gain, counterbalances the increase in energy intake that gave rise to the weight-gaining process (Forbes 1990). Assuming a permanent increase in energy intake (or a permanent decrease in EE) of 100 kcal/day, the body must accumulate (or lose) 6 kg before reaching a new energy equilibrium. At this point, the BW stabilizes once again, although at a higher level (Forbes 1990). The weight gain process obviously takes a long period of time due to the substantial energetic cost of weight accumulation. A kilogram of tissue consisting of fat and lean tissue in the proportion 3:1 contains about 7,000 kcal and, as such, 6,000 kcal beyond the actual EE must be introduced cumulatively (Fig. 59.2). In addition, while BW accumulates, the body's EE progressively increases and the difference between energy intake and expenditure gradually decreases, further slowing down the weight gain process (Forbes 1990; Tremblay et al. 1992).

The same applies when energy intake is permanently decreased (or EE permanently increases) and BW reduces. In subjects of normal weight, the weight loss implies a loss of both fat and lean tissue in proportion of 3:1, thus obviously leading to a reduction of EE of 17/20 kcal/kg/day for each kilogram of
Fig. 59.1 Composition and energy expenditure of the weight gained (or lost). The weight gained or lost by a person of normal weight includes 70% of adipose tissue and 30% of lean body mass. Taking into account the energy expenditure of adipose tissue and lean body mass, one kilogram of weight gain (or lost) leads to an increase (or a decrease) of the total energy expenditure of 17 kcal/day
Fig. 59.2 Composition and energy cost of weight gained (or lost). The weight gained by a person of normal weight includes 70% of adipose tissue and 30% of lean body mass. Taking into account the energy content of adipose tissue and lean body mass, for accumulating one kilogram, an amount of 6,000 kcal beyond the energy expenditure has to be cumulatively introduced
Fig. 59.3 The composition and energy content of the tissue broken down in the weight loss process. The weight lost by a person of normal weight includes 70% of adipose tissue and 30% of lean body mass. Taking into account the energy content of adipose tissue and lean body mass, for losing one kilogram of body weight it is necessary to cumulatively reduce the energy intake under the current energy expenditure of 5,500 kcal

weight lost (Forbes 1987). When the reduced EE due to the weight loss process quantitatively matches the reduced energy intake when the weight loss process itself has initiated, weight loss comes to a standstill, and BW stabilizes at a lower level. As with weight gain, weight loss requires a lengthy interval of time because of the sizeable energy content of the tissue broken down to meet energy requirements (Fig. 59.3) and because of the progressive reduction of the energetic imbalance (van der Kooy et al. 1992).

The composition of weight gain is substantially dependent on initial BW, with heavier subjects accumulating a greater percent of adipose tissue in comparison with their leaner counterparts (Fig. 59.4). Consequently, overweight and obese individuals have an EE of accumulated mass that is lower than that of leaner persons, and values tend to decrease progressively with the increase of BW. Therefore, in comparison with lean people, overweight or obese individuals must build up more weight to compensate for the same permanent increase in food intake, and need smaller energy imbalances to put on the same weight. From a bioenergetic perspective, the control of BW would be poorer in the overweight and in obese subjects than in leaner individuals (Forbes 1987).
Fig. 59.4 Relationship between body weight and composition or weight gained (or lost). The composition of weight gained (or lost) is dependent on the initial body weight, with the heavier subjects accumulating (or losing) a greater percent of adipose tissue than the leaner ones. Therefore, 1 kg of weight gained (or lost) by an obese patient necessitates that a greater amount of energy be built up and implies a smaller increase in energy expenditure that that gained (or lost) by a lean individual

In contrast, the composition of weight loss is not only accounted for by the initial BW. It is also quite dependent on the degree of the food intake imbalance that has promoted the weight loss itself. A quantitatively reasonable decrease in food intake leads to the loss of lean and fat mass in the physiological proportion predicted by the initial BW. In the same way as for weight gain, when faced with a negative energy imbalance the body loses fat mass and lean tissue in a 3:1 ratio. Conversely, when food consumption is drastically reduced, the percentage of lean tissue lost sharply increases, reaching 50–60% of the total. In fact, when the supply of carbohydrates is notably reduced, the body is forced to breakdown muscle proteins to synthesize glucose for the requirements of encephalic structures that are unable to use different energy sources. Therefore, when energy intake of food is considerably reduced, overphysiological erosion of lean body mass occurs, with a resulting overdecrease of EE. In conclusion, drastic reduction of food intake causes rapid weight loss that is due to loss of lean tissue with higher water content, which then results in the prompt decrease of EE. Excessive loss of lean mass causes a sharp decrease of EE both in absolute and in percentage values, thus making a subject more prone to weight regain which can even exceed initial values (Flatt and Tremblay 2006; Chaston et al. 2007).

59.2.2 Conclusions

From such close relationships between food intake and EE, three important conclusions may be drawn. First of all, under steady conditions, a particular individual food intake matches a particular individual BW. A subject's BW is dependent on actual eating habits through the years, and is not affected by occasional episodes of "over" or "under" eating. Furthermore, it is worthwhile to note that slight and nearly imperceptible differences in customary food intake correspond to very clear and significant differences in BW. It can therefore be argued that obese and overweight people may indeed eat more than their lean counterparts, although not as much as is commonly believed and, in particular, not in proportion to their greater body mass. Furthermore, when interindividual differences in genetics, body composition, and in EE are taken into account, it is possible for an overweight person to eat less than a leaner one, or for individuals with the same BW to have quite

different food intakes. Thirdly, due to the particular lengthiness of the process, weight gain (or loss) is not result clearly and directly associated with the increase (or decrease) in energy intake. In fact, actual weight is a consequence of behavioral changes that occurred much earlier, and often a subject feels that he or she is getting fatter without any appreciable change in food intake. This might certainly cause doubts and cognitive dissonances.

59.3 The Regulation of Body Weight and Food Intake

As said above, insignificant and nearly imperceptible changes in food intake correspond to substantial and very clear changes in BW. Also to be considered is that food intake represents the effects of substantially unpredictable individual behavior. However, in the long run, although a very large quantity of calories is processed, the subject's BW remains essentially constant. Clearly, to obtain such a result a very subtle, accurate, and precise regulatory system is required.

59.3.1 The Set-Point Theory

Over the last few decades, a great deal of attention has been paid to the mechanisms that regulate food intake and, indirectly, body weight (Berthoud 2002). According to a biomedical model of homeostasis, the body and the brain act in a self-regulatory manner to produce an optimal and stable status for the organism. According to such a model, if we eat more and put on weight, then several signals will act in the brain to inhibit food intake and, conversely, if we eat too little, the system will increase food seeking and intake. The net result of these actions would be the relative stability of BW over time (Berthoud 2002; Harris 1990). The regulating center is located in the hypothalamus, in strict relationship with the forebrain (via direct and indirect neural and neurochemical connections) and also with the body (via hormone receptors and substrate sensors assigned to the neuron membrane). The regulation center receives a mix of information pertaining to the size of energy stores and the body metabolic status, as well as the presence of acute or chronic conditions that can potentially impact the energy balance. Furthermore, it collects signals on the characteristics of food via the olfactory and gustatory systems, on the status of the gastrointestinal tract, and on the body's capacity to take and absorb food. From the forebrain, moreover, the hypothalamus receives information about the general status of arousal and about the availability of food in the environment via visual and auditory cues. Finally, regulating center activity is strongly influenced by higher cortical function such as memory, representations, learned experiences, and cognition. From the regulation center, two types of output signals begin. At first, the hypothalamus leads the forebrain to stimulate the individual to proper specific actions with the aim of procuring and ingesting food, in parallel with the cognitive, emotional, and motivational processes that influence the behavioral action. Furthermore, it is thought that the pituitary–endocrine axis hypothalamus modulates the gastrointestinal handling and processing of food. Obviously, the brain should be regarded as more than a processor of information. It is in fact a self-activation organ that issues commands to the somatic, autonomic, and endocrine systems. The input systems transmit a varied and rich pattern of stimuli potentially available for the organization and for the execution of ingestive behavior. It appears plausible, however, that the conscious 'executive brain' cannot possibly listen to all of these inputs all the time, and the concepts and mechanisms of arousal and selective attention are thought to sharpen the sensitivity of the conscious brain to behavior-specific information. Such monitoring of

most of the myriad of inputs is constantly going on at a subconscious level, and although not resulting in overt behavior, can lead to autonomic and endocrine adjustments as well as the modulation of other ongoing behaviors (Berthoud 2002).

59.3.2 Population Data and the Bioenergetic Hypothesis

The problem is the nonconformity of weight stability predictions that should be the comprehensive results of this model and the actual situation in the western world, where the rise in mean BW among the general population and the increase in the prevalence of overweight and obesity are evident problems (Ogden et al. 2006). In addition, even individuals of normal and stable BW often employ deliberate or cognitive strategies to remain stable, including dietary restraint and exercise regimens. Consequently, in an environment that is hostile toward weight stability, these physiological signals relating to internal energy status are weak and not as potent in controlling eating behavior (Rowland et al. 2008).

In accordance with the aforementioned bioenergetic mechanisms, a slight and imperceptible increase in customary food intake leads to a very evident and sizeable increase in body weight. Furthermore, in overweight and obese subjects the weight gain is facilitated. A similar increase in customary food intake would therefore produce a greater increase of body mass than in their lean counterparts (Weinsier et al. 1993). Due therefore to the weakness and insufficient functions of the biological self-regulatory system, in the favorable environment (food readily available) existing in western developed countries, an unavoidable increase in food intake with foregone weight gain does occur, and an increasing number of individuals are biologically or behaviorally vulnerable to becoming overweight or obese. From the bioenergetic hypothesis follows that most people get fatter when they are unaware they are eating more and without having changed their feeding patterns. In other words, in our affluent society, a person eating of his or her own free will and according to his or her culture is doomed to put on weight in the end. Therefore, it is quite understandable that a subject can become obese even without profound changes in eating habits and behavior. Often a small and unconscious increase in customary food intake is sufficient. Therefore, in the majority of cases, eating patterns of the overweight and obese individuals do not include feeding patterns that are characteristic of weight status. Current BW simply results from the fact that in the past these individuals have eaten more than their EE. At present, regardless of the body mass index level, a stable BW means that food intake is equal to EE. If food consumption is, however, greater than EE, body weight augments, and vice versa (Garrow 1988). In conclusion, actual BW is determined by the amount of energy overall introduced via food in comparison with energy expenditure, and this is not primarily dependent on eating habits or behavior.

While in humans weight gain is made easier, some physiological mechanisms offer strong resistance to weight loss. These biological functions have undoubtedly been essential to the survival of mankind during an evolutionary period of millions of years. When food intake is sharply reduced, the loss of an overphysiological amount of lean tissue causes a reduction in EE in absolute terms, and therefore tends to limit weight loss (van der Kooy et al. 1992; Rumpler et al. 1991). Furthermore, when the energy balance becomes negative, lean body mass energy requirements decreases, thus determining a reduction of body energy expenditure as percentage values (Rumpler et al. 1991). In addition, laboratory studies and clinical experience have demonstrated that food deprivation, in and of itself, is a strong impulse toward the loss of control over food intake, and therefore leads to overeating for the purpose of compensating energy imbalance (Herman and Mack 1975). In western developed countries, an environment rich in food compels individuals to eat more and to store energy surpluses. Furthermore, food is easily available for nearly all of the population and famine is only a vague memory (Rowland et al. 2008). It is therefore unsurprising that not only weight loss but also weight maintenance throughout the years becomes the consequence of a cognitive and voluntary effort to restrict energy intake.

59.3.3 Social Stigmatization Against Obesity

In contrast to an environment noted for the great abundance and availability of food, in today's western industrialized world all individuals are pressured to be thin, and a strong and widespread stigmatization against obesity does exist. However, certain people have a genetic predisposition toward obesity, and others are more inclined biologically or psychologically to be overweight. Basic human biological, psychological, and genetic makeup has not changed in the last century, and the radical shift in weight, at the population level, has been triggered in large part by the current environment. It stands to reason that patients therefore have absolutely no personal responsibility for their overweight or obese status. Nevertheless, overweight and obese subjects experience a pattern of denigration and condemnation that is pervasive in western developed countries, and which is common for both genders, of all ages, and in all socioeconomic levels. Individuals who have a body mass that is higher than the standard accepted body mass are considered unattractive and repulsive, and quite frequently have difficulties at work and with their personal lives. A common belief is that being overweight is a direct consequence of overeating and of lack of physical activity. The obese person is therefore considered a greedy and lazy person, who refuses the principles of activity, thrift, and moderation that are the bases of the affluence of industrialized western countries starting from the Protestant Reform of the seventeenth century. Therefore, a large number of obese and overweight people make continuous but unsuccessful attempts to lose weight, and feel guilty about their weight status. As mentioned above, in an environment with an abundance of food, the vast majority of normal subjects keep food intake cognitively under control in order to avoid undesirable weight gain. The pervasive social weight bias may indirectly induce some lean individuals with psychological distress and body image disparagement to further reduce energy intake simply to improve somatic morphology and then relieve psychological discomfort. Social hatred directed against the overweight and obesity may therefore be harmful for obese and lean subjects alike (Puhl and Brownell 2003).

59.3.4 Laboratory Data

In past years, a great deal of investigation has been carried out with the aim of detecting one or more characteristic eating patterns in obese patients. If aberrant eating behavior of deviant eating style had been demonstrated, the modification of such aspects would have resulted in permanent weight loss and then in the steady recovery from obesity.

Several studies have been performed in experimental settings that compared lean subjects and obese patients. Evaluated were: meal size, frequency of food consumption, correlation between the size of a meal and interval before the next meal, timing of eating, the individual's susceptibility to hunger, satiation duration, eating topography, food consumption rate, attitudes, and beliefs about food. However, only highly contrasting and inconclusive results were achieved. When data on customary food intake are analyzed, the fact that weight gaining process takes place over time must be considered, and that the individual's current BW is substantially dependent on ingestive behavior that had taken place over many months or years. In a laboratory setting, only the current feeding pattern can be described, which obviously might well be independent of the daily eating style and does not take the subject's motivations, expectations, and emotional aspects regarding food consumption into account (Blundell and Gillett 2001; Blundell and King 2000). On the other hand, human food intake is strictly dependent upon eating habits and behaviors, which are highly variable among different populations and cultures, and which are completely unpredictable on an individual basis; as it is essentially subject to individual will and environmental pressure. Furthermore, as aforementioned,

the amount of food eaten (i.e. energy introduced which is the main determinant of BW) may be increased (or decreased) without perceptible modifications of eating habits and behavior, and the subject may be completely unaware of these quantitative changes. It is clear that few and nearly imperceptible changes in habits or behaviors in the end are nearly impossible to detect and to quantify even with careful interviews or instruments structured for behavioral assessment.

Since the main determinant of BW is the amount of energy cumulatively introduced with food, only alterations in eating habits and behaviors actually involving permanent changes in energy intake can produce body weight modification. By contrast, changes in energy intake *do* produce changes in BW even without having an effect on eating habits and behavior.

59.3.5 Conclusions

Summing things up, in human beings feeding behavior is essentially influenced by external and cultural cues resulting from an evolutionary period with food shortages lasting ten of millions of years and with biological control that is not potent enough to control BW stability in a current environment rich in food. Furthermore, according to the bioenergetic model, minor and nearly imperceptible changes in current food consumption can cause quite significant and sizeable increases in body mass, without any change in eating patterns and behavior. These facts account for the dramatic increase in the prevalence of overweight and obesity occurring in the western developed world. These considerations, moreover, along with the inconclusiveness of behavioral research on this topic, support the assumption that specific eating patterns or eating behaviors do not exist that on their own characterize the obese and the overweight status.

59.4 Eating Patterns in Overweight Individuals and Obese Patients

Clinical experience, psychometric investigations, and epidemiological studies indicate that there are different behavioral traits that are more common in obese patients and in overweight subjects in comparison with lean individuals. These are: cognitive restraint (CR), the tendency to disinhibition (DIS), and night eating (NE). However, no evident correlation between the presence of these behaviors and BMI level or the degree of obesity was observed. In addition, these eating patterns can be present in lean individuals who have never been obese as well as in eating disordered patients with very low levels of BMI. Conversely, a significant number of obese or overweight patients have completely normal eating patterns, and do not demonstrate any of these behavioral aspects. Therefore, the hypothesis that these behaviors represent a characteristic eating pattern for the obese or the overweight can be excluded. On the contrary, it can be hypothesized that only in susceptible patients do these behavioral traits lead to weight gain and to the maintenance of a BW greater than is standard, while other subjects can put on weight and become obese without demonstrating any of these behaviors.

59.4.1 Assessment of Cognitive Restraint and Disinhibition over Food Intake

There are some methodological difficulties in the population as well as in the clinical assessment of restrained eating and disinhibition over food intake.

Restrained eating describes the tendency of people to cognitively and voluntarily restrict food intake and eat less than desired to achieve weight loss or to prevent weight gain. CR is assessed by self-reported questionnaires that explore the subject's capacity to limit alimentary consumption and the cognitive and behavioral strategies used for this purpose. The most widely used questionnaires are: the "Restraint Scale", a ten-item instrument evaluating dieting behavior and weight loss (Herman and Polivy 1975), the "Three Factor Eating Questionnaires", that measures both the CR and the tendency to disinhibition over food intake (Stunkard and Messick 1985), and the "Dutch Eating Behavior Questionnaire", that taps restraint, external, and emotional eating. The Restraint Scale includes some questions about the extent of weight loss achieved in past years and the weight reduction actually obtained during a dieting period, while the Three Factor Eating Questionnaire and the Dutch Eating Behavior Questionnaire do not require specific answers on weight variations and therefore may highlight much more easygoing and flexible individual attitudes toward food limitation. Disinhibition over food intake reflects a tendency toward overeating, and includes eating in response to negative emotion, overeating when others are eating, not being able to resist the stimulation to eat, and overeating in response to the palatability of food.

The loss of control over food intake can be highlighted as only isolated binge eating (BE) episodes, whereas eating behavior in the nonbinge period may be completely normal. In these cases, the assessment of DIS requires clinical evaluation and/or a structured or a semi-structured interview. CR and DIS can also be evaluated by the Eating Disorder Examination in these cases, which assesses a broad range of eating behaviors and attitudes toward BW and shape (Faiburn and Cooper 1993). This survey also provides a semi-quantitative evaluation of the degree of eating disturbances as well as a profile of individuals according to scores on four subscales that assess key aspects of eating disorder psychopathology: Restraint, Eating Concern, Shape Concern, and Weight Concern.

59.4.2 Cognitive Restraint and BMI

The notion of CR was introduced to describe individuals' tendency to restrict food intake and consume less food than desired for the purpose of achieving weight loss or preventing weight gain. Anorexia nervosa and some cases of bulimia nervosa patients exert very firm control over food intake and actually markedly reduce their energy intake thus maintaining BMI values for years at very low levels. The hypothesis that eating disorders are caused by an antecedent mental disorder, currently believed to be an obsessive compulsive disorder, has been clinically implemented over the course of many years (Kaye et al. 2004). However, a long period of semi-starvation by healthy human volunteers demonstrated not only the emergence of psychiatric symptoms including obsessive–compulsive symptoms but also the same pattern of eating behavior characterized by a low level of intake, slow eating rate, and a high level of satiety typical of anorexia nervosa patients. It has therefore been suggested that the pattern of eating behavior might mediate between the starved condition and the psychopathology of anorexia nervosa, and that effective nutritional support plays a key role in the therapy of the patients with eating disorders (Zandian et al. 2007).

59.4.3 Cognitive Restraint and Food Intake

Though eating disordered patients very often refer that they exert strong control over food intake, cross-sectional population studies have shown positive association between CR and BMI values;

heavier subjects more frequently reporting self-limitation of customary food consumption and/or a CR at higher degree in comparison with their lean counterparts (Lluch et al., 2000; Beisiegel and Nickols-Richardson 2004). This apparently contradictory fact may be accounted for by biological, behavioral, and psychological factors. As said above, in developed western countries the obese and the overweight status is subject to strong social discrimination, which in some cases leads to psychological distress. It is therefore not surprising that overweight or obese individuals make constant, though fruitless, efforts to reduce food consumption in order to lose weight. So far in our culture, physical appearance is rated more important for women than for men and it is not surprising that in some studies the positive association between CR and BMI was found to be stronger in the female gender. However, most population and clinical studies failed to evidence a clear relationship between the degree of CR and the current food intake. Presumably, the high degree of CR in obese and overweight patients is completely useless and represents only vain attempts that cannot be put in practice. Furthermore, in the end, restrained eating may alter metabolic functioning toward anabolism, which may increase the degree of difficulty in losing weight and may even cause weight gain. The chronic limitation of food intake triggers energy sparing mechanisms that have been evolutionarily conditioned throughout the course of million of years of food scarcity and which have allowed mankind to survive and thrive across the planet.

Finally, it has been observed that subjects with high degrees of CR tend to overeat when self-control is undermined due to psychological or environmental reasons. In the end, they therefore eat more than their low restraint counterparts, consequently put on weight. This is assumed to be support for the hypothesis of counter-regulatory eating among restrained eaters, at least in laboratory settings. Specifically, studies have noted that if restrained eaters are forced to "violate" their diet by eating high-caloric foods (or foods they think are high caloric) or by drinking alcohol, their subsequent laboratory consumption of food is increased. Unrestrained (or nondieting) subjects, on the other hand, appropriately regulate the effects of the high-caloric food or drink by reducing their laboratory consumption of food.

59.4.4 Cognitive Restraint and Body Weight Changes

To verify the association between CR and weight changes, longitudinal investigations were conducted during weight reduction programs, only a few of which evaluated the general population. The majority of these studies carried out on clinical samples of overweight or obese patients show that baseline dieting or dietary restraint is actually associated with an increased risk of weight gain, sometimes exclusively in women. The magnitude of the risk is modest, but this finding represents the clears empirical evidence that dieting facilitates weight gain. In contrast, when the general population is considered, restrained eating, though cross-sectionally associated with BMI levels and other adiposity variables, would not promote weight gain over time either in normal people or in overweight subjects (de Lauzon-Guillan et al. 2006). This supports the hypothesis that this behavioral strategy is more developed in subjects who are prone to put on weight and/or ask for professional help with slimming. In general, it can be employed safely for the control of BW or to avoid weight gain without detrimental effects on metabolic activity or eating overall.

59.4.5 Two Different Forms of Restraint

The apparent incongruity of these statements can be explained by the existence of two different types of CR, which affect daily eating behaviors in different ways, and which represent distinct characteristics of restraint because they relate differently to disturbed eating patterns and to successful weight

control. Flexible control is associated with lower self-reported energy intake, moderate and realistic weight loss expectations, and avoidance of drastic and extreme attitudes about limitation of food consumption. This flexible CR is well evidenced by the Three Factor Eating Questionnaire, and yields the high probability of successful weight reduction during the 1-year weight loss program. By contrast, the rigid and drastic CR registered by the classical Restraint Scale most likely leads to the loss of control over food intake, to overeating and then weight gain, and can be based on psychological distress (Westenhoefer et al. 1999). The existence of two different types of CR is indirectly supported by the changes in eating behavior observed following biliopancreatic diversion, a very effective procedure for the surgical treatment of severe obesity that can be used as an effective experimental model for understanding human eating behavior (Scopinaro et al. 1998). Due to the permanent limitation of intestinal absorption of energy-rich foods because of gastrointestinal tract rearrangement, patients operated on achieve and maintain satisfactory weight loss with a completely free diet. It must therefore be assumed that they have completely abandoned any concerns about weight, food, and diet. In these patients, a sharp reduction of the Restraint Score was obviously observed, while the CR score of the Three Factor Eating Questionnaire remains substantially unchanged with respect to the preoperative data (Adami et al. 1993, 2001). As a result, it may be suggested that in comparison with the behavior evidenced by the classical Restraint Scale, the CR score of the Three Factor Eating Questionnaire taps into an eating pattern that is quite different, i.e. a much more flexible and reasonable CR promoting weight loss and maintenance and counteracting overeating (Adami et al. 1993, 2001). Therefore, for the successful result of weight loss strategies, behavioral and attitudinal changes must be governed by the principles of flexible and reasonable control over food intake. Drastic and rigid restraint however should be discouraged. The literature, moreover, provides a greater consensus that in individuals unaffected by eating disorders deleterious effects of restrained eating are mediated by disinhibition. Most population and clinical investigations in fact have demonstrated that subjects were more susceptible to weight gain when restraint eating is accompanied by other behaviors showing a tendency toward a loss of control, such as emotional eating, binge eating, or eating with a highly uncontrolled eating score (Polivy and Herman 1999; Westenhoefer et al. 1994).

59.4.6   Conclusions

As mentioned above, in population and in laboratory studies, CR is not related to current food intake, while in dieters and in "free" eaters the tendency toward disinhibition is positively associated with overeating. These findings lead to important clinical conclusions. CR may be associated with a higher tendency to overeat and to disinhibition over food intake, and it is very likely that the high BMI levels observed in restrained eaters is substantially due to the concomitant behavioral trait that leads to the loss of control. Further evidence of this theory comes from the cross-sectional studies that have revealed that those individuals who were heaviest had a high disinhibition and low restraint score, while those individuals who expressed a high disinhibition and high restraint score had a somewhat lower BMI level. It therefore appears that at lower disinhibition levels CR may represent a highly efficient strategy for weight loss and maintenance (de Lauzon-Guillan et al. 2006).

In conclusion, the positive association between BMI levels and CR is mediated by the tendency to disinhibition over food intake. Therefore, extreme and drastic CR would easily bring about the disruption of control over eating and then subsequently to overeating, in that such behavior was assumed to counteract an excessively high degree of DIS (Bryant et al. 2007).

59.5 Disinhibition and BMI

Control over food intake can be disrupted intermittently during the so-called BE episodes. Daily eating behavior, however, may show a general tendency toward the loss of control over food intake which is *not* characterized by acute events. Moreover *both* aspects may be present in the same person (Dykes et al. 2004; de Zwaan 2001; Wadden et al. 1993). All of these behavioral traits can be associated positively with BMI values and other adiposity variables. However, these eating attitudes may also be observed in eating disordered patients with low or very low BMI levels.

59.5.1 Binge Eating

An episode of binge eating is characterized by the consumption of a large quantity of food in a moderate amount of time, accompanied by a subjective sense of loss of control over eating. In patients with anorexia and bulimia nervosa, the BE episode is followed by purging type behavior which the patient, in order to avoid weight gain, specifically engages in to eliminate an excess of calories consumed. The most common purging behaviors are vomiting, taking diuretics or laxative drugs, or engaging in strenuous exercise. In these cases, BE is associated with low or very low BMI values in anorexic patients and with normal or low BMI values in the bulimic ones. Moreover, overweight and obese individuals may complain of episodes of BE without assumption of compensatory behaviors. When BE episodes which are not followed by purging behavior occur more than three times a week and are accompanied by marked psychological distress about the BE episode itself, patients must be considered as having a Binge Eating Disorder (BED), which can be considered as a distinct and significant eating disorder associated with obesity (Spitzer et al. 1993) (Table 59.1). Patients with BED usually also have behavioral indicators of the tendency to lose control over food intake such as eating more rapidly than is normal, eating until uncomfortably full, eating large amounts of food when not hungry, eating alone because they are embarrassed and feeling depressed, disgusted and guilty about overeating (Spitzer et al. 1993). The lifetime prevalence of BED among the general population is 0.5–4%, while among obese patients seeking treatment, BED is observed in 15–50% of patients. Prevalence of BED reaches 50–60% in bariatric surgery patients with higher BMI values (Adami et al. 1996; Stunkard and Allison 2003). The frequent association of BED with psychiatric comorbidity, the very good response to many forms of treatment, and the difficulties of establishing definite diagnostic criteria have given rise to the hypothesis that BED should not be considered a specific clinical eating disorder; it could, how-

Table 59.1 Diagnostic criteria for binge eating disorder

1. Recurrent episodes of binge eating
2. During the binge eating episodes at least three behavioral indicators of loss of control
3. Marked distress regarding binge eating
4. The binge eating occurs on average at least twice a week for a 6-month period
5. Does not currently meet the criteria for bulima nervosa

A binge eating episode is characterized by eating in a discrete period of time (e.g., 2 h) an amount of food that is definitely larger that most people would eat during a similar period of time. Eating much more rapidly than usually, eating until feeling uncomfortably full, eating a large amount of food when not hungry, eating with no planned mealtimes, eating alone because of being embarrassed and feeling disgusted with oneself, and very guilty after overeating are behavioral indicators of loss of control

ever, could simply represent a marker for psychopathology or psychological distress in obese patients (Dingemans et al. 2002). BED patients generally report a far greater number of reducing diets in their past compared with their nonbinge counterparts at similar BMI levels. Both clinical as well as population studies have demonstrated the positive association between dietary restraint and the tendency toward disinhibition with respect to food intake (de Zwaan 2001; Adami et al. 1996). A question arises over whether patients complaining of BE or showing a high tendency to disinhibition should increase their CR in order to limit the effects of BE and overeating on BW. Or does excessive CR leads itself to the loss of control and to bingeing? Longitudinal investigations carried out in nonclinical populations have clearly demonstrated that in patients with BED, CR is used as long-term compensatory behavior with the goal of preventing weight gain provoked by disinhibition or BE episodes. In other words, dietary restraint is probably only a secondary effect of disinhibition (Dingemans et al. 2002). In contrast, in formerly obese subjects, long after biliopancreatic diversion, when BW has steadily returned to within nearly normal limits and any concern of the subjects for food, dieting, and body shape should have been completely abandoned, binge eating tends to disappear and the tendency to DIS reduces. This suggests a causal effect for CR over disinhibition (Adami et al. 1993, 1996). Stable weight loss attributed to bariatric surgery is followed in the majority of postoperative obese subjects by marked improvement not only in eating behavior, but also of the quality of life and psychological status (Adami et al. 1996; Herpetz et al. 2003). Considering that BE is a marker of psychopathology, it may be suggested that the complete abandonment of rigid dieting behavior, as well as the relief of psychological distress which was due to the obese status, plays a fundamental role in the postoperative disappearance of BE and in the reassuming of satisfactory control over eating.

59.5.2 Disinhibition in the Everyday Eating Pattern

In the everyday eating pattern, disinhibition is a behavioral trait that reflects a tendency toward the loss of control over food intake and to overeating when faced with an environment dense in alimentary stimuli. Examples include eating in response to negative influences, overeating when others are eating, not being able to resist the stimulation to eat, and overeating in response to the palatability or to the variety of food (Bryant et al. 2007).

59.5.3 Disinhibition and Body Weight

Clinical and population studies have demonstrated that DIS is positively associated with BMI and obesity variables. Studies using a cross-sectional design show positive association in groups of individuals of differing dieting status and in individuals with varying weight histories between DIS and BMI across different socioeconomic gradients and degrees of obesity. Furthermore, it is widely reported that obese and overweight individuals have higher DIS scores compared with normal weight individuals (Dykes et al. 2004). In addition, prospective studies show that DIS predicts current BMI and can predict weight gain over several years, and that in weight loss regimens, disinhibition is predictive of poorer success with weight loss as well as long-term weight regain (McGuire et al. 1999).

Disinhibition may not act in isolation; however, it frequently exerts its effect by interaction with the level of CR. When a high level of disinhibition is combined with a high level of restraint, the relationship between DIS and weight is weakened. In fact, cross-sectional studies have shown that

those individuals with the highest BW had a high DIS and low restraint, while those who expressed a high DIS and high restraint had a somewhat lower BMI. Likewise, among the high restraint patients, higher BMI levels were observed in those subjects showing a greater tendency to disinhibition in comparison with the BMI level of individuals who demonstrated better control over food intake (Polivy and Herman 1999; Westenhoefer et al. 1994).

59.5.4 Disinhibition and Food Intake

While CR is generally unrelated to the actual food intake, a sizable number of population, clinical, and laboratory investigations employing a wide variety of techniques together have demonstrated that DIS leads in fact to greater food consumption both in normal subjects and in overweight and obese patients (Westenhoefer et al. 1994; Ouwens et al. 2003). In other words, disinhibition is almost inevitably linked to the increased tendency to eat when people are subjected to various challenges or interventions which threaten to disturb their energy balance, while CR may only reflect an individual objective that is not actually achieved. Individuals with greater tendencies of DIS tend to be sedentary, and when engaged in physical activity they usually increase food consumption (Bryant et al. 2007). Studies investigating the relationship between DIS scores and the peptides (ghrelin and leptin) known to play significant roles in energy homeostasis have only produced inconclusive results (Adami et al. 2002a; St Pierre et al. 2004). In fact, though in severely obese patients a high DIS score is associated with high and low ghrelin and leptin levels, respectively, there is no evidence that low ghrelin or high leptin levels can trigger disinhibition. Furthermore, the hypothesis that abnormal serum ghrelin or leptin serum levels simply reflect hormonal resistance caused by the obesity – without any association to eating behavior patterns – cannot be ruled out.

Other studies highlighted that high DIS scores are positively related to a greater taste for and consumption of high-fat foods, sweet foods, and alcohol, and negatively related to the consumption of vegetables, fruits, and high-fibre breads. These unhealthy food choices may not only contribute to overweight and obesity, but also to poorer general health (Higgs and Eskenazi 2007).

In conclusion, longitudinal prospective studies found an association between disinhibition over food intake and BE on the one hand and being overweight and putting on weight over a 20-year period on the other. Clinical investigations, moreover, have demonstrated that reducing disinhibition binge cessation tends to be associated with weight stabilization, while continued BE is associated with ongoing weight gain, thus undoubtedly indicating a link between DIS and the risk of obesity. Based on this data, it is difficult to avoid the conclusion that DIS and BE are associated with weight gain and, in many cases, ultimately contribute to the development of obesity.

59.5.5 Disinhibition and Psychological Status

Moreover, disinhibition emerges as an important and dynamic trait, with influences that go beyond eating patterns, and incorporate other behaviors that contribute to weight regulation and obesity and may play a role in the development of eating disorders (Brown et al. 2006). In fact, some researchers have shown that DIS is associated with personality factors that are counterproductive to the maintenance of a good level of control over food intake, encourage overeating, and promote adverse psychological health (de Zwaan et al. 2003; Ghiz and Chrisler 1995; Lawson et al. 1995). In bulimia nervosa patients, DIS is related to BE severity and to more severe eating disorder pathology. Moreover, in eating

disordered patients, DIS was also found to be associated with a lower level of psychological health, with higher neuroticism, lower extroversion, lower self-esteem, and with the presence of severe depression, anxiety, and body disparagement. It must be suggested that the conflict created by high CR, which is the rule among most eating disordered patients, and the presence of a high degree of DIS cause derangement in the control of eating and exacerbate psychological symptoms. In summary, individuals with a high of DIS are characterized by a strong propensity to overeat, put on weight easily, have a greater taste for food, a preference for high-fat foods, and have a lower EE due to sedentary behavior. These data can be considered in relation to the thrifty genotype that favored genetic adaptation allowing humans to survive for millions of years in the face of food scarcity and famine, by selective pressure on physiology (Bryant et al. 2007). The adaptive potential of physiology protective against periodic food scarcity can be extended to a behavioral dimension leading to overeating when food is available, favors high-fat foods, promotes fat deposition, and encourages energy conservation by being sedentary. In the course of the million of years of the evolutionary period, this highly advantageous eating behavior led to the individual's survival and has made the diffusion of mankind possible. Proposals have been made that the behavioral trait "disinhibition" be more appropriately renamed as "opportunistic eating". In an obesogenic environment, such as the western developed world, opportunistic eating has become counterproductive behavior promoting weight gain and may be the main cause of the greatly increased prevalence of overweight, obesity, and other metabolic diseases observed in the last few decades. Opportunistic eating is furthermore at odds with the prevailing health message in the western world, and appears to be highly dysfunctional. The unavoidable conflict between biological disposition and environmental forces could lead to the degradation of emotional well-being, to loss of self-esteem, and other indications of poor psychological health, thus contributing to the onset and maintenance of eating disorders. In this context, disinhibition seems to play a significant mediating role between the 'person' and the 'environment', and has multiple physiological and psychological components (Bryant et al. 2007).

59.5.6 Night Eating and BMI

Night eating was first described as a specific behavior pattern more than 40 years ago (Table 59.2). Since then, NE has not aroused great interest and has only recently attracted a great deal of attention. The original criteria for defining NE is: no appetite for breakfast, 50% or more of total food intake after 7:00 p.m., and trouble getting to sleep and/or staying asleep. In addition, positive association between the presence of NE and BMI levels was observed in the population as well as in clinical studies (Stunkard 1959; Stunkard and Allison 2003).

Recent epidemiological investigation studies have highlighted a link between night eating and obesity. The NE syndrome is fairly uncommon in the general population. It is present in nonobese people, but is more common among the obese (Striegel-More and Franko 2008). The prevalence of NE increases with increasing weight from 10% to 20% in obesity clinics and from 30% to 50% among

Table 59.2 Diagnostic criteria for night eating

1. No appetite for breakfast
2. About 50% or more of total food intake after 7:00 p.m.
3. Trouble getting to sleep and/or staying asleep

The diagnostic criteria for night eating may change according to the eating habits of the reference population. In the population with a Mediterranean eating style, consuming food after the evening meal or in the night is considered an inclusion criterion for night eating

obese patients evaluated for surgical treatment (Stunkard and Allison 2003; Adami et al. 1999; Colles et al. 2007). Moreover, the association between NE and stress and a depressed mood has been described consistently (Pawlow et al. 2003; Marshall et al. 2004). The original inclusion criterion is not suitable in populations in which current eating styles are different from those in the USA or Northern European countries. Different criteria were adopted: eating hyperphagia, eating after dinner, fully alert night time awakenings accompanied by snack consumption (Powers et al. 1999; Adami et al. 2002b). The core clinical feature of NE appears to be a delay in the circadian timing of food intake (O'Reardon et al. 2005). Energy intake is reduced in the first half of the day and greatly increased in the second half so sleep is disrupted in the service of food intake. NE is distinguished from bulimia nervosa and BED by the lack of associated compensatory behaviors, the timing of food intake, and the fact that food ingestion amounts are small, amounting to repeated snacks rather than true binges. Different inclusion criteria are necessary in populations with different daily eating styles. A link between abnormal neuroendocrine patterns and NE has been suggested, with elevated serum cortisol levels consistent with the hypothesis that NE may be a stress-related disorder (Birketvedt et al. 1999). In addition, the usual rise of both melatonin and leptin levels at night was blunted among NE patients, suggesting that these hormones were not performing their usual functions of maintaining sleep and suppressing hunger, respectively (Birketvedt et al. 1999). Obese patients with NE continued to exhibit this behavior even long term, following biliopancreatic diversion after BW had nearly normalized, BE episodes had disappeared, and disinhibition over food intake had markedly reduced (Adami et al. 1999). This finding indicates that BE and NE are distinct though sometimes overlapping eating behaviors, and it strongly supports the neurohormonal hypothesis for NE.

While NE is traditionally considered as an obesity-related eating pattern, and retrospective recall in clinical samples suggests that NE may often precede the onset of obesity, there are indications that half of the overweight people presenting with NE reported being of normal weight before the onset of NE. This suggests that NE may be a pathway to excess weight. However cross-sectional community studies have not borne out this association (Striegel-More and Franko 2008; O'Reardon et al. 2005; Devlin 2007).

The clinical significance of NE is still unclear due to the very different diagnostic criteria preventing comparison between different cohorts and the lack of accurate and large longitudinal populations of interventional investigations. Data in the literature indicate that NE is a behavior that is closely related to obesity, with an increase in frequency corresponding with an increase of BMI. NE appears to be clearly distinct from BE; therefore, overeating of NE seems to be independent from the physiological mechanism that leads to the loss of control over food intake.

59.6 Conclusions

BW accurately depicts the energetic relationship between the individual and the environment. When food intake, and then energy intake, permanently increases, BW increases and consequently EE increases. When the increase of EE matches the increase of energy intake that initiated the weight gain process, the BW will stabilize again, though at a higher level. The same applies to the reduction of energy intake and to weight loss. For each individual, therefore (assuming any other condition is constant), a particular amount of current food intake corresponds to a particular BW. Longitudinal and cross-sectional investigations have showed that very little and nearly imperceptible differences in current food intake correspond to quite important changes in BW. Therefore, it is easily conceivable for an individual to put on weight without being aware of increasing food intake. Furthermore, the differences in food intake between lean individuals and overweight and obese patients could be very little and,

considering the interindividual variations in EE, it is quite possible for a heavier person to eat less than a leaner one. Obesity is due to the concomitant action of genetic predisposition and the environment, and patients have no responsibility for their overweight or obese status. Ten million years of natural evolution in a hostile environment favored the genetic adaptation that has allowed humans to survive in the face of food scarcity and famine. The structural, metabolic, and behavioral characteristics acquired by selective pressure on physiology on the one hand compel individuals to eat and to consume energy-rich food and on the other hand facilitate energy sparing. In an obesogenic environment such as developed western countries, these characteristics have become counterproductive and in predisposed subjects promote obesity, along with different comorbidities that accompany excess adiposity.

Most cross-sectional and longitudinal investigations produce clear evidence that the amount of food consumed plays a major role in the development or maintenance of obesity for the vast majority of overweight people or obese patients, while specific eating patterns may lead to over consumption or may simply be associated with the obese status.

CR is an eating pattern that describes the tendency to cognitively and voluntarily restrict food intake and eat less than desired in order to achieve weight loss or to prevent weight gain. CR is positively associated with overweight and obesity, and reflects the patient's need to improve his or her health, social acceptability, and quality of life. However, CR does not necessary correspond to an actual limitation of food intake and in some cases even leads to the loss of control and to overeating and therefore to an exacerbation of the overweight and obese status. In contrast, individuals demonstrating a high tendency of disinhibition and loss of control over food intake have food consumption that is actually greater than their counterparts with low disinhibition levels; disinhibition is believed to be an eating pattern that may lead to overweight and obesity. In an evolutionary perspective, disinhibition is considered to be an adaptive behavior which contrasts food shortage and famine, and in an environment which is dense in food, can ingenerate cognitive distortion and emotional distress. In fact, in eating disordered patients, high disinhibition levels or the presence of binge eating is generally associated with poor psychological functioning. NE is a feeding pattern that has not yet been defined precisely and which is associated positively with obesity and is characterized by sleep disturbances and by delay in circadian assumption of food. NE may play an important role in the weight gain process via biochemical and/or behavioral pathways different from that of disinhibition over food intake.

59.7 Applications to Other Areas of Health and Disease

Obesity results from the interaction between a biological structure programmed to spare energy and an environment with plenty of food. A specific feeding pattern differentiating overweight and obese patients from lean persons does not exist. Weight gain and the maintenance of a BW in the overweight or in the obese range is a quantitative phenomenon, requiring for the weight gain process an energy intake that is higher than EE, or sufficiently high-energy intake for weight maintenance. The feeding patterns that are commonly associated with obesity simply favor the increase in food intake and/or are simply a consequence of the obese status. In perspective, the fight against obesity as social disease must be more focused on the environment than on the individual.

Summary Points

- Slight and nearly unapparent permanent increases in energy intake lead in the end to a consistent and well appreciable increase in body weight. Therefore, the amount of food consumption by overweight or obese patients might be very similar to that of normal persons.

- Longitudinal clinical and population studies failed to highlight clear and specific differences in eating habits and behaviors between obese patients and normal weight individuals.
- A million year evolution period has conditioned the human body to continue to exist in spite of famine and food shortages. In an environment dense in food that characterizes western developed countries, the mechanisms that guaranteed survival for most in bygone centuries now account for the dramatic rise in the prevalence of overweight and obesity.
- In this sense, obesity should be considered as a true social disease.
- Most of the eating habits and behaviors observed in overweight and obese individuals simply favor weight gain and must be considered as consequences more than causes of the obese status.
- In perspective, the fight against obesity as a social disease should be focused more on the environment that on individual behavior.

Definitions of Key Terms

Body mass index (BMI): Body mass index is the ratio of body weight in kilograms and stature in meters squared. It is the most reliable parameter of the degree of obesity, normal values being 20–25 kg/m², and higher values indicating the obese status.

Energy expenditure: The amount of energy required by the body for living, eating, and for moving in the environment.

Lean body mass: Lean body mass is represented by all body sectors containing water and which do not comprise fat such as muscle, viscera, bone. Interstitial fluid and fat is the body sector that consumes energy.

Eating habits and behavior: Behaviors that the individual engages with respect to eating. Eating habits comprise food selection, the daily timing of eating, and habitual eating patterns.

Social stigmatization toward overweight and obesity: In western developed countries, overweight subjects and obese patients are considered ugly, avid, and lazy, and unable to fit the current physical standard of leanness and effectiveness. Stigmatization leads to blame and discrimination in the workplace and social life, determining impairment of psychological functioning and a very poor quality of life.

Cognitive restraint: The subject's efforts to limit food intake for the purpose of losing weight or avoiding weight gain. Due to the great social stigmatization existing in the western developed world toward overweight and obesity, cognitive restraint is a common eating attitude both in obese patients and in persons of normal weight. However, cognitive restraint does not correspond in every case to an actual decrease in food intake.

Disinhibition: The tendency to lose control over food intake in the daily eating pattern. This behavior compels the subject to overeat when food is available, and may therefore represent a factor promoting individual survival in conditions of food shortage.

Binge Eating: An episode represented by the consumption of large amounts of food in a limited period with the clear feeling of loss of control. In anorexia and bulimia nervosa patients this eating behavior is accompanied by purging behaviors such as vomiting or assuming diuretics or laxatives taken to eliminate the excess of calories and to avoid weight gain.

Night eating: The habit of consuming food late in the evening after dinner or when waking at night.

TDBG   Transient declines in blood glucose

60.1 Introduction

Curiosity, interest, and questions about the acquisition, preparation, and presentation of food, the cultural importance of food, appropriate diet and menu selection to promote optimal nutrition, states of hunger and satiety, regulation of body fat, body weight, and energy balance naturally arise in most of us from our daily experiences and contact with food. Among scientists with interests and training in nutrition, physiology, behavior, neuroscience, metabolism, physiological psychology, and/or behavioral neuroscience, many have given at least passing thought and perhaps even a little professional attention and effort to the regulation of feeding behavior. However, a few become so captivated by this complex, multifactorial regulatory system at the interface between "internal" physiology and the "external" world that they then devote their working scientific lives to grappling with these issues. These scientists from many different disciplines continually try to tease out and identify the fundamental facts, the organs, tissue, cells and molecules, the physiological mechanisms, the levels and patterns of organization, and the decision algorithms and rules involved. Their ultimate goal is to provide a deep and complete mechanistic understanding of the regulation of feeding behavior. The subject of this review is our perspective on the current status and, what we believe are, promising future directions of this search for a more complete understanding of the regulation of feeding behavior in laboratory rats and humans. We attempt to provide a new framework for understanding the control of feeding behavior, with special emphasis on the evolution of hunger and the initiation of feeding, including theoretical and experimental components.

60.2 Technological Innovation and a Rebirth for the Role of Blood Glucose in the Control of Meal Initiation

A signal for the initiation of freely taken meals in rats with continuous access to familiar food has been identified: a brief fall and rise in blood glucose concentration before ingestion of food (Fig. 60.1). The identification of this signal was a direct result of a series of technological innovations leading to computer-based continuous monitoring of blood glucose in freely moving rats (Steffens, 1969; Nicolaidis, 1974; Louis-Sylvestre and Le Magnen, 1980; Campfield et al., 1985).

The ability to monitor blood glucose continuously in freely behaving animals, in contrast to discrete blood sampling at fixed 10-, 15-, or 30-min intervals, led to renewed consideration of the role of blood glucose in meal initiation. Transient declines in blood glucose were first described by Louis-Sylvestre and Le Magnen (1980), who showed that a fall in blood glucose was correlated with meal initiation in the rat. They observed that blood glucose concentration declined 6–8% at 5.0 ± 0.3 min before meal onset in both the dark and light phases of the light–dark cycle. Other experimental studies have defined the composite time course of the functional coupling between transient decline in blood glucose and meal initiation that is shown in Fig. 60.1.

We have confirmed and extended these initial findings. We have provided experimental evidence supporting the hypothesis that spontaneous, self-resolving transient declines in blood glucose precede and signal meal initiation in free-feeding rats. This evidence was obtained using online, computer-based technology for continuous monitoring of blood glucose concentration in freely behaving rats. The experimental set-up used in the experimental studies is shown in Fig. 60.2. In nondeprived free-feeding rats, this signal precedes food-seeking behavior and the initiation of a meal but does not predict the size of the meal or the timing of meal termination (Table 60.1).

To evaluate the role of insulin in meal initiation, another series of experiments characterized the time course of plasma insulin concentrations before, during, and after meal initiation. In these and related studies, blood was continuously withdrawn from freely moving male and female Wistar rats at the rate of 25 µL/min and pooled over 4-min intervals. Sampling began at least 40 min. before an
Fig. 60.1 Composite time course of the functional coupling between transient decline in blood glucose and meal initiation. Average time course of blood glucose concentration is expressed as percent change from baseline concentrations. Data are mean values. Estimates of the onset and offset times for the meal initiation signal to be above threshold are indicated by downward and upward arrows, respectively. Table 60.1 Key features of transient declines in blood glucose

1. A signal for the initiation of freely taken meals in rats with continuous access to familiar food has been identified: a brief fall and rise in blood glucose concentration before ingestion of food. The identification of this signal was a direct result of a series of technological innovations leading to computer-based continuous monitoring of blood glucose in freely moving rats.

2. Transient declines in blood glucose were first described by Louis-Sylvestre and Le Magnen in 1980, who showed that a fall in blood glucose was correlated with meal initiation in the rat.

3. A spike of insulin in the plasma, probably vagally mediated, may play a role in the origin of the transient declines in blood glucose that precede meal initiation.

4. Any changes in blood glucose concentration from baseline values are detected by peripheral and central glucose responsive neural elements and recognized by the central neural network that controls feeding behavior.

5. Unless other events interfere with the meal initiation program or the act of feeding, the meal initiation program, when activated, generates all of the motor acts required for expressing meal initiation behavior.

6. If the peripheral metabolic state cannot maintain glucose homeostasis over the next time interval, without additional energy intake from a meal, a transient decline in blood glucose in response to a probe signal will occur. On the other hand, if glucose homeostasis can be maintained over the next time interval without additional energy intake (e.g., liver glycogen breakdown and utilization), a transient decline in blood glucose will not occur.

7. The necessary conditions for a fall and rise in blood glucose concentration in rats to be recognized as a transient decline in blood glucose have been calculated from our experimental data set.

8. The following necessary conditions must be met sequentially by all transient declines in blood glucose that signal meal initiation in rats: (1) the slope of the falling phase must be within -0.4 and -1.5 mg/dL.min; (2) the nadir of the decline must be at least 6% below baseline and must occur between 40% and 60% of the total duration of the decline, and the total duration of the transient decline must be longer than 6 min; and (3) the slope of the rising phase must be within 0.5 and 1.5 mg/dL.min.

9. The goal of this research is not the *pattern* but rather the *patterns* that together form the central representations of meal initiation, maintenance, and termination.

This table lists the key facts of the transient declines in blood glucose that precede and signal meal initiation. Transient decline in blood glucose are a spontaneous, self-resolving pattern of blood glucose concentration that falls and then rises back toward the stable baseline level that precede and signal meal initiation in nondeprived, free-feeding rats. This signal precedes food-seeking behavior and the initiation of a meal but does not predict the size of the meal or the timing of meal termination

anticipated meal and was continued for up to 100 min. Plasma insulin was stable during intermeal intervals, briefly increased by 50%, and then returned to basal levels. The peak of the insulin spike occurred at 26 or 13 min (males and females, respectively) before meal initiation and preceded the transient decline in blood glucose. The plasma insulin concentration in female rats before meal initiation is shown in Fig. 60.3. However, in experiments in which feeding did not occur, plasma insulin remained constant (coefficient of variation 11%) throughout the sampling period. Hepatic vagotomy abolished the insulin spike. Plasma insulin reached its lowest point just before the meal in most experiments, as reported originally by Strubbe et al. (1977). These data suggest that a spike of insulin in the plasma, probably vagally mediated, may play a role in the origin of the transient declines in blood glucose that precede meal initiation (Campfield and Smith, 1990a, b, 1999, 2003; Inoue and Bray 1979; Ritter and Taylor, 1990). However, the presence of the insulin spike is not required for meal initiation.

60.3 The Pattern as Signal Model: Pattern Detection and Recognition Theory of Meal Initiation

Increasing attention has been focused on behavioral sequences or patterns. Well-established orosensory motor patterns have been described by Grill and Norgren (Grill and Norgren, 1978; Norgren, 1983). Also, stereotypic satiety behavioral sequences have been described by GP Smith and co-workers
Fig. 60.3 Plasma insulin and blood glucose concentration profiles before meal initiation in lean female rats. The figure is a composite; the continuous blood sampling for insulin (*top*) and continuous recording of blood glucose (*bottom*) were performed in different experiments. Note the spike in plasma insulin before meal initiation, indicated by the left-hand edge of the rectangle labeled "meal" (From Campfield and Smith, 1986. With permission from Elsevier Science)

(Antin et al., 1975; Gibbs et al., 1973; Smith and Gibbs, 1994). Thus complex motor programs underlying feeding are thought to reside in the central nervous system (CNS), and signals related to body stores or specific molecules may "initiate" or "trigger" them under appropriate circumstances (Stricker, 1990).

The consideration of sequences in which a complex temporal and/or spatial pattern fulfills the role of initiator of these motor programs has emerged as an alternative theoretical construct (Campfield and Smith, 1990a, b, 2003). Thus the temporal pattern of a specific molecule (e.g., transient decline in blood glucose), the pattern of several molecules (e.g., nutrient flux across the intestine), the temporal pattern of a specific molecule in a specific context of other patterns (e.g., insulin before, during, or after a meal; oral signals; or gastric distension) or the spatial pattern caused by the passage of a specific molecule through body compartments (e.g., glucose interacting with multiple glucose receptive neural elements; insulin in the brain and cerebrospinal fluid; leptin from adipocytes to the brain) may act as control signals that the CNS uses to organize feeding behavior. Within this conceptual framework, it is not the store or molecule (neither its concentration nor the absolute amount) but rather the "dynamic pattern" of the molecule that conveys critical "information" to the CNS.

Another key element of the pattern as signal concept is the notion of *representation* of peripheral events and states within the CNS. The CNS may contain "*representations*" or "*maps*" of metabolic and behavioral states: absorptive and postabsorptive states, hunger, and satiety. Although often thought of in terms of spatial maps, transformations, or homunculi, *representation* in this context is considered to be a dynamic pattern of activity in a set of neurons that function as a central analog of sensory somatic or visceral events. Thus, we seek these *representations* of peripheral body stores, the metabolic state, and the external world, and how these *representations* interact to control feeding behavior (Damasio, 2003).

What form would these *representations* take? These *representations* would probably be patterns of electrical and/or neurochemical activity of one or more neural networks controlling feeding. Thus, in this theoretical construct, patterns in the periphery carry information that is detected and recognized by central neural networks, which results in modified patterns of activity of these neural networks. Specific patterns of activity of these networks are postulated to correspond to the behavioral states associated with meal initiation and meal termination. If we could capture a visual image of the patterns of activity of the feeding network before, during, and after a meal, we would see a transition from the pattern characteristic of the intermeal interval to that of meal initiation and food ingestion, followed by a transition back to the pattern corresponding to satiety. Perturbation or shaping of feeding behavior would be then translated into modulation of these complex activity patterns and their integration by the brain.

Since formulating this conceptual framework for feeding behavior in a review published in 1990 (Campfield and Smith, 1990a, b) and expanded in 2003 (Campfield and Smith, 2003), experimental results have confirmed its utility both in terms of explanatory power and an ability to tightly link feeding behavior and physiology. We remain optimistic about its potential to refocus our field on the *message* rather than the *messenger*. This point of view also has the potential to synthesize much of our field because, rather than debating the merits of transient declines in blood glucose, or hypothalamic norepinephrine, or hindbrain CCK, or circulating leptin, or brain insulin, we can ask how all of these components or elements of the pattern are integrated to elicit specific behaviors underlying feeding. This hypothesis is also focused on the detection and recognition of these multiple patterns by the widely distributed neuronal networks controlling feeding. Thus the goal of the search is not the *pattern* but rather the *patterns* that together form the central representations of meal initiation, maintenance, and termination. The integrative focus of this conceptualization has much in common with and is a descendent of earlier integrative approaches of the balance of lipogenesis and lipolysis rates (Le Magnen, 1980, 1985, 1992; Kennedy, 1953), combining energy flux in the plasma

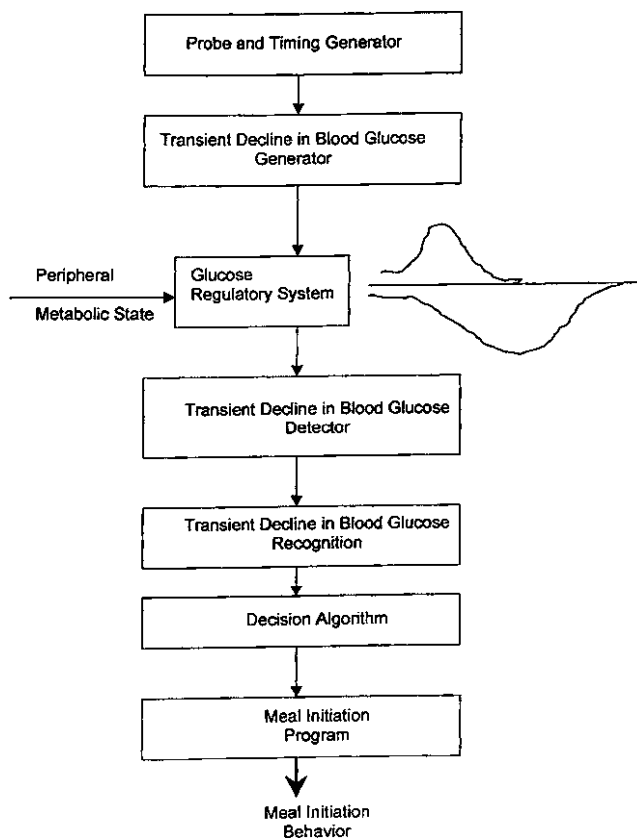
(Booth, 1968, 1978) and neurons that integrate specific molecular signals (Nicolaidis, 1974; Nicolaidis and Even, 1984; Stricker, 1990). However, this concept has an even broader focus on the totality of central representations of peripheral events related to feeding (e.g., glucose concentrations (Niijima, 1983)). Finally, the ability of the "pattern as signal" construct to integrate the dynamics of blood glucose before, during, and after meals into one or more important messages related to feeding behavior suggests that a similar focus on the patterns of insulin, leptin, and CCK rather than a focus on the location or concentration of these hormones may also yield important insights.

The experimental studies presented and reviewed in our previous publications (Campfield et al., 1985, 1996; Campfield and Smith, 1986, 1990a, b, 2003; Smith and Campfield, 1993) have led to the formulation of a signal detection and recognition theory of meal initiation. The major assertions of this theory are that: (1) transient declines in blood glucose represent "endogenous metabolic patterns," (2) transient declines in blood glucose are signals in the form of "patterns" that are detected and recognized by the central neural network that controls feeding behavior, and (3) these patterns are "mapped into" meal initiation under free-feeding conditions. The phrase *mapped into meal initiation* is meant to describe the process of transformation, in the mathematical sense, or establishing a unique correspondence between the recognition of the transient decline in blood glucose and the activation of the motor program for feeding within the CNS.

The distinguishing feature of this assertion is that it is the temporal pattern, shape, or waveform of blood glucose dynamics rather than the glucose molecule, or the absolute decrease in blood glucose, or blood glucose concentration, or glucose utilization that is detected and contains "critical information" that is extracted by the central nervous system to control meal initiation.

We propose that the processes of detection and recognition of a transient decline in blood glucose, and its mapping into meal initiation behavior are accomplished by the set of spatially and temporally distributed processes shown in Fig. 60.4. Meal initiation will occur only if a "timing or probe signal" was generated recently and a transient decline in blood glucose is detected in the brain and recognized. Figure 60.4 depicts the information and signal flow through the set of sequential processes without regard to the anatomical localization of the process. The "timing or probe signal" represents an "inquiry" or "interrogation" or "probing" of the periphery by the CNS regarding its ability and capacity to maintain glucose homeostasis in upcoming time interval. This signal is generated by a signal generator (in the CNS) that controls its frequency or timing. The signal acts on the biochemical subsystem that regulates blood glucose concentration and, depending on the peripheral metabolic state and its ability and capacity to "maintain glucose homeostasis" over the next time interval, a transient decline in blood glucose (TDBG) will be generated or not. An averaged transient decline in blood glucose is shown in Fig. 60.1.

Any changes in blood glucose concentration from baseline values are detected by peripheral and central glucose responsive neural elements, which form the "TDBG detector" process shown in Fig. 60.4. The recognition of the presence of a transient decline in blood glucose that meets all the necessary criteria from among the many changes in blood glucose concentration occurring in the peripheral blood is reported by the TDBG recognition process. This process is located in both the CNS and the periphery, and its output acts on the "decision algorithm" process. The decision algorithm unit computes the conditional probability of activating the stored meal initiation program given the state of the three inputs it receives: (1) output from the TDBG recognition process, the recognition of TDBG; (2) peripheral metabolic state; and (3) presence of a recent "probe or timing signal." If a transient decline in blood glucose is recognized in the presence of a favorable peripheral metabolic state along with the recognition of recent generation of the "probe of timing" signal, then the output of the decision algorithm will be "yes" and the meal initiation program will be activated. By a "favorable metabolic state" we mean the later part of the intermeal interval, which would allow a transient decline in blood glucose in response to the probe or timing signal. The transient decline in blood

Fig. 60.4 Proposed information and signal flow in the pattern detection and recognition model of meal initiation. The information flow chart is shown without regard for the anatomic location of each process. The process of meal initiation begins with the generation of a "probe or timing signal" within the brain, continues as this signal "passes through" the peripheral metabolic system acting on the blood glucose regulatory system, and ends with an affirmative decision to activate the "meal initiation program." The blood glucose regulatory system generates an insulin spike and a transient decline in blood glucose (represented by the sketch; *middle*). See text for details (From Campfield and Smith, 2003. With permission from American Physiological Society)


glucose will indicate that additional energy intake from a meal may be required to maintain blood glucose over the coming time interval (see below). An "unfavorable" metabolic state would be just after a meal. Unless other events interfere with the meal initiation program or the act of feeding, the meal initiation program, when activated, generates all of the motor acts required for expressing meal initiation behavior (Campfield and Smith, 2003).

Our current working hypothesis is as follows. In free-feeding rats, we have shown that there are brief, spontaneous plasma insulin peaks antecedent to each decline in blood glucose (Campfield and Smith, 1990a, b, 2003). We postulate that a "probe or timing signal" generated by the CNS results in a brief change in the firing rate of the parasympathetic (vagal) and/or sympathetic nervous system efferents that innervate pancreatic B-cells, liver, adipose tissue, and the gastrointestinal tract. The change in autonomic firing rate causes a brief insulin spike from pancreatic B-cells, along with other responses, which, in the presence of an appropriate peripheral metabolic state, induces a transient decline in blood glucose by decreasing hepatic glucose production and/or increasing peripheral glucose disposal. In the presence of sustained hyperglycemia, the brief insulin spike, along with other responses, may have to be larger in magnitude to induce a transient decline in blood glucose. The peripheral metabolic state is postulated to "condition," in a probabilistic sense, or "gate," in a signal flow sense, the likelihood of a feeding response to the activation of vagal and/or sympathetic efferents. Thus, a central/peripheral interaction is proposed in which a centrally generated meal initiation signal must "pass through" the peripheral metabolic system, and it will be mapped into feeding behavior only if a transient decline in blood glucose of the correct shape or pattern occurs in response to a recent probe signal.

If the output of the decision algorithm remains in the "no" state, either because of the absence of a transient decline in blood glucose or the failure of a decline to meet all the criteria for meal initiation or failure of recognition, or an unfavorable peripheral metabolic state (e.g., recent meal), the TDBG recognition unit will be reset to the "no decline" state. If the peripheral metabolic state cannot maintain glucose homeostasis over the next time interval, without additional energy intake from a meal, a transient decline in blood glucose in response to a probe signal will occur. On the other hand, if glucose homeostasis can be maintained over the next time interval without additional energy intake (e.g., liver glycogen breakdown and utilization), a transient decline in blood glucose will not occur. However, if a transient decline in blood glucose occurs but is ignored and no food is eaten, the only consequence may be the occurrence of the next transient decline in blood glucose sooner than expected. In this case, blood glucose may be maintained through novel involvement or activity of the liver or other organs.

The model assumes that some "probe or timing signals" will not result in transient declines in blood glucose and, therefore, meal initiation will not be observed. Therefore, a prediction of our model is that the number of probe or timing signals should be greater than the number of meals.

The processes of *detection* and *recognition* are considered distinct in our formulation because we interpret our experimental results to mean that the minute-by-minute blood glucose concentration is detected by glucose responsive peripheral afferents and central neurons. Thus blood glucose is continuously represented and always available to the CNS. The process of *detection* begins with a representation of the relatively steady intermeal concentration of blood glucose ("baseline") and "reports" the detection of all departures in blood glucose concentration from that baseline to the TDBG recognition unit. In contrast, the unique process of *recognition* that an ongoing pattern of blood glucose concentration "matches" or "fits" the criteria for a transient decline in blood glucose is the function of the TDBG recognition unit. Thus the *recognition* of a transient decline in blood glucose is the result of a two-step process: (1) detection that the blood glucose concentration is changing and (2) the recognition that the pattern of the blood glucose change meets the criteria for transient declines in blood glucose. Another way of looking at the function of these two processes is that the *TDBG recognition unit* must recognize the shape or pattern of transient declines, but only transient declines, out of the set of all other changes in blood glucose concentration detected throughout the day.

The necessary conditions for a fall and rise in blood glucose concentration in rats to be recognized as a transient decline in blood glucose have also been calculated from our experimental data set. The following necessary conditions must be met sequentially by all transient declines in blood glucose that signal meal initiation in rats: (1) the slope of the falling phase must be within -0.4 and -1.5 mg/dL.min; (2) the nadir of the decline must be at least 6% below baseline and must occur between 40% and 60% of the total duration of the decline, and the total duration of the transient decline must be longer than 6 min; and (3) the slope of the rising phase must be within 0.5 and 1.5 mg/dL.min.

These necessary conditions, which specify an approximately symmetrical fall and rise in glucose concentration, shown in Fig.60.1, provide a first-order approximation of the criteria for recognition of a transient decline in blood glucose by the TDBG recognition unit in our model. The conditions required for a "yes" output of the decision algorithm and activation of the meal initiation program are proposed to be as follows: the recognition of a transient decline in blood glucose that was generated by a receptive or favorable peripheral metabolic state in response to the "recent" generation of a probe or timing signal by the CNS. As discussed above, if the output of the decision algorithm remains in the "no" state, because these criteria were not met, the TDBG recognition unit will be reset to the "no" decline state.

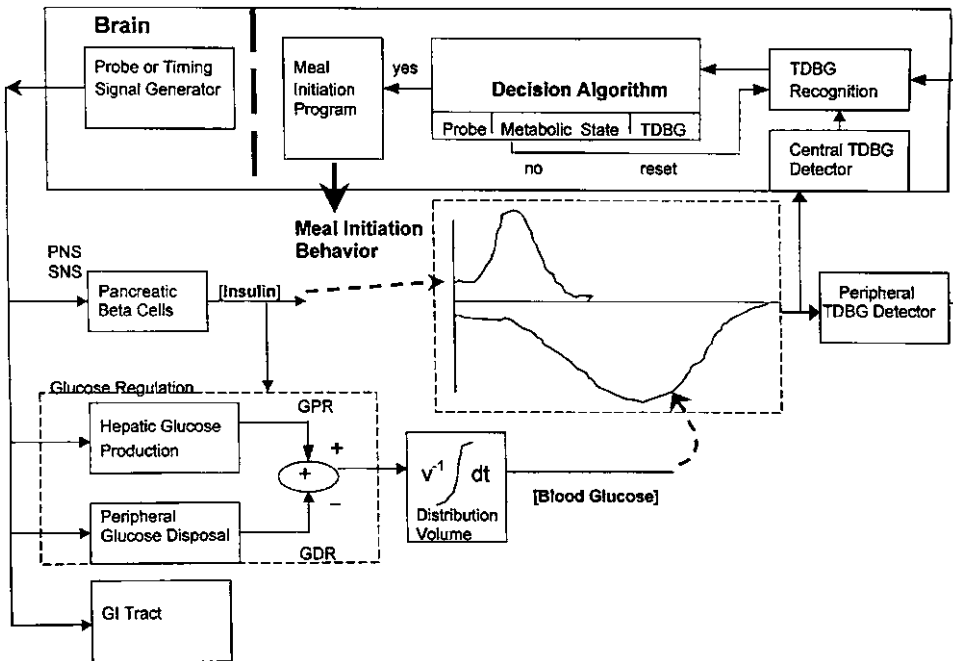
The conceptual basis and a basic structure of our working hypothesis are represented in our working model shown in Fig.60.5. Many aspects of the model remain to be determined in quantitative


Fig. 60.5 Block diagram representation of the information and signal flow in our conceptual model of the pattern detection and recognition theory of meal initiation. A "probe or timing signal" is generated within the brain (*top left*) and causes a brief change in firing rate of the parasympathetic (PNS) and/or sympathetic (SNS) afferents which innervate pancreatic B-cells, glucose regulatory system, and gastrointestinal (GI) tract (*middle* and *bottom left*). If additional energy (a meal) is needed to maintain glucose homeostasis over the next time interval, the probe signal (e.g., insulin spike) will "pass through" the peripheral metabolic system acting on the blood glucose regulatory system and generate a transient decline in blood glucose (represented by the sketch; *middle*). Changes in blood glucose concentration will be detected by peripheral and central glucose responsive neural elements (*middle* and *top right*) and then the transient decline in blood glucose is "recognized" in the brain (*top right*). If the criteria of the decision algorithm (*top*) are satisfied (transient decline recognized, favorable peripheral metabolic state, recent probe signal), the "meal initiation program" will be activated and meal initiation behavior will be observed (*top left*). If the decision criteria are not satisfied, the "recognition" unit will be reset and meal initiation will not be observed until the next transient decline in blood glucose occurs. *TDBG* transient decline in blood glucose, *GPR* glucose production rate, *GDR* glucose disposal rate, *probe* Probe signal (see text), *Metabolic State* Peripheral metabolic state, v Effective blood volume through which glucose is distributed (From Campfield and Smith, 2003. With permission from American Physiological Society)

terms. This model, and the hypotheses on which it is based, provide a new framework for the understanding of feeding behavior, with special emphasis on the evolution of hunger, the initiation of feeding and its dependence on patterns of blood glucose.

60.4 Physiological and Behavioral Studies of Transient Declines in Blood Glucose as a Signal for Meal Requests and Increased Hunger Ratings: Studies in Humans

The purpose of our human studies was to examine the hypothesis that hunger and meal initiation in humans could be related directly to patterns of blood glucose. Our specific objective was to answer the following questions: (1) Do transient declines in blood glucose concentration occur in human

subjects? (2) If so, do they precede changes in hunger ratings and meal requests? A major limitation of the previous human experiments on the role of blood glucose in hunger has been the necessity of discrete blood sampling on experimenter-determined schedules (Stunkard et al., 1955; VanItallie et al., 1953; VanItallie and Hashim, 1960; Pollack et al., 1989; VanItallie, 1990; Campfield and Smith, 2003).

Each of 18 healthy adults (nine males and nine females) was housed individually in a room isolated from time cues the night before and during the study at the Clinical Research Center of The Rockefeller University Hospital. They were informed that blood glucose and other biorhythms including hunger and thirst would be monitored. Following an overnight fast, a double-lumen cannula for blood withdrawal was placed in the antecubital vein; blood and heparin mixture was withdrawn at a rate of 55 μL/min (blood withdrawal rate ~25 μL/min), and blood glucose concentration was monitored over a 2–6-h period. Breakfast was not served. Subjects controlled the room lighting and rested, slept, read, or wrote during the experiment. Visual analog ratings of internal state including hunger and satiety were completed approximately twice each hour using a quasi-random schedule when the subjects were not asleep. Subjects could request a meal at any time but were not required to do so. A verbal (spoken) request was required to obtain a meal. The experiment ended when the meal was presented to the subject. The methodology utilized in these studies is described in more detail elsewhere (Campfield et al., 1996).

The average time course of blood glucose concentration during the experiment is shown in Fig.60.6a. Overall, in 83% of the 18 subjects, both changes in hunger ratings and spoken meal requests were preceded by, and significantly correlated with, spontaneous, brief transient declines in blood glucose (nadir: ~ -10% below baseline at 27 min). The recordings of blood glucose concentration during the experiment for two subjects are shown in Fig.60.6b and c. The pattern, magnitude, and time course of these declines was similar to those observed in rats (Campfield et al., 1996).

The significant association between increased expression of hunger and transient declines in blood glucose observed was tested in a second study in which insulin infusions were used to induce transient declines in blood glucose that mimicked the spontaneous transient declines observed before meal requests. Subjects were admitted to a metabolic research room isolated from food and time cues in the Clinical Research Center of The Rockefeller University Hospital where they remained for 3 days. Each subject was studied twice. After an overnight fast, cannulas for blood withdrawal and intravenous infusion were placed in the subject's veins, blood glucose concentration was monitored, and visual-analog hunger ratings were obtained over a 2–4-h period. Breakfast was not served. After a stable blood glucose baseline was obtained, a sterile solution of either saline or insulin (5 mU/kg) was injected intravenously in <2 min. Hunger ratings were obtained up to four times an hour. This dose of insulin was selected based on pilot studies in other healthy subjects. Two days later, the experiment was repeated and the other solution (either insulin or saline) was infused.

Combining the results in five subjects indicates that hunger ratings increased (mean delta -22 ± 5 mm) after insulin-induced transient declines in blood glucose concentrations (nadir ~ -11% at 38 min). These results support and strengthen the conclusion that the transient decline in blood glucose represents a temporal pattern that reflects an antecedent physiological event or provides a signal related to the expression of hunger in humans. These results are consistent with many reports in the literature of hunger after insulin administration (Campfield and Smith, 2003).

Fig. 60.6 (continued) were 83.3 ± 3 mg/dL. (**b**) and (**c**) Examples of temporal evolution of blood glucose concentration before meal requests in two subjects. Blood glucose concentration is shown on the ordinate and is expressed as mg/dL. The abscissa is time in minutes. Spoken meal requests are indicated by the dotted *arrow* (From Campfield et al. 1996. With permission from Elsevier Science)

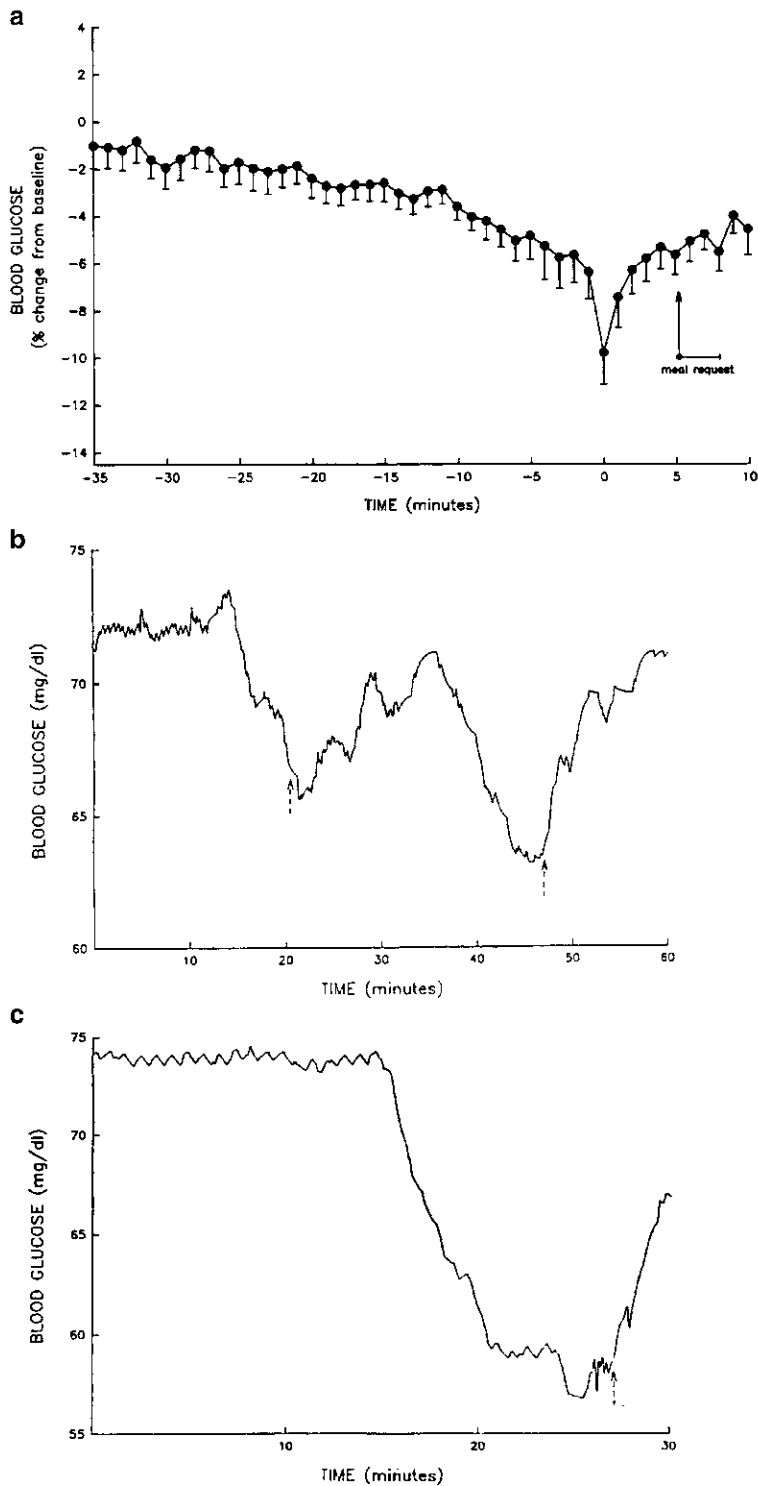
BLOOD GLUCOSE DYNAMICS PRIOR TO MEAL REQUEST IN HUMAN SUBJECTS


Fig. 60.6 (a) Average time course of the transient decline in blood glucose in time-isolated humans. Blood glucose concentrations are expressed as percent change from the baseline concentration in this figure. The minimum glucose concentration has been taken as the *time 0* reference. Data were selected each minute from the reference point and averaged in each of 18 experiments. Data are means ± SEM. The meal request is indicated by the vertical *arrow*. Mean baseline glucose concentrations

These combined behavioral and metabolic experiments answer both of the specific questions we posed in the affirmative under these experimental conditions. These experiments, using continuous, online monitoring and visual analog ratings of hunger, have demonstrated an association between transient declines in blood glucose concentration and meal requests and changes in hunger ratings in human subjects isolated from food and time cues. This association was observed following both spontaneous and insulin-induced transient declines in blood glucose. Most of the deviations in blood glucose observed closely resemble the patterns of blood glucose dynamics shown to precede and signal meal initiation in rats (Campfield et al., 1985; Campfield and Smith, 1986, 1990a, b, 2003; Smith and Campfield, 1993). This suggests that, at least under these experimental conditions, a signal for hunger in humans is associated with transient declines in blood glucose that is similar to that observed in rats.

These results are consistent with some, but not all, previous studies of the relationship of blood glucose and human hunger (Bernstein and Grossman, 1956; Hervey 1971, 1988; Stunkard et al., 1955; VanItallie, 1990, VanItallie et al., 1953; VanItallie and Hashim, 1960). A retrospective analysis of blood samples collected at random intervals averaging 20 min before and after lunch from seven subjects living in time isolation for several days was conducted (Pollack et al., 1989). This study failed to demonstrate a significant deviation in plasma glucose concentration before meal requests. This failure in the absence of continuous monitoring of blood glucose, based on discretely measured and mathematically interpolated plasma glucose levels, does not imply that no such correlation exists and does not invalidate the extension of the hypothesis, supported by these results summarized here, that blood glucose dynamics play a role in the onset of human hunger.

Although there is evidence, reviewed above, supporting the proposition that the transient decline in blood glucose is causally related to meal initiation in rats and meal request in humans, the "true" signal for meal initiation may be (1) an "originating event," neuronal and/or biochemical, that causes the transient decline in blood glucose concentration; (2) the "transient decline in blood glucose concentration"; (3) a covarying "metabolic and/or neural signal"; or (4) an "event," neuronal and/or biochemical, "in response" to the transient decline in blood glucose concentration. The determination of which of these alternatives is correct will require further research on meal initiation. Nevertheless, the studies reviewed here strongly suggest that transient declines in blood glucose (1) represent an "endogenous signal" for meal initiation; (2) their detection and mapping into meal initiation can be viewed as a "pattern detection and recognition problem"; (3) may be useful "probes," or experimental interventions, to elucidate the operation, nature, and decision algorithms of the widely distributed neural network that controls meal taking and, thus, feeding behavior; and (4) play an important role in the regulation of individual meals and by interacting with longer-term regulatory systems, such as the brain insulin system (Woods and Nolan, 1997; Woods et al., 1998), or the leptin pathway (Campfield and Smith, 1990a, b, 1999, 2003; Campfield et al., 1995; Woods et al., 1998; Zhang et al., 1994), also may play an important role in the regulation of body energy storage.

60.5 Implications

The identification of a potential signal for meal initiation imbedded in blood glucose dynamics is significant because it provides a biological basis, and, thus, additional justification, for the continued experimental study of feeding behavior in humans in both the laboratory and metabolic ward. This finding, therefore, gives added confidence to the investigation of metabolism and biochemistry as related to human feeding behavior. The existence of a biochemical and physiological signal for hunger and meal requests in humans argues strongly for renewed interest in the experimental study of

hunger and the development of biologically based strategies for the reshaping of disordered feeding behavior. This new research may provide important information about the interaction and relative importance among the several factors in the decision-making process that ultimately leads to the perception and behavioral expression of hunger in humans. These results may provide a biological foundation for a more complete and complex understanding of human feeding behavior that should emerge from future, biologically based behavioral research. It is also hoped that this increased understanding will allow more precise diagnosis of disordered feeding and improved and more efficacious treatment of these devastating conditions.

On a more speculative note, transient declines in blood glucose may also play a role in the behavioral and metabolic adaptation or "learning" that occurs following alterations in food availability and lighting schedules, food and diet options, cost of working for food, as well as the conditioned feeding situation. Studies of rats working for food and in conditioned feeding suggest such a role (Campfield and Smith, 2003; Weingarten and Martin, 1989), but additional studies will be required to fully explore this possibility.

Is the "pattern as signal" conceptualization advocated here simply a complementary theoretical construct to the other more established concepts in the control of feeding or is it a competing, alternative notion with more explanatory power? The ultimate ability of this construct to explain adequately meal initiation and/or the intermeal interval or other aspects of feeding behavior remains to be determined by further research. However, the successful extension of this paradigm in the last 2 decades to additional animal models of disordered feeding (e.g., experimentally diabetic and genetically obese rats) and the successful extension to the domain of human meal requests and changes in hunger ratings demonstrate the explanatory power, the applicability of a general theoretical construct from rats to humans, and provide increased confidence in this approach. These patterns of blood glucose and plasma insulin concentration in rats and humans must be subjected to further and more rigorous experimental tests and additional patterns have to be identified and tested. The impressive successes of this approach suggest to the authors that its application to the numerous disparate and competing findings in feeding research may provide insight and, possibly, facilitate the development of a more complete understanding.

60.6 Final Thoughts

Has the description and appreciation of the pattern of blood glucose concentration that precedes and signals meal initiation in rats and meal requests in humans led us to a new conceptual "world view" and established the "pattern as signal paradigm" for future consideration of the problem of the regulation of feeding behavior? Alternatively, has the path we followed to our current formulation just led us full circle back to a more complex, but not substantially different, formulation of Mayer's glucostatic hypothesis? (Mayer, 1953, 1955; Campfield and Smith, 2003) The answer to these questions is both yes and no. Mayer's original proposal was consistent with the state of knowledge regarding the regulation of metabolism with its emphasis on tissues utilization of metabolic substrates in the early 1950s. During this period of rapid growth of metabolic biochemistry, the mechanistic details of the utilization of these substrates or "fuels" in newly emerging metabolic pathways in the peripheral tissues were being described. Yet Mayer made the insightful and essential link between peripheral metabolism, brain metabolism, and the regulation of feeding behavior and body energy balance by defining as critical the *rate of glucose utilization in an undefined brain region*. Our current theoretical formulation still contains as a critical element the peripheral and central detection and recognition of not the utilization of glucose but rather the pattern of blood glucose concentration.

Yet it makes a much more explicit and dynamic statement about the shape of transient declines in peripheral blood glucose that are required to initiate spontaneous feeding behavior in rats or the perception of hunger in humans. We have now defined the precise antecedent conditions required, in terms of the shape of the transient declines in blood glucose, for meal initiation or meal requests. Although the precise pattern required to be detected and recognized by the central and peripheral nervous system has been specified, the neural mechanisms that underlie this detection and the algorithms used to perform this pattern recognition and map this pattern into the initiation of feeding or meal requests remain to be elucidated by future research. In our formulation we have specifically defined the "what," the transient decline in blood glucose, which signals a transition in the prevailing behavioral state to meal initiation, but leaves the "how," the origin of the transient decline in blood glucose and its detection, as a theoretical construct. This situation is in marked contrast to the glucostatic theory, in which both the signals responsible for organizing feeding behavior (what) and the origin and the detection of those signals (how) were only vaguely, at best, specified. Whether this theoretical construct will serve the same important role as an organizing principle and have same positive impact on the focus, direction, productivity, and increased understanding as Mayer's glucostatic hypothesis based on glucose utilization remains to be seen as the future of our field emerges.

We hope that the unraveling and identification of the mechanisms responsible for the origins and the detection of transient declines in blood glucose will be a focus of the feeding research in the coming years. However, this search will only be a special case of the more general and, in our opinion, the most critical and important problem in our field: the central and peripheral integration of both peripherally and centrally generated signals into the exquisite and elegant regulation of feeding behavior and body energy balance. If the theoretical concept presented here proves to be helpful in resolving this essential problem and continues to be useful in thinking about feeding behavior and its physiological bases, then a small change in blood glucose will have indeed had a large effect on behavior.

60.7 Applications to Other Areas of Health and Disease

A more complete understanding of the control of feeding behavior, with special emphasis on the evolution of hunger and the initiation of feeding, will have direct applications to the understanding and, hopefully, the treatment of eating disorders: anorexia, bulimia, binge eating, and night eating, as well as the epidemic metabolic diseases – obesity, type 2 diabetes, and metabolic syndrome. In addition, this conceptual framework may provide a deeper understanding of both normal and disordered metabolic regulation. Successful extension of this paradigm in the last 2 decades to additional animal models of disordered feeding (e.g., experimentally diabetic and genetically obese rats) and the successful extension to the domain of human meal requests and changes in hunger ratings demonstrate the explanatory power, the applicability of a general theoretical construct from rats to humans, and provide increased confidence in this approach.

Secondly, the experimental study of hunger may lead to the development of biologically based strategies for the reshaping of disordered feeding behavior. This research may provide important information about the interaction and relative importance among the several factors (learning, memory, past experiences, emotions, feelings) in the decision-making process that ultimately leads to the perception and behavioral expression of hunger in humans.

Finally, transient declines in blood glucose may also play a role in the behavioral and metabolic adaptation or "learning" that occurs following alterations in food availability and lighting schedules, food and diet options, cost of working for food, as well as the conditioned feeding situation. Studies

of rats working for food and in conditioned feeding suggest such a role, but additional studies will be required to fully explore this possibility. This research may have application to a better understanding of adaptation to crossing time zones and shift work.

Summary Points

- This chapter provides a new framework for understanding the control of feeding behavior, with special emphasis on the evolution of hunger and the initiation of feeding, including theoretical and experimental components.
- Experimental evidence supports the hypothesis that spontaneous, self-resolving transient declines in blood glucose precede and signal meal initiation in nondeprived, free-feeding rats. This signal precedes food-seeking behavior and the initiation of a meal but does not predict the size of the meal or the timing of meal termination.
- The precise antecedent conditions required, in terms of the shape of the transient declines in blood glucose, for meal initiation or meal requests have been defined.
- In the signal detection and recognition theory of meal initiation, patterns in the periphery carry information that is detected and recognized by central neural networks. These specific patterns of activity are postulated to correspond to the behavioral states associated with meal initiation and meal termination.
- The major assertions of the theory are that: (1) transient declines in blood glucose represent "endogenous metabolic patterns," (2) transient declines in blood glucose are signals in the form of "patterns" that are detected and recognized by the central neural network that controls feeding behavior, and (3) these patterns are "mapped into" meal initiation under free-feeding conditions.
- The distinguishing feature of the theory is that it is the temporal pattern, shape, or waveform of blood glucose dynamics rather than the glucose molecule, or the absolute decrease in blood glucose, or blood glucose concentration or glucose utilization that is detected and contains "critical information" that is extracted by the central nervous system to control meal initiation.
- If a transient decline in blood glucose is recognized in the presence of a favorable peripheral metabolic state and the recognition of recent generation of the "probe or timing" signal, then the output of the decision algorithm will be "yes" and the meal initiation program will be activated.
- If the peripheral metabolic state cannot maintain glucose homeostasis over the next time interval, without additional energy intake from a meal, a transient decline in blood glucose in response to a probe signal will occur. On the other hand, if glucose homeostasis can be maintained over the next time interval without additional energy intake (e.g., liver glycogen breakdown and utilization), a transient decline in blood glucose will not occur.
- Experimental results have confirmed its utility both in terms of explanatory power and an ability to tightly link feeding behavior and physiology.
- This model, and the hypotheses on which it is based, provide a new framework for the understanding of feeding behavior, with special emphasis on the evolution of hunger, the initiation of feeding and its dependence on patterns of blood glucose.
- An association between transient declines in blood glucose concentration and meal requests and changes in hunger ratings in human subjects isolated from food and time cues has been demonstrated. This association was observed following both spontaneous and insulin-induced transient declines in blood glucose. Most of the deviations in blood glucose observed closely resemble the patterns of blood glucose dynamics shown to precede and signal meal initiation in rats.

- These results support and strengthen the conclusion that the transient decline in blood glucose represents a temporal pattern that reflects an antecedent physiological event or provides a signal related to the expression of hunger in humans.
- This suggests that, at least under these experimental conditions, a signal for hunger in humans is associated with transient declines in blood glucose that is similar to that observed in rats.
- Studies reviewed here strongly suggest that transient declines in blood glucose: (1) represent an "endogenous signal" for meal initiation; (2) their detection and mapping into meal initiation can be viewed as a "pattern detection and recognition problem"; (3) may be useful "probes," or experimental interventions, to elucidate the operation, nature, and decision algorithms of the widely distributed neural network that controls meal taking and, thus, feeding behavior; and (4) play an important role in the regulation of individual meals and by interacting with longer-term regulatory systems, such as the brain insulin system or the leptin pathway, also may play an important role in the regulation of body energy storage.
- Successful extension of this paradigm in the last 2 decades to additional animal models of disordered feeding (e.g., experimentally diabetic and genetically obese rats) and the successful extension to the domain of human meal requests and changes in hunger ratings demonstrate the explanatory power, the applicability of a general theoretical construct from rats to humans, and provide increased confidence in this approach.

Definitions of Key Terms

Meal initiation: Meal onset – the transition from the intermeal interval (with no feeding behavior) to the beginning of feeding (meal) resulting from the activation of the motor program for feeding within the CNS.

Transient decline in blood glucose: A spontaneous, self-resolving pattern of blood glucose concentration that falls (approximately 10% below baseline) and then rises back toward the stable baseline level that precede and signal meal initiation in nondeprived, free-feeding rats. This signal precedes food-seeking behavior and the initiation of a meal but does not predict the size of the meal or the timing of meal termination.

Representation: Construction of "analogs", "surrogates" or "maps" of metabolic and behavioral states within the CNS: absorptive and postabsorptive states, hunger (meal initiation, maintenance and termination), and satiety. Both peripheral and central components are included in the maps.

Central representation of peripheral events: Representation of peripheral blood glucose, plasma insulin or plasma leptin concentrations or other metabolic events within the CNS.

Pattern as signal model/construct: A theory which is distinguished by the assertion that it is the temporal pattern, shape, or waveform of blood glucose dynamics rather than the glucose molecule, or the absolute decrease in blood glucose, or blood glucose concentration or glucose utilization that is detected and contains "critical information" that is extracted by the central nervous system to control meal initiation.

Signal detection and recognition theory of meal initiation: Specific patterns of blood glucose concentration in the periphery carry information that is detected and recognized by central neural networks. These specific patterns of activity are postulated to correspond to the behavioral states associated with meal initiation and meal termination.

Mapped into meal initiation: Description of the process of transformation, in the mathematical sense, or establishing a unique correspondence between the recognition of the transient decline in blood glucose and the activation of the motor program for feeding within the CNS (meal initiation).

Timing or probe signal: Representation of an "inquiry" or "interrogation" or "perturbation" of the periphery by the CNS to determine its ability and capacity to maintain glucose homeostasis in upcoming time interval. This signal is generated by a signal generator (in the CNS) that controls its frequency or timing.

Favorable metabolic state: The later part of the intermeal interval, which would allow a transient decline in blood glucose in response to the probe or timing signal.

Parasympathetic and sympathetic NS: Firing rate of the parasympathetic (vagal) and/or sympathetic nervous system efferents which innervate pancreatic B-cells, liver, adipose tissue, and the gastrointestinal tract. The change in autonomic firing rate causes a brief insulin spike from pancreatic B-cells, along with other responses, which, in the presence of an appropriate peripheral metabolic state, induces a transient decline in blood glucose by decreasing hepatic glucose production and/or increasing peripheral glucose disposal.

Pass through: A centrally generated meal initiation timing or probe signal is applied to the peripheral metabolic system. Depending on the response of the peripheral metabolic system, it may result in the onset of feeding; it will be mapped into feeding behavior only if a transient decline in blood glucose of the correct shape or pattern occurs in response to a recent probe signal.

Detection: The process of detection begins with a representation of the relatively steady intermeal concentration of blood glucose ("baseline") and "reports" the detection of all departures in blood glucose concentration from that baseline.

Recognition: A unique process of determining that an ongoing pattern of blood glucose concentration "matches" or "fits" the criteria for a transient decline in blood glucose.

TDBG detection process: Any changes in the patterns of blood glucose concentration from baseline values are detected by peripheral and central glucose responsive neural elements.

TDBG recognition process: A unique process of determining that an ongoing pattern of blood glucose concentration "matches" or "fits" the criteria for a transient decline in blood glucose.

Decision algorithm: The decision algorithm unit computes the conditional probability of activating the stored meal initiation program given the state of the three inputs it receives: (1) output from the TDBG recognition process, the recognition of TDBG; (2) peripheral metabolic state; and (3) presence of a recent "probe or timing signal."

Vagotomy, hepatic: Complete surgical cutting of the vagus nerve that innervates the liver.

Coefficient of variation: A measure of the variation of a mean; CV = SD/mean.

Chapter 61
Dynamics of Feeding Behavior: Role of Hypothalamic and Satiety Signals

B.S. Zanutto and J.E.R. Staddon

Abbreviations

NTS	Nucleus tractus solitarius
SSs	Satiety signals
CCK	Cholecystokinin
PYY	Peptide YY
Set Point$_{ST}$	Set point for short-term regulation
Set Point$_{LT}$	Set point for long-term regulation
PVN	Paraventricular nucleus
LHA	Lateral hypothalamic
$x(t)$	The satiation value
Φ	Satiation value of a specific food
θ	Threshold value equal to Set Point$_{ST}$
SS	Output of a cascaded series of leaky integrators
i	Number of integrator
V_i	State of integrator i
a_i	Time parameter of integrator i ($0 < a_i < 1$)
b_i	Input weight
PIM	Post-interruption meal
IMI	Intermeal interval
CINT	Cascaded INTegrator

61.1 Introduction

Animals do not feed at random. Even grazers, like whales and cattle, who must ingest low-energy-density food for many hours each day, tend to prefer to eat at certain times. Omnivores such as rats, cats, dogs – and humans – whose food has more energy, eat in *meals*, relatively short bouts of concentrated eating that are approximately periodic and separated by intervals when the animal either rests or does other things. Meal patterns are affected by external factors such as taste (the evolutionary predictor of food quality) learning, social situation, stress and emotion, and many others, and the way that these variables interact is complex and not fully understood.

For many years, beginning perhaps with Le Magnen (1985), repletion–depletion has been implicitly assumed to be the process that underlies feeding behavior. This approach has led to numerous attempts to identify the physiological signal that triggers eating (Campfield and Smith 2003; Zorrilla et al. 2005), an essential ingredient of any homeostatic model. Unfortunately, as research progressed, the number of candidate trigger signals increased to the point that a homeostatic model seemed to be unworkable. But recent behavioral data from our laboratory and others (Staddon and Zanutto 1997; Staddon 2001; Zanutto and Staddon 2007) has shown that the effects of eating interruption on meal patterns in rats can be accounted for by a relatively straightforward feedback model that is consistent with neurophysiological data. Describing this model and its relationship to current physiological understanding is the topic of this chapter.

61.2 Signals for Satiety and Long-Term Weight Regulation

Endogenous factors that modify the size of an ongoing meal are called satiety signals (SSs). For example, cholecystokinin (CCK), generated during and after a meal, provides information to the brain that inhibits feeding and leads to meal termination. SSs are generated in the gastrointestinal tract and abdominal viscera, as well as in the mouth (taste factors: Travers and Norgren 1987; Ritter et al. 1994). They provide information about mechanical (e.g., stomach stretch, volume) and chemical properties of food (e.g., via peptides such as cholecystokinin (CCK), ghrelin, and peptide YY (PYY)), that have been linked to short-term (within-a-day) feeding behaviors. Amylin (Chance et al. 1991) and glucagon (Geary 1998), secreted from the pancreatic islets during meals, reduce meal size. SSs are relayed to the hindbrain, mainly to the nucleus tractus solitarius (NTS), either indirectly via nerves from the gastrointestinal tract, especially the vagus (e.g., CCK and glucagon), or else circulate via the blood and interact with local receptors in the hindbrain (e.g., amylin) (Woods 2004).

The hindbrain (mainly the NTS), via several hypothalamic nuclei, also receives signals that are influenced by the fat mass of the body. The best-known adiposity signals are the hormones leptin and insulin. The amount of leptin secreted from fat cells (adipocytes) is directly related to the amount of stored fat (Havel et al. 1996; Ahren et al. 1997). Insulin is secreted from pancreatic ß cells in response to increases in glucose. Moreover, basal insulin in the absence of elevated glucose is directly related to total body fat (Bagdade et al. 1967; Polonsky et al. 1988). Obese individuals have high basal insulin, whereas lean individuals have relatively low levels. Thus, circulating leptin and insulin levels are each a good indicator of body fat, and both hormones are able to enter the brain from the blood and stimulate specific neural receptors. These two adiposity signals (leptin especially) have been linked to longer-term weight regulation (over months and years) (Marx 2003).

Some gut-related peptides are also long-term regulators. Rodents and humans with reduced PYY levels in response to food intake tend to obesity. Chronic administration of PYY reduces adiposity in rodents. Also, PYY-null mice (unable to produce the hormone because the gene for PYY has been knocked out) are hyperphagic and develop marked obesity and are hypersensitive to exogenous PYY: chronic treatment with PYY reverses their obese phenotype (Batterham et al. 2006). The effect of this hormone has also been studied in obese children, where there is a reciprocal relationship between obesity and PYY (Roth et al. 2005; Ellacott et al. 2006).

These data suggest that there is substantial redundancy in the orexigenic (appetite-stimulating) system, with an evolutionary bias toward energy storage. Despite this redundancy, the neurophysiological pathways suggest that feeding is regulated by a negative feedback loop, where the hypothalamus provides the long-term regulatory input to the NTS, which acts as the set point for short-term regulation (Set Point$_{ST}$).

Many areas of the brain are sensitive to long-term regulators. Leptin receptors have been found on the paraventricular nucleus (PVN) and lateral hypothalamic (LHA) neurons, implicating them as direct targets for regulation by circulating adiposity signals. PVN stimulation inhibits food intake, whereas the opposite is true for stimulation of the LHA (Bray et al. 1990) and adjacent perifornical area (Stanley et al. 1993). Correspondingly, bilateral PVN lesions cause a hyperphagic obesity syndrome, whereas bilateral lesioning of the LHA causes anorexia and weight loss (Stellar 1954; Bray et al. 1990).

Several neuropeptides synthesized in PVN neurons reduce food intake and body weight when administered centrally. Hypothalamic areas including the PVN, zona incerta, perifornical area, and LHA are richly supplied by axons from the arcuate nucleus, which has greater concentrations of leptin and insulin receptors than other hypothalamic sites (Elmquist et al. 1998; Schwartz et al. 2000; Elmquist and Flier 2004; Cone 2005; Fan et al. 2004). The arcuate nucleus has at least two distinct populations of neurons with opposite effects on food intake, responding not only to leptin and insulin, but also to gut hormones (the best studied are ghrelin and, recently, PYY). The first population produces orexigenic neuropeptide Y and agouti-related protein (NPY/AgRP). The second population produces the anorexigenic (appetite-suppressing) proopiomelanocortin and cocaine- and amphetamine-regulated transcript (POMC/CART).

61.3 Computational Theory of Feeding Behavior

The NTS (and other hindbrain regions) integrates endogenous inputs transmitted through the parasympathetic and sympathetic fibers and blood as well as the hypothalamic input involved in energy homeostasis. The NTS is so important that appropriately lesioned rats may even starve to death. We showed that the NTS works like a comparator in a control system (Zanutto and Staddon 2007). These endogenous NTS-inputs are regulatory, acting to oppose external factors, such as a reinforcement schedule or interruption of feeding that tends to reduce the SSs below the Set Point$_{ST}$. They express the short-term motivation for eating. It is this system that regulates meal duration and intermeal interval.

Signals related to body fat (adiposity signals) regulate long-term feeding behavior and therefore body weight. Administration of insulin into the brain reduces food intake and body weight (Wood et al. 1979; Schwartz et al. 1992; Wood et al. 2000), and mice with a genetic deletion of neuronal insulin receptors are hyperphagic and obese (Bruning et al. 2000). Intraventricular administration of leptin reliably reduces food intake and body weight in rats (Seeley et al. 1996) and mice (Campfield et al. 1995). Also, chronic administration of PYY reduces adiposity in rodents and in PYY- null mice (Batterham et al. 2006). In obese children there is a reciprocal relationship between obesity and PYY (Roth et al. 2005; Ellacott et al. 2006).

Figure 61.1 shows how these data fit into our computational model. The hypothalamic efferents to the NTS are concerned with long-term regulation. The Set Point$_{LT}$ in the hypothalamus is modulated by signals for adiposity as well as some gut signals and external factors (learning, emotion, etc.) The output of this modulation then becomes the short-term set point. Set Point$_{ST}$ is then compared with a variety of satiety signals, both neuronal and hormonal associated with taste and bulk factors of ingested food (CCK, glucagon, etc.). The output of this comparison, after a delay, initiates or terminates eating.

The CINT[1]1 Model We consider feeding behavior with factors such as habit (learning), social situation, stress, and arousal held as constant as possible and in the absence of competition among motivational systems (hunger versus sex, versus thirst, etc.) (Staddon and Zanutto 1997; Staddon 2001); i.e., we look at feeding assuming that the only relevant factors are metabolism and food intake.

_____

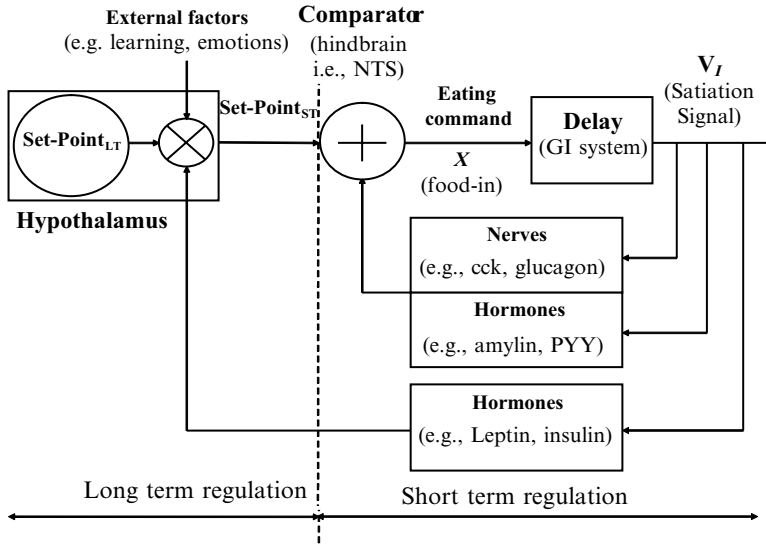
[1]**C**ascaded **INT**egrator


Fig. 61.1 The block diagram of a system modeling long- and short-term regulation of feeding. Eating leads to delayed SSs (grouped in V_I). When the feedback SSs falls below Set Point$_{ST}$, the command is "eat": otherwise, the command is "stop eating." Set Point$_{ST}$ is made up of the hypothalamic inputs resulting from the modulation of Set Point$_{LT}$ in the hypothalamus by adiposity, some gut signals, and external factors (learning, etc.)

If the feeding schedule is ad libitum (i.e., food is always available), then the equations for the I-unit cascaded (delay-block) system are:

$$x(t) = \Phi, \quad \text{if } V_I(t) < \theta, \quad \text{otherwise}, \quad x(t) = 0, \tag{61.1}$$

where $x(t)$ is the satiation value which is the input to the system at each discrete time step, and Φ is a constant which is some function of the physical properties of the food (e.g., weight, type, caloric, and protein values, etc.) provided by the experimenter (i.e., bang-bang control). The response rule is: if $x(t)$ is below Set Point$_{ST}$ (θ): eat (satiation value = Φ); otherwise, do not eat. Because rats show some spontaneous variation in eating patters from day to day, the details are never identical from one day to the next; in simulations we therefore include a small "noise" variation in the Set Point$_{ST}$, θ.

The SS is the output of a cascaded series of leaky integrators where the output of integrator i is the input to the next integrator $i + 1$. V_I, the SS, is the output of the last integrator in the series, which is determined as follows. In discrete time, for the first integrator:

$$V_1(t+1) = a_1 V_1(t) + b_1 x(t), \tag{61.2}$$

and for subsequent integrators:

$$V_i(t+1) = a_i V_i(t) + b_i V_{i-1}(t), \quad 1 < i \leq I, \tag{61.3}$$

where V_i is the state of integrator i, a_i is the time parameter of integrator i ($0 < a_i < 1$), and b_i is the input weight.

Two integrators are the minimum necessary to produce a delayed signal SS, but three ($I = 3$) give a better fit to our data. The behavior of the model depends much more on its sequential structure than

on particular parameter values, or even the number of integrators, so long as there are more than two. Moreover, to accommodate feedback from physiological satiety signals with different delays, the output of each integrator can be fed back separately without changing the model's essential properties.

61.4   The Model Accounts for Experimental Effects on Feeding Behavior

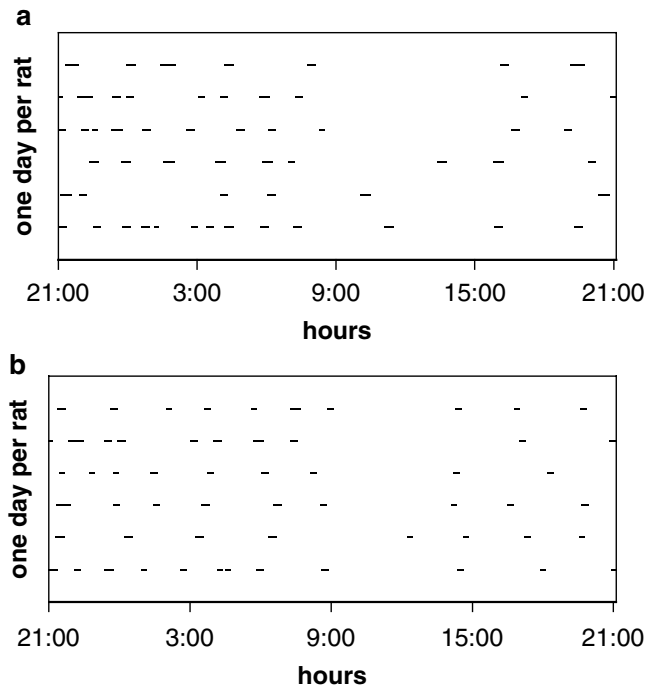
1. *Eating patterns in free-feeding rats*. Figure 61.2 compares raster plots of eating patterns in six rats and model predictions. The top panel shows meal pattern; model predictions are shown on the bottom. The patterns generated by the model (which include a small "noise" term added to the Set Point$_{ST}$, θ) are indistinguishable from the pattern of eating bouts shown by the rats.
2. *Meal-intermeal correlations*. We analyzed the correlation between the meal and the following intermeal interval (IMI). Correlations between meal size and the following intermeal are reported


Fig. 61.2 Meal patterns in six rats under free feeding conditions. Compare rasters of meals in six rats (**a**) and simulated by the model (**b**). Parameters of the model: $a_1 = \lambda$, $a_i = a_i - 1 + \lambda(1 - a_i - 1)$, $b_i = 1.7(1 - a_i)$. $\lambda = 0.985$, $\Phi = 1.1$. One time step = 1 s. Set point$_{ST}$ (θ) varies smoothly between two saturation values, θ_{dark} and θ_{light}: θ $(t + 1)$ = θ (t) × $(1 - 0.00005)$ + 0.00005 × $(\theta_{day}$ + noise); θ_{day} could take two values depending on the simulated period (*light* or *dark*): $\theta_{dark} = 0.13$, $\theta_{light} = 0.12$. Noise = white noise (amplitude = 0.007) to simulate observed spontaneous variation in meal size and IMI. The set time to eat a pellet was 6 s, followed by a refractory period of 4 s. A meal began with the first pellet after $V_1 < \theta$ and was considered to end after 3 min of no eating ($V_I \geq \theta$; the 3 min were not included in meal duration). Initial conditions: At the beginning of each condition, V_1 and V_2 were set to 0; $V_3 = 0.12$, to allow for eating on the previous day. To simulate the limit on IMI, V_I was bounded between zero and $0.0017 + \theta$. The relation between eating tendency and operant lever pressing was: when eating tendency >0, lever-press rate was 2/s (estimated from observational data) (Modified from Zanutto and Staddon 2007: doi:10.1371/journal.pcbi.0030097.g001)

to be moderately positive, but intermeal interval and the following meal size correlations are rare (Levitsky 1974; Collier and Johnson 1990). Using a linear regression analysis, we found in rats (Zanutto and Staddon 2007) that at night and under free conditions, IMI increased as a function of the previous meal size and the meal size increased as a function of the previous IMI. The CINT model reproduces this same pattern.

3. *Meal patterns after enforced fasting.* The model can reproduce the pattern of ingestion of food following days-long fasting in naive rats. Figure 61.3 compares cumulative eating data showing the effects of enforced fasts of 1–4 days on food intake in a group of rats (Levitsky et al. 1976) with predictions from the CINT model. The model and data cumulative curves match closely.

We also studied the eating pattern in rats when feeding is unpredictably interrupted (for 1, 2, or 3 h), the interruption being initiated when the animal attempts to begin a new meal (Zanutto and Staddon 2007). Figure 61.4 compares raster plots of eating patterns in individual rats and the model prediction. On the top, there are ten consecutive days; the first day has no interruptions and the following days have them at onset times indicated by diamonds. The figure shows that the model (bottom two panels) duplicates the general eating pattern.

The model shows that a short (<3 h) interruption in feeding is limited to the first postinterruption meal (PIM), which is larger than preceding and subsequent meals; i.e., an interruption affects only the first PIM. This is in agreement with Le Magnen (1985), who found that when eating is interrupted for a few hours, the first (and only the first) meal is extra long. Eating rate and meal size thereafter both revert to normal values (the *first-meal effect*).

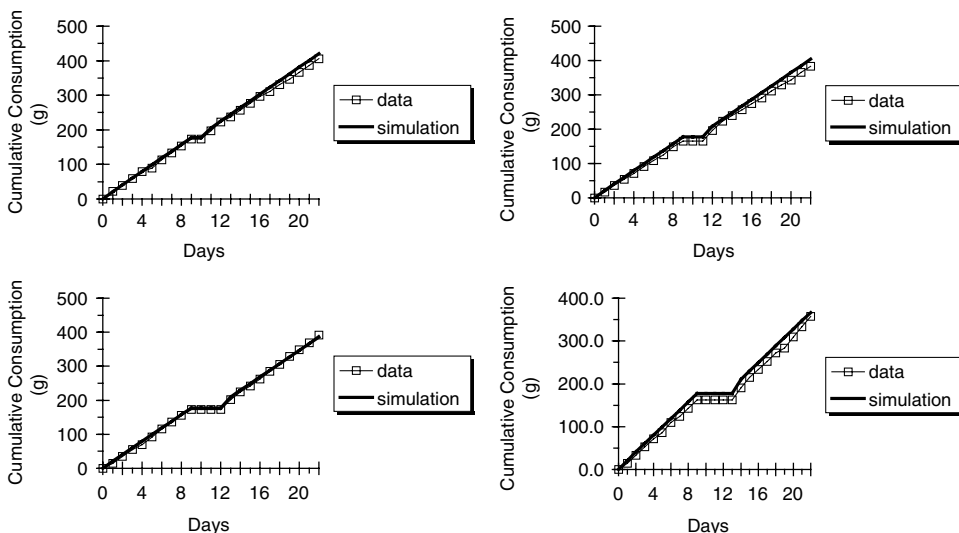
The difference between the number of pellets of the PIM and the number of pellets of the previous meal is proportional to the duration of the interruption. We also analyzed the IMI after the PIM. We found that it is longer than usual, although smaller than the saturation (maximum possible) value. There is no correlation between the size of the PIM and subsequent IMI. The size of the meals after


Fig. 61.3 *Top panel*: The effects on cumulative daily ingestion of 1–4 days of food deprivation starting on the ninth day. *Inset* shows a typical cumulative eating record across the whole 22-day experiment for the 4-day condition. *Fine lines and markers*: group–average data from Levitsky et al. (1976); *heavy line*: Simulation
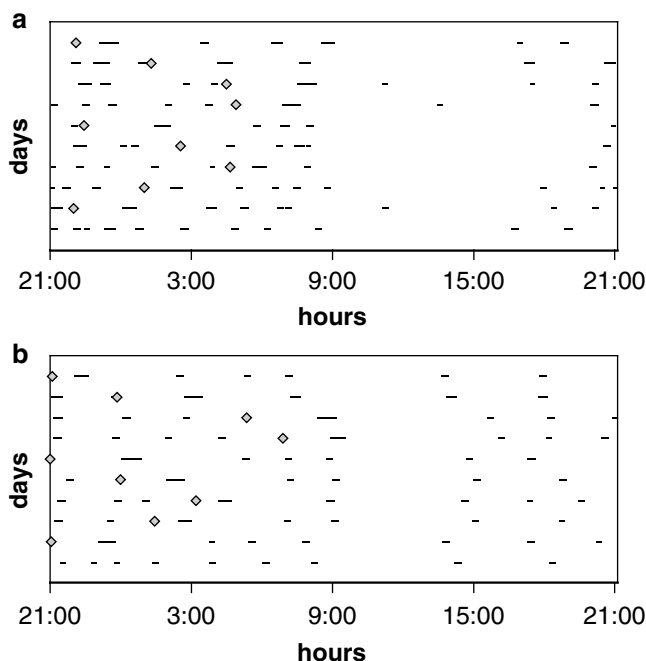

Fig. 61.4 Meal Patterns in Rats under free feeding and with unpredictable interruptions. Compares rasters of meals in a single rat (**a**) and as simulated by the model (**b**). (a) shows ten consecutive days, the first with no interruptions and the following with interruptions. The *diamonds* show times when the rat attempted to start a new meal, but was interrupted. (b) shows the model predictions (Modified from Zanutto and Staddon 2007: doi:10.1371/journal.pcbi.0030097.g001)

the PIM is not significantly different from other meals. Finally, the interruption (plus the previous IMI) evokes a larger subsequent meal size than a spontaneous IMI of similar length, indicating a change in the animal's motivation to eat. CINT duplicates all these effects.

4. *Adaptation to operant schedules.* In experimental procedures extensively explored by George Collier and his associates, rats in a "closed economy"[2] are required to make two types of operant response (usually, lever-pressing), termed "procurement" and "consumption" responses. Procurement responses earn the opportunity to engage in consumption responses. Consumption responses are made for the opportunity to eat. When the animal has ceased (for at least 10 min, usually) to make a consumption response the animal must make another round of responses on the procurement lever for further access to the consumption lever.

Figure 61.5 compares model predictions of mean meal size and meal frequency as procurement cost (ratio value) increases, with data from Collier et al. (1972). The simulation shows data from the fifth day of training. The simulation duplicates the increasing meal size and decreasing meal frequency as procurement cost is increased.

Figure 61.6 compares the effect of increasing consumption cost in data from Collier et al. (1972) with a CINT simulation. Simulation and data both show that meal size and meal frequency are relatively invariant as consumption cost increases.

61.5 Implications for Obesity and Health

In the CINT model, total food intake is essentially independent of parameter values other than the set points. Different parameters will yield fewer, larger meals or more frequent smaller ones. But the total amount ingested remains roughly constant.

According to the CINT model, one way to change feeding behavior over the long term is to change Set Point$_{ST}$. Since Set Point$_{LT}$ is assumed to be fixed, the only routes to change are via the two variable pathways (hypothalamic inputs to the NTS): signals for body fat (e.g., leptin and insulin) as well as for some gut signals (e.g, PYY) and psychological factors (learning, arousal, etc.). In animal studies, a drop in leptin levels results in an increase in food intake until the leptin levels are restored. Similar effects have been seen with changes in insulin (Wood et al. 1979; Schwartz et al. 1992; Campfield et al. 1995; Seeley et al. 1996; Wood et al. 2000; Bruning et al. 2000).

In humans, psychological factors such as learning and arousal (as well as adiposity signals) affect overall food intake in ways that are not fully understood. Hence the effects of, for example, mechanical fat reduction are hard to interpret. On the one hand, clinical data from liposuction patients report that although leptin level goes down (e.g., after liposuction), food intake increases until levels are back up. On the other hand, in one study (Talisman et al. 2001) patients report loss of appetite 1–3 weeks after liposuction. These data do not contradict our computational theory, since psychological factors may well affect the outcome of elective surgery.

There are other ways to modify the hypothalamic inputs to the NTS. As was said, PYY is a hormone released into the bloodstream from the gut that regulates hunger and acts in the arcuate nucleus of the hypothalamus. From a regulatory point of view, PYY might be used directly as a slimming agent (Roth et al. 2005; Chelikani et al. 2006; Batterham et al. 2006). There is a connection between protein intake and PYY: when the amount of protein in a person's diet is increased, it speeds up and prolongs the feeling of satiation (Batterham et al. 2007).

According to the computational theory, the role of external factors such as taste, learning and habits, social situation, stress, and emotion modulates the Set-Point$_{LT}$, yielding an output that comprises Set-Point$_{ST}$, which in turn affects the initiation and termination of meals. In this way a very tasty food would increase the Set-Point$_{ST}$ (θ) so that meal size would be greater, and vice versa if the food is not tasty. If Set-Point$_{ST}$ increases, the meal size will increase and IMI will decrease (and vice versa if Set-Point$_{ST}$ decreases).

As was said earlier, SSs provide information about mechanical (e.g., stomach-stretch, volume) as well as chemical properties of food. High-fiber (low-caloric) foods, even with satiation value (Φ, the value of the satiation variable x) similar to that of other foods of comparable caloric value, have greater volume; consequently, the stomach-stretch and volume components of SSs will increase faster than with other foods. Thus, people will end a meal of high-fiber food sooner, after ingesting fewer calories, than a low-fiber meal.

Recall that after a period when feeding is interrupted (fasting) only the first meal is longer than others and occasional fasting causes no weight loss, compared with control animals who do not fast. Fasting does cause changes in metabolism, however, which becomes more efficient in converting food into energy (Levitsky et al. 1976). An obvious possibility, therefore, is that a short diet that involves some fasting or much-reduced eating will only produce a temporary weight loss. Lost weight may be restored when the dieting regimen comes to an end.

Because feeding is the prototypical motivational system, controlling feeding is equivalent to controlling the motivation for eating. In the model ingested food inhibits eating, but the inhibitory effect is delayed; so, if you want to lose (or not gain) weight eat slowly or in small bites, just like your mother told you! In this way, you will give the process of satiation ($V_I \geq \theta$,) time to catch up – rather than outrunning it by eating fast.

The simulations make three simple points: (1) feeding regulation in rats is bang–bang rather than proportional control. Eating is regulated in on–off fashion under most conditions rather than being proportional to the difference between set point$_{ST}$ and SSs. (2) The satiating effects of eating are delayed in a way that can be modeled by a simple first-order linear system. Finally (3) long-term regulation (i.e., control of body weight) is separable from short-term regulation (i.e., control of meal pattern). Long-term regulation is controlled by a set-point$_{ST}$ provided by the hypothalamic input, which comprise set-point$_{LT}$ modulated by adiposity and some gut signals, and external factors (e.g., learning and motivation). Short-term regulation is controlled by SSs that vary from minute to minute rather than over days.

Chapter 62
Food Unpredictability and Foraging

Sarah E. Overington and Louis Lefebvre

62.1 Introduction

The primary aim of this book is to examine the interactions between diet, nutrition, and behavior in humans. It is useful, however, to broaden that scope by examining variation in feeding behavior across a wide range of species, to see if general rules apply. When we consider all organisms as part of a global food web, we soon recognize the immense diversity of food types and food distributions. Some food types are abundant and found in high densities such as krill, insect swarms, or forests full of leaves. Other foods come in smaller packages, such as solitary animals that, once killed, provide a single meal for a predator. Some food types, like grasses and leaves, can be available year-round, whereas others, like nectar and fruit, may only be edible for a few weeks or days. Some foods are highly mobile, such as animal prey; others are sessile but distributed in small dense clusters, such as nectar and fruit, while still others are distributed over a large area, such as grasses and herbivores. Each of these food characteristics imposes specific demands on the behavior and cognition of foragers. On top of all this, the fact that food is not always predictably distributed across space and time adds an additional layer of complexity. In this chapter, we examine the ways in which the predictability of food can drive changes in four key aspects of behavior related to foraging: (1) Feeding specialization, (2) sampling and information use, (3) food defense, and (4) movement patterns. We then discuss strategies that individuals may use to make food more predictable, such as agriculture in humans or hoarding of food in rodents and birds. We begin by considering what food predictability means.

62.2 Defining Food Predictability

In foraging theory, food is considered predictable if an individual can make an accurate estimate of its location, quality, and/or quantity based on factors such as season, time of day, landmarks, or temperature (Stephens and Krebs 1986). Given this definition, it would be difficult to define a given food source in absolute terms as "predictable" or "unpredictable," because this depends on the forager's ability to perceive the cues that provide information about food. While humans may be able to communicate the degree to which they perceive food to be predictable ("on Saturday the farmer's market

S.E. Overington (✉)

e-mail: sarah.overington@mcgill.ca

will be open unless it rains"), it is much more difficult to determine whether or not other animals have the information necessary to predict the quantity, quality, or location of food. Nonetheless, we expect that if food is stable through time and in space (Fig. 62.1A), a forager should consider it to be more predictable than if it appears, like seeds in desert environments, in patches that depend on where and when it happens to rain (Fig. 62.1B). Anthropogenic food sources – such as a well-stocked birdfeeder – are examples of highly predictable food.

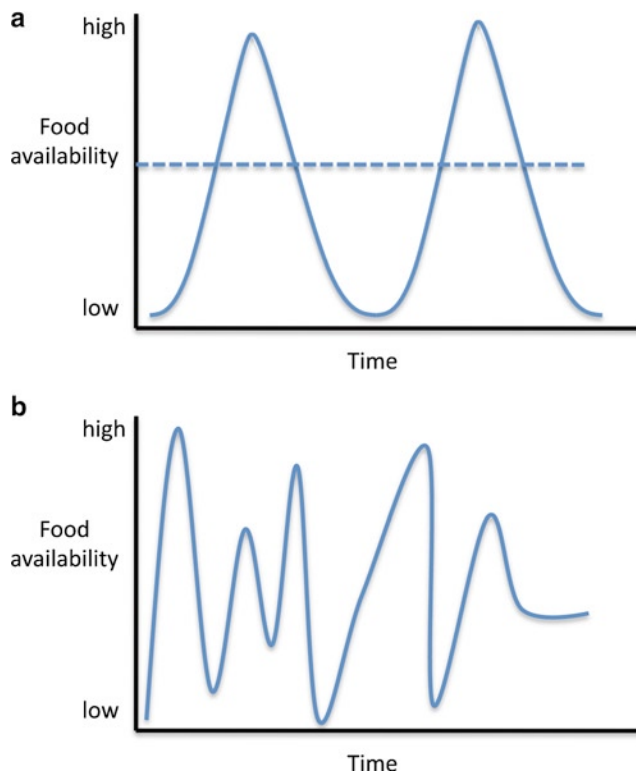
The availability of food may change over many different time scales, from minutes to decades. Although this means that food is not consistently available at a given time or at a given place, this variability may be generally predictable (Fig. 62.1A). Cherry trees bloom in the springtime; apples mature on their trees in autumn; millions of ungulates move across the Western Serengeti in Africa in late May, as the local habitat dries up. Foragers can plan their yearly activities based on the availability of these food sources, and it is reasonable to assume that foragers can predict that many flowers will bloom in the springtime. On the other hand, there are many unpredictable qualities of these foods (Fig. 62.1B). For example, individual hunters may not be able to predict when and where the best feeding opportunities will arise within the great ungulate migration. Although fruit trees may ripen in the fall, they may not be perfectly synchronized. If they are far apart from each other, foragers may not be able to predict the best location for finding food at a given time. In nature, nothing is perfectly predictable. In this chapter, we consider predictability as a continuum


Fig. 62.1 A general overview of the way food availability may change through time. This figure illustrates several ways that food may vary through time. Food availability may be consistent throughout the year (**a**, *dashed line*), or it may vary in a predictable (**a**, *solid line*) or unpredictable manner (**b**). For examples, please see main text

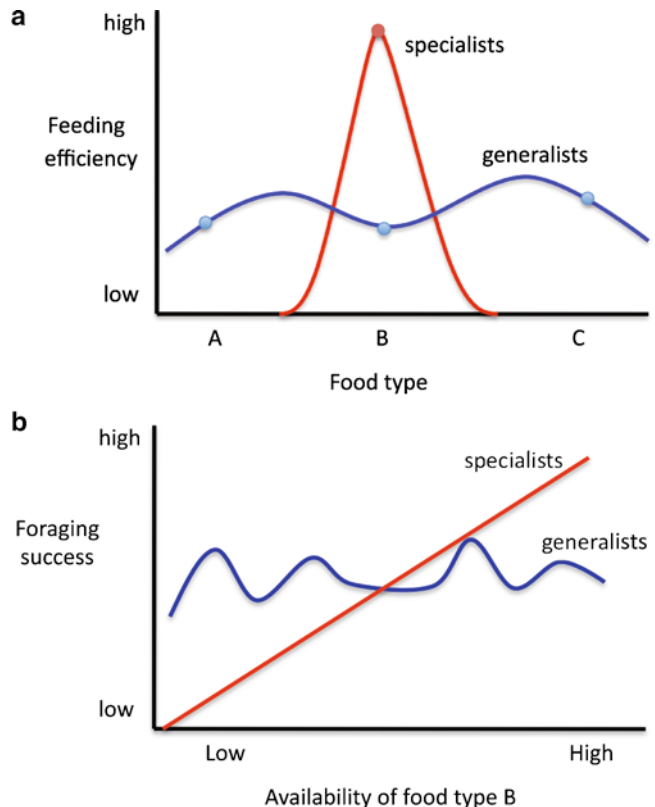
and base our discussion on the relative predictability of one food type compared to another. Using historical, natural, experimental, and theoretical examples, we will examine how changes to the relative predictability of food influence foraging behavior. Given the great diversity of food types and the difficulty in classifying a food as "predictable," "unpredictable," "variable," or "stable," we strive to present examples as clearly as possible and to rely on the researchers' definitions of these terms. We explore these definitions in more detail in a box devoted to the topic ("Key facts on defining food unpredictability").

62.3 Jack-of-All-Trades, Master of None? Feeding Specialization and Food Predictability

In the neotropics, army ants (*Labidus praedator*) flush other insects from their hiding places as they move across the landscape. When a raid begins, birds that are nearby get an easy meal, plucking startled insects from the ants' wake. Although this is a very efficient way for the birds to feed, none of them rely entirely on this ant species, because the timing and size of raids are very unpredictable (Dobbs and Martin 1998).

When food is predictable, foragers may optimize their feeding efficiency by specializing on one type of food. Some animals have evolved feeding structures that are uniquely adapted to their preferred foods. Hummingbirds, for example, are highly efficient at extracting nectar from flowers due to their elongated bills. Anteaters have modified snouts to feed exclusively on ants and termites. Animals may also develop specialized behavioral patterns. A striking example is the use of tools by New Caledonian crows (*Corvus moneduloides*). These birds feed on insects, but cannot reach their bills deep enough into tree bark to extract prey. Instead, they make tools out of stiff Pandanus leaves and *Cunonia vieillardii* twigs to reach into crevices (Hunt and Gray 2004). It is generally assumed that with specialization comes increased efficiency (Bernays 1999). Social insects (e.g., ants, bees) provide examples of this; the efficiency of caste specialization is presumed to be a major factor in driving their success (Chittka and Muller 2009).

Specialists may be highly efficient at foraging on their preferred food type, but they are also dependent on this food type being consistently available. The trade-off between generalist and specialist foraging strategies is illustrated in Fig. 62.2. When the availability of a particular food is unpredictable, it may be better to compromise feeding efficiency and instead broaden the diet, thereby increasing the probability of finding suitable food. In a field study of hummingbirds, Pimm (1978) demonstrated that some individuals began to eat a wider variety of nectars when feeders were stocked in an unpredictable manner. Another example comes from Darwin's finches on the Galapagos Islands. In the early 1980s, there was a period of unusually heavy rains followed by many years of severe drought. This unpredictable climatic fluctuation served as a natural experiment on the islands. In a study of young birds born around the time of this transition, Grant and Grant (1989) found that the only individuals that survived the drought were those that used a wide variety of feeding techniques; birds that did not shift their behavior died. Thus, by expanding their feeding repertoire they were able to thrive despite the unpredictable food availability. The relationship between generalism and unpredictability appears to hold true in many systems. In plant-pollinator communities in California, areas with variable (and unpredictable) climatic conditions contain a greater proportion of generalist species (Moldenke 1975). For Platyhelminth monogeneans, a group of parasites that live on the gills and skin of fish, specialization on a single host species appears to be linked to the degree to which the host species is predictably available (Simkova et al. 2006). Even human societies may broaden their usual diets when unpredictable events lead to resource scarcity (e.g., Harris and Mohammed 2003).

Fig. 62.2 Potential trade-offs between feeding specialization and feeding generalizm. Although specialists may be more efficient at feeding on their preferred food type (**a**), they are dependent on the availability of that food for successful foraging. Part (**b**) illustrates the presumed costs and benefits of specialization vs. generalism: As the abundance of food type B increases, specialists on that food type will be highly successful. Generalists do not forage as efficiently, but their foraging success is independent of the fluctuations in food type B because they can find other food


An individual's diet breadth may also change based on early experience, as demonstrated by an experiment carried out by Gray (1981). In this experiment, the predictability of food given to young white-footed mice (*Peromyscus leucopus*) was manipulated. One group received a constant diet of Brazil nuts, shredded coconut, oatmeal, and sesame seeds. The other group was given a different amount of one of these food types, chosen randomly, each day. When the mice were 3 months old, their food preferences were tested. Individuals who had been raised on the fluctuating food types chose a much greater diversity of foods than those raised in a stable environment, supporting the prediction that fluctuating (unpredictable) food conditions can lead individuals to widen their diet breadth. This strategy might also carry over into reproductive decisions. In some species, mothers "hedge their bets" when the environment is unpredictable by producing offspring that show a greater variety of sizes, increasing the chances that at least one of the offspring will be able to live under whatever environmental conditions arise (Crean and Marshall 2009).

62.4 Models of Feeding Specialization and Food Unpredictability

The idea that individuals should be generalists when food is variable and/or unpredictable is well supported in theoretical biology. Classic models by Levins and MacArthur established that environmental instability is one factor that limits the degree to which species can specialize (e.g., MacArthur and Levins 1967). Lynch and Gabriel (1987) focused on the effect of environmental variability on tolerance curves, graphical representations of the types of environmental conditions an organism can

withstand. In this model, the variance of a given environmental state could increase or decrease around a mean value. They noted that when temporal environmental variance is high, genotypes with a broad tolerance are favored. We would expect that an even broader tolerance would result from a variable, unpredictable resource.

Given that so many species feed in flocks, schools, or other social groups, game theory can also be a useful theoretical tool for determining the best strategy that an individual should use in a given situation. In this type of model, we assume that individuals behave in a way that maximizes their "payoffs," which may represent either the energetic gains for each individual or their fitness gains depending on the time scale we are interested in (i.e., within one generation, or over multiple generations). We can then describe alternate behavioral strategies that individuals in the population may use. We recently used this approach to examine the way in which unpredictability influences foraging behavior (Overington et al. 2008). We considered a situation in which there were two different types of food in the environment, and two different feeding strategies: Specialists that could eat only one food type, and generalists that could eat both. In this simple situation, we would expect that all individuals should be generalists, because this would allow them to eat whatever food they encountered. When we varied food predictability in our model, the results changed. Specialists were modeled to be much more efficient than generalists at feeding on their preferred food type. Thus, we found that when food was entirely predictable, the proportion of specialists in the population was 90%. As food became less predictable, however, this proportion decreased steadily until specialists made up just over 50% of the population, despite their much greater feeding efficiency (Fig. 62.3). It is important to note that in this model all types of food were always available, though their predictability and abundance varied. In reality, unpredictable food types may sometimes be entirely unavailable. In this case, only generalists would survive and all specialists would perish. Thus, the situation described in our model and in Fig. 62.3 is a conservative one.
Fig. 62.3 Outcome of a game theory model testing the effects of food predictability on the proportion of specialist feeders in a population. The results of a game theory model testing the optimal feeding strategy as a function of food (prey) predictability. This figure shows that for each value of prey predictability, from 0 (completely unpredictable) to 1 (completely predictable) the population reaches an equilibrium proportion of specialists and generalists. Despite a significant advantage in terms of feeding efficiency for specialists, generalists make up almost 50% of the population when food is unpredictable. For details of the model, see main text (Reproduced from Overington et al. (2008). With permission)

62.5 Constraints on Feeding Specialization or Generalism

Although both theoretical and empirical evidence shows that individuals should generalize when food is unpredictable, the transition from specialization to generalism may not always be possible within one individual's lifetime. While a specialist may use innate behavior to locate prey, a generalist must be able to recognize a wider range of food types and adjust foraging behavior accordingly. This kind of behavioral flexibility presents both physical and cognitive challenges for individuals.

If we return to the example of the hummingbird, the physical challenges of generalizing are clear. If a competing species takes all of the birds' preferred flowers, it may be able to switch to a new flower type to find nectar. But if a sudden drought wipes out all flowers, its small size and specialized bill limit its ability to switch to a different food type. In some cases, physical limitations can be overcome through behavioral flexibility. The woodpecker finch of the Galapagos Islands provides an elegant example. This bird sometimes uses small twigs or cactus spines to extract insects from tree bark by holding the tool in its bill. Tebbich and colleagues (2002) observed birds in two locations on Santa Cruz, one of the islands of the Galapagos archipelago off the coast of Ecuador. One site had abundant and consistently available food, while the other had less food overall, and highly variable amounts of different food types. Through field observations at these sites, they found that birds living at the less predictable site used tools much more frequently than birds living in the predictable habitat. Although tool-use takes more time and energy than just using the bill to get food, this behavior allows individuals in less predictable habitats to eat a wider variety of food.

There may also be cognitive limits to feeding flexibility. Cognition includes many of the processes that allow individuals to interact with the environment, such as perception, learning, and memory (Shettleworth 1998). All else being equal, an individual that uses a wider variety of feeding techniques will need to assess a wider variety of foods and make a greater variety of decisions about when, where, and how to forage than a specialist. Bumblebees (*Bombus impatiens*), for instance, take longer to learn the most efficient foraging techniques when they are feeding on a greater variety of flowers (Dukas and Real 1993). For cabbage butterflies (*Pieris rapae*), learning about a new flower type decreases their ability to feed on a flower type they have eaten in the past (Lewis 1986). Empirical studies support the idea that species that are able to feed on a wider variety of foods have greater cognitive capacity than those that specialize. In birds and primates, the frequency of novel feeding behavior reported for a species is positively correlated with brain size, after taking into account body size (Lefebvre et al. 1997; Reader and Laland 2002). In bats, species that use a wider variety of hunting techniques have greater relative brain volumes than those using fewer techniques (Ratcliffe et al. 2006), and a study of 24 mammalian species found that behavioral repertoire was positively correlated with relative brain size (Changizi 2003). Indeed, feeding flexibility and the ability to innovate are central to one of the major hypotheses for increases in brain size across species, and unpredictable food sources may play a role in brain size evolution.

62.6 Finding Out About Food: Sampling and Social Information

In this chapter, we consider food to be predictable if an individual can estimate with a high probability the location, quality, and/or quantity of food based on environmental cues. Within this definition, there are different ways we might consider predictability. First, the environment may vary in a random manner, thus being unpredictable for everyone. Alternatively, an individual may enter a new, unfamiliar habitat that is highly variable, but where locals can predict food availability. These two forms of predictability can have important consequences for the way in which individuals use information – their own, or that of others.

In sea birds such as kittiwakes, the location of food is driven by highly predictable tidal cycles, and experienced individuals use their local knowledge to find food by focusing their search adjusted to the season and time of day (Irons 1998). When individuals cannot predict the location, quality, or quantity of food available based on environmental cues, they may invest more of their time in exploring and testing out local areas to gain more information (Dall et al. 2005). Returning to an area that did not previously contain food is known as "sampling" (Shettleworth et al. 1988), and the frequency with which an individual samples is therefore the "sampling rate." When the quality or location of food is uncertain, individuals are expected to increase their sampling rates. Alternatively, individuals may look for information from others instead of through their own sampling (Hall and Kramer 2008). Consider the following scenario. You arrive in a new neighborhood, and you are looking for a place to buy bread. There are several stores that appear to sell bread, but you cannot judge their relative quality based on physical characteristics (e.g., the brightness of the sign or the cleanness of the windows), or previous knowledge of the company. In this case, you might instead compare how busy each place is, or the type of people entering and leaving each store. By doing this, you are relying on social information to reach your decision. This scenario is illustrated in Fig. 62.4. Many animals appear to shift to using social information when they do not have sufficient information to predict the location or quality of a food source.

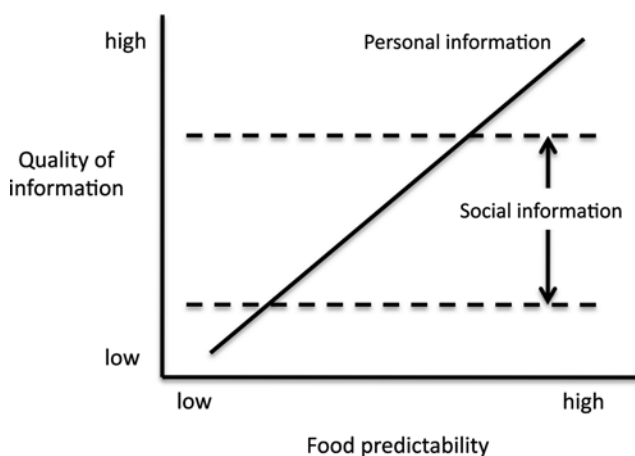
The value of social information was demonstrated in a recent simulation model by Hancock and Milner-Gulland (2006). In this model, individual foragers move around a lattice containing cells that represent patches of a resource. Foragers use rules to decide where to move in each round of the simulation. The environment is heterogeneous, with each patch containing food of different value. This variability can be made unpredictable by changing the accuracy with which individuals can predict the direction of the nearest high-value cell, and thus the likelihood that they will move in the best direction. The authors found that when foragers could not predict the best patches on their own (i.e., they had an equal probability of moving to a high-value or low-value patch), social information could greatly increase foraging efficiency. In the model, social information was of the simplest kind: when another forager was in a good patch, they exerted a "pull" on others, attracting them to the same patch. When the authors added this simple social pull, all foragers were much more successful.


Fig. 62.4 The relative value of personal and social information when food is unpredictable. This figure illustrates the idea that as an individual is better able to predict the value or location of food, the value of his/her own information increases (we use a linear relationship here, but other relationships may also be valid). On the other hand, when they are unable to predict the location or quality of food, social information may be more valuable. The reliability of social information may be high (*upper line*) or low (*lower line*), thus changing the value of the information

Empirical evidence also shows that animals shift to using social information when they cannot predict the location of food. In an experimental study of blue jays (*Cyanocitta cristata*), McLinn and Stephens (2006) manipulated both food certainty and signal reliability. They gave individual birds two options for where to look for food: a green box, and a red box. In the "certain" condition, food was consistently found in the same colored box in each trial, whereas in the "uncertain" condition the food was randomly assigned to a given box, and the bird could not predict its location. The signal was a light that flashed when food could be found in, for example, the red box. The reliability of the signal was measured as the probability that it gave the correct information. Overall, they found that individuals relied on signals when the location of food was uncertain and signals provided accurate information. This result is not surprising and can likely be generalized. When the location or quality of food is unpredictable, individuals will rely on signals given by others, as long as those signals are reliable.

62.7 Defending Food

Once an animal finds food, it must decide whether it is better to expend energy searching for more food, or to have a guaranteed food source and expend some energy defending it against others. The relative value of these options may depend on both the spatial distribution of food (whether it is spread out or found in dense clusters) and its predictability. Resource Defense Theory (Brown 1964) provides a useful framework. This theory states that individuals should behave aggressively during feeding if this maximizes the energy they can obtain from the food source. Thus, an individual that is too aggressive when food cannot be defended would spend too much time fighting and not enough time eating. When food is predictable, an individual may benefit from guarding the area surrounding the food source, as the energetic costs of fighting will be paid back by consistent access to food. In contrast, if food is unpredictable, the individual may not be physically able to defend the food, as it will be impossible to be accurately positioned to defend food of which the location is unknown. The relative value of defending food increases with predictability, as illustrated in Fig. 62.5. It may also be impossible for the animal to assess whether the cost of fighting is worth the food reward. Thus, when food is unpredictable, foragers should be less aggressive toward one another.
Fig. 62.5 The value of defending food as a function of food predictability. This figure illustrates the predictions of Resource Defense Theory (see main text and Definitions) as they relate to food predictability. As food becomes more predictable, the value of defending that food increases for an individual. As a result, we would expect that territorial defense would be more prevalent for animals feeding on a predictable, spatially clumped resource

An example of this principle in action is behavior of the Zenaida dove (*Zenaida aurita*) of Barbados. One population of these birds lives near a harbor, feeding on huge piles of spilled grain. The piles are abundant, but only available when there is overflow from a delivery – the timing of which is not predictable. Birds in this population do not defend territories, but instead feed close to one another in large aggregations. In almost all other areas of the island, mated pairs of Zenaida doves aggressively defend year-round territories. These birds forage on seeds that are uniformly distributed in the grass, and consistently available. Experimental manipulations of seed supplies at the harbor cause group-feeding doves to start defending their food. A small patch of seed provided every day at the same time and place leads to a large increase in aggression and a decrease in the number of doves that attempt to feed there. Conversely, the same amount of seed scattered over a wide area and provided at random times and in random places leads to the same nonaggressive aggregative feeding normally seen at the harbor (Goldberg et al. 2001).

Experiments in captivity also show that predictability leads to increased aggression. Dubois and Giraldeau (2004) recorded the aggressive behavior of nutmeg manikins (*Lonchura punctulata*) on a large feeding grid, where food was hidden in small holes at regular intervals. In some tests the holes containing food had clearly marked covers. In other tests, none of the holes were marked as containing food. Thus, in one case birds could predict the spatial distribution of food, and in the other they could not. Birds behaved much more aggressively toward one another when food was predictable than when it was unpredictable. However, this aggressiveness decreased when food was in very high density, whether it was predictable or not. When food is found in high densities, it is often uneconomic to defend because it attracts too many competitors arriving from all directions.

A classic model approach to understanding aggressive interactions between individuals is the "hawk–dove" game theory paradigm. In the foraging version of this game, two foragers arrive at a resource at the same time, and each contestant has the same two possible strategies (hawk or dove). Imagine two students arriving late to a dessert table to find that there is only one remaining piece of cake. The hawk strategy would involve fighting for the piece of cake, and either winning or losing the entire piece. The dove strategy would split the piece of cake in two so that each student gets half. Of course, the success of each strategy depends on what other individuals are doing. If most students are doves, a hawk could be very successful because he or she would be likely to win the fight for the cake. If everyone fights for the cake, the chance of actually winning the fight might be low and the costs of fighting (e.g., physical injury) could be high. This hawk–dove game can be seen as a way of predicting the conditions under which individuals should defend their food against others. In a recent modification of the basic hawk–dove model, we found that food predictability can influence the proportion of hawks and doves in a population. In this model, we maintained a relatively low cost of fighting. Even so, the proportion of individuals using the hawk strategy increased as food became more predictable, and decreased when it was unpredictable (Overington et al. 2008).

62.8 The Effects of Food Predictability on Movement Patterns

If an individual plans to spend her entire life in one location, she must be sure that there is sufficient food to sustain her. If food is abundant and predictable, a sedentary lifestyle allows individuals to invest their energy in maintaining their home, and they may also defend their resources against intruders. On the other hand, when food is unpredictable, individuals may not have the option of becoming sedentary. A possible example of this principle is the invention of agriculture (the Neolithic Revolution) around 10,000 years ago. Although the reasons for this transition are still under debate (Weisdorf 2005), it is clear that through the domestication of plants and animals – and

the creation of a predictable, abundant food supply – humans were able to adopt a sedentary lifestyle. Indeed, differences in the nomadic tendencies of many species can be closely tied to the availability of food.

Many animals migrate toward the equator as temperatures drop and their preferred food becomes less abundant. The decision to migrate may depend on both the variability and the predictability of food. For example, trout begin their migration when environmental cues suggest that conditions will soon shift toward unpredictability (Ovidio et al. 1998). Migratory behavior varies widely among species of birds, and even among populations of a single species. One pattern that has been observed is called "leap-frog" migration, in which birds such as Dunlins (*Calidris alpina*) that breed in the Northern part of the species range migrate further South in the winter that birds living closer to the mid-point range. Alerstam and Hogstedt (1980) suggested that this could be driven by the unpredictability of the start of spring in temperate regions. They argued that the timing of spring is more predictable in the more Northern zones, allowing birds to time their return based on cues such as light. On the other hand, the arrival of spring in temperate zones is less predictable. Because birds that breed in the temperate part of the range have greater competition for nest sites and cannot accurately predict when spring will arrive, they must stay relatively close by to time their migration. If this is indeed the case, then predictability could be an important ecological factor driving the variation in migratory behavior within some bird populations.

The predictability of food can drive yearly movement patterns, like migration, but it can also influence movement on shorter timescales. Along the coast of Australia, waves batter the shore. At midshore levels wetting is driven by tidal cycles and is therefore relatively predictable. In the highest parts of the intertidal zone, the temporal and spatial patterns of wetting are unpredictable, changing based on weather patterns. Some animals, such as the periwinkle (*Littorina unifasciata*), must wait to be submersed in water to feed, and in these high intertidal zones they cannot predict when they will be submersed. Accordingly, periwinkles in the highest areas have highly variable feeding behavior, changing the direction and distance they move while foraging much more than snails in more predictable sites (Chapman 2000). On a smaller spatial scale, coral reefs can be variable environments, with some parts of a reef containing more predictable food sources than do others. Ongoing research by Katrine Turgeon and colleagues suggests that longfin and dusky damselfish (*Stegastes diencaeus and S. adustus*) seek out these predictable habitats, and that males with high-quality territories (with predictable access to food) have greater reproductive success (K. Turgeon, personal communication).

In addition to these field observations, there is also experimental evidence that food predictability influences movement. European starlings (*Sturnus vulgaris*) that are unexpectedly shifted to a new, less desirable food source will reduce the amount of food they eat and spend more time exploring the environment for other options (Freidin et al. 2009).

62.9 Making Food Predictable (Hoarding, Caching, Agriculture)

Not all animals track changes in food supply by moving. Instead, some deal with unpredictable food by making them more predictable. The Neolithic Revolution can be viewed in this way; by growing plants and domesticating animals approximately 10,000 years ago, humans were able to create predictable sources of food. Similarly, the damselfish we described above increase the predictability of their food patches by cultivating algae on their territories within the coral reef (Hata and Kato 2006).

Some animals respond to variable and unpredictable food sources by hoarding or caching food when it is abundant. Squirrels, chipmunks, and many birds gather seeds and nuts to store for the winter when these foods will not be available. If the variability of food were perfectly predictable, individuals would be able to store just the optimal amount of food before winter. However, the timing and location of re-appearance of food after the winter varies each year, and individuals must store as much as they can to account for this unpredictability.

Individuals might also build up fat reserves to prepare for times of low food availability, and there is evidence that they may over-store when conditions seem less predictable. Although Great tits (*Parus major*) are very small (around 20 g), these birds thrive in Britain throughout the year and therefore deal with large climatic fluctuations. In an experimental study, Bednekoff and Krebs (1995) found that birds gain more mass when their access to food is unpredictable, even when the overall amount of food is controlled for. This seems to be true for many small passerines in Northern climates. In a study of Dark-eyed juncos (*Junco hyemalis*), Rogers and Reed (2003) found that birds increased their fat storage when temperature dropped faster than expected, and when there was more snowfall than usual. They interpreted these observations as evidence that birds-stored more fat – which is energetically costly for them to carry around – when there are unexpectedly sudden changes in temperature, suggesting that food availability will be less predictable than usual.

62.10 Costs of Food Unpredictability

Based on the topics discussed in this chapter, we would expect that food predictability could have far-reaching consequences for the health of humans and other animals, as, in theory, unpredictable food should drive individuals to: (a) eat a wider variety of foods, potentially giving up the advantages of specialization; (b) spend more time watching and learning from others; (c) share their food instead of defending it for themselves; (d) increase movement and exploration of the landscape; and/or (e) invest in storing or hoarding food to deal with periods of food shortage. All of these may have energetic costs for individuals, potentially influencing health and reproduction.

The direct costs of food unpredictability on health have been documented for a range of species. For example, brown capuchin monkeys (*Cebus apella*) that are fed on a predictable schedule are more active, more social, and less tense than those that are not (Ulyan et al. 2006). As illustrated above, physiological traits such as body mass may also be affected by food unpredictability. Small passerines are able to build up excess body mass to compensate for unpredictability of food during the winter months (Bednekoff and Krebs 1995). On the other hand, quail (*Coturnix c. japonica*), hooded crows (*Corvus cornix*) and magpies (*Pica pica*) all lose body mass when they are fed on an unpredictable food cycle, even when the total amount of food is controlled (Acquarone et al. 2002; Boon et al. 1999; Cucco et al. 2002). In magpies, unpredictable feeding also leads to decreased levels of haematocrit and lowered T-lymphocyte cell-mediated immune response (Cucco et al. 2002). Food predictability also appears to affect the timing of reproduction in birds, with birds in less predictable environments breeding later in the season (Bridge et al. 2009).

Natural variation in human food supplies across the globe suggests that food predictability affects the well being of human populations both psychologically and physiologically. In a study of folktales in human cultures, Cohen (1990) found that tales written during times of food unpredictability included more capricious aggression, and saw this as a reflection of increased social unrest. As evidenced by the chapters in this volume, food availability (or the lack thereof) has major impacts on human health, and the prospect of local food scarcity is therefore an important concern.

62.11 Applications to Other Areas of Health and Disease

Diet seems to be closely linked to the evolution of our own species. The metabolic demands of a large brain may have necessitated dietary shifts toward sufficiently nutrient-rich foods (Leonard, this volume). When food is unpredictable but nutritional demands are high, there is a great deal of pressure to increase the efficiency of techniques to find, capture, and process foods. In this chapter, we have seen that food unpredictability can favor group foraging, a generalist diet and flexible, innovative strategies of opportunistic feeding. These behavioral strategies may also be cognitively demanding; both innovativeness (Reader and Laland 2002) and group living (Dunbar and Shultz 2007) are associated with increasing size of the cortex in nonhuman primates. Many of these traits have been pushed to extremes in humans, and it has been proposed that resource predictability may thus be an important factor to consider in human evolution. For instance, Richerson and Boyd (2000) have proposed that climate unpredictability has been one of the major drivers of both neural and cultural evolution in humans. "Since the late Miocene," they write, "organisms have had to cope with increasing variability in many environmental parameters at time scales on which strategies for phenotypic flexibility would be highly adaptive (…) The largest increases in encephalization per unit time by far is the shift from Miocene and Pliocene species to modern ones, coinciding with the Pleistocene climate deterioration." Ideas like these are necessarily a bit speculative, but it is difficult to apply to humans the methods on which most of this chapter is based: experimental manipulations of food predictability cannot be conducted on human populations for obvious reasons, and comparative interspecific comparisons are impossible because there is only one extant hominin species.

Food unpredictability may also be relevant to the study of food-borne diseases. If animals faced with unpredictable food distributions should be opportunistic, innovative generalists, they also face the associated risks of food poisoning and exposure to a wider array of pathogens because of their broad, flexible diets. A carrion or leaf specialist can more easily evolve defenses against bacteria, parasites and plant toxins than can a species exposed to a wide diversity of pathogens that change frequently. This idea is supported by the results of a recent study by Garamszegi et al. (2007), in which the authors found that highly innovative bird species (based on the number of reports of innovative feeding behavior in the literature) also had higher blood parasite loads and larger immune organs than less innovative species. Path analysis suggests that innovative feeding behavior exerts increased demands on the immune system.

Flexible, generalist, feeding behavior may also increase the risk of contracting specific diseases, such as salmonellosis (Tizard 2004), or mycoplasmal conjunctivitis (Fischer et al. 1997) in birds. Although extension of these results to humans is difficult, in part because of the methodological limitations mentioned above, we can nevertheless predict that exposure to a wide and frequently changing array of pathogens and food toxins has had a strong influence on mortality patterns in our hominid past, as well as the evolution of our immune systems.

On a more contemporary note, the importance of predictable access to food for human populations is well documented by nutritionists (e.g., this volume). However, it is important to consider the fact that humans form part of a global food web, and that many of our food sources are themselves predators. Thus, as development and deforestation lead to massive changes in the environment, food sources become less predictable for many species. As food becomes less predictable, this can cause species to change their behavior patterns either through behavioral flexibility or on evolutionary timescales (as described throughout this chapter), or may ultimately lead to extinction. The ideas laid out in this chapter can provide a predictive framework for how species will deal with these changes. For example, we would expect that highly specialized species will have more difficulty than generalists in adjusting to less predictable conditions. Species that are able to feed in groups (e.g., pigeons)

may be better able to take advantage of clumped resources (e.g., garbage piles) than species that defend exclusive territories. Depending on where they are found, mobile species will be able to seek out better conditions, while sessile species are more limited. All of these patterns, in turn, have consequences for the human food supply.

Box 62.1 Key facts on human foraging behavior in an ecological context

1. Foraging behavior can be defined such that it includes all aspects of feeding behavior, from searching for food, handling food, to ingesting food.
2. Under this definition, all food decisions including, for example, food purchases can be considered components of foraging in the broadest sense.
3. Differences in human foraging behavior can be studied at different scales, from the individual to the whole species level.
4. Foraging behavior in humans can vary along several axes, including (1) degree of food specialization, (2) amount of movement and travel required to find food, (3) type of information used to find food or make feeding decisions, and (4) the degree to which food can be monopolized or defended.
5. Some aspects of foraging behavior are limited by biology; there are some foods that humans cannot digest.
6. Many aspects of human foraging behavior are flexible, and can be adjusted based on current conditions and food availability.
7. Many species arrive at similar ways of dealing with similar ecological conditions, either through behavioral flexibility or convergent evolution. It can therefore be useful to compare some aspects of human behavior to that of other animals. This need not imply that our behavior is determined by genetics or even by ecology, but it may provide some insight into food decisions of individuals.
8. In this chapter, we focus on food unpredictability. When food is unpredictable, the foraging behavior that is optimal may change (see Table 62.1), and humans can adjust themselves accordingly. Many of these changes can occur within an individual's lifetime. For example, when food is unpredictable or scarce, a greater variety of foods may be incorporated into the diet.

Table 62.1 Predicted effects of food unpredictability on foraging behavior

Aspect of foraging behavior	Effects of increasing unpredictability	Illustrative examples
Feeding specialization	Shift from specialist to generalist feeding	Parasites (Simkova et al. 2006), hummingbirds (Pimm 1978), mice (Gray 1981)
Sampling and information use	Increase sampling rate	Pigeons (Shettleworth et al. 1988)
	Increase reliance on social information	Blue jays (McLinn and Stephens 2006)
Food defense	Less food defense and aggression	Zenaida doves (Goldberg et al. 2001)
Movement patterns	Greater exploration and movement	Periwinkle (Chapman 2000)

This table summarizes four ways in which food unpredictability can shift foraging behavior in a range of species, and provides an example of each of these shifts

Box 62.2 Key facts on defining food unpredictability

Experimental studies of the effects of food predictability require an operational definition of predictability. In this box, we describe a series of studies, some of which are also covered in the main text, and highlight the way in which the authors have defined unpredictability.

A recent experimental study with humans showed that food rewards (juice and water) had a greater influence on brain activity when they were unpredictable (Berns et al. 2001). In this study, the rewards were considered predictable when a drink was given every 10 s, and juice and water were alternated. In the unpredictable treatment, the interval between rewards was randomized, as was the order of juice and water. This is similar to a study of hooded crows (*Corvus cornix*) in which unpredictable feeding schedules was linked to greater fluctuations in weight and lower overall weight (Acquarone et al. 2002). In one experiment, some individuals were fed 100 g of food per day, while others were given a different amount each day, though the average amount of food was 100 g/day. In a second experiment, both the amount of food and the timing of feeding each day were randomly assigned for the unpredictable group, while the predictable group was fed the same amount of food (in this case, 150 g) at the same time each day. This same approach was used in study of magpies in which food predictability was shown to have negative impacts on immune responses (Cucco et al. 2002).

Given that stereotypic behavior is known to be a problem in captive animals, some studies have sought to test whether unpredictability of feeding schedules or food types are preferred. This was tested in a recent study on pigs (De Jonge et al. 2008), in which individuals were first trained on a feeding device, and then given choices between predictable and unpredictable feeding, in terms of (a) the amount of time before they received the food after activating the task and (b) the type of food reward they received. In each case, the variable (time/type of food) was chosen randomly in the unpredictable treatment, while it was kept constant in the predictable treatment. Overall, subjects preferred the predictable choices.

Another way to define predictability is by manipulating the information available to an individual. Two studies discussed in this chapter have used this approach (nutmeg manikins, Dubois and Giraldeau 2004; blue jays, McLinn and Stephens 2006). In these studies, individuals may either learn that a particular color signals the location of food (predictable), or that the color of the signal is unrelated to the location of food (unpredictable).

Summary Points

- The spatial and temporal distribution of food plays an important role in shaping individual behavior.
- When the spatial and temporal distribution of food is unpredictable, there are a number of ways that individuals should shift their behavior to maximize feeding efficiency.
- Although specialists can be more efficient at finding/processing food, they suffer a cost when their preferred food source is unpredictable. Thus, food unpredictability favors feeding generalism.
- When individuals cannot predict the location or quality of food, they may increase their sampling of the environment to gain information. Alternatively, they may rely on information from others.
- Food predictability may influence movement patterns of individuals across many spatial scales.
- Unpredictable food is unlikely to be defendable against others. Thus, food predictability can play a role in the degree to which animals aggressively defend territories or search and feed instead in unaggressive groups.

- Agriculture, food hoarding, and excess fat storage are all strategies to make food more predictable.
- Food predictability may have direct effects on health, increasing stress levels and decreasing immune responses.

Definitions

Foraging: In the broadest sense, foraging involves the search, capture, handling, and ingestion of food.

Food abundance: The amount of a given food type which is available in a given section of the environment.

Food variability: The degree to which the location, quality or quantity of a given food type fluctuates through time or space.

Food predictability: The degree to which an individual can accurately estimate the location, quality, or quantity of food, before actually sampling the food, using information from the physical or social environment.

Food distribution: The manner in which food is spread throughout the environment.

Spatial food distribution: The location and density of food in different parts of the environment.

Temporal food distribution: The changes over time in presence and/or density of food in different parts of the environment.

Feeding specialist: An individual/species whose diet is composed of very few or even a single food type.

Feeding generalist: An individual/species whose diet encompasses many different types of food.

Feeding flexibility: The degree to which an individual/species is able to change the types of food it eats or the foraging techniques it uses.

Resource defense theory: Introduced by Brown (1964), this theory states that individuals will only fight aggressively for a resource (i.e., food, access to mates) if this allows the individual to retain the benefits from that resource that outweigh the costs of aggression. RDT provides a predictive framework for the evolution of territorial defense.

Opportunism: The speed with which an animal searching for or exploiting one food type can shift to another food type when physical or social cues about its immediate availability arise.

Chapter 63
The Impact of Family Meals on Diet and Food Behaviors

Sarah J. Woodruff and Rhona M. Hanning

63.1 Family Meals

Potential influences on healthy eating have recently garnered much research attention, particularly those that affect children and adolescents, given the high prevalence of overweight and obesity (Shields 2005; Ogden et al. 2006). Using the construct of social cognitive theory, individuals can be influenced by myriad factors, including the individual, interpersonal, organizational, community, and public policy. Very little is known about the influence of the family (i.e., interpersonal factor) on youth food intake and behaviors even though the family is the main socializing agent until adolescence. The family directly determines the physical and social environment which can ultimately influence behaviors, habits, and attitudes through socialization and modeling (Ritchie et al. 2005). In particular, one possible explanation/influence may include food availability and access. Parents/siblings have the potential to influence diet quality and food behaviors through demographics (e.g., socioeconomic status, food expenditures, education, or employment of parent/adolescent), behavior modeling (e.g., food preferences/aversions, modeling), the shared environment (e.g., food availability/supply, food rules, communication), and parenting style (e.g., use of food reward/restrictions) (Woodruff and Hanning 2008). Food per se or mealtimes are often a common forum for communication in the home and can be used as a health promotion and intervention strategy.

Given the importance of family influence on diet quality, one easy-to-measure variable that may be a proxy for family food behaviors is the family meal. The family meal is usually an occasion for communication and interaction among family members, in which all family members consume similar types of food. With regard to diet quality and food intake, Fig. 63.1 illustrates how family meals can potentially influence food intake and behaviors. The family meal (e.g., scheduling, food preparation/purchasing patterns, television use), individual characteristics (e.g., age, weight status, culture/race, schedules), and food-related behaviors (e.g., food availability/accessibility, vegetarianism, dieting status, fast food use) all interact to potentially influence food intake (Woodruff and Hanning 2008). However, not only can family meals potentially influence diet quality and food behaviors, but other health behaviors (e.g., physical activity, behaviors

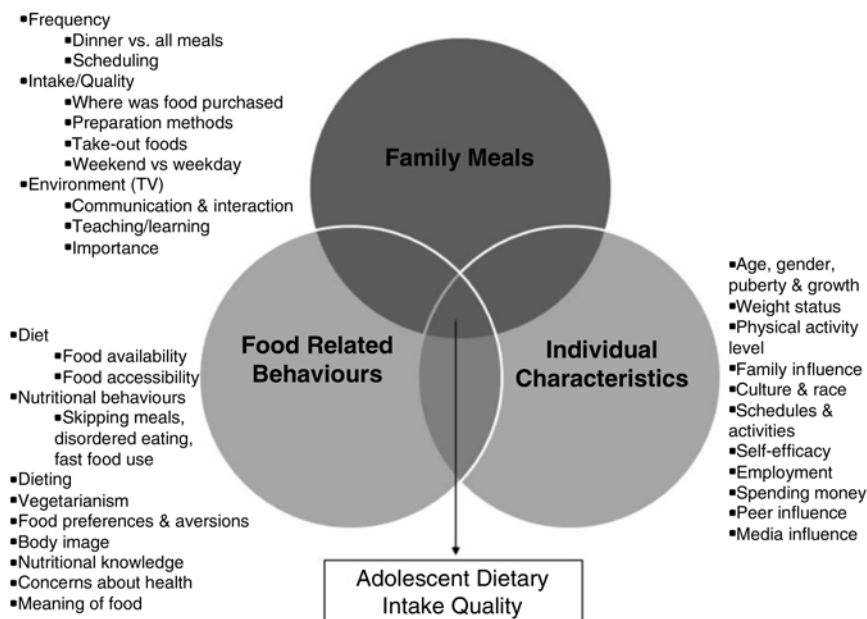

Fig. 63.1 Family meals, individual characteristics, and food related behaviours influence on diet quality. This figure depicts the influence of family meals, individual characteristics, and food related behaviours on adolescent dietary intake quality. Factors can work in isolation or can be inter related with others. Figure reprinted from: Woodruff SJ, Hanning RM. A Review of Family Meal Influence on Adolescents' Dietary Intake. Canadian Journal of Dietetic Practice and Research. 2008:69(1):14-22

leading to eating disorders/obesity, psychological adjustment, high-risk behaviors, and school performance) too.

63.2 Definition

Family meals can have many different meanings for each individual. Perhaps it invokes a blissful family image of everyone sitting happily around a large dining room table; for others it might be picking up something on the go and eating in the car on the way to soccer practice. Some families may have a special night of the week that is dedicated to a family ritual (e.g., pizza night or Sunday roast beef supper), while children and/or adolescents who live between two households, may have one ritual in one household and something completely different in the other. In an earlier focus group study among adolescents, Neumark-Sztainer et al. (2000) found that there were large variations in frequency of family meals, not only between participants but also within participants. Ever changing family demographics, busy schedules, and the development of convenience foods seem to have decreased the importance and/or frequency of family meals in today's society.

Defining family meals can be problematic as both individuals and researchers struggle with how to capture something that is so unique to each family. Table 63.1 lists the research definition of family meals by study, as some researchers have utilized the *dinner* meal (Gillman et al. 2000; Videon

Table 63.1   Key definitions of family meals

Dinner

- How often do you sit down with other members of your family to eat dinner or supper? (Gillman et al, 2000; Granner et al, 2004; Taveras et al, 2005)
- How many times was at least one parent was present when they ate their evening meal in the past seven days (Videon and Manning, 2003)
- How often do you sit down with other members of your family to eat dinner or supper?
- In the last 5 school days, how many times did all or most of your family living in your house eat an evening meal together? (Utter et al, 2008)
- The respondents reported the number of days in a typical week their family ate dinner together (Sen 2006 & 2009)
- How often they ate dinner together with their family (Custers and van den Bulck, 2009)s
- Typically, how many days per week do you eat dinner or supper with at least one parent? (Woodruff and Hanning, 2009a)

All meals

- During the last seven days, how many times did all, or most, of your house eat a meal together? (Neumark-Sztainer, 2003 & 2004; Burgess-Champoux et al, 2009; Eisenberg et al, 2009; Fulkerson et al, 2009)
- How often do you have breakfast/evening meal together with your mother or father? (Verzeletti et al, 2009)
- How often they ate breakfast/lunch together with their family (Custers and van den Bulck, 2009)

This table lists the research definition of family meals used by various studies.

and Manning 2003; Granner et al. 2004; Taveras et al. 2005; Veugelers et al. 2005; Utter et al. 2008; Sen 2009; Woodruff and Hanning 2009a) while others have included *eating breakfast* or *all meals* (Boutelle et al. 2001; Neumark-Sztainer et al. 2003; Eisenberg et al. 2004; Neumark-Sztainer et al. 2004; Marquis et al. 2005; Burgess-Champoux et al. 2009). This makes comparison across studies difficult; however, there is no reason to believe that the benefits of eating the evening meal together would differ from eating other meals and/or snacks together.

To avoid a nuclear family bias, researchers have also had to consider who must be in attendance in order to for a meal to be defined as a *family* meal. Various circumstances have been used within the literature (see Table 63.1), such as *when at least one parent is present* (Videon and Manning 2003; Woodruff and Hanning 2009a) or *when all or most of the family living in a house is there* (Neumark-Sztainer et al. 2003; Neumark-Sztainer et al. 2004; Utter et al. 2008; Burgess-Champoux et al. 2009; Sen 2009). The influence of including other members of a family (e.g., grandparents, aunts, and/or uncles) and/or friends has not been carefully examined. Some literature is emerging on the nutritional impact of *family-style* meals and/or social eating with friends, for example in lunch rooms at schools (Woodruff and Hanning 2009b) or in older adult facilities (Altus et al. 2002; Nijs et al. 2006).

63.3 Prevalence

Regular family meals (five or more meals per week) have been reported by 25–70% of children and adolescents and 11–44% report family meals on 2 or fewer days per week (see Table 63.2) (Gillman et al. 2000; Neumark-Sztainer et al. 2003; Videon and Manning 2003; Neumark-Sztainer et al. 2004; Veugelers et al. 2005; Sen 2006; Utter et al. 2008; Verzeletti et al. 2009; Burgess-Champoux et al. 2009; Custers and Van den Bulck 2009; Eisenberg et al. 2009; Fulkerson and Neumark-Sztainer et al. 2009; Sen 2009; Woodruff and Hanning 2009a). The large variation can be partly attributed to the age of participants from the different studies as family meal frequency seems to decline with

Table 63.2 Family meal frequency

Authors	N	Age	Study/Region	Family Meal Frequency
Gilman et al (2000)	16,202	9-14 yrs	Nurses' Health Study II (USA)	Everyday 35% Most days 40% Never/some 17%

This table lists family meal frequency by individual study (including author, sample size and age, and geographical area). FM: family meal, T1: time 1/baseline, T2: time 2/follow-up.

increasing age (Gillman et al. 2000; Granner et al. 2004; Burgess-Champoux et al. 2009; Wurback et al. 2009). Further, it is interesting to note that the majority of studies have been conducted using one family member's account of meal time (usually the child or adolescent); yet when two family members are questioned, some discord exists between parent and child responses. Parents tend to report more regular family meals than adolescents (Boutelle et al. 2001; Fulkerson et al. 2006), while adolescents tend to report greater scheduling difficulties (Fulkerson et al. 2006). However, social

eating tends to be valued among children/adolescents and parents. Overwhelmingly, 89% of male and 93% of female young adults agree that eating together with family or friends is enjoyable and 76% of males and 82% of females believe it to be important to sit down and eat at least one meal a day with other people (friends or family) (Larson et al. 2009). Among adolescents (7th–12th grade), the majority (63%) and most of their parents (98%) reported the importance of eating a meal together as a family (Fulkerson et al. 2006).

The potential significance of family meals is that it passes on family traditions/values to the next generation. At the table, parents are able to act as role models, teach life lessons, and interact with their children in a meaningful way every day. Parents reported many benefits of family meals, including time for conversation, feelings of togetherness, shared nutrition, and ceremony (Fulkerson et al. 2008). Shared family meals can be a time for education. An earlier study investigating parents as role models reported that nutrition is often a topic of conversation at the dinner table (Gillespie and Achterburg 1989), which suggests that the dinner table can used as a teaching and learning environment (e.g., food and table manners, cooking/preparation techniques). Finally, parental modeling was specifically reported among low income adolescent girls, who consumed more calcium when they saw important others (mother, father, friends) drinking milk (Lee and Reicks 2003), which is similar to another study of daughters who eat fruits and vegetables modeled after their parents (Fisher et al. 2002).

Many health promotion/nutrition specialists are increasingly becoming aware of the importance of family meals. For example, in many countries (e.g., Malaysia, Thailand, Japan), family meals are promoted in their national food guide recommendations. Specifically, the *Dietary Guidelines for Japanese* suggests "happy eating makes for happy family life; sit down and eat together and talk; treasure family taste and home cooking," and the *Malaysian Nutrition Guide for Early Childhood Care* suggests "making mealtimes an enjoyable experience." Unfortunately, North American food guides seem to focus on specific food groups and serving sizes and tend to stay away from food behaviors.

63.4 Family Cohesion

As Story and Neumark-Sztainer (2006) wrote, "family meals have long been considered essential for the unity of the family and a symbol for family interactions" (p. 261). Regular family meals may be a proxy for family connectedness and cohesion as family members are spending time together at the table. Family meals often become ritualistic, and as earlier reported, "Family rituals and routines often reinforce the importance of family and its members" (Woodruff and Hanning 2008, p. 17). Families that have more frequent family meals also tend to have rules/rituals about other things, thereby creating greater family cohesion. In a large study (n = 81,247 of 9th–12th grade adolescents), family connectedness was a protective factor for disordered eating patterns (Croll et al. 2002), and according to data from the longitudinal (10 years) National Heart, Lung, and Blood Institute Growth and Health Study (NGHS), family meals during childhood were related to various health outcomes in adolescents through the mediating factors of family cohesion and coping skills (Franko et al. 2008). More frequent family meals during the first 3 years of the study predicted greater family cohesion and problem and emotion-focused coping in Years 7 and 8; family cohesion mediated family meals and risk of smoking in Year 10; and problem-focused coping mediated family meals and both stress and disordered eating-related attitudes and behaviors in Year 10 (Franko et al. 2008). Finally, measures of general family connectedness, priority of family meals, and positive mealtime environment were significantly positively associated with psychological wellbeing and inversely associated with depressive symptoms and unhealthy weight-control behaviors among an ethnically diverse sample of at-risk-for-overweight and overweight youths (n = 1,351 adolescents) (Fulkerson et al. 2007).

63.5 Obstacles

Anywhere from half to a third of children and adolescents do not have regular family meals. There are numerous potential reasons, but the most often cited reason for not eating together is lack of time due to work/sports/activity schedules (Neumark-Sztainer et al. 2000; Fulkerson et al. 2006; Larson et al. 2009). Other reasons for lack of family meals include: no time to cook/buy groceries, don't know how to cook (Fulkerson et al. 2006), family doesn't all like the same foods (Neumark-Sztainer et al. 2000; Fulkerson et al. 2008), healthy food takes longer to prepare (Fulkerson et al. 2006), can create hostile reactions (Fulkerson et al. 2006), shared meals are unpleasant due to dissatisfaction with family relationships (Neumark-Sztainer et al. 2000), teen desire for autonomy (Neumark-Sztainer et al. 2000) and/or that eating together is idealized, so therefore unattainable. Approximately 55% of adolescents and 79% of parents suggested that they somewhat or strongly agree that different schedules make it difficult for the family to eat meals together (Fulkerson et al. 2006). Among 50 employed parents, long hours and/or nonstandard hours and schedules were positively associated with take-out meals, missed family meals, choosing preprepared entrees, eating while working, restaurant meals, and missed breakfast (Devine et al. 2009). See Table 63.3 for suggestions for parents trying to increase the frequency of family meals.

63.6 Family Meals and Diet Quality

A recent systematic literature review identified that, in most studies, family meals were linked to higher overall diet quality (Woodruff and Hanning 2008). Specifically, research has shown that family meals are associated with higher intakes of fruit and vegetable (Gillman et al. 2000; Neumark-Sztainer et al. 2003; Videon and Manning 2003; Utter et al. 2008; Fulkerson et al. 2009), grains (Neumark-Sztainer et al. 2003), dairy (or calcium-rich) foods (Neumark-Sztainer et al. 2003; Videon and Manning 2003), proteins (Neumark-Sztainer et al. 2003), minerals (iron, folate, fiber; Gillman et al. 2003; Neumark-Sztainer et al. 2003), and vitamins (A, C, E, B_6, B_{12}; Gillman et al. 2003; Neumark-Sztainer et al. 2003). Furthermore, family meals have been negatively associated with having fried foods away from home (Gillman et al. 2000) and sugar sweetened beverages (Gillman et al. 2000; Neumark-Sztainer et al. 2003; Verzeletti et al. 2009; Woodruff and Hanning 2009a). Lastly, family meals were reported to be positively associated with overall diet quality, using various diet quality indices (Veugelers et al. 2005; Woodruff and Hanning, 2010).

Table 63.3 Suggestions for parents to increase family meal frequency

- Try to make family meals a priority
- Aim for at least 3-4 family meals/week
- Look for creative ways to increase family meals
- Avoid topics likely to lead to arguments at meals
- Plan ahead; know what you are having for dinner before dinner time
- Buy the groceries ahead of time, choose foods that will please everyone
- Start with one or two meals a week, gradually increase
- If dinner doesn't fit into schedules, try for breakfast
- Try to incorporate all family members into planning, preparing, and clean up
- Turn off the television
- Avoid contentious issues

This table lists key suggestions for parents trying to increase family meal frequency (some taken from Neumark-Sztainer, 2009a).

In the first longitudinal study of adolescent food behaviors, family meals during middle school were associated with healthier food behaviors (e.g., breakfast consumption, less fast food consumption) 5 years later (Burgess-Champoux et al. 2009). Further, family meal frequency during adolescence predicted higher intakes of fruit, vegetables, dark green and orange vegetables, more breakfast meals (females only), more frequent family meals, and lower intake of soft drinks during adulthood (Larson et al. 2007). Larson et al. (2007) advise that family meals during adolescence may have lasting positive influence on diet quality and meal patterns in young adulthood. Future research needs to investigate whether the positive influence persists into adulthood.

Finally, family meals may influence other food behaviors also (Woodruff and Hanning 2008). Family meals have been reported to be associated with consuming breakfast (Videon and Manning 2003; Utter et al. 2008; Fulkerson et al. 2009; Woodruff and Hanning 2009a), limiting soft drink and/or sugar sweetened beverage consumption (Gillman et al. 2000; Neumark-Sztainer et al. 2003; Verzeletti et al. 2009; Woodruff and Hanning 2009a), and having high self-efficacy for healthy eating (Woodruff and Hanning 2009a). We recently reported (Woodruff and Hanning 2009a) that participants who consumed breakfast (versus skipped breakfast) were likely to have higher dinner meal frequency (OR = 1.81) even after adjusting for dieting status and concerns of high body weight. Families who are more likely to eat dinner together may understand the importance of healthy food behaviors; thus they may be more likely to consume breakfast together (Woodruff and Hanning 2009a). Our work (2009a) also identified that participants who reported consuming soft drinks two to six times/week (OR = 1.54), once/week (OR = 1.93), once/month (OR = 1.94), or rarely/never (OR = 1.79) were likely to have a higher family meal frequency compared to those consuming soft drinks at least once/day. These results are similar to those from US studies, which also reported negative associations between family meal frequency and soft drink consumption (Gillman et al. 2000; Neumark-Sztainer et al. 2003; Verzeletti et al. 2009). It is possible that children and adolescents who consume more frequent family meals may also have family meal rules that prevent soft drink consumption (in favor of milk and/or water) during meals (Woodruff and Hanning 2009a).

63.7 Location and Environment

The location of family meals may be an important predictor of overall diet quality. When a meal is consumed at home with other family members present, most often some of the food consumed will be shared (although, not always) and therefore will be of similar quality. Alternatively, when food is consumed outside of the home (such as at a restaurant), each individual usually has their choice of what to eat and, therefore, overall quality of the meal can vary between family members. In a recent study, we (2009b) used a cluster analysis to group together meal environments in just over 3,000 grade six, seven, and eight students from Ontario and Nova Scotia, Canada and reported that 72% of the sample consumed dinner at home, with family and prepared by family members (versus (1) 7% who ate at home, with family, but was self-prepared, (2) 4% who ate at home, with family, from food that was purchased at a convenience store/vending machine/other place, (3) 8% who ate at home alone, (4) 6% who ate with family at a restaurant/fast food outlet, and (5) 3% who skipped dinner altogether). Interestingly, the likelihood of a lower diet quality increased when students consumed dinner in a restaurant/fast food outlet, even though it was consumed with family (OR = 0.51), or skipped dinner altogether (OR = 0.53) rather than consuming dinner at home with, and prepared by, family members (Woodruff and Hanning 2009b). In the United States, frequent fast food use for family meals (at least three times per week) was associated with less milk and vegetables being served with meals at home and higher total intake of fast foods and salty snack foods for both parents

and adolescents, in addition to higher weight status among parents (Boutelle et al. 2007). Furthermore, eating outside of the home for family meals may be becoming more popular. In a small study of parents (n = 107) of 8–10 year olds who reported frequent family meals, family dinners were reportedly eaten at full-service restaurants, purchased from fast-food establishments, or picked up as take-out foods at least weekly (47%, 28.3%, and 23.8%, respectively; Fulkerson et al. 2008). Consuming food outside of the home (as opposed to inside the home) has been associated with higher intakes of fat, sugar, and salt, and lower intakes of fiber and calcium (Lin et al. 1999a; Cluskey et al. 2008) in addition to contributing more energy as a percentage of total calories compared to eating in the home (Lin et al. 1999b). In terms of overall diet quality, family meals may provide better nutrition if consumed in the home, possibly due to more control over types of food served, cooking preparation, and portion size.

In a recent review paper, we (2008) suggested that distractions during family meals (such as the television) may reduce or eliminate communication and interaction for those eating together. Figure 63.2 illustrates the prevalence of watching television during family meals among a small sample (n = 395) of grade six students from Ontario, Canada. The finding is similar to that of grade 5 students from Nova Scotia, Canada for whom 44% reported watching supper in front of the television less than once/week (Liang et al. 2009). Results from the United States are similar, such that watching television during family meals was reported in 27–33.5% of adolescents (Feldman et al. 2007; Eisenberg et al. 2009). Adolescents (n = 4,746) who reported watching television during family meals consumed lower intakes of vegetables, dark green/yellow vegetables, calcium-rich food, and grains and higher intake of soft drinks compared to those not watching television during meals (Feldman et al. 2007). Coon et al. (2001) also reported that students in grade 6–8 consumed higher amounts of pizza, snack foods, and soda and fewer fruits and vegetables than those who did not watch television while eating with family meals. A potentially confounding variable between family meals and overweight/obesity status, however, might be watching television while eating, as dinner in front of the television was positively and independently associated with overweight status among grade 5 students from Nova Scotia (Liange et al. 2009). Nevertheless, eating together while watching
Fig. 63.2 Watching television during family meals (n=395 grade six students). This graph depicts the percentage of students (n=395 grade 6 students) watching television during family meals

television was associated with better diet quality than not eating together at all (Feldman et al. 2007). Other possible distracters from family meals include cell phone use, computer game play, and book reading, as identified among 12, 14, and 16 year olds from Belgium (Custers and van den Bulck 2009). However, these newer technologies are so far limited in the research literature.

63.8 Eating Disorders and Obesity

Body weight status is arguably a measure of diet quality, and family meals have the potential to decrease the risk of eating disorders and obesity among children and adolescents. The strength of the research is stronger for family meals and eating disorders (versus obesity), such that eating in a social setting seems to discourage unhealthy eating behaviors and secretive eating. Family meal frequency has been negatively associated with extreme and less extreme weight control (males and females; Neumark-Sztainer et al. 2004; Fulkerson et al. 2006), chronic dieting (females; Neumark-Sztainer et al. 2004), bulimia (Ackard and Neumark-Sztainer 2001; Fulkerson et al. 2006), and concern about high body weight (Woodruff and Hanning 2009a).

In a longitudinal study, regular family meals (≥5 meals/wk) at baseline were associated with lower prevalence of extreme weight control behaviors (e.g., self-induced vomiting, use of laxatives, diet pills, or diuretics) (OR = 0.71) after 5 years, even after adjusting for sociodemographic characteristics, body mass index, family connectedness, parental encouragement to diet, and extreme weight control behaviors at baseline among females (Neumark-Sztainer et al. 2008). Family meals may also have a protective effect against other disordered eating behaviors (e.g., eating very little, fasting, using food substitutes, skipping meals, smoking, binge eating, and chronic dieting), however findings with bivariate analyses were not confirmed in adjusted models (Neumark-Sztainer et al. 2008). It may be possible that individuals with weight issues and/or disordered eating patterns prefer to not eat in front of others. It may also be possible that poor body image and/or disordered eating behaviors are a result of a negative family meal atmosphere and/or poor family relations (Neumark-Stzainer et al. 2008; Woodruff and Hanning 2009a). Neumark-Sztainer et al. (2004) suggests that families may be able to protect their children from engaging in harmful disordered eating behaviors through enhanced communication, caring relationships, and for females, more enjoyable family meals.

Conflicting results exist for the correlation between family meals and overweight/obesity status. In many cases, associations between family meal frequency and obesity often exist cross-sectionally, yet disappear in longitudinal analyses (Taveras et al. 2005; Fulkerson et al. 2008; Utter et al. 2008). For example, among a large cohort of 9–14 year old children (n = 14,431) participating in the *Growing up Today* study (Taveras et al. 2005), the odds of being overweight was 0.85 among children who ate family dinner on *most days* or *every day* compared with those who ate family dinner *never or some days*. However, in a longitudinal model, the odds ratios between previous year frequency of eating family dinner and 1-year incidence of becoming overweight were 0.95 and 1.04 for children who ate family dinner on *most days* and *every day*, respectively, compared with those who ate family dinner *never or some days* (Taveras et al. 2005). Only in one longitudinal study (3 years) following normal weight students from the time they entered kindergarten, were there significant inverse associations between family meal frequency and overweight by the third grade. Children who were consistently overweight were also more likely (OR = 1.08) to consume fewer family meals (Gable et al. 2007). However, the age of participants may influence the longitudinal results (as Gable et al. (2007) participants are much younger than Taveras et al. (2005), Fulkerson et al. (2008), and Utter et al. (2008)).

Some studies have reported an inverse relationship between family meals and overweight/obesity status (Veugelers et al. 2005; BeLue et al. 2009; Wurbach et al. 2009), particularly among adoles-

cents at risk of academic failure (Fulkerson et al. 2009) and those attending alternative high schools (Kubik et al. 2009). For example, at-risk adolescents who reported never eating family dinner were significantly more likely to be overweight (OR = 2.8), and food insecure (OR = 6.0) than adolescents who reported five to seven family meals per week (Fulkerson et al. 2009). Interestingly, Sen (2006) suggested that family dinner frequency may be associated with overweight status in white participants, but not blacks or Hispanics. Possible reasons for the racial and ethnic differences may include differences in the types and portions of food consumed at family meals; however, limited research exists. Finally, a potential confounding variable between family meals and overweight/obesity status might be watching television while eating, as dinner in front of the television was positively and independently associated with overweight status among grade 5 students from Nova Scotia (Liang et al. 2009).

The protective nature of family meals on weight status may be confounded by sex, as reported in an interesting paper on shared risk and protective factors for overweight and disordered eating in adolescents (Neumark-Sztainer et al. 2007). Family meals (in addition to regular meal patterns and media exposure to messages about weight loss) were associated with eating disorder and overweight/obesity status, particularly among females but not males (Neumark-Sztainer et al. 2007). In a recent review paper discussing recommendations for health care providers to prevent obesity and eating disorders in children and adolescents, Neumark-Sztainer (2009b) encourages more frequent and more enjoyable family meals as one of the top five recommendations. Although the associations observed in epidemiological studies do necessarily *prove* that eating family meals more frequently will result in change, many agencies have adopted similar guidelines. For example, the American Medical Association Expert Committee recommendations for childhood obesity was to *encourage family meals on most, and preferably all, days of the week* (Rao 2008), and the Ontario Ministry of Health and Long Term Care report *Healthy Weights, Healthy Lives* recommend *enjoying family meals whenever possible* (MHLTC 2004).

63.9 Applications to Other Areas of Health and Disease

63.9.1 *Psychological Adjustment, High Risk Behavior, and School Performance*

Family meals are known to be associated with better psychological adjustment, decreasing high risk behavior, and better school performance in children and adolescents (see Table 63.4). In a large study of 6–12 grade students (n = 99,462) from 25 states in the United States, family meal frequency was consistently positively associated with both internal (e.g., commitment to learning, positive values, social competencies, and positive identity) and external assets (e.g., support, boundaries, and expectations) (Fulkerson et al. 2006). Most noticeably, family meals may provide a formal or informal check in time for family members, thereby allowing parents to be aware of their children's emotional well-being (Eisenberg et al. 2004). Family dinner frequency was also inversely related to depressive symptoms and suicide involvement in adolescents (Eisenberg et al. 2004) and adolescents at risk (Fulkerson et al. 2009). Fulkerson et al. (2007) argue that greater psychological well-being is associated with making family time at meals a priority and creating a positive mealtime atmosphere.

Furthermore, family meals were consistently negatively associated with all high-risk behaviors (e.g., substance use, sexual activity, depression/suicide, antisocial behaviors, violence, school problems,

Table 63.4 Family meal associations to other areas of health and disease

Health Issue	Specific Factor
Psychological adjustment	• Internal assets (+)
	• External assets (+)
	• Depression (−)
	• Suicide (−)
High risk behaviours	• Substance abuse* (−)
	• Cigarette smoking* (−)
	• Alcohol* (−)
	• Marijuana* (−)
	• Sexual activity (−)
	• Antisocial behaviour (−)
	• Violence (−)
	• School problems (−)
	• Binge eating/purging (−)
	• Excessive weight loss (−)
Academic performance	• Grade point average (+)
	• High motivation to do well in school (+)
	• School engagement (+)
	• Reporting 1 or more hours of homework (+)

This table lists the associations (positive or negative) of family meals to other areas of health and disease. Positive association (+), negative association (−), and association only evident among females *

binge eating/purging, and excessive weight loss) (Fulkerson et al. 2006). Regular family activities, including family meals and/or religious activities, prospectively predicted declines in a lower frequency of adolescent risky sexual behaviors (Coley et al. 2009). Significantly higher prevalence of cigarette smoking, alcohol, and marijuana use were found for adolescent reporting regular family meals versus no regular family meals (Eisenberg et al. 2004; Eisenberg et al. 2009). It is noteworthy that many of the significant associations were found in females and not in males (Fisher et al. 2007; Eisenberg et al. 2009), which may be a function of how females (versus males) interact with other family members (Davies and Lindsay 2004; Eisenberg et al. 2009). Long term protective effects of family meals were also evident among females in a longitudinal study, as family meal frequency at baseline was associated with significantly lower odds of cigarette smoking, alcohol use, and marijuana use at 5 years follow up, even after for controlling for baseline substance abuse and additional covariates (again, no differences were observed for males; Eisenberg et al. 2008). It may be that family meals reflect more supervised time and therefore less time to engage in risky behaviors (Eisenberg et al. 2004). It is also possible that family meals make children and adolescents spend more time at home and therefore are restricted from potentially negative peer pressure situations (Eisenberg et al. 2004).

The association between family meals and school performance also seems to be apparent in children and adolescents. Eisenberg et al. (2004) reported that greater family meal frequency decreased the odds (OR = 0.88 and OR = 0.99 for males and females, respectively) of a low grade point average. Furthermore, in a large sample of adolescents (nearly 100,000 grade 6–12 students) greater family meal frequency increased the likelihood of having a high motivation to do well in school (OR = 1.5), school engagement (OR = 1.6), and reporting one or more hours of homework daily (OR 1.5), even after adjusting for demographic and family variables (Fulkerson et al. 2006).

Summary Points

- The family may influence childhood and adolescent food behaviour and attitudes through demographics, behaviour modeling, shared environment, and parenting style.
- Family meals are difficult to define (e.g., dinner or all meals; at least one parent or do all family members have to be present; location; does everyone have to be eating the same thing).
- Family meals occur regularly (5 or more days/week) in approximately 25-70% of children and adolescents, and 11-44% on two or fewer days/week.
- Family meals seem to have a positive association with diet quality, food behaviours, body weight status, psychological adjustment, high risk behaviours, and school performance.
- Family meals may be a proxy for family connectedness and family cohesion.
- Obstacles for family meals include scheduling, lack of knowledge regarding food preparation, dissatisfaction with family relationships, and adolescent desire for autonomy.
- Tips to increase family meal frequency include planning ahead (e.g., know what you are having for dinner before dinner), get all family members involved (planning and preparation), be flexible about timing (e.g., if dinner doesn't work for your family, what about breakfast?), be a good role model, turn off the television, discuss non-contentious issues.

Definition

Family meal: usually an occasion for communication and interaction among family members, in which all family members consume similar types of food
Diet quality: a measure of how well one's dietary intake meets the current dietary recommendations
Food behaviour: any behaviour (action) that is related to food and/or food intake

64.1 Introduction

This chapter considers the extent to which television can affect our food preferences, choices, and consumption. Television is an extremely popular leisure time pursuit worldwide and is the dominant sedentary pastime among children and adolescents (Swinburn and Shelly 2008). However, in the context of a global obesity epidemic and concerns over poor diet quality, particularly in young people, questions have been raised as to the impact television viewing has on our dietary choices and subsequently our overall health.

64.2 Childhood Diet, Ill Health, and Obesity into Adulthood

The prevalence of overweight and obesity has risen dramatically in both developed and developing countries over the last few decades. A 2004 survey estimated that 18% of European school children (approximately 14 million children in the 25 EU member states) are overweight, of whom three million are thought to be obese (Lobstein et al. 2004). Worldwide, 1.1 billion adults and 10% of children are now classified as overweight or obese (Haslam and James 2005). Obesity in childhood has numerous adverse consequences in the short-term, including psychological ill health, cardiovascular

risk factors, asthma, chronic inflammation, diabetes (types I and II), orthopedic abnormalities, and liver disease (Reilly and Wilson 2006). Additionally, there is considerable evidence to suggest that obesity persists from childhood (particularly adolescence) into adulthood. Around 60% of obese children and 80% of obese adolescents are likely to become obese adults; thus, in the longer term, pediatric obesity is associated with further problems as an adult, such as adverse socioeconomic outcomes, cancers, depression, arthritis, and premature mortality (Reilly and Wilson 2006).

Although obesity is a well publicized and highly recognized public health concern, a lack of clarity over the etiology of obesity has been a particular barrier to the development of effective strategies for obesity prevention (Prentice and Jebb 1995). Whilst genetic and familial associations with obesity suggest that individual susceptibility may play a role, the recent rapid rise in levels of overweight and obesity suggests that environmental and behavioral changes are largely responsible, as the epidemic has occurred against a relatively constant genetic (and therefore metabolic) background (Prentice and Jebb 1995). As obesity is ultimately a consequence of energy intake exceeding energy expenditure, it can be concluded that the current epidemic is due to an environment that promotes the behaviors that cause obesity – namely, a virtually unlimited supply of convenient, relatively inexpensive, highly palatable, energy dense foods – all factors promoting overconsumption (Hill and Peters 1998). Epidemiological studies have previously shown a positive relationship between dietary fat intake and obesity and, indeed, the proportion of fat in the British diet has increased from 0.6 kJ of fat for each kilojoule of carbohydrate in the diet in 1940, to 0.9 kJ fat per kilojoule of carbohydrate in 1990 (Prentice and Jebb 1995).

In the USA, trends in young peoples' nutrient intakes and eating patterns between the 1970s and 2004 have recently been highlighted (McGinnis et al. 2006). The report indicates that carbohydrate intake has increased over this time, total fat and saturated fats consumed remain at levels that exceed dietary recommendations, snacking has increased steadily during this period, and that currently a large proportion of total calories are consumed from foods and beverages with high calorie and low nutritional content (McGinnis et al. 2006). The survey also suggests that consumption of fruits, vegetables, and whole grains is well below the recommended daily intake. The report concludes that, overall, young people in the USA are in energy imbalance due to a significantly increased caloric intake over the past 25 years (McGinnis et al. 2006).

During the 1970s and earlier, the term "diet quality" referred to the consumption of a diet with sufficient calories, protein, and micronutrients as to prevent diseases of deficiency. In contrast, it is now based upon "the principles of adequacy, variety, proportionality, and moderation" (McGinnis et al. 2006, p. 45), as well as recommending high intake of fruits, vegetables, and whole grains (nutrient-dense foods) and limited intake of fats and added sugars (McGinnis et al. 2006). Nevertheless, despite increases in our understanding of nutrition, it is clear that there is still much discrepancy between habitual food consumption and the recommended diet. It has been suggested that television may play a role in this disparity, at least partially through the introduction of food cues in advertisements, potentially affecting food preferences and choice.

64.3 The Importance of Childhood Food Preferences and Diet

It is widely believed that children 'eat what they like' and that children's food preferences are highly indicative of their habitual consumption (Cooke and Wardle 2005). Each of us is born with a few genetic predispositions that govern early development of food preferences, notably a liking for sweet and salty foods and an aversion to sour and bitter flavors (Birch 1999). Indications of such early preferences can be rapidly ascertained by examining infants' facial expressions (Benton 2004). Children typically prefer sweeter tastes than adults, and the preference for a salty taste develops by approximately 4 months of age (Benton 2004).

Also, we are predisposed to initially rejecting novel foods (neophobia) and to learn preferences by creating associations between foods and the contexts in which they are consumed and the consequences of their consumption (Birch 1999). Therefore, as consuming an energy-dense food is a satisfying subjective experience, there is a tendency to learn to prefer energy-dense foods (those high in fat and/or sugar) (Benton 2004). This tendency may have been adaptive in the past in times of famine, or for particularly young children requiring energy for growth, but in the context of today's readily available supply of palatable food it can be a considerable risk factor predisposing an individual to obesity (Benton 2004). Indeed, a preference for fatty foods in children between the ages of 3 and 5 years has previously been found to predict skinfold thickness which is a reliable index of adiposity (Fischer and Birch 1995). Additionally, neophobia typically declines with age, potentially as a result of children having tried a greater number of foods without experiencing adverse postingestive consequences (Cooke and Wardle 2005).

Given the rising levels of obesity (discussed in the next section), it appears that food preferences are currently influencing food selection to be inconsistent with recommended dietary guidelines and thus are promoting eating behaviors causing weight gain and ultimately leading to overweight and obesity (Birch 1999). However, because, beyond initial predispositions, learning plays a central role in the development of food preferences, this suggests that preferences are modifiable and that learned preferences towards healthier foods could be encouraged (Birch 1999).

It is, therefore, critical to ascertain those factors that influence the development of food preferences and choice in children, in order to identify those aspects of the environment that are potentially obesigenic for those individuals with a genetic susceptibility to weight gain. One such factor that has been implicated in food preference and choice is television viewing.

64.4 Television Viewing Is Linked to a Poor Diet and Obesity

For over 20 years television has consistently been linked with negative health effects, particularly in children, including violent behavior, academic performance, and perhaps most notably nutrition, dieting, and obesity (AAP 2001). Given that television is a pervasive source of entertainment, particularly amongst children and adolescents, this is a concern. In the UK, children between the ages of 4–15 years watch an average of 17.2 h of television per week (Ofcom 2004). In addition, it has been reported that 71% of 8–11 year olds and 75% of 12–15 year olds have a TV set in their bedroom (Ofcom 2006), a factor that has been associated with an even greater risk of overweight (Dennison et al. 2002).

64.4.1 Obesity

A 1985 study by Dietz and Gortmaker was the first to link high television viewing with a greater risk of overweight and obesity. In a sample of over 10,000 children, this study demonstrated significant associations between time spent watching television and the prevalence of obesity, such that obesity prevalence was shown to increase by 2% for each additional hour of television viewed (Dietz and Gortmaker 1985). Since that study, much additional evidence has been gathered to support this relationship both in childhood and extending into adulthood. Importantly, it has even been shown that television viewing in childhood can independently predict increased adult body mass index, indicating that there could be a causal link (Viner and Cole 2005).

In a cross-sectional study, Andersen et al. (1998) found that boys and girls who watched 4 or more hours of television each day had greater body fat and a greater body mass index than those who watched less than 2 h per day. Furthermore, Dennison et al. (2002) found that not only was the amount of time spent viewing television related to the prevalence of overweight, but that the presence of a television in a child's bedroom increased their weekly viewing by 4.8 h and further strengthened the risk of overweight. The effects appear to persist into adulthood, and as Jeffery and French (1998) showed, television viewing hours were positively associated with both energy intake and body mass index in women aged 20–45 years.

Importantly, the association between television viewing and obesity remains significant even when other potential confounding variables such as socioeconomic status, familial tendency to overweight (Hancox and Poulton 2006) and, critically, levels of physical activity (Epstein et al. 2008) are taken into account. Therefore, it is not simply the case that television viewing is linked to obesity because it is a sedentary activity, displacing physical activity, and thus lowering overall energy expenditure; rather, the association appears to be due to the effects of television viewing on food intake.

64.4.2 Diet

Several studies have demonstrated that energy intake increases during television viewing. Crespo et al. (2001) found that girls who watched 5 or more hours of television a day consumed on average an extra 732 kJ (175 kcal) a day compared to those watching 1 h or less of television per day. Wiecha et al. (2006) found an even bigger increase in intake, with each additional hour of television viewing associated with an additional 167 kcal per day. The cumulative effect of a small daily increase in kcal intake could contribute to a positive energy balance (intake exceeding expenditure) and therefore at least partially explain the relationship between television viewing and obesity (discussed above).

Typically, increases in caloric intake associated with television viewing are mainly due to increases in the consumption of foods that are both energy dense and low in nutrients (Davison et al. 2006), so television viewing is associated with poor overall diet quality. The amount of time spent viewing television is predictive of unhealthy conceptions about food and poor eating habits generally (Signorielli and Lears 1992). One study found that television viewing was inversely associated with intake of fruit and vegetables among adolescents, whereby fruit and vegetable intake decreased by 0.16 servings per day with each additional hour increase in television viewing (Boynton-Jarrett et al. 2003). Another found that children from families with high television use derived more of their daily energy intake from meats, pizza, salty snacks, and soda and less from fruit, vegetables, and juices than children from families with low television use (Coon et al. 2001).

In addition, eating whilst watching television (whether it is eating snacks in front of the television or having television viewing as part of the meal time routine) has been shown to affect food choice and caloric intake. Marquis et al. (2005) showed that eating in front of the television was positively correlated with children's general consumption of French fries, salty snacks, ice cream, confectionery, pastries, sweetened cereals, fruit beverages, and soft drinks, and negatively correlated with overall consumption of raw vegetables. It has been suggested that children in particular consume a substantial proportion of their daily energy whilst watching television, 20% and 25% for weekdays and weekend days respectively (Matheson et al. 2004), therefore television viewing could have a significant impact on both the types of foods selected and the overall level of consumption.

This section of the chapter has demonstrated that there is a considerable amount of evidence to suggest that television viewing has a detrimental effect on food choice, overall diet quality, and levels

of adiposity in children, adolescents, and adults. It has been suggested that these effects may be due to the influence of television food advertising.

64.5   The Extent and Nature of Television Food Advertising

Internationally, television remains the primary medium used for advertising food and drink products, comprising approximately 75% of all advertising spend in the UK in recent years (Hastings et al. 2003). Although both the nature and extent of such advertising varies between countries, typically a majority of the advertisements broadcast are for unhealthy products. It has been estimated that for every US$1 the World Health Organisation (WHO) spends on promoting healthy nutrition, US$500 is spent by the food industry promoting processed foods (Escalante de Cruz et al. 2004). In the UK in 2003, Nestle alone spent £43 million promoting breakfast cereals and chocolate, Kellogg spent £30 million promoting their cereals and Coca-Cola funded their soft drink advertising with £26 million (Escalante de Cruz et al. 2004).

An international study in 1996 found that food advertising comprised the largest category of advertised products to children in the vast majority of countries, and that confectionery, breakfast cereals (often sweetened), and fast food restaurants overall accounted for over half of all food advertisements (Dibb 1996). Also noted was the lack of advertising of healthier food products, with adverts for fruits and vegetables virtually nonexistent (Dibb 1996). Food advertising ranged from 84% of all advertisements (Netherlands) to 12% (Sweden) (Dibb 1996).

Dibb (1996) also carried out a nutritional analysis of the foods advertised to children on UK television, and found that over 60% were products high in fat, 50% were high in sugar, and over 60% were high in salt. Overall, 95% of the advertisements were for high fat, sugar, and/or salt foods, and worryingly, this was a fairly consistent pattern found across the countries studied (Dibb 1996). In 1998, Lewis and Hill reported that during their 91 h recorded sample of UK television, 828 adverts were broadcast of which half were for food products. 60% of these were for breakfast cereals and confectionery/snacks (Lewis and Hill 1998). It is clear that the foods advertised reflect a dietary pattern that would be associated with increased risk of obesity and are not in line with recommended nutritional guidelines (WHO 2003).

Advertising to children on television has come under much criticism, relating to the types of products advertised (typically energy-dense foods not conducive to a healthy diet) and the way in which they are advertised (use of persuasive marketing techniques such as brand equity characters, celebrity endorsement, etc). There are also concerns over young children's cognitive ability to understand the persuasive nature of advertising and therefore their ability to judge it critically (Oates et al. 2003). Such concerns have led Sweden to ban advertising to children under-12 years old on their terrestrial television stations (Oates et al. 2003), and for the UK to bring in new legislation to limit the advertising of unhealthy food products to children on television (Ofcom 2007).

64.6   Television Food Advertising Effects on Food Preferences, Choices, and Consumption

Food advertising has often been proposed as a candidate for the association between television viewing and adiposity. In an interesting study, Lobstein and Dibb (2005) found that there was a significant and positive correlation between the prevalence of overweight amongst school children and the number of

adverts for sweet or fatty foods broadcast per 20 h of children's television broadcast. Crucially, it was also found that prevalence of overweight negatively correlated with the number of healthy foods advertised over the same period of time (Lobstein and Dibb 2005).

In addition to this, there is now a considerable body of evidence from experimental studies to suggest that food advertising on television does impact upon food preferences, choices, and consumption.

64.6.1 Food Preferences and Choice

As far back as 1976, it was reported that the hours of commercial television children watched each week correlated significantly with purchasing-influencing attempts made to their parent while food shopping (Galst and White 1976). Brody et al. (1981) also noted that, in their study, the children who watched a cartoon embedded with food commercials made more requests for the advertised foods in a subsequent artificial shopping environment than the children who had watched the cartoon with no commercials.

Borzekowsi and Robinson's (2001) much cited randomized, controlled trial showed preschool children a videotape of a cartoon either with or without embedded commercials, and then asked the children to identify their food preferences from pairs of similar products, one of which had been shown in the commercials. Children who had seen the videotape with the embedded commercials were significantly more likely to select the advertised product than children who had not seen the commercials (Borzekowsi and Robinson 2001). More recently, Robinson et al. (2007) reported that children preferred the taste of food and drink items displaying the McDonalds branded packaging to identical products in matched but unbranded packaging. Interestingly, it was also found that children with a greater number of television sets in their homes were more likely to prefer the taste of the products in McDonalds branded packaging (Robinson et al. 2007).

Halford et al. (2008) demonstrated that following exposure to nonfood advertisements, overweight and obese children showed a significantly greater preference for branded items than normal weight children; however, following food advertisements these weight status differences were not apparent. This suggests that television food advertisement exposure can produce an obesigenic food preference response in normal weight children that is typically found in overweight and obese children (Halford et al. 2008).

64.6.2 Consumption

In an early study, Gorn and Goldberg (1982) found that children who viewed daily candy commercials were more likely to select candy than fruit as an afternoon snack. Hitchings and Moynihan (1998) interviewed 9–11 year olds regarding their recall of food advertisements and obtained 3-day food diaries to ascertain consumption. Parents of the children were also interviewed to establish the food requests that had been received. A significant positive association was found between the food advertisements recalled and the foods consumed, particularly for soft drinks, crisps, and savory snacks (Hitchings and Moynihan 1998). Four out of the ten of the most requested food items were amongst the ten most frequently recalled television food advertisements (Hitchings and Moynihan 1998).

More recently, Halford et al. (2004) exposed 9–11 year old children to eight food or eight nonfood advertisements followed by the same cartoon in a within-participant, randomized study. Following

viewing, children's consumption of sweet and savory, high and low fat snack foods was measured. Exposure to food advertising increased food intake in all children (Halford et al. 2004) (Fig. 64.1). This finding was later replicated in 5–7 year old children (Halford et al. 2007a) (Fig. 64.2). Interestingly, a further study demonstrated that not only did food advertising exposure produce a substantial and significant increase in caloric intake (of high fat and/or sweet energy-dense snacks) in all children, but also that this increase in intake was largest in the obese children (Halford et al. 2007b). This suggests that overweight and obese children are more responsive to food promotion, and that such promotion specifically stimulated the intake of energy-dense snacks (Halford et al. 2007b) (Table 64.1). Indeed, in this study there was a significant, positive correlation between BMI (as standard deviation scores for age and gender) and food intake after exposure to food adverts (Halford et al. 2007b) (Fig. 64.3). Buijzen et al. (2008) found that children's exposure to food advertising was significantly related to their consumption of both advertised brands and generic energy dense product categories.

An Australian survey study showed that heavier TV use and more frequent viewing of commercial television were independently associated with more positive attitudes towards junk food; heavier TV use was also independently related to higher self-reported junk food consumption (Dixon et al. 2007). However, advertisements for healthier food products have also been shown to have an impact. Dixon et al. (2007) also found that advertisements for nutritious foods promoted positive attitudes and beliefs concerning these foods.

Hastings et al. (2003) carried out a systematic review of the existing literature and concluded that food promotion "is having an effect, particularly on children's preferences, purchase behavior, and consumption." The report states that "the advertised diet contrasts sharply with that recommended by public health advisors, and themes of fun and fantasy or taste, rather than health and nutrition, are used to promote it to children. Meanwhile, the recommended diet gets little promotional support." (Hastings et al. 2003). A report by the World Health Organization and the Food and Agriculture Organization of the United Nations also acknowledged that the promotion of energy-dense foods is a "probable" cause of increasing prevalence of overweight and obesity in children worldwide (WHO
Fig. 64.1 Lean, overweight and obese children's food consumption after toy and food advert exposure. A graph to show the weight of food eaten after viewing the advertisements by lean, overweight, and obese groups in the session with nonfood advertisements (*open columns*) and in the session with food advertisements (*filled columns*); mean values with SE bars; ***$p < 0.001$; **$p < 0.01$; *$p < 0.05$
Fig. 64.2 Normal weight and overweight/obese children's food consumption after toy and food advertisement exposure. A graph to show the weight of food eaten after viewing the advertisements by normal weight and overweight/obese groups in the session with nonfood advertisements (*open columns*) and in the session with food advertisements (*filled columns*); mean values with SE bars; ***$p < 0.001$; **$p < 0.01$; *$p < 0.05$

2003). The Institute of Medicine (IOM) reviewed 155 studies of food advertising and its effects on children and concluded that exposure to television advertising is associated with adiposity in children aged 2–11 years (IOM 2005).

64.7 Intervention Strategies: Reduce Television Viewing and Limit Food Advertising

Previous sections have discussed the association between television viewing and obesity, and particularly the role of television food advertising in this relationship. It is therefore logical that intervention strategies must be designed to address these issues (Tables 64.2 and 64.3).

One randomized, controlled trial in the US has already demonstrated that interventions designed to reduce television viewing can be effective at reducing body mass index. In the Robinson (1999) study, 192 children were randomly assigned to either an intervention or a control group. The intervention group received 6 months of guidance sessions to encourage reduced television, videotape, and videogame use. Subsequently, those children in the intervention group had significantly decreased television viewing and number of meals eaten in front of the television and most importantly, decreased body mass index in comparison to the control group (Robinson 1999). Interestingly, another study found that in a group of obese children and their parents, reinforcing decreased sedentary behaviors such as television viewing resulted in greater weight loss than directly reinforcing increased physical activity (Epstein et al. 1995).

Table 64.1 Intake of each food item in toy and food advertisement conditions

Food item	Mean intake (g) after toy adverts (±SEM)				Mean intake (g) after food adverts (±SEM)				Significance (whole group)
	NW	OW	OB	Whole group	NW	OW	OB	Whole group	
Crisps	6.4 (±1.1)	8.8 (±2.0)	10.2 (±2.7)	7.7 (±1.0)	12.4 (±1.5)	15.2 (±2.8)	22.3 (±3.0)	14.9 (±1.3)	$p < 0.001$
Snack a Jacks	3.3 (±0.6)	1.7 (±0.4)	7.5 (±1.9)	3.7 (±0.5)	4.0 (±0.7)	2.9 (±0.8)	9.3 (±3.0)	4.7 (±0.7)	Non sig. $p = 0.052$
Chocolate Buttons	18.7 (±2.7)	20.9 (±4.5)	17.7 (±3.3)	19.1 (±2.0)	42.9 (±3.7)	42.5 (±7.6)	71.9 (±9.8)	48.2 (±3.6)	$p < 0.001$
Jelly Sweets	33.3 (±3.4)	30.4 (±5.9)	28.7 (±7.5)	31.7 (±2.8)	55.7 (±4.9)	72.2 (±8.2)	58.8 (±8.7)	60.5 (±3.8)	$p < 0.001$
Grapes	48.1 (±6.5)	61.7 (±9.8)	45.5 (±13.1)	51.0 (±5.0)	76.7 (±10.8)	77.7 (±12.4)	64.4 (±17.2)	74.7 (±7.5)	$p = 0.001$

This table shows the mean intake of each food item after both toy (control condition) and food advertisements (experimental condition). Figures are presented as mean (± SEM) for each weight status group. *NW* normal weight, *OW* overweight, and *OB* obese
Fig. 64.3 A correlation between body mass index (BMI) standard deviation score and food intake after exposure to food advertisements. This figure shows a significant and positive correlation between BMI standard deviation score (*x* axis) and energy intake in kilocalories after exposure to food advertisements (*y* axis)

As previously mentioned, concerns over television food advertising have led campaigners to call for regulatory changes regarding such advertising, particularly to children. The UK has recently implemented new legislation designed to limit the advertising of high fat, sugar, and/or salt (HFSS) foods to children, as of January 2009 the advertising of HFSS foods is banned on dedicated children's channels (Ofcom 2007). Advertising of such foods is also prohibited in and around programming of particular appeal to children on all channels (Ofcom 2007). However, it remains to be seen if these new laws are effective at reducing children's exposure to HFSS advertising, particularly because of the way programs "of particular appeal to children" are calculated, using the proportion of children in the audience as opposed to the overall viewing figure; therefore, if a program is also watched by adults it is unlikely to be covered by the restrictions even if over a million children are watching (Which 2006). Indeed, one survey found that there is a clear discrepancy between the most popular programs watched by children and the programs covered by the restrictions. Out of the 30 most popular programs with 4–15 year olds, the first program to be included in the restrictions is the 27th most popular program in the list – HFSS advertising would be free to continue around the 26 more popular programs before this (Which 2006).

There has been much debate in the UK and around the world regarding the negative effects of "junk food" advertising, but unfortunately, very little attention has been devoted to potential strategies to increase healthy food advertising to encourage healthy eating amongst children. This is despite evidence that such "counter-advertising" can be an effective strategy for promoting healthy behavior, either through ensuring that television channels must broadcast "antijunk food" messages or requiring a greater proportion of healthy food than unhealthy food advertisements be shown (Dixon et al. 2007).

Future intervention strategies must focus on combined efforts to reduce television viewing, limit unhealthy food advertising, and promote healthy food advertising in order to influence children's

Table 64.2 Key points about obesity and food choice

1. Levels of overweight and obesity have risen at dramatic rates in recent decades.
2. Worldwide, 1.1 billion adults and 10% of children are now classified as overweight or obese.
3. Obesity in childhood has numerous adverse consequences in the short-term, including psychological ill health, cardiovascular risk factors, asthma, chronic inflammation, diabetes (types I and II), orthopedic abnormalities, and liver disease.
4. Obesity is caused by energy intake consistently exceeding expenditure over time.
5. Children's food preferences are key determinants of their habitual diet.
6. Each of us is born liking sweet and salty foods and disliking sour and bitter flavors.
7. A preference for fatty foods in children between the ages of 3 and 5 years has previously been found to predict adiposity (fatness).

This table lists the key points of food choice and how this relates to obesity, including current levels of obesity, the effects of obesity on health, the principle cause of obesity, why we like certain foods, and how this food choice may lead to weight gain

Table 64.3 Key facts of television viewing and food advertising

1. Television viewing is related to overweight and obesity.
2. This relationship may be related to the effects of television viewing on food intake.
3. There is considerable evidence that television food advertising affects food and brand preferences, caloric intake, purchase requests, and purchase behaviors in children and adolescents.
4. Strategies to reduce television viewing in order to tackle obesity in young people appear to be promising.
5. The effectiveness of recent food and drink advertising restrictions in the UK are yet to be assessed.
6. Parallels can be drawn between efforts to restrict television food advertising, the previous banning of cigarette advertising, and potential restrictions on alcohol advertising on television.

This table lists the key facts of television viewing and food advertising as they relate to eating behavior. This includes the link between television viewing and obesity, how television viewing (via exposure to food advertising) may affect our food choices, the importance of strategies to reduce television viewing in young people and lessons that can be learnt from other similar issues such as the banning of advertising of alcohol and tobacco products to children

food preferences and choices toward a more nutritious and balanced diet, perhaps helping to limit the rising rates of obesity in children and adolescents.

64.8 Applications to Other Areas of Health and Disease

Parallels have been drawn between efforts to change the balance food advertising exposure in order to improve children's food preferences in relation to nutritious foods as opposed to energy-dense food items, and efforts to reduce cigarette smoking and alcohol consumption in youth through restrictions in advertising.

Evidence from the literature on cigarette smoking suggests that this is a potentially worthwhile strategy. In the late 1960s the US Federal Communications Commission required that any television station that broadcast cigarette commercials must also provide free air time for public service announcements with an antismoking message (Dixon et al. 2007). During the three years that these announcements were being broadcast cigarette consumption fell at a much greater rate than in the years immediately before or after this initiative – suggesting that these negative messages about smoking were largely responsible for the reduced rates (Dixon et al. 2007).

In common with obesity, alcohol consumption amongst children and adolescents is a significant and growing health problem often causing negative health consequences and potentially premature mortality. Also, there is evidence to suggest that exposure to alcohol advertising influences alcohol

consumption, particularly relating to patterns of heavy drinking (Nicholson and Hoye 2009). Between 2001 and 2007, spending by the alcohol industry on television advertising rose by more than 50% to $923 million, providing over 300,000 advertisements in 2007 alone (Nicholson and Hoye 2009). Evaluation of the impact of restrictions in food advertising on food preferences and choice is essential in order to discern the most effective strategies for modifying eating behaviors, and such evaluation may also inform future strategies designed to tackle the problem of youth alcohol drinking.

64.9 Conclusion

In summary, amid the current obesity epidemic, questions have been raised about the influence of television viewing and particularly television food advertising on the development of food preferences and therefore food choice in children. Considerable research evidence has been assimilated to demonstrate effects of exposure to food advertising on children's brand preferences, food preferences, food intake, and the number of requests children make to parents for products they have seen advertised. The effectiveness of recent restrictions regarding television advertising of energy-dense foods has yet to be fully elucidated, but certainly empirical evidence suggests that interventions to reduce television viewing, to limit exposure to high fat, sugar, and/or salt foods and to increase the media promotion of healthy, nutritious food groups could be beneficial in encouraging children to make better dietary choices.

Summary Points

Childhood diet, ill health, and obesity into adulthood

- Levels of childhood and adult obesity have risen dramatically over the last 30 years.
- Overweight and obesity are associated with a number of adverse health and psychosocial consequences.
- Obesity is caused by an energy imbalance, whereby energy intake exceeds expenditure over time.
- Overconsumption of dietary fat is a contributing factor to the obesity epidemic.

The important of childhood food preferences and diet

- Food preferences are crucial determinants of children's habitual diets.
- Although some preferences are innate, others are learnt through experience.
- It is critical to understand the factors that affect the development of food preferences in order to promote healthy eating behaviors.

Television viewing is linked to a poor diet and obesity

- Television is one of the most popular leisure time pursuits across the globe.
- Television viewing is associated with obesity in children and adults.
- Television viewing is specifically associated with increased caloric intake, increased snacking, reduced intake of fruit and vegetables and poorer overall diet quality.

The extent and nature of television food advertising

- Television is the primary medium used for advertising food and drink items.
- A majority of the foods advertised are high in fat, sugar, and/or salt.

Television food advertising effects on food preferences, choices and consumption

– There is a correlation between the frequency of energy-dense food advertising on television and the prevalence of obesity in numerous countries.
– Television food advertising influences children's purchase requests, brand preferences, food preferences, and consumption.
– Advertisements for healthier food products increases positive attitudes toward these items and also have a small but beneficial effect on consumption.

Intervention strategies: reduce television viewing and limit food advertising

– Reduced television viewing can effectively reduce body mass index
– Both, limiting energy-dense food advertising and encouraging healthy food advertising could be effective strategies towards improving children's food preferences and choices.

Applications to other areas of health and disease

– Reducing exposure to advertising for potentially harmful products is a strategy that has been shown to be effective at decreasing cigarette consumption.
– Similar strategies are also likely to be useful for reducing alcohol consumption in young people.

Definitions of Key Terms

Obesity: An excess of body fat. Obesity is defined as a body mass index (BMI) of 30.0 kg/m^2 or greater.
Adiposity: The accumulation of adipose (fatty) tissue.
Food preference: The selection of one item over another, with liking as the basis for selection.
Energy-dense foods: Foods with a high number of kilojoules or calories per amount of food.
Energy intake: The caloric content of food ingested, related to hunger, satiety, and nutrient absorption.
Energy expenditure: The amount of calories expended through resting metabolic rate, thermogenesis, and physical activity.

Chapter 65
The Construction of Eating Episodes, Food Scripts, and Food Routines

Carole A. Bisogni, Margaret Jastran, and Christine E. Blake

65.1 Introduction

Food choice involves how people think, feel, and act related to food and eating. Food choice not only affects the health and well-being of individuals and families, but it also impacts agriculture, the environment, business, culture, and the economy at local, regional, national, and global levels. Complex and dynamic, food choice involves a wide array of interacting factors and processes that are biological, psychological, social, cultural, geographic, political, and economic (Sobal et al. 2006; Sobal and Bisogni 2009).

Understanding food choice at the individual level is particularly challenging when the food system provides a myriad of options and culture accepts eating in many different ways, times, and places. In many groups, traditional ways of eating (e.g. meals prepared at home or a pattern of three meals per day) are being replaced by eating more foods prepared away from homes, consuming fewer family meals, and eating in individualized ways. Researchers and health practitioners need ways to conceptualize food choice to allow for the different styles by which people, think, feel, and act related to food and how they do this in specific situations. Studies of dietary change for health reasons indicate that people often have trouble maintaining new food behaviors because of situational factors, the surrounding details or the specific circumstances in which they eat (Janas et al. 1993; Falk et al. 2000).

This chapter discusses concepts and methods developed by the interdisciplinary Cornell Food Choice Research Group for understanding how people experience their eating situations. The chapter begins with a description of the conceptual model developed by this group, the Food Choice Process Model, a representation of the factors and processes involved in individual food choice from people's perspectives. The next sections describe a study of situational eating and the concepts of eating episodes, food scripts, and food routines that emerged from this study. The chapter concludes with a discussion of ways that the model and these concepts may be applied in research and health promotion (Table 65.1).

65.2 The Food Choice Process Model

The Food Choice Process Model (Fig. 65.1) is an inductive, conceptual model of food choice that is based on how adults construct their thoughts, feelings, and actions related to food and eating (Furst et al. 1996; Sobal et al. 2006; Sobal and Bisogni 2009). This model was developed using

e-mail: cab20@cornell.edu

Table 65.1 Key Features of eating episodes, food scripts and food routines

1. The concept of eating episodes seeks to capture the multidimensional experience of eating and drinking in specific situations by describing the details of the food/drink, time, location, social setting, mental processes, physical condition, and other activities
2. The concept of food scripts draws upon schema theory to understand how a person's cognitions are linked to food behavior in specific situations. Food scripts encompass the person's food choice values, expectations, and plans for behaving in the situation
3. Food routines are the repeating food behavior episodes and sequences of episodes that become best-fit solutions for a person's food choice values and schedules. Food routines provide stability but are modifiable as circumstances change

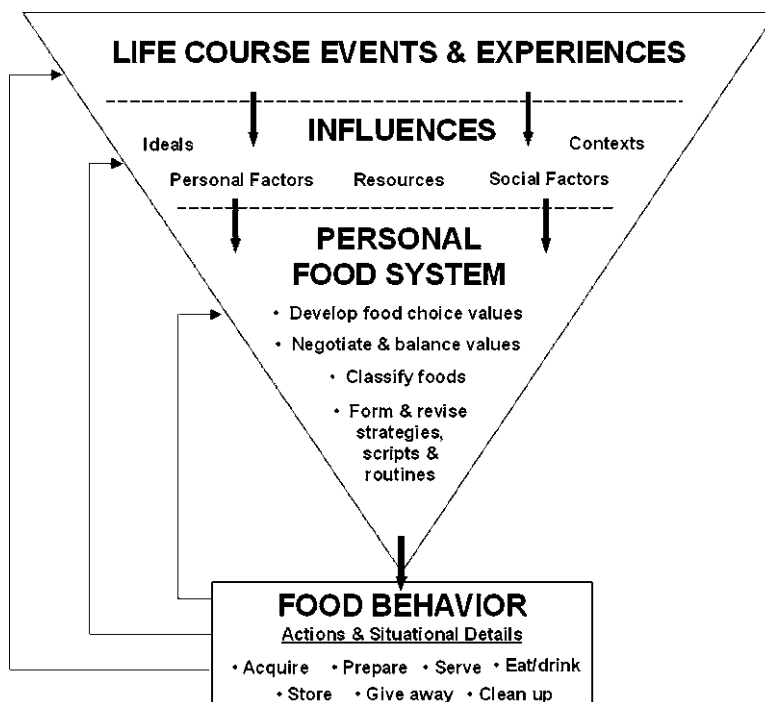
This table describes the key features of eating episodes, food scripts, and food routines derived from research reported in Bisogni et al. (2007), Blake et al. (2008), and Jastran et al. (2009)


Fig. 65.1 A Food Choice Process Model. The Food Choice Process Model has four major components: Life Course Events and Experiences, Influences, Personal System, and Food Behavior. The first two parts of the model represent the many diverse and extensive factors shaping a person's food choice in general, while the third and fourth parts of the model portray a person's cognitive, affective, and behavioral processes of food choice (Adapted from Furst et al. 1996; Sobal et al. 2006; Sobal and Bisogni 2009)

qualitative methods that involved in-depth, open-ended interviews with adults and analysis of verbatim transcripts (Furst et al. 1996). The model has been refined and elaborated upon through several studies (Falk et al. 1996, 2001; Devine et al. 1998; Furst et al. 2000; Connors et al. 2001; Smart and Bisogni 2001; Blake and Bisogni 2003; Bisogni et al. 2007; Blake et al. 2007, 2008; Jastran et al. 2009). By focusing on the factors and processes in food choice that people themselves describe, the model takes a different perspective from other models of food choice that are developed primarily from experts' perspectives (Sobal et al. 2006; Sobal and Bisogni 2009).

The Food Choice Process Model portrays people as actively involved in constructing the ways that they think, feel, and act related to food in response to their past experiences and a host of factors

both personal and environmental. The model emphasizes people's own interpretations of the general and specific circumstances in which they eat and their perceptions of how they think, feel, and act. This view of food choice helps understand individual differences while also representing that people construct food choice in biological, physical, and social worlds that are changing and beyond their control. In this way, the model views a person as having agency in that they direct their own food choice to a large extent, but it also acknowledges the roles of biological factors and societal structures (Sobal et al. 2006; Sobal and Bisogni 2009).

This model has four major components: Life Course Events and Experiences, Influences, Personal System, and Food Behavior. The first two parts of the model represent the many diverse and extensive factors shaping a person's food choice in general while the third and fourth parts of the model portray a person's cognitive, affective, and behavioral processes for food choice. In this model, Life Course Events and Experiences are viewed as creating a wide array of Influences that affect the Personal Food System, which a person constructs to guide Food Behavior. However, a person's food behavior in different situations subsequently becomes a life course experience that may impact the Influences or cause a person to modify the Personal Food System.

Life Course Events and Experiences represent the historical, social, and geographic setting of birth and upbringing that affect how a person thinks, feels, and acts related to food and eating (Devine et al. 1998, 1999; Devine 2005). Also important are other events and experiences throughout a person's life such as changing roles and relationships, changing areas of residence, changing resources, the acquisition of knowledge and skills, or development of health conditions. These past events and experiences shape people's meanings and feelings related to food and eating, and provide models for behaving.

As a result of the Life Course, a person's food choice is shaped by a myriad of factors, which are grouped into five types of Influences: Ideals, Personal factors, Resources, Social factors, and Context (Sobal et al. 2006; Sobal and Bisogni 2009). Ideals represent the cultural meanings and standards for food and eating that people have developed through socialization and acculturation. Personal factors encompass the characteristics of the individual, including physiological factors (e.g. sensory perceptions, health conditions) and psychological characteristics of the person (e.g. preferences, personality, identity). Resources are the assets available for food choice, including tangible resources (e.g. money, facilities, equipment) and intangible human resources (e.g. time, knowledge, skills). Social factors are the relationships with other people that affect food choice, such as spouses, children, parents, relatives, coworkers, employers, employees, or friends. Contexts are the broader environmental factors that impact food choice, including physical surroundings (e.g. climate, geography, living space, workplace), the food system (e.g. agriculture, food manufacturing, grocery stores, restaurants), and the information setting (e.g. advertising, health information, nutrition information).

The Personal Food System represents the mental processes through which people manage these influences and develop options, tradeoffs, and approaches to food behaviors (Sobal et al. 2006; Sobal and Bisogni 2009). The Personal Food System considers how people make sense of food and eating given the opportunities and the boundaries set by the Influences. Research to date has proposed six processes within the Personal Food System, but these processes do not necessarily occur in sequence. The dynamic and interacting processes involve: (1) constructing food choice values (Furst et al. 1996; Falk et al. 2001; Smart and Bisogni 2001); (2) negotiating food choice values (Furst et al. 1996; Connors et al. 2001; Smart and Bisogni 2001); (3) classifying foods (Furst et al. 2000; Blake et al. 2007; Blake 2008); (4) forming and revising strategies to implement food choice values (Furst et al. 1996; Falk et al. 1996); (5) forming and revising food scripts (Blake et al. 2008); and (6) forming and revising food routines (Jastran et al. 2009).

Food choice values are the important considerations that a person constructs related to food and eating (Furst et al. 1996; Falk et al. 1996, 2001; Smart and Bisogni 2001). Common categories of food choice values are taste, health, cost, convenience, and managing relationships, but people may

have other important considerations, such as ethics, religion, family traditions, and the environment. People may hold culturally shared or individualized meanings for these values. For example, people's meanings for healthy eating may vary (e.g. low-fat, low-calorie diet, nutrient dense, natural, or organic foods; Falk et al. 2001).

Although people may seek to achieve all of their food choice values in food behaviors, their options often involve conflicts between food choice values (Furst et al. 1996; Connors et al. 2001; Sobal and Bisogni 2009). For example, a person may perceive the healthiest food as too expensive or as taking too long to prepare; a wife may sometimes compromise the food she enjoys to accommodate the preferences of her spouse. Therefore, people regularly have to make tradeoffs among their food choice values in different situations. People describe constructing unique systems for setting priorities and balancing their values over different food behaviors. They do this using personally defined time frames (e.g. meals, workdays/nonworkdays, school year/summer vacation, or before/after activities) and in ways that feel comfortable to them (Connors et al. 2001; Smart and Bisogni 2001).

People construct classification systems for foods that help them make decisions. (Furst et al. 2000; Blake et al. 2007; Blake 2008). Classification systems group foods in ways that people find meaningful from perspectives that are cultural (e.g. symbolic foods, high status foods), social (e.g. foods my friends eat, foods my children like), contextual (e.g. what is available in the setting), and personal (e.g. foods that relax me, vegetables I like) (Furst et al. 2000; Blake et al. 2007; Blake 2008). Whereas health professionals typically categorize foods into groups based on the properties of the food (i.e. commodity type or nutrient composition), people use a variety of classifying systems including personal experience (e.g. what I like, what makes me feel good) and context (e.g. what others like, what is available in this setting) (Blake et al. 2007).

Food strategies are the heuristics, guidelines, and rules that people develop to achieve their food choice values (Falk et al. 1996; Sobal et al. 2006; Sobal and Bisogni 2009). Developing and using strategies is another way that people simplify the many decisions they encounter in daily food and eating. Some examples of strategies are always having a vegetable at lunch and dinner to promote health, usually splitting desserts in restaurants to save money and calories, or turning off the telephone at family dinners so that the meal can be relaxing (Falk et al. 1996; Sobal et al. 2006; Bisogni et al. 2007; Blake et al. 2008).

The processes of the Personal Food System that are closest to behavior are the formation and revision of food scripts and food routines (Sobal and Bisogni 2009). Scripts address the detailed mental processes that guide food behavior in specific settings including appraisal of situations and procedural knowledge about what to do (Blake et al. 2008). Routines involve repetitive food behaviors and the details in which these behaviors occur (Jastran et al. 2009). Later sections of the chapter will elaborate on food scripts and food routines.

The final component of the Food Choice Process Model is Food Behavior. This component includes food-related actions as well as the situational details in which an action occurs as experienced by the person (Bisogni et al. 2007). Situational details involve not only what food is consumed but also who is present, where the action happens, when the action happens, what else is going on, and other factors involved as perceived by the person. Food-related actions encompass a wide spectrum that can be organized into the following types: food acquisition, preparation, serving, eating, storing, giving away, and cleaning up (Sobal and Bisogni 2009). These types of behaviors may be considered individually, but they must also be viewed as interconnected. For example, to cook a big dinner on Sunday that will provide leftovers for Monday dinner, a substantial amount and variety of food must be purchased and prepared. The dinner involves extensive serving, consumption, and cleaning up. Storage of the leftovers is thoughtful so that Monday's dinner can involve fewer and less complex steps of preparation, eating, and cleanup.

Overall, the Food Choice Process Model views the factors and processes involved in food choice as complex, interacting, dynamic, and interpreted from the person's perspective (Sobal et al. 2006; Sobal and Bisogni 2009). People develop personal food systems in an ever-changing environment as they proceed through their life course and experience a multitude of influences. Their food behaviors become part of their life course experiences and also impact the influences in an ongoing manner. People's food behaviors also shape their personal food systems as people interpret and evaluate food behavior experiences. As a result, they may revise food choice values or the ways that they negotiate values. They may also revise their food classifications, strategies, scripts, and routines.

In the Food Choice Process Model, the distinctions between the components of the model are blurry, and the model is not intended to be mechanistic. Instead the goal is to provide a conceptual framework that identifies and organizes the extensive array of disparate factors and processes that are involved in food choice from people's perspectives (Sobal et al. 2006; Sobal and Bisogni 2009). The model is unusual in attempting to represent a holistic perspective that integrates ideas from multiple disciplines, attends to factors and processes at both macro and micro levels, and accounts for structural factors, personal agency, and time. Researchers could draw upon the model to generate hypotheses about how people think, feel, and act related to food (e.g. Devine et al. 1999).

65.3 Situational Eating Study

Applying the perspective that people construct food choice (Sobal et al. 2006; Sobal and Bisogni 2009), researchers studied situational eating among working adults to learn about the individualized ways that these adults experienced eating in their daily lives (Bisogni et al. 2007). Forty-two adults (21 men, 21 women) working in nonmanagerial, nonprofessional positions provided seven, consecutive-day, 24-h qualitative recalls of their food and beverage consumption. In daily recalls participants reported foods and beverages consumed, the location, people present, their feelings at that time, and other activities in which they were involved while eating or drinking. Interviewers used open-ended questions and avoided using traditional meal labels such as breakfast, lunch and dinner to be open to participants' interpretations. Additional qualitative interviews provided supplementary information about the factors and processes that were important to these adults and their typical food behaviors in different locations, such as evening meals at home (Blake et al. 2007).

This study of situational eating provided rich data about how people eat in their natural settings that enabled researchers to elaborate on components of the Food Choice Process Model. The concepts of eating episodes, food scripts, and food routines emerged from this study and are described in the next sections.

65.4 Eating Episodes

Eating episodes are characterized by seven dimensions experienced at the time of consumption: food and drink, location, social setting, time, mental processes, activities, and physical condition (Bisogni et al. 2007). As shown in Table 65.2, each dimension is a cluster of features that can be used to further characterize the eating episode from the person's perspective. For example, food can be described as type of food, quantity of food, preparation, source, and how eaten. Time involves chronological time but also the timing of the episode in relation to other activities (before work, after school) and the perception of time (e.g. killing time, in a hurry).

Table 65.2 Dimensions and features of eating episodes that a person may experience using an example from the case of a working mother of a 2-year-old daughter (Adapted from Bisogni et al. 2007)

Dimension	Features	Examples
Food and drink	Types; Forms; Amounts; Sources; Packaging, Nutrient composition	Coffee, black, large mug, made at home
Location	General, Specific	Home, at kitchen table
Time	Chronological, Relative, Perceived	6:30 am, before work
Social setting	Persons present, Social processes	Caring for daughter
Mental processes	Dominant values	Feeling rushed, Being a good mom
Physical condition	Nourishment, Other	Waking up
Activities	Type, Salience	Feeding daughter

This table lists the seven dimensions of an eating episode and the features within each dimension that can be used to understand an eating episode from a person's perspective

This concept of eating episodes with multiple dimensions is consistent with and extends work by other food choice researchers (Meiselman 1996; Sparks and Shepherd 1992) that describe situational eating as involving the person, the food, and the setting. This view is also consistent with psychological models of person–environment interactions that emphasize the importance of a person's perception of the situation (Lewin et al. 1936) and the dynamic and reciprocal nature of person–environment interactions (Magnusson and Torestad 1992)

Participants in the situational eating study used various types of descriptors to label their eating episodes as they reported their 24-h recalls (Bisogni et al. 2007). As shown in Table 65.3, 73% of episodes had conventional meal labels (e.g. breakfast, lunch, dinner), other conventional labels (e.g. break, snack), or modified conventional labels ("early dinner," "little snack"). More than one-fourth of the episodes were assigned uniquely constructed labels ("my little pick me up," "morning coffee," "my relaxing time"). The common use of conventional labels shows the shared language that existed among these participants. The modified conventional labels and uniquely constructed labels gave clues to the dimensions of the episode that were salient to the person. For example, "my relaxing time" was used by a grounds keeper to describe his lunch time at home where he could rest and get away from work.

Figure 65.2 shows how the concept of eating episodes relates to the Food Choice Process Model. Eating is one type of food behavior that can be viewed as occurring in multidimensional episodes to represent the person's experience. People assign their own labels to these episodes. People develop scripts and routines as part of their personal food systems that shape these eating episodes. The scripts and routines are shaped by other parts of the personal food system and also by the influences and life course events and experiences. Eating episode experiences then become life course experiences and also may affect the influences and the personal food system. Based on a particular eating episode, a person may choose to alter the script or routine.

To further illustrate the concept of eating episodes, Table 65.4 summarizes the sequence of eating episodes on a workday reported by a mother of a young child. This mother begins the day with "my first coffee" at home before going to work and while feeding her toddler. After driving her daughter to childcare and while still en route to work, she fuels herself quickly and cheaply at a fast food restaurant with more coffee and a breakfast sandwich, which she calls her "morning food stop." By noon she is hungry again so she heats up a frozen entrée and has a "working lunch" at her desk where she is trying to catch up. In midafternoon she buys her "afternoon treat" from the vending machine, which she eats at her desk. After work, she picks up her daughter and heads home where by 6:00 she is feeding her daughter, having her own "bite before dinner," and planning what she will eat for dinner. Her husband is out of town so her "supper without Dan" is a ham sandwich, soup, and salad, but she feels tired of ham and thinks she should be eating more vegetables. During dinner she is watching and talking to her

Table 65.3 Types of labels adults used to describe eating episodes in study of situational eating that analyzed 1,448 eating and drinking episodes reported in 7-day situational recalls by 42 US working adults (Adapted from Bisogni et al. 2007)

Label types	Percent of episodes assigned label type (n = 1448)	Examples of labels
Conventional	40%	*Breakfast, lunch, dinner, supper, brunch*
Other conventional	23%	*Drink, snack, break*
Modified conventional	9%	*Big dinner, quick and easy dinner*
Uniquely constructed	28%	*Midnight eating, relaxing time, morning coffee*

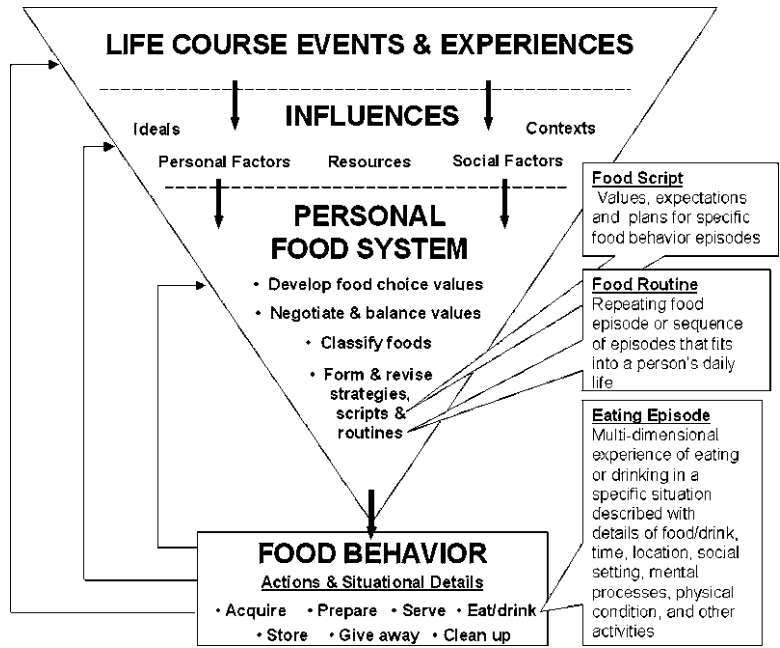
Study participants used conventional labels to describe eating episodes 40% of the time, other conventional labels 23% of the time, modified conventional labels 9% of the time, and uniquely constructed labels 28% of the time across 1,448 eating episodes. Examples of each type of label are shown


Fig. 65.2 Elaboration on eating episodes, food scripts, and food routines in the Food Choice Process Model. This figure of the Food Choice Process Model shows that food scripts and food routines are components of the personal food system. Eating episodes are a way to describe eating and drinking behaviors (Adapted from Furst et al. 1996; Sobal et al. 2006; Bisogni et al. 2007; Sobal and Bisogni 2009)

daughter who is playing. At 9:30 this mom relaxes while watching a favorite TV show when she has some crackers and soda before going to bed.

The representation of episodes as multidimensional emphasizes that to understand situational eating, researchers must be open to the person's perspective on the experience. For the person involved, the episode may be less about food and more about the other dimensions such as social setting or other activities. Whereas time, location, appetite, and people present are often considered characteristics of eating episodes, researchers have paid less attention to other dimensions, particularly social processes (i.e. how the people are interacting), mental processes (what people are thinking about related and unrelated to food), and the other nonfood activities occurring at the same time.

Table 65.4 Summary of eating episodes, dimensions, and labels in 1 day for a working mother of a 2 year-old daughter

Episode dimensions	Episodes in a 24-h period and labels used by person to describe them						
	My first coffee	My morning food stop	Working lunch	Afternoon treat	Bite before dinner	Supper without Dan	My TV snack
Food	Coffee	Coffee, Fast food breakfast sandwich	Juice, Frozen entrée from home	Chocolate bar from vending machine	Crackers, Juice	Ham sandwich, Canned soup, Salad, Water	Crackers, Diet soda
Time	6:30 a.m. before work	7:45 a.m. on way to work after child at daycare	Noon	3:00 p.m., a few hours before end of work	6:00 p.m. after work, before cooking	7:00 p.m. before putting daughter to bed	9:15 p.m. before going to bed
Location	Home at kitchen table	Car in driver's seat	Work at desk	Work at desk	Home in kitchen	Home in kitchen on floor	Home in living room
Mental processes	Feel rushed, Be a good mom	Feel rushed, Get fueled, Get good buy	Get fueled, Catch up with work	Deserve a treat, Chocolate keeps me going	Plan what's for my dinner, Feel happy to be home	Tired of ham sandwich, should buy more vegetables	Enjoying favorite show, Relaxing
Social setting	Caring for daughter	Alone	Alone	Alone	Talking with daughter	Talking with daughter	Alone
Physical condition	Waking up	Feeling hungry	Hungry	Sluggish	Tired	Awkward sitting on floor	Tired
Activities	Feeding daughter	Driving to work	Answering e-mail	Reading reports	Feeding daughter	Watching daughter	Watching TV

The columns of this table show the seven eating episodes reported by a working mother for 1 day. The rows show how the dimensions can capture the details of her experience

65.5 Food Scripts

To simplify decision making processes in recurring eating episodes, people develop food scripts that guide their behavior. Food scripts are a person's expectations and plans for acting in the situation. The term script is derived from schema theory which is used to explain how people store, retrieve, and use information (Spradley 1972; Markus 1977; Rumelhart 1984; Nishida 1999; Wagner 2005). Schemas are generalized collections of knowledge stored in long-term memory and constructed from past experience that contain organized and related categories and scripts that guide behavior in subsequent familiar situations (Olson 1981; Baldwin 1992; Axelson and Brinberg 1992; Blake and Bisogni 2003).

An individual's current food scripts are based on past food and eating experiences (Furst et al. 1996). Scripts are derived from past planning, prior actions that were successful, or habitual actions, and their invocation in new situations is thought to immediately precede the initiation of action (Schank and Abelson 1977; Baldwin 1992). How a person interprets an eating episode is important because perception of a present situation as similar to a past well-known situation can evoke an existing script (Baldwin 1992). Schema theory assumes that people actively construct their lives, including ways of eating that are tailored to different situations. The concept of food scripts elaborates on the cognitive processes within the Personal Food System of the Food Choice Process Model to provide a better understanding of how people translate Influences into episode-specific food behaviors (Furst et al. 1996; Connors et al. 2001; Sobal et al. 2006).

Scripts guide behavior in recurrent eating episodes because they contain sequential information about key events common in those episodes (Schank and Abelson 1977; Abelson 1981; Baldwin 1992; Holmberg and MacKenzie 2002; Wagner 2005). The elements of a script usually have an inherent temporal sequence that is logically determined and collectively describes an episode (Lakshmi-Ratan and Iyer 1988). In some instances the temporal sequence is less rigid and scripts contain if–then statements to accommodate different possibilities within a given situation (Baldwin 1992; Blake et al. 2008).

Researchers explored the concept of food scripts in the situational eating study that was previously described (Bisogni et al. 2007; Blake et al. 2008). Researchers focused on understanding food scripts for the evening meal, considered to be one of the most important eating episodes of the day by many nutrition professionals because it has significant social and nutritional implications (e.g. Gillman et al. 2000; Bove and Sobal 2006). In a series of open-ended questions participants were asked to talk about the things they do when they eat, how they do them, and why they do these things in each eating episode with further probing questions about the importance of the episode, foods, other people, roles, identities, emotions, and activities.

Researchers analyzed participants' reports about their evening meals through an iterative process of reviewing the literature and analyzing emergent themes. Researchers formulated and delineated seven key concepts for comparing and contrasting participants' evening meal scripts: dominant values, expectations, plans, strategies, procedures, scope, and flexibility. Dominant values were considerations that participants explained as important for the evening meal (Connors et al. 2001). Expectations were participants' descriptions of how the evening meal would proceed and what would be happening, such as time, place, people, activities, and emotions. Plans consisted of the behavior sequences involved in the evening meal episode, such as shopping, deciding what to have for a meal, and cooking. Each behavior in the sequence was associated with strategies and procedures (Schank and Abelson 1977; Baldwin 1992). Strategies were seen as typical approaches to the behaviors (Baldwin 1992) or "knowing what to do," such as sharing meal preparation responsibilities. Procedures were the "knowing how" to do these behaviors, or the details of who would be doing

what in preparing the meal. Scope referred to the starting and ending points of the script in terms of the number of different types of food behaviors that were involved. Flexibility considered how many if-then statements the script contained as the person explained alternative expectations, strategies, plans, and procedures for the meal.

Using these concepts, the researchers summarized the evening meal script for each participant. Script summaries depicted participants' interconnected dominant values, expectations, and plans that included strategies and procedures. The researchers then examined scripts for the evening meal across participants using the constant comparative method to identify commonalities and differences (Strauss and Corbin 1990). From this analysis, eight kinds of scripts for the evening meal emerged, with each of the participants represented in one kind of script. Researchers named each kind of script to reflect the group of participants it represented (e.g. "Provider Script," "Anything Goes Script," "Family Cook Script," "Just Eat Script").

Dominant values. Participants expressed many values for the evening meal with the most common being "family time." For example, participants said "the most important thing about dinner at home is for the family to be together eating together" and "that time is just family time." Others expressed valuing uninterrupted quiet so they could relax during the evening meal. These participants said, "having some down time, relaxing… not rushing around [is important]" and "[I try to] eat without interruption. It don't happen that often. I mean that's my relax time. After a hard day's work, all I want to do is come home, chill out, relax." Other values included getting the family fed, having foods that everyone likes, just eating, having a nutritious meal, recreating childhood experiences, and entertaining guests. Dominant values frame an individual's food script and are similar to goals described in the schema literature as a desired end to a sequence of actions (Schank and Abelson 1977; Trzebinski 1985; Baldwin 1992).

Expectations. General expectations for the evening meal were represented in participants' overall summaries of how things would "go" for this meal. Participants described what they expected to happen at the evening meal (e.g.,"Dinner is usually about 6:30 to 7:00"), who they expected to be there and how they would behave (e.g., "I expect anyone that sits at my kitchen table to be somebody who respects and cares about the people at that table"), their own anticipated emotional state (e.g., "So I usually feel relaxed and content and happy to be there."), expected satisfaction with the outcome ("[I'm satisfied] when things go smoothly and you don't burn anything and everything tastes good and everything goes together and it's a nice time together when there's not a lot of static"), and whether the episode would be a positive or negative experience (e.g., "[dinner is] the most relaxed situation, it's the best situation…because there's less pressure and we don't have to follow any food chain guidelines or whatever. (laughs) Just him and me. It's fun that way.") Participants' general expectations provided insight about their conceptualization of the evening meal as a whole.

Plans, strategies, and procedures. Information about what to do in various situations is contained in the plans, strategies, and procedures (Baldwin 1992; Nishida 1999). Evening meal scripts included planned sequences of different behaviors that included but were not limited to arranging, shopping, deciding what to have, getting input from others, preparing food, serving food, announcing the meal, arranging seating, eating, meal time conversation, other meal time activities, and cleaning up. Evening meal plans also included interconnected detailed strategies for the different behaviors and specific procedures used to carry out these strategies.

Strategies describe behaviors that are linked to dominant values. For example, a participant who valued "family time" described strategies that would encourage an extended and enjoyable time for the family members to eat together such as arranging seating for a sit-down dinner or putting food on the dining table instead of having people serve themselves from the kitchen.

Procedures differentiate the "knowing what" of strategies from "knowing how" by providing specific steps and rules for behavior. Procedures are specific to the different behaviors participants described for the evening meal such as planning, cooking, or interacting and for the strategies employed.

Script scope and flexibility. Participants' evening meal scripts varied in scope. Scripts began and concluded at different points depending on participants' involvement and the importance they placed on the evening meal. Some scripts began many hours before the actual consumption of food. The plans of these participants included multiple food-choice behaviors such as premeal arranging, shopping or buying food, preparing food, eating, meal interactions, and cleaning up. Although many of these activities occurred before or after consumption, participants still included them as part of their scripts for the evening meal. Other participants' plans were smaller in scope because they began and ended at or near the consumption of food.

Participants with more meal responsibilities tended to have more detailed scripts. They described thinking about the evening meal in advance and making various decisions like where to eat, what to have, or who to eat with. Although many of the food behaviors occurred before or after consumption, participants included them as part of their evening meal scripts. Participants with less detailed scripts often began their plans with waiting for the food to be ready and did not include much detail about meal preparation or cleanup.

Participants' evening meal scripts differed in flexibility depending upon the extent to which they had to accommodate day-to-day variations in timing, weather, people, foods, other activities, and moods. Participants used "if-then" statements as they explained the alternative behaviors, strategies, and procedures that occurred when different aspects of the evening meal changed. Participants with irregular schedules used more if-then statements in their evening meal scripts compared to participants with more consistent schedules.

Examples of evening meal scripts with different levels of scope and flexibility are shown in Fig. 65.3. The "Provider Script" shows extensive scope and some flexibility. In contrast, the "Anything Goes Script" has considerable flexibility but not much scope.

Kinds of evening meal scripts. Figures 65.4 and 65.5 present examples of script summaries for two participants with very different kinds of behaviors related to evening meals. The "Family Cook Script" example represents the evening meal of a working father who is the cook for these meals. The "Just Eat Script" example represents the evening meals of a man who lives with his girlfriend. These scripts show the household's behaviors leading up to the evening meal, how household members share or do not share in the responsibilities with their spouses/partners, and how spending time with children is related to the food choice scripts.

Case studies. Two evening meal case studies (Tables 65.5 and 65.6) elaborate on the scripts summarized in Figs. 65.4 and 65.5 by showing the relationships between dominant values, expectations, strategies, and procedures. The first case presents a father who described himself as "head of the table" (Table 65.5). Researchers considered his script to be representative of a "Family Cook Script" because it covered a wide range of food behaviors from planning to cleanup. He used many if-then statements to describe different possibilities and his script contained a lot of detail. His dominant value was "for the family to be together, eating together," and his script shows what this means and how he makes this happen.

The second case study (Table 65.6) presents the evening meal script of a man who lived with his girlfriend and had no involvement in meal planning, preparation, or cleanup. His script is representative of the participants having a "Just Eat Script" because it is very simple with limited detail. His dominant value was to "get full" and his script demonstrates how he achieves this value.

65.6 Food Routines

The idea of repetitive eating episodes and repetitive sequences of eating episodes is not surprising, but the concept of food routines has not been examined extensively in research. Much of daily life includes repetition. Work and family life provide structures that are similar day-to-day, promoting

construction of food routines to create greater ease in daily life (e.g. Khare and Inman 2006). Routines are well recognized behavior patterns that people often employ to provide organization, simplicity, efficiency, and security in life, as well as a sense of comfort (Connors et al. 2001; Zisberg et al. 2007). Routines bring stability and familiarity to daily and weekly events and create a feeling of normalcy (Ilmonen 2001). Predictable routines are an adaptive resource for dealing with change (e.g. Zisberg et al. 2007). Consequently, most people have routines for many aspects of daily life, especially activities involving work and family. Time scarcity, common in modern life, also prompts many people to develop and maintain routines that streamline recurrent decisions and tasks (Jabs et al. 2007).

In the situational eating study described earlier, participants frequently reported repetition in food/drinks consumed, time and location for eating, social features, activities, thoughts/feelings, or physical conditions (Bisogni et al. 2007; Jastran et al. 2009). In addition, they often reported repetitive patterns of episodes over a day in that the number, timing, and order of eating episodes were similar over a number of days when the person's family or work schedule remained the same. They often referred to "my routine," and the seven consecutive days of recalls prompted them to acknowledge this repetition to themselves and the interviewers. Typical comments from participants included "Then after work I had some peanuts, which you'll be hearing from me every day…" and "just like yesterday. I follow the same exact routine on the days I work early".

When the working mother's daily eating episodes shown in Table 65.4 are viewed from the perspective of food routines, it shows the repetitive nature of eating episodes for this working mother and the sequences of episodes that create a typical food routine for her on a workday. The day begins with "my first coffee," which precedes a larger morning meal with more coffee, which is linked to lunch and so on. Her uniquely constructed labels for these episodes, such as "my first coffee," "my morning food stop," and "bite before dinner," indicate how familiar and predictable these eating episodes are to her. In each episode, dimensions such as a regular time of day for a certain food or a certain social setting create the routine. For example, the working mother has a workday routine of drinking coffee as she feeds her young child in the morning and then, after delivering the child to the

Table 65.5 Summary of general expectations, dominant values, and the strategies and procedures for different behaviors in an evening meal script from a father whose script was considered by researchers to be a "Family Cook Script"

Participant example of "Family Cook Script" for evening meals	
"Typically" me, my wife, and our two sons	
General expectation	"I think that's the one time of the day that all other differences are set aside and that's why it's so special. It doesn't matter if we've all had a bad day. Dinner is when we're together, and, nothing else matters as far as, who did what, or, who's mad at who"
Dominant values	"The most important thing about **dinner at home** is for the family to be together, eating together"
Get input	
Strategy	"…somewhere during the week, I try to get it…we try to get input…from the kids mainly, on what they want to eat"
Procedure	"They give suggestions of things they'd like. They'll have eaten something in a restaurant and say 'can you make this?'…. Or…I've made something and they'll say 'wow that's really good!'…for example, rice pilaf. Now that they know I know how to make rice pilaf…they don't buy the prepackaged mix….So we make it from scratch and it's actually a lower cost…. And they actually eat everything that's there. Like I said they make a lot of suggestions on different foods"
Shop together	
Strategy	"Me and [my wife] do [the shopping] together…we make the decisions together…On food"
Decide what to have for dinner	
Strategy	"[I think] 'what are we gonna eat and how can we do it without causing a battle?'…it doesn't makes sense to…make something and know the kids aren't gonna eat any of it…. Or something that [my wife] doesn't like."
Procedure	"There's enough foods out there that all four of us can be happy at the same time…as far as foods that we would eat for **dinner**, we never fix anything that the four of us won't eat…. If there's something I particularly want, I can have it for a different meal… because we're talking **dinner** when it's the four of us…. And if it's something I really want, I will make it to bring for **lunch**, or make it when the boys aren't there."
	"if it's just, my wife and the boys, we keep it pretty simple. We know they're not that vegetable eaters so, we don't, elaborate on vegetables…. Almost all of our **dinners** are a **protein based meal**. So these are just our, again, proteins, um, and there's some fast foods in here. Um, we do eat fast food sometimes…[protein food] is our **main meal**. … And then we build around it…Dessert…dessert, uh, for us is something that, we do have a couple hours later…beverages varies…. I mean it goes from water, the boys drink regular soda. Tammy and I drink diet sodas. We only have 2% milk. Sometimes the boys drink juice, occasionally [my wife] and I have a glass of wine"
Decide what to have if we have family or friends come	
Strategy	"[if we have family come] The quantity of food [is different]…. And the variety."
Procedure	"If it's other family, we will, do a lot more salads, a lot more, variety in the meal. I mean everybody will, it's almost like a **potluck dinner**. Where everybody'll bring a lot more things…. So, it ends up being a lot more food. …if the whole family's there, we do desserts occasionally, they bring it…cause they bring it"
Cook	
Strategy	"I usually do all…I usually do the majority of the cooking."
Procedure	"I was in food service for 25 years before coming to [my present work]. I like to really, well I guess I can say simplify. Last night's **dinner** was simple, it was just grilled chicken. But I also like at the same time to experiment with different sauces, like that. Or, there are times when I cook that I really super-garnish everything…. One thing is as far as the tasks, I am capable of having everything come off the stove at the exact same time. Or off of two different cooking surfaces. Like you know I can be out at the grill and have something on the stove or and in the oven and have everything get done at the exact same time. From years of experience for one thing. But also the task that has to go along with it that I'm not as good as I should be, or at least my wife tells me I'm not, is you know cleaning everything as I go. (laughs)…if I'm prepping vegetables, I don't prep them on the counter next to the stove, I prep them on the counter next to the sink. Because that's where the garbage disposal is"

(continued)

Table 65.5 (continued)

Participant example of "Family Cook Script" for evening meals

Sit together, eat, and talk cordially

Strategy	"**Typical dinner at home** now is that we all sit at the dining room table, and eat dinner. Occasionally, we will, congregate in the uh, living room or the TV room. **Typical dinner** now is around the dining room table, all of us talking, eating, taking our time."
Procedure	"At our dinner table I think I'm Robert Young [paternalistic father character in 1950's TV show].… I'm at the head of the table…. I don't steer the conversation, but [my wife] and I sit side by side. And the boys sit side by side…there's 4 of us at the table…[my wife] sits across from [my older son]. I sit across from [my younger son]. …they can talk to each other without talking across the table. …And, I really do at times feel like Robert Young, that I am at the head of the table. And that's my spot at the table…and we're cordial and, we don't argue at the dinner table"

Sit, eat, and talk if we have family or friends come

Strategy	"So we all sit together"
Procedure	"When you have family come in, whether it's my mom or mother in-law, father in-law, sister in-law like that, it's typically around the dining room table unless it's a **barbeque** or **picnic**…but even then we'll set a table up outside and sit around a table…it takes a lot longer to eat because we're doing a lot more conversation"
Strategy	"It's a hit or miss thing where somebody might pop in, and, if they're there at mealtime, we eat…. I would just include them in the meal"
Procedure	"We don't hold off meals because somebody is there…we just go ahead and start eating, and invite them to stay. It would more than likely be at the dinner table again, if it's dinner…we would pretty much make them part of the family for that meal"

This is a summary of an elaborate evening meal script. The top of the table shows the general expectations and dominant values for this meal. The remaining parts of the table show the strategies and procedures for each of the behaviors: Get input; Shop together; Decide what to have for dinner; Decide what to have if we have family or friends come; Cook; Sit together, eat, and talk cordially; Sit, eat, talk if we have family or friends come

Table 65.6 Summary of general expectations, dominant values, and the strategies and procedures for different behaviors in an evening meal script from a man whose script was considered by researchers to be a "Just Eat Script"

Participant example of "Just Eat Script" for evening meals

Dominant value	"To get full"
General expectation	"[I'm usually] Glad to be home, relaxed…. …I'm just happy the way it is, [just me and] my girlfriend"

Find out what is for dinner

Strategy	"I don't decide anything for dinner."
Procedure	"Dinner's there when I get there, so I don't know. I don't decide any dinners…. I say what's for dinner?…. I don't like that part of it, if I have to wait, that's why I'm glad dinner's done when I get there…. I like it when I want it"

Talk with girlfriend while she prepares dinner

Strategy	"[while she makes it I] Talk about what's going on, watch a little TV….That's about it really"

Eat and watch TV

Strategy	"I really don't like to sit there and talk, I'd rather eat…. We can talk after…. I don't want it to get cold…[my girlfriend is] the same. She'd rather just eat unless something's important"
Procedure	"[I'm usually] Watching TV. Talking about what else I had to do at my house…[we sit] In the living room. I don't eat at the kitchen table ever…. I've got one there, it's stacked full of papers and everything else on it"

This is a summary of a simple evening meal script. The top of the table shows the general expectations and dominant values for this meal. The remaining parts of the table show the strategies and procedures for each of the behaviors: Find out what is for dinner; Talk with girlfriend while she prepares dinner; Eat and watch TV

childcare facility, the mother stops at the same fast food restaurant each day that she passes on her way to work to get a breakfast sandwich and more coffee. There are occasional deviations from this workday food routine, but she reports that it is fairly typical for her.

Food routines are linked to work and family schedules. Sequences of eating episodes that recur on work days, days off, and weekends illustrate how closely food routines are tied to work and family schedules. People's food routines are shaped by many aspects of their own and others' lives including physical needs (i.e. hunger or fatigue at a certain time of day), food availability in particular places and time, norms for eating in different locations and social settings, mode and duration of transportation to and from activities, and patterns of sleep and relaxation. For parents, the presence, ages, and activities of their children impact food routines a great deal (Devine et al. 2009). Very often, day of the week, time of day, specific activities, and particular foods are linked in food routines. For example, a father explained, "During the fall, when the kids have late soccer practices, we'll pick up a pizza or subs on Tuesdays and Thursdays." A mother reported that she was sure of the time of a meal because it coincided with her young child's favorite TV show. "That's an everyday routine (time for lunch) just because Sponge Bob is on at 12:30."

For workers, the conditions and activities of employment may impose particular limitations or opportunities for eating that determine food routines (Bisogni et al. 2007; Jastran et al. 2009; Devine et al. 2009). Some people do not eat at work because of the hours, nature, or location of the job whereas others may have access to abundant foods and beverages. Standardized break times, lunch rooms, and coworkers' preferences may also determine food routines. People develop routines for eating that fit their personal preferences, job requirements, and family circumstances in different ways. For example, after the morning bus run, a school bus driver eats "breakfast" at the same restaurant Monday through Friday, with time, social setting, location and even food repeating 5 days a week. "I always sit at this table and get the same breakfast…5 days a week after my morning bus run." Another example is a man who worked from 11 p.m. to 7 a.m. who never ate during his work hours because he wanted to eat on his family's daytime meal schedule.

Figure 65.6 illustrates how the workday eating routine for the mother described earlier (Table 65.4) is linked to her family and work responsibilities on a typical workday. She adjusts her own eating around her parenting and job requirements, often multitasking when she is caring for her daughter or working at her desk. Her routine for lunch may predictably vary depending upon her workload and her coworker's availability. Her evening meal will also vary in a planned way depending on whether or not her husband is home.

The modified and conventional episode labels this mother uses (e.g. "working lunch," "social lunch," "supper with Dan") reflect how she sees her eating routines as linked to her work and family responsibilities. Other examples of how people's eating episode labels reveal the connection of eating routines to work and family schedules are "family night out," "unwind time," or "swim lesson night dinner" (Bisogni et al. 2007).

The concept of food routines and schematics for representing them (e.g. Fig. 65.6) are useful ways to capture regularity in eating from the perspective of the individual. People may construct ways of eating different from the traditional pattern of three meals per day that are labeled with the conventional terms of breakfast, lunch, and dinner. A weekday versus weekend distinction may not be appropriate for people who work on weekends but have some weekdays off. A parent who cares for a child on some days of the week but not others may report even different types of repetition over the week. Using traditional meal patterns as the sole reference point for examining food patterns is limiting. Food routines focus on the regularity in episodes and sequences of eating episodes

MOTHER'S WORKDAY SCHEDULE		ROUTINE EATING EPISODES

Early morning, feeding toddler, waking up → "My first coffee"

After bringing toddler to childcare, driving to work → "My morning food stop"

Noon at work → If too much work → "Working lunch"
Noon at work → If co-workers available → "Social lunch"

When especially hungry in afternoon at work → "Afternoon treat"

At home while fixing & feeding toddler's dinner → "Bite before dinner"

Evening meal → When Dan is working → "Supper without Dan"
Evening meal → When Dan is home → "Hot supper with Dan"

After toddler is asleep → When Dan is working → "My TV snack"
After toddler is asleep → When Dan is home → "Our late treat"

Fig. 65.6 Example of how one working mother's food routines are linked to her work and family schedule on a workday. The mother's workday schedule shows the sequence of daily activities for her work and family responsibilities. At certain times (e.g. noon at work and the evening meal), her eating routine changes in a predictable way, depending upon certain conditions

from the person's perspective and the ways that food behavior is linked to other important aspects of life. Asking people to explain their food routines in their own words, rather than asking them to describe what they eat for breakfast, lunch, or dinner, enables researchers to learn much about how they eat and why.

Food routines are developed as best-fit solutions for food choice values. Gallimore and Lopez (2002) described routines for everyday decisions as related to repeating situations and representing the compromises between goals and practical limitations. Personal goals and typical situations have previously been identified as contributing to routine development (e.g. Betsch et al. 1998). The participants in the situational eating study also explained that they constructed food routines in response to their food choice values, such as taste, cost, convenience, health, and managing social relationships (Bisogni et al. 2007; Jastran et al. 2009). For example, when social relationships are the most important value, people develop routines around the need to spend time with others. "Our regular Sunday night routine is to just watch TV while we eat and talk and cuddle together on the couch." Routines are often part of the solutions to complex circumstances. Conflicting food preferences among family members can encourage developing routines for eating certain foods when particular people are absent from meals. "When my husband has to work late and won't be home for dinner, I always fix a salad, which he would not like to eat for dinner if he were home. It's my chance to eat what I like."

To balance food choice values that conflict, people often construct sets of routines, with one routine for restricting certain foods and another for indulging in them (Connors et al. 2001; Jastran et al. 2009). People who are usually very frugal might eat only foods purchased from discount stores, but routinely eat an expensive food when visiting a relative because it is the relative's routine way of treating them. "Friday nights we get take out" is a common food choice routine for

those who save money by cooking meals at home on most other days of the week. People also balance their values through routines for eating out once a week and giving the family cook a break on a weekly basis.

Routines that emphasize convenience ("quick and easy meal") and no decision making ("pizza night routine") are especially important to people such as working parents who often feel that time is very scarce and life is exhausting (Jabs et al. 2007). For example, a working mother explained, "I know in the morning at [specific fast food restaurant] what I'm going to get to eat on the way to work…. So I'm not taking time to think about it." Routines may be developed to involve multitasking with other activities such as child care, work, home care, or personal care. Persons for whom saving time is a priority in food routines might explain "I supervise homework and do laundry while I eat my dinner." A "relaxing dinner" may be rare in this stage of their lives and never considered as routine.

Food routines provide stability but are adaptable to change. Routines enhance people's lives by setting boundaries and allowing a person to plan and predict (Gallimore and Lopez 2000). Families benefit from organized routines (Fiese et al. 2006) that can promote adaptability to unforeseen stressful events (Zisberg et al. 2007) and improve health outcomes (Denham 2003). Food routines add predictability to life and contribute to simplification of daily tasks related to food and eating. As best-fit solutions, food routines become predictable and even comfortable. People who like their routines want to keep things the same "I don't like it when things at work disrupt my usual routine… it's more comfortable to keep doing it the same way." Food routines are described as feeling "normal" and something "I can count on." The security of having a personally designed system that works well and feels good makes routines something people strive to preserve. Stable food routines also provide a sense of comfort. A woman whose family had just returned from a trip described their eating while away as "off balance" and getting back to normal as "a relief."

Although routines that work well persist and provide stability, they are also modifiable as a person's circumstances and schedule changes. Job changes may cause changes in food routines. For example, one woman said, "I was eating better when I had a long commute to work. I'd pack a sandwich to eat on the way. And now that I work close to home, I don't do that and wind up missing my breakfast most days."

Disruptions to family or school schedules may also mean modified food routines. Food routines organized around children's schedules change as the children's activities change, such as school year to summer vacation, or fall sports to winter sports. Parents may develop new routines for eating when the children are away or leave home. A father whose son was away at summer camp explained, "My eating schedule is all off this week… now that [my son] isn't there."

Viewing food routines through the framework of eating episodes allows the nature of the repetition and changes to be identified. Repetition in particular dimensions of an eating episode may be essential for the existence of a routine, while other dimensions can vary. For example, eating out together on Friday nights at the same family restaurant may be a routine for some families but the foods consumed may vary.

People reflect on their food routines and sometimes develop an identity from them. People often think about and evaluate their food routines. Reflections can be negative, such as a person who states, "It's the same old routine…it's pathetic." In contrast, another person with a positive evaluation might say proudly, "We have a great evening meal routine. The kids take turns choosing the vegetables."

People also compare their eating routines to those of others, often using cultural ideals as the basis for what they view as "normal." One single mom reflected that her friends had to be home to cook dinner for a husband who expected to eat at a certain time. Her life did not include that structure and she said "with just me and [my son] to think about, our routine is very different."

Comparisons help people make sense of their routines for themselves and others. "I don't eat the same food at the same time each day. I eat when I feel hungry. I'm just not a scheduled eater like my sister."

Work by other researchers (e.g. Giddens 1991) supports the connections between a person's identity and routine behavior patterns that make up an individual's daily world. Bisogni et al. (2002) described the influence of one's identity on eating practices as well as the opposite, the influence of food behavior on identity formation. A person who values health in food choice and repeatedly emphasizes healthy foods in their eating episodes may proudly consider herself as a "healthy eater" or "the healthiest eater I know" (Bisogni et al. 2002). A person who is proud to be a gourmet may have difficulty incorporating healthy eating practices into her routines because she must revise her identity. The strong link between food routines and identities must be considered when asking people to change their food behaviors.

65.7 Applications

The Food Choice Process Model provides a way for organizing the many different factors and processes involved in food behavior. It enables researchers and practitioners to be mindful of the overall complexity and dynamic nature of a person's thoughts, feelings, and actions related to food, while allowing them to focus on particular parts of the model in their professional work.

Developed using data from samples of free-living individuals in the USA, the model has a number of limitations (Sobal et al. 2006; Sobal and Bisogni 2009). It may not apply well to people living in other cultures, historical times, places, or food systems. It organizes an array of factors and processes involved in food choice based on people's perspectives into broad categories, but does not elaborate on all components in a systematic way. The model is not intended to direct health promotion interventions, although it provides useful insights into why and how people behave the way that they do and how both structure and agency are potentially involved in adopting and maintaining new behaviors for health promotion.

The concept of eating episodes underscores how important it is to take a detailed look at how people experience eating situations. Those who wish to study or modify a person's food behaviors must recognize that the person may experience eating situations as much more than involving food and drink. Traditional 24-h recalls focus on the nutritional quality of the foods consumed and typically pay less attention to the surrounding details, even though these details may help understand the barriers and opportunities to change. The concept of eating episodes with multiple dimensions suggests ways for researchers and practitioners to ask about and summarize the details of the situation in which food behaviors occur.

Food scripts demonstrate how to conceptualize linkages between cognitions and behavior that depict the complex constructions people may hold for a single eating episode. Evening meal scripts highlight important individual similarities and differences in the conceptualization of a single eating episode. The study of food scripts may provide a valuable set of conceptual tools for dietary assessment, nutrition counseling, message tailoring and targeting, and program design and evaluation. People develop scripts for food and eating behaviors as ways to provide predictability and simplicity in decision making (Connors et al. 2001). However, when a particular eating episode is encountered repeatedly, parts of the episode script may begin to function automatically and may even be used in episodes where it is inappropriate (Baldwin 1992). Asking people to add, modify, or delete a given food or way of eating may require them to adjust many aspects of their scripts including the values, expectations, strategies, and procedures for several different food behaviors.

The concept of food routines reminds researchers and practitioners that regularity of many food behaviors is linked to many other elements of a person's life. Asking a person to change the way that they eat requires them to alter individual episodes and sequences of episodes that have been established over a long period of time to fit the person's food choice values and particular life circumstances, such as work and family schedules. Incorporating new food behaviors into existing routines requires mental attention and persistence because the person may have to resolve new food choice value conflicts or negotiate with other people. The person may have to lose the comfort and security of long established behaviors. Time and trial and error are required to develop a new satisfactory routine. Some changes in food behavior may be impossible to achieve until structural factors change, such as a person's employment, family responsibilities, or access to food.

65.8 Conclusions

To advance health promotion, researchers and practitioners need concepts and models that will enable them to better understand how people adapt their food-related behaviors to their needs, preferences, and environments both situationally and over time. The Food Choice Process Model and the concepts of eating episodes, food scripts, and food routines provide insight about how people experience food choice and ways for researchers and practitioners to consider the many factors and processes that are involved. The concepts of eating episodes, food scripts, and food routines provide ways to understand how individuals construct situational and recurring food behaviors. Additional studies are needed to extend and elaborate upon how these concepts can advance research and practice.

Summary Points

- People construct their thoughts, feelings, and actions related to food and eating in individual ways based on their life course experiences, ideals, personal factors, resources, social setting, and contexts. The inductive Food Choice Process Model portrays these factors and the processes involved in food choice from people's perspectives.
- People develop personal food systems, the cognitive processes for food choice that include developing food choice values, negotiating and balancing food choice values, classifying foods, and developing and revising strategies, scripts, and routines.
- People experience eating as involving more than just food and beverage consumption. The concept of multidimensional eating episodes helps capture the surrounding details in which eating behavior occurs by recognizing the dimensions of time, location, social setting, mental processes, physical conditions, and other activities.
- Food scripts represent the complex cognitions that people develop to guide behavior in specific situations and include their values, strategies, and detailed behavioral plans.
- People construct food routines consisting of recurring eating episodes or repeating sequences of eating episodes that match work and family schedules, reflect their food choice values, and provide stability and predictability for daily life.
- Understanding eating episodes, food scripts, and food routines will help practitioners effectively work with clients toward the adoption and maintenance of healthy eating practices.

Definitions and Explanations of Key Terms

Eating episodes: Any acts of eating or drinking with the surrounding situational details.

Eating episode dimensions: Categories of characteristics used to describe the situational aspects of an eating episode from people's perspectives: of food/drink, time, location, activities, social setting, mental processes, physical condition.

Food behavior: All actions related to food (includes acquiring, preparing, serving, eating/drinking, storing, giving away, and cleaning-up).

Food choice: Thoughts, feelings, and actions related to food and eating.

Food choice values: Important considerations a person constructs and weighs in food choice.

Food routines: Recurrent eating episodes and sequences of eating episodes a person uses.

Food scripts: Mental processes that guide food behavior in specific situations including expectations about the situations and plans for acting.

Food strategies: Heuristics, guidelines, and rules that people develop to help them achieve food choice values in food behavior.

Personal food system: The mental processes that people construct to interpret and manage the many factors that shape their food behavior including construction of food choice values, negotiation values, classification of foods, development of strategies, development of food scripts, and development of food routines.

Schema: Generalized collections of knowledge stored in long-term memory and constructed from past experience that contain organized and related categories that guide behavior in subsequent familiar situations.

Script flexibility: Adaptability of scripts to accommodate the day-to-day variations in dimensions of eating episodes.

Script scope: Includes the starting and ending points of a script as well as the details of the plan.

Situational eating: Acts of eating/drinking including the specific surrounding details (i.e. time, place, activities, people present, activities, physical and mental conditions).

Value negotiation: Process of setting priorities and making tradeoffs among food choice values.

24 hour situational recall: Retrospective recall of all food and beverages consumed on the previous day along with the surrounding details of the situations in which the consumption occurred, such as where food was consumed, who was present, time of day, physical conditions, mental processes, activities coinciding with eating and reoccurrence of the episode.

Chapter 66
Endogenous Opioids, Opioid Receptors, and Incentive Processes

Mauricio R. Papini and Leonardo A. Ortega

Abbreviations

cE	Consummatory extinction
CNS	Central nervous system
cSNC	Consummatory successive negative contrast
DOR	Delta opioid receptor
EFF	Escape from frustration
iE	Instrumental extinction (operant lever pressing)
iSNC	Instrumental successive negative contrast
KOR	Kappa opioid receptor
MOR	Mu opioid receptor
ORL-1	Opioid-receptor-like receptor
pE	Pavlovian extinction (autoshaped lever pressing)

66.1 Introduction

Endogenous opioid peptides and their receptors are involved in the modulation of a variety of behavioral functions because of their relatively diffuse distribution in the CNS. Recent research suggests that endogenous opioids modulate incentive processes. Incentives are environmental resources that motivate the organism to behave. Incentive motivation is activated by expectancies which, in turn, are the result of learning and memory processes. Thus, the study of endogenous opioids in relation to incentive processes encompasses behavioral topics including motivation, emotion, learning, and memory (Table 66.1).

66.2 Opioid Peptides and Receptors

Endogenous opioid peptides consist of short sequences of amino acids synthesized from precursor polypeptides. There are five major groups of opioid peptides, and their precursors are known for four of them (Table 66.2). A model example of the posttranslational changes that result in the sequential

Table 66.1 Key features of opioid system and incentive processes

1. The four types of opioid receptors are diffusely distributed in the mammalian brain, thus playing a role in many different behavioral processes.
2. Opioid peptides and their receptors have significant functions in relation to incentive processes, i.e., the attribution of hedonic value to environmental resources such as food and fluids.
3. Incentive value can be viewed in an absolute (e.g., food palatability) or relative manner (e.g., incentive contrast effects).
4. Food palatability, also known as food liking (as different from food wanting), depends on the degree of opioid activation during consummatory behavior.
5. Endogenous opioids are naturally released during episodes involving the unexpected omission or devaluation of food reinforcers (incentive contrast).
6. The initial reaction to incentive contrast involves DORs, whereas the recovery from incentive contrast involves KORs.

This table lists the key facts about the relationship between endogenous opioids, opioid receptors, and incentive processes

Table 66.2 Precursors and products

Precursor	Peptide
Pro-opiomelanocortin	γ-MSH (melanocyte stimulating hormone)
	ACTH (adrenocorticotropic hormone)
	α-MSH (melanocyte stimulating hormone)
	γ-LPH (lipotropin hormone)
	β-LPH (lipotropin hormone)
	β-endorphin
Pro-enkephalin	Met-enkephalin
Pro-dynorphin	Dynorphin A
	Dynorphin B
	Neoendorphin
Pro-nociceptin	Nociceptin/orphanin
(Unknown)	Endomorphin-1
	Endomorphin-2

This table illustrates the polypeptide precursors and their opioid and nonopioid products
Fig. 66.1 Gene products of pre-proopiomelanocortin. Cleavage of opioid and nonopioid peptide products from the pre-proopiomelanocortin gene

cleavage from an opioid precursor is provided by proopiomelanocortin (POMC) in Fig. 66.1. The pre-proopiomelanocortin gene codes for the precursor POMC. This gene contains 7,665 bp in three exons and two introns (Raffin-Sanson et al. 2003). The resulting polypeptide, consisting of 241 amino acids, is processed and, depending upon the enzymes present, cell-specific patterns of cleavage

generate the opioid peptides β-endorphin and β-lipotropin, as well as nonopioid peptides such as the adrenocorticotropic hormone (ACTH), other lipotropins (LPH), corticotropin-like intermediate peptide (CLIP), and different types of melanocyte-stimulating hormones (MSH).

Opioid receptors are G-protein-coupled receptors that exhibit a high degree of structural similarity (Lord et al. 1977; Sim-Selley et al. 2003). Four opioid receptors have been identified and are known as MOR, KOR, DOR, and ORL-1 (also known as nociceptin opioid peptide receptor). These receptors are distributed throughout the CNS, with somewhat differential concentrations of each receptor across brain areas (Fig. 66.2) (Mansour et al. 1995; Sim-Selley et al. 2003). They have been described in mammals, birds, reptiles, amphibians, and teleost fish, but not in chondrichthyes (sharks), cephalochordates (lancelets), urochordates (tunicates), or arthropods (fruit fly) (Dreborg et al. 2008;

CNS Compartment	Receptor and CNS Areas

MOR: Presubiculum
      Basolateral amygdala
      Cortical amygdaloid N
DOR: External plexiform layer
      Anterior olfactory N
      Caudate-putamen   ORL-1: Cingulate cortex
      N accumbens   Insular cortex
      Olfactory tubercle   Perirhinal cortex

Spinal cord

Fig. 66.2 Distribution of opioid receptors in the mammalian CNS. CNS areas with very high density of receptor binding (Region data from Mansour et al. 1995; Sim-Selley et al. 2003; Yaster et al. 2003)

Table 66.3 Selective ligands for opioid receptors

Function	MOR	DOR	KOP	ORL
Agonist	DAMGO	DPDPE	U50,488H	Nociceptin
	Endomorphin-1	SNC 80	U69595	
	Endomorphin-2			
Antagonist	CTAP	Naltrindole	Nor-binaltorphimine	(Unknown)

A variety of ligands have been developed that, unlike endogenous opioids, bind selectively to specific opioid receptors. These compounds play a key role in identifying opioid receptors that are selectively involved during specific behavioral processes

Stevens 2009). Although the amino acid sequences of opioid receptors are very similar across species and within species, nonmammalian opioid receptors are more similar to each other than are mammalian opioid receptors (Stevens et al. 2007).

In mammals, endogenous opioid peptides bind differentially, but not exclusively, to each opioid receptor. The exception is the ORL-1 receptor, which does not bind endogenous opioids. For instance, β-endorphin and enkephalins have a higher affinity for the MOR and the DOR, than for the KOR. In turn, dynorphins bind preferentially to the KOR and nociceptin binds to the ORL-1 receptor. Finally, endomorphin-1 and endomorphin-2 bind specifically to the MOR. In addition to these endogenous opioids, a number of receptor-selective ligands have been developed (Table 66.3).

66.3 Opioid Receptors and Absolute Incentive Value

One strategy used to clarify the role of the opioid system in behavior has been to study the opioid effects in combination with the stimulation of specific brain areas. Following this rationale, it has been proposed that opioid receptors located in the hindbrain may be involved in sensory and metabolic functions, opioid receptors located in the amygdala may regulate the hedonic (i.e., appetitive or aversive) properties of food, and opioid receptors in the hypothalamus may control energetic needs. In addition, opioid receptors located in the basal ganglia may be involved in the modulation of motor patterns (Aubert et al. 2007). This section emphasizes opioid modulation of food incentives.

The role of the opioid system on taste palatability was suggested by the reduction of drinking behavior in animals exposed to solutions of saccharine, sucrose, saline, and hydrochloric acid while under the influence of the nonselective opioid antagonist naloxone (Levine et al. 1982). Similar results were reported using sweetened or unsweetened food and manipulating the food deprivation states. Levine et al. (1995) found that naloxone reduced consumption of sweet food, when compared to unsweetened food, independently of the type of deprivation. In addition, naloxone reduced sucrose preference in two-bottle tests (sucrose vs. water) for wild-type and β-endorphin knockout mice, but it had no effect on enkephalin and dynorphin knock-out strains (Hayward et al. 2006). Naloxone blockage of opioid receptors seems to devalue the palatability of sucrose solutions, rather than the postingestional effects of sucrose. This is suggested by two series of experiments using naloxone-induced suppression of sucrose in a preparation of feeding by open gastric fistula. In the first series of experiments, naloxone reduced sucrose consumption on rats exposed to sham drinking (Rockwood and Reid 1982). In the second series of experiments, naloxone reduced sucrose intake in rats exposed to 10% and 20% sucrose to a level similar to that of saline controls exposed to 5% and 10% sucrose (Kirkham and Cooper 1988).

Following an incentive-motivation framework, Berridge (2004) suggested a distinction between "liking" and "wanting." Liking is defined as the hedonic reaction triggered by the immediate presentation

of a reward, whereas wanting refers to the incentive significance of the reward. This distinction is consistent with Craig's (1918) classification of behavior in terms of consummatory (i.e., liking) and appetitive components (i.e., wanting), and it was proposed to reconcile the effects of some physiological manipulations on behavior supported by access to incentives. For example, dopamine antagonists that disrupt the effects of the mesolimbic dopaminergic system reduce wanting, thus decreasing motivation to seek incentives. However, when incentives are delivered passively (e.g., intraoral sucrose infusions), animals show normal liking responses (e.g., lip licking, tongue protrusion). Conversely, naloxone blockage of opioid receptors in key areas of the reward system (e.g., nucleus accumbens, ventral pallidum) eliminates orofacial liking responses, whereas microinjections of endogenenous opioids increase them.

Endogenous opioid and cannabinoid mechanisms in the nucleus accumbens are critical for the orofacial responses to sweetness used as an index of liking (i.e., consummatory-like responses; Berridge 2004). Administration of DAMGO (a selective MOR agonist) in the medial accumbens shell increases these orofacial liking responses (Peciña and Berridge 2005). Additional studies with opioids shed light on the functional connection between the nucleus accumbens and the posterior ventral pallidum. For example, the enhancing effects of DAMGO administered in the posterior ventral pallidum on liking responses were blocked by microinjections of naloxone in the nucleus accumbens. Moreover, opioid activation in any of the two areas causes an increase in Fos protein expression in the other area, an effect suppressed by naloxone (Smith et al. 2009). Thus, opioid release in the nucleus accumbens, amygdala, and ventral pallidum are intimately involved in incentive palatability.

66.4 Opioid Receptors and Relative Incentive Value

Incentive relativity involves a comparison process, usually between present and remembered incentives. Behavioral preparations used to study incentive relativity typically involve some type of unexpected reward devaluation or reduction that triggers the comparison (Flaherty 1996). The role of the opioid system in incentive relativity has been studied in several preparations (Table 66.4; Papini 2009).

Table 66.4 Effects of opioid manipulations on incentive relativity

Preparation	Drugs	Dose	Administered	Reference
cSNC	Morphine	0.5–16.0 mg/kg	Pretrial	Rowan and Flaherty (1987)
	DPDPE	24 µg/kg	Pretrial	Wood et al. (2005)
	DPDPE	24 µg/kg	Post-trial	Daniel et al. (2009)
	U50,488H	1–10 mg/kg	Pretrial	Wood et al. (2008)
	U50,488H	1–3 mg/kg	Post-trial	Wood et al. (2008)
	Naloxone	0.25–1.0 mg/kg	Pretrial	Rowan and Flaherty (1987)
	Naloxone	2 mg/kg	Pretrial	Pellegrini et al. (2005)
	Naloxone	2 mg/kg	Post-trial	Daniel et al. (2009)
	Naltrindole	1 mg/kg	Pretrial	Pellegrini et al. (2005)
	Naltrindole	1 mg/kg	Post-trial	Daniel et al. (2009)
iSNC	FK33–824	0.3 mg/kg	Pretrial	Lynch and Clark (1983)
	Naloxone	1–10 mg/kg	Pretrial	Lynch and Clark (1983)
cE	Naloxone	2 mg/kg	Pretrial	Norris et al. (2008)
iE	Naloxone	2 mg/kg	Pretrial	Norris et al. (2009)
pE	Naloxone	2 mg/kg	Post-trial	Daniel et al. (2009)
EFF	Naloxone	2 mg/kg	Pretrial	Norris et al. (2009)

This table summarizes research on the effects of opioid drugs on situations involving unexpected incentive devaluations. Opioid administration was intraperitoneal, except in Lynch and Clark (1983), who used subcutaneous administration

Most of the information originates in the consummatory successive negative contrast (cSNC) situation, in which the consummatory behavior of a group exposed to a downshift in sucrose concentration (e.g., from 32% to 4% sucrose) is compared to that of an unshifted control group only exposed to the lower concentration (e.g., 4% sucrose). The incentive downshift leads to a sharp and transient suppression of consummatory behavior and opioid drugs modulate the degree of suppression. The use of an unshifted control allows an assessment of the extent to which opioids effects are selective to the incentive downshift experience. For example, morphine attenuated consummatory suppression (i.e., attenuated cSNC), whether administered before the first or before the second downshift trial (Rowan and Flaherty 1987). Naloxone reversed the effects of morphine (Rowan and Flaherty 1987) and also enhanced cSNC (Pellegrini et al. 2005). Except for the highest morphine dose (16 mg/kg), neither morphine nor naloxone affected the consummatory behavior of unshifted controls, suggesting that the effect was selective to the downshift experience and therefore unrelated to potential opioid effects on motor, sensory, or palatability aspects of the task. Naloxone acts by distorting the normal process of detection of the incentive downshift, which involves a ratio comparison between pre- and postshift sucrose concentrations (Papini and Pellegrini 2006). Opioid blockage shifts the incentive comparison from a ratio to an absolute difference comparison (Daniel et al. 2009). However, neither naloxone nor naltrindole (selective DOR antagonist) affects the course of cSNC when administered immediately after the first downshift trial.

Naloxone also leads to similar results in other training situations. For example, naloxone increases behavioral suppression in the iSNC situation (Lynch and Clark 1983), facilitates instrumental extinction of lever-press responses acquired by pairings with food or sucrose pellets (Norris et al. 2009), and promotes consummatory extinction of licking responses paired with sucrose solutions (Norris et al. 2008). Naloxone also eliminates the escape-from-frustration effect in which rats exposed to appetitive extinction have the opportunity to "escape" to a neutral compartment by jumping over a barrier (Norris et al. 2009). However, as in the cSNC situation, posttrial naloxone administration during appetitive extinction leads to no detectable effects on lever-press responses (Daniel et al. 2009). All together, these results suggest that: (1) opioid receptors are normally engaged during exposure to incentive downshifts; (2) their role is to attenuate the emotional impact of the downshift; and (3) they probably play no direct role in the consolidation of the emotional memory of the downshift event.

Opioid modulation of cSNC is also quite selective with respect to the amount of downshift experience. For example, the DOR agonist DPDPE reduces cSNC on the first downshift trial, but has no effect on the second downshift trial (Wood et al. 2005). Similarly, the DOR antagonist naltrindole enhances cSNC selectively on the first downshift trial (Pellegrini et al. 2005). Thus DORs are engaged during the initial response to the incentive downshift, but are less relevant as the animal learns about the situation with more extended practice. Interestingly, the KOR agonist U50,488H has the opposite profile. It attenuates cSNC when administered on the second downshift trial, but has no effect when administered on the first downshift trial (Wood et al. 2008). Because both morphine (Rowan and Flaherty 1987) and naloxone (Pellegrini et al. 2005) influence cSNC on both the first and second downshift trials, and because these drugs have greater affinity for the MOR, it is tempting to conclude that the MOR is not trial selective in the cSNC situation. The picture emerging from these results is that different combinations of opioid receptors are engaged as a function of the amount of experience with the downshifted incentive. A MOR–DOR combination is active during the early stages of downshift detection, whereas a MOR–KOR combination becomes active as the animal interacts further with the downshifted solution. Such combinations await further research with selective MOR opioids, but it is intuitively consistent with heterodimerization of MOR–DOR complexes. MOR–DOR heterodimers have been postulated to underlie enhanced hypoalgesia after spinal cord administration of morphine (Gomes et al. 2004; Snook et al. 2008).

66.5 Applications to Areas of Health and Disease

The experiments reviewed in the previous section demonstrate that endogenous opioids are normally activated by an episode of incentive downshift. Thus, further activation by opioid agonists (e.g., morphine, DPDPE, U50,488H) reduced cSNC, whereas interference by antagonists (e.g., naloxone, naltrindole) enhanced cSNC. But, like most behavioral phenomena, recovery from incentive downshift is a variable process, with individuals exhibiting behavioral phenotypes ranging from very fast recovery (i.e., normal consummatory levels after a single exposure to the downshifted solution) to very slow recovery (i.e., little or no evidence of recovery after five trials, the usual length of the postshift phase in cSNC experiments). Even rats that show very similar consummatory suppression on the first downshift trial can differ dramatically in the speed of recovery from cSNC (Pellegrini et al. 2005). Interestingly, if these individual differences in recovery were related to differences in some property of the opioid system, one would predict a direct correspondence between recovery from reward downshift and general sensitivity to opioid treatments.

MORs are known to exhibit allelic variation in rodents and humans (e.g., Mayer and Höllt 2001; Zimprich et al. 1995). MORs are important for health-related reasons because they are one site of action for morphine and naloxone, two drugs with extensive clinical applications. Allelic variations differ in the efficacy with which the MOR interacts with opioid agonists and have clinical implications for addiction and pain treatments (Drews and Zimmer 2010; Klepstad 2007). Thus, if individual differences in opioid receptor efficacy and recovery from cSNC are related, then slow recovery animals should differ from fast recovery animals in terms of sensitivity to opioid blockage. Consistent with this hypothesis, rats that recovered more slowly from incentive downshift exhibited greater sensitivity to naloxone treatment in an activity test than rats that recovered faster (Pellegrini et al. 2005). Slow- and fast-recovery animals did not differ in their level of suppression during the first downshift trial, as well as in terms of growth rates or water intake. However, siblings were significantly more likely than chance to be assigned to the same recovery group.

The opioid system (receptors and endogenous neuropeptides) participates in a wide variety of behaviorally relevant processes. The role of this neurochemical system in nutrition relates to its ability to modulate incentive value, both absolute and relative. As a result of this incentive function, it is not surprising that the area of influence of opioid modulation extends beyond that of food reinforcement processes. For example, in addition to the well-established role in pain and analgesia, opioids participate in fear conditioning, social stress, drug tolerance and drug dependence, drug abuse, gastrointestinal function, and mental disorders among others (Bodnar in press).

Summary Points

- Opioid receptors and endogenous peptides play a role in a wide variety of behavioral and physiological processes.
- Four types of opioid receptors have been identified: mu (MOR), delta (DOR), kappa (KOP), and opioid-receptor-like receptor (ORL-1).
- A variety of endogenous opioids have been identified, including β-endorphin, met-enkephalin, dynorphins, and nociceptin, among others.
- Several receptor-selective compounds are available for research (e.g., DAMGO, DPDPE, and U50,488H selectively agonize MOR, DOR, and KOR, respectively).
- Opioid receptors and neuropeptides modulate the absolute (palatability) and relative (incentive contrast) value of incentives.

- Incentive value refers to the hedonic dimension of stimuli such as food and fluids, that is, to their appetitive or aversive value.
- Opioid peptides and receptors modulate food palatability and so-called liking orofacial responses.
- Endogenous opioids are released during events involving unexpected incentive devaluations.
- Different opioid receptors affect behavior at different points in the process of adjustment to incentive devaluation.

Key Terms

Endogenous opioids: Gene products expressed in the vertebrate CNS, acting on membrane receptors to modulate synaptic transmission.

Opioid receptors: Gene products of the G-protein-coupled type, expressed in the vertebrate CNS, sensitive to a variety of endogenous and exogenous opioid peptides, and modulating synaptic transmission.

Absolute incentive value: The direct hedonic (i.e., appetitive–aversive) dimension of environmental resources such as food and fluids.

Relative incentive value: The hedonic value of a current incentive in relation to the incentive expected on the basis of prior experience.

Negative incentive contrast: Greater rejection of a small incentive in animals previously exposed to a large incentive, relative to animal always exposed to the small incentive.

General and Normative Aspects: Appetite

Chapter 67
Central Regulation of Appetite and Satiety Behavior

Edward B. Lee and Rexford S. Ahima

Abbreviations

3v	Third ventricle
AGRP	Agouti related protein
Arc	Arcuate nucleus
CART	Cocaine-and amphetamine regulated transcript
CCK	Cholecystokinin
CCK-1R	Cholecystokinin-1 receptor
CN	Cranial nerve
CNS	Central nervous system
CNTF	Ciliary neutrotrophic factor
CRH	Corticotropin-releasing hormone
DMV	Dorsal motor nucleus of the vagus
LHA	Lateral hypothalamic area
MCH	Melanin concentrating hormone
α-MSH	α-Melanocyte stimulating hormone
NAc	Nucleus accumbens
NPY	Neuropeptide Y
NTS	Nucleus of the solitary tract
OB-Rb	Leptin receptor b (longest isoform)
OXY	Oxytocin
POMC	Proopiomelanocrotin
PVN	Paraventricular nucleus
STAT	Signal transducers and activators of transcription
TRH	Thyrotropin-releasing hormone
VMN	Ventromedial nucleus
VTA	Ventral tegmental area

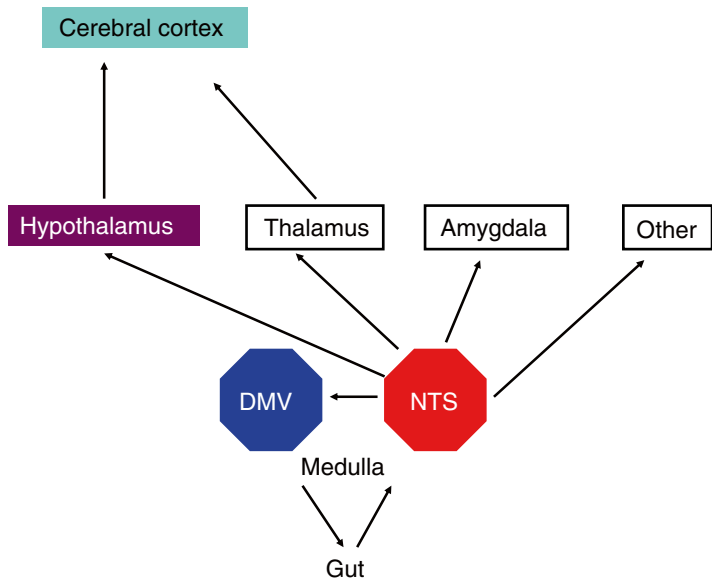
67.1 Introduction

Energy homeostasis is the process whereby an organism regulates food intake, energy expenditure, and energy stores. Many aspects of energy homeostasis are regulated by the central nervous system. Appetite and satiety are the subjective feelings of hunger or adequacy generated by the central nervous system in order to regulate food intake. Towards this end, the CNS serves as an integrator of several peripheral signals, including those generated by nutrient intake and adiposity (Fig. 67.1). Integration of these peripheral signals triggers the expression of neurotransmitters and neuropeptides with orexigenic or anorexic effects. Several brain circuits will be discussed within the context of peripheral signals which influence their activity. Although appetite and satiety primarily affect food intake, they are inexorably intertwined with a complex network of homeostatic and nonhomeostatic processes which regulate energy homeostasis.

67.2 Gut–Brain Axis

The primary role of the gastrointestinal tract is to digest and absorb nutrients. Secondarily, the gut plays a role in energy homeostasis via mechanoreceptors and chemosensors which detect the volume and quality of food intake. The vagus nerve extensively innervates the gut, carrying afferent mechanical and chemical signals from the gut to the dorsal vagal complex in the medulla, terminating primarily on the medial and dorsomedial parts of the nucleus of the solitary tract (NTS; Schwartz 2000,
Fig. 67.1 Cross-talk between the brain and peripheral organs. Several organs communicate with the central nervous system via signals reflective of energy input (food intake) and energy storage levels (adiposity). The gastrointestinal system is the source of nutrient and hormonal signals that act through the vagus nerve to regulate neuronal circuits in the brainstem, and ultimately the forebrain. Adipose tissue secretes adipokines such as leptin and adiponectin which act in the hypothalamus and other brain areas. Insulin is secreted by the pancreas and has pleotrophic effects on metabolism in the periphery, but also can act centrally to influence appetite and feeding behavior. The brain in turn sends efferent neuronal and hormonal signals to liver, gut, muscle, and adipose tissue to regulate energy homeostasis

Fig. 67.2 Neuronal connections of the nucleus of the solitary tract. The nucleus of the solitary tract (NTS), located in the medulla, receives visceral sensory information from the gut via the vagus nerve, and taste information from the facial, glossopharyngeal, and vagus nerves. NTS neurons project to the dorsal motor nucleus of the vagus, hypothalamus, thalamus, and limbic regions (amygdala and cingulate gyrus)


2006). There is also a small projection to the area postrema, a circumventricular organ which lies in the rhomboid fossa in the floor of the fourth ventricle. Multiple projections from the NTS are known (Fig. 67.2). Signals are carried forward to motor nuclei such as the dorsal motor vagal nucleus, which then project back out via the vagus nerve to peripheral targets including the gut and liver, forming a viscera–brain–viscera loop. Aside from its role in appetite and satiety, these gut–brain–viscera circuits regulate other metabolic parameters. For example, gastrointestinal infusion of long chain fatty acids results in signals via the vagus nerve from the gut to the hindbrain, which then signals back to the liver via the vagus to regulate glucose production (Wang et al. 2008). NTS neurons also project to higher brain regions such as the visceral sensory thalamus, which in turn projects to the visceral sensory neocortex, thereby forming the conscious feeling of fullness and satiety. NTS projections are also sent to several other brain regions including the hypothalamus, parabrachial nucleus, amygdala, and insular cortex.

The regulation of feeding behavior through vagal afferents from the gut has been well studied. Satiety can be induced by direct vagal stimulation, mechanical stimulation by balloon distension, and chemical stimulation via infusion of solutions rich in fat, carbohydrates, and proteins (Schwartz 2000, 2006). These effects are inhibited by blocking the vagal afferent signal, either by vagotomy or by peripheral application of capsaicin, a sensory neurotoxin (Smith et al. 1985; South and Ritter 1988). These peripheral manipulations of vagal signaling also increase meal size and duration. Centrally, blocking *N*-methyl-d-aspartate receptor glutamatergic transmission in the brainstem also increases meal size, probably by inhibiting the neurons which integrate vagal afferent signals (Treece et al. 1998). These findings demonstrate a potent negative-feedback mechanism whereby signals of food intake generated in the gut are transmitted via the vagus nerve to the brain, thereby inducing satiety and inhibiting food intake.

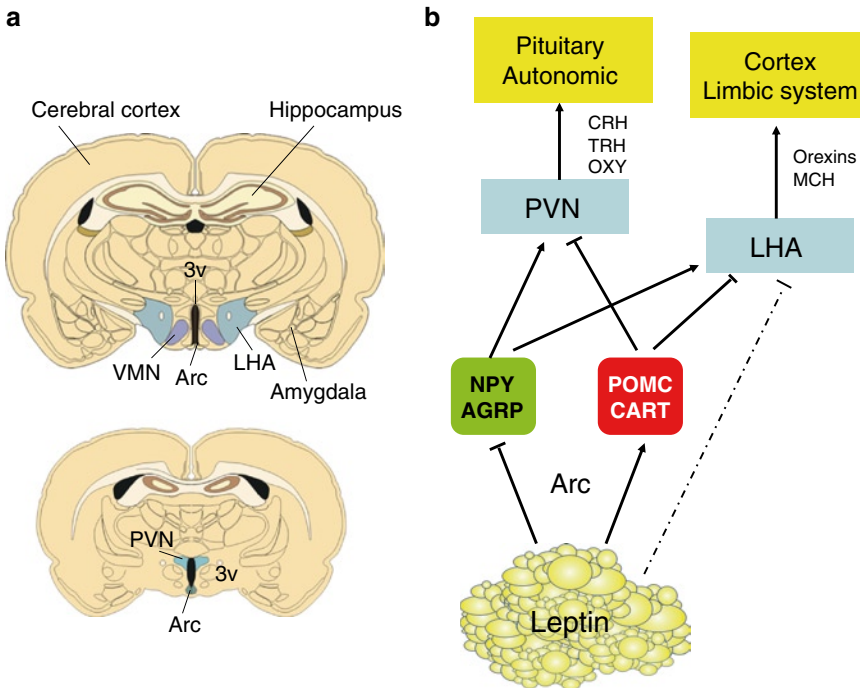
The hormonal signals which affect the gut–brain axis can also be mediated by autonomic signals via the vagus nerve. In response to food intake, the gut responds to nutrient intake by secreting hormones such as cholechystokinin (CCK), some of which act on the nervous system to regulate appetite and satiety (Liebling et al. 1975). CCK is secreted by the duodenum and ileum in response to luminal lipid or protein, resulting in the release of digestive enzymes and bile. CCK also has effects on satiety, inhibiting eating behavior and meal size (Gibbs et al. 1973; Kraly et al. 1978). This is


Fig. 67.3 Hypothalamic circuits involved in feeding behavior. (**a**) Coronal sections of mouse brain showing the locations of key nuclei involved in regulation of feeding behavior and energy homeostasis. (**b**) The arcuate nucleus is an important integrator of peripheral metabolic signals such as leptin and insulin. Neurons coexpressing NPY and AGRP are directly inhibited by leptin, whereas neurons expressing POMC (precursor of α-MSH) and CART are stimulated by leptin. Arcuate neurons project to the hypothalamus including the lateral hypothalamic area (*LHA*) and the paraventricular nucleus (*PVN*). Rising leptin levels in the fed state inhibit feeding by suppressing NPY/AGRP and stimulating POMC/CART. Recent evidence suggests that leptin is able to directly inhibit LHA neurons. Conversely, the fall in leptin levels during fasting potently stimulates feeding. Arcuate projections indirectly regulate the neuroendocrine axis, as well as limbic and higher cortical functions, thereby enabling feeding to be integrated with metabolism, sleep–wake cycles, and complex behaviors

consistent with the finding that CCK receptor antagonists increase feeding behavior and postpone satiety (Dourish et al. 1989). CCK exerts its satiety-inducing effects by modulating afferent autonomic signals to the CNS. CCK binds to CCK-1 receptors (CCK-1R) on vagal sensory afferent terminals, thereby transmitting a satiety signal via the vagus nerve to the NTS (Schwartz 2000, 2006). Thus, blocking the vagal afferent signal either chemically or by vagotomy abolishes the effect of CCK on satiety (Smith et al. 1985; South and Ritter 1988). Furthermore, rats lacking functional CCK-1R are hyperphagic and obese when exposed to a high fat diet (Bi et al. 2007). However, in mice, absence of CCK signaling has no effect on long-term body weight maintenance (Kopin et al. 1999), indicating that CCK signaling is likely a short-term satiety signal that does not play a major role in long-term energy homeostasis. Additional gut hormones with satiety-inducing effects have been identified, including glucagon-like peptide 1, oxyntomodulin, peptide YY, and amylin.

In contrast with the satiety-inducing effects of CCK, ghrelin is an appetite-inducing factor synthesized predominantly by fundic cells in the stomach with a relatively small amount generated by the pancreas (Tschop et al. 2000; Wiedmer et al. 2007). Ghrelin levels rise prior to meals and in periods of fasting, and exogenous administration of ghrelin results in increased feeding behavior (Tschop et al. 2000). Ghrelin signals through the growth hormone secretagogue receptor, a G protein-coupled receptor

expressed in several neuronal populations including the arcuate and ventromedial nuclei in the hypothalamus (Guan et al. 1997; Bailey et al. 2000). Neurons expressing the ghrelin receptor also express both neuropeptide Y (NPY) and agouti-related protein (AGRP). By activating these hypothalamic neurons, an orexigenic signal is generated which leads to increased appetite and feeding behavior (see Fig. 67.2 and the section below on the adipose-brain axis for a more detailed description of the arcuate-hypothalamic circuit). Extra-hypothalamic ghrelin signaling may also affect appetite. Ghrelin activates the mesolimbic reward system, and thereby may stimulate appetite behaviors by enhancing the hedonic response to food intake (see Fig. 67.3; Naleid et al. 2005; Abizaid et al. 2006). Effects on learning, memory, anxiety, and depression have also been identified, although the connection between these effects and the induction of appetite are yet poorly understood (Diano et al. 2006; Lutter et al. 2008).

67.3 Adipose–Brain Axis

The major energy store in mammals is in the form of adipose tissue. The regulation of adiposity, therefore, is critical to maintenance of energy homeostasis. It is not surprising, therefore, that there are signals related to adiposity which are integrated by the CNS which affect appetite and satiety. Adipose tissue generates several secreted factors called adipokines which regulate appetite and satiety in part by signaling to the brain. The best understood adipokine is leptin. Leptin is secreted primarily by adipose tissue and is transported into the brain to effect neuronal signaling (Ahima and Flier 2000; Ahima et al. 2000). Of the five leptin receptor splice variants, only the longest isoform, OB-Rb, results in downstream intracellular signaling via a Jak (janus kinase)-STAT (signal transducers and activators of transcription) signal transduction pathway. This signaling cascade is critical to the central effects of leptin on eating behavior and energy homeostasis.

Leptin concentrations correlate with adiposity, and the absence of leptin or OB-Rb results in a constellation of phenotypes which include hyperphagia and severe obesity (Zhang et al. 1994; Chua et al. 1996). Although originally thought to be an antiobesity hormone, high endogenous levels of leptin in obese individuals does not inhibit overeating and obesity. Therefore the concept of leptin-resistance has emerged in which leptin-responsive circuits do not respond adequately to prolonged hyperleptinemia (Myers et al. 2008). Conversely, low concentrations of leptin are a signal of fasting, which triggers a compensatory response, including stimulation of appetite, activation of the hypothalamic–pituitary–adrenal axis, and suppression of thyroid and reproductive function (Ahima et al. 1996).

There are numerous central targets of leptin including OB-Rb-expressing neurons within the arcuate nucleus, ventromedial hypothalamus, dorsomedial hypothalamus, ventral premammilary nucleus, preoptic area, periaqueductal grey, dorsal raphe, parabrachial nucleus, and NTS (Myers et al. 2008). Although these diverse neuronal groups are thought to respond to leptin due to their expression of OB-Rb, the effect of leptin signaling in most of these neurons is largely unknown, and the projections from these leptin-responsive neurons is obscure. Of these diverse neuronal groups, the effects of leptin signaling on hypothalamic arcuate neurons are best understood (Fig. 67.3, Elias et al. 1999; Ahima et al. 2000). Low leptin levels due to fasting results in activation of neurons which express the orexigenic neuropeptides NPY and AGRP, with a concomitant inhibition of neurons expressing anorexic neuropeptides proopiomelanocortin (POMC, precursor to α melanocyte-stimulating hormone α-MSH) and cocaine and amephetamine-regulated transcript (CART). As is the general rule in CNS circuits, arcuate neurons likely project to multiple second-order neurons. However, there is a strong projection to several hypothalamic nuclei including the paraventricular nucleus (PVN) and the lateral hypothalamic area (LHA). PVN neurons synthesize neuropeptides with anorexic effects when administered centrally including corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone

(TRH), and oxytocin. LHA neurons express the orexigenic neuropeptides, melanin concentrating hormone (MCH), and orexins. Again, the arcuate-hypothalamus circuit projects to many regions including the NTS (Myers et al. 2008, 2009). As already mentioned, NTS neurons also express OB-Rb and thus may respond directly to leptin signals. In doing so, the nutrient intake signals associated with vagal signaling from the gastrointestinal system (described above) and the energy storage signals from leptin secretion by adipose tissue converge, and activate or deactivate higher order circuits which produce the subjective feelings of appetite and satiety. Perhaps it is this convergence of signals which underlies the experimental finding that leptin and CCK can act in concert to decrease meal size (Emond et al. 1999).

Although the arcuate-hypothalamus circuit is a critical regulator of leptin-dependent appetite and satiety behavior, leptin signaling in extrahypothalamic regions may also influence feeding behavior. The mesolimbic reward system is a dopaminergic circuit in which ventral tegmental area (VTA) neurons project to the nucleus accumbens (ventral striatum), amygdala, hippocampus, and medial prefrontal cortex (Fig. 67.4). This circuit is involved in feelings of reward and is thought to be important in processing the hedonic aspects of appetite, particularly in terms of more palatable foods. Leptin can act on OB-Rb expressing neurons in the VTA and thus may modulate the mesolimbic reward circuit (Fulton et al. 2006; Hommel et al. 2006). Direct administration of leptin to the VTA decreased food intake, while downregulation of the leptin receptor in VTA neurons increased food intake (Fulton et al. 2006; Hommel et al. 2006). In human studies, leptin replacement therapy for individuals with congenital leptin deficiency results in increased activity in satiety centers (prefrontal neocortex) and decreased activity in hunger centers (ventral striatum; insular, parietal, and temporal neocortex, Baicy et al. 2007; Farooqi et al. 2007). Similarly, serial functional magnetic resonance imaging (fMRI) measurements in obese individuals at baseline and after weight loss reveals altered neuronal activation in numerous brain regions (Rosenbaum et al. 2008). These changes in neuronal activation are reversible after exogenous leptin treatment. It is unknown whether these changes in neuronal activation in humans are due to the direct action of leptin on these neuronal groups.
Fig. 67.4 Neuronal circuits mediating reward. The regulation of appetite and satiety by higher order brain regions is in part due to the activation of the mesolimbic reward system in response to palatable foods. The mesolimbic reward system comprises a dopaminergic pathway which activates feelings of reward or motivation. The circuit involves the ventral tegmental area of the midbrain, the nucleus accumbens (ventral striatum), and other limbic and cortical regions (amygdala, hippocampus, and medial prefrontal/orbitofrontal cortex)

Adiponectin is an adipokine which, in contrast to leptin, is inversely correlated with adiposity (Ahima and Lazar 2008). Thus, obesity results in low circulating adiponectin levels and fasting results in high adiponectin levels. Adiponectin is found in the periphery as a homotrimer, low-molecular weight hexamer, and higher molecular weight complexes, and the absence of adiponectin results in insulin resistance and hyperlipidemia (Ahima and Lazar 2008). Although high molecular weight species are unlikely to cross the blood–brain barrier, cerebrospinal fluid contains trimeric and low molecular weight adiponectin species (Spranger et al. 2006; Kusminski et al. 2007). Evidence of central effects of adiponectin stems from the inhibition of food intake and the potentiation of energy expenditure, secondary to intracerebroventricular administration of adiponectin (Qi et al. 2004). Adiponectin signals through one of two seven-transmembrane domain containing receptors, AdipoR1 and AdipoR2, which are widely expressed in the CNS and induce an AMP kinase phosphorylation signal transduction cascade (Kubota et al. 2007). The anorexic effects of central adiponectin are dependent on the presence of AdipoR1 (Coope et al. 2008). Although the site of central adiponectin signaling is not clear, intracerebroventricular adiponectin activates hypothalamic intraneuronal signal transduction cascade which overlaps with those of leptin and insulin (Coope et al. 2008). Adiponectin is also known to activate neurons in area postrema (a circumventricular organ which is exposed to the peripheral circulation) and inhibit oxytocin-expressing neurons in the PVN (Fry et al. 2006; Hoyda et al. 2007). Although adiponectin has effects on these neuron groups, it is not clear which neurons are responsible for adiponectin-dependent anorexia.

Insulin is another peripheral factor which increases in proportion to body fat. Insulin is secreted by the pancreas and regulates blood glucose concentration via pleotrophic effects in the periphery. However, insulin also has central effects on food intake behavior. Insulin crosses the blood–brain barrier via a receptor-mediated process, and direct infusion of insulin into the brain reduces both food intake and body weight (Woods and Porte 1983). Inhibition of insulin signaling has an opposite effect, increasing food intake and decreasing body weight (Niswender et al. 2003). Insulin receptors are widely expressed in the brain including the NPY/AGRP and POMC-expressing neurons in the arcuate nucleus. Consistent with its anorexic activity, insulin activates POMC neurons, and insulin deficiency results in decreased NPY expression (Niswender et al. 2003; Xu et al. 2005). Thus, insulin and leptin both act on the arcuate nucleus, consistent with the finding that insulin and leptin have additive effects on feeding behavior (Air et al. 2002). Insulin and leptin signaling pathways converge at the level of PI3 kinase, and pharmacologic inhibition of PI3 kinase inhibits the anorexic effects of insulin (Niswender et al. 2003; Xu et al. 2005). However, there are key differences between the effect of insulin and leptin on arcuate neurons. Although deletion of neuronal insulin receptors results in very mild obesity in female mice (Bruning et al. 2000), downregulation of insulin receptors or PI3 kinase in POMC and AGRP neurons does not affect feeding behavior or weight (Konner et al. 2007; Hill et al. 2008). Therefore, while the acute effects of insulin on feeding behavior are well documented, insulin signaling in the arcuate nucleus does not seem to play a major role in the long-term regulation of energy homeostasis.

67.4 Additional Peripheral Signals

Endocannabinoids also have effects on appetite and metabolism. Endocannabinoids signal through G-protein coupled cannabinoid receptors which are widely expressed in the brain and periphery (Kunos 2007). Endocannabinoids induce food intake while cannabinoid antagonists reduce food intake and increase energy expenditure. Furthermore, deletion of the cannaboid receptor 1 reduced caloric intake and decreased body fat through both peripheral and central mechanisms. Finally, overnutrition results

in activation of the endocannabinoid system, in concert with increased feeding, decreased energy expenditure, and obesity. Centrally, endocannabinoids may act through the arcuate–hypothalamic circuit, or via projections from the lateral hypothalamus to the mesolimbic reward system.

Excess glucocorticoids increase feeding behavior, total body weight and central adiposity. Administration of glucocorticoids in the brain increases NPY expression in the hypothalamus, and affects the mesolimbic reward system resulting in increased intake of palatable foods (Dallman et al. 2007). On the other hand, glucocorticoid deficiency secondary to adrenalectomy results in decreased food intake and weight, even in the markedly obese leptin or leptin receptor-deficient mice (Shimomura et al. 1987). Estrogen may also modulate feeding behavior, as peripheral and central estrogen administration enhances the anorexic effects of leptin and insulin (Clegg et al. 2006).

Proinflammatory cytokines such as tumor necrosis factor-α and interleukin-6 inhibit feeding and induce thermogenesis, and are largely responsible for the wasting and cachexia associated with infection and cancer. Although many of the effects of proinflammatory cytokines are certainly due to their many peripheral activities, their effect may be in part due to effects on the hypothalamus (Buchanan and Johnson 2007). For example, ciliary neutrotrophic factor (CNTF) inhibits food intake, increases energy expenditure, and reduces body weight (Buchanan and Johnson 2007). Although CNTF treatment can suppress NPY expression and therefore inhibit food intake, the anorexic effects of CNTF persist after cessation of treatment. This long-lasting effect may be due to enhanced hypothalamic neurogenesis in which newly generated neurons are responsive to leptin (Kokoeva et al. 2005). Integration of these neurons in the arcuate-hypothalamic circuit may therefore lead to the long-lasting effects of CNTF on feeding and metabolism.

67.5 Application to Other Areas of Health and Disease: The Hedonic Response to Food

Classic examples of brain diseases affecting feeding behavior include individuals with large pituitary tumors which encroached on the ventral forebrain, leading to voracious feeding, morbid obesity, and hypogonadism. Relatively crude rodent experiments involving lesions to the ventromedial hypothalamus (the so-called "satiety center") recapitulated these findings, whereas lesions to the lateral hypothalamus (the so-called "feeding center") resulted in anorexia and starvation (Hervey 1959). These findings led to the "dual center model." While we now know that these lesions resulted in more extensive damage to adjacent areas and axonal projections passing through the lesion, and that the "dual center model" is likely too simplistic, these experiments formed the basis of the central regulation of satiety and feeding behavior. However, while the hypothalamus and hindbrain is critical to the detection and integration of peripheral signals, it is unlikely to be the brain region ultimately responsible for hedonic responses to food and subjective feelings of satiety. Earlier, the impact of leptin on the mesolimbic reward system was outlined. There are brain disorders in which this circuit is dysfunctional and hedonic responses to food are dysregulated. One such example is frontotemporal dementia, the second most common dementia after Alzheimer's disease. Many individuals with frontotemporal dementia exhibit hyperphagia with episodes of binge eating and weight gain. Neuroanatomic analysis in affected individuals indicates that abnormalities of a right orbito-frontal–insular–striatal circuit are closely correlated with abnormal feeding behavior (Woolley et al. 2007). A lesion in this circuit can also lead to Gourmand's syndrome in which an individual becomes preoccupied by food, especially fine dining (Regard and Landis 1997). This circuit is also implicated in other disorders which feature feeding abnormalities including obsessive-compulsive disorder and bulimia. Interestingly, individuals with frontotemporal dementia may continue eating

despite feeling full, suggesting that dysfunctional reward circuits may induce appetite despite feelings of satiety (Woolley et al. 2007). In this regard, satiety is often described in terms of satisfaction and the physical sensation of fullness, whereas appetite is often described in terms of a hedonic drive for food.

These diseases highlight that feeding behavior is strongly influenced by pleasure and reward circuits. The peripheral signals discussed thus far are largely homeostatic signals related either to short-term factors (such as ingestion of food) or long-term factors (such as adiposity and energy stores). In contrast, hedonic responses to food are largely nonhomeostatic and can lead to imbalances in energy homeostasis, as evidenced by increasing obesity rates secondary to the overabundance of high calorie, palatable food. Aside from the mesolimbic reward system already discussed, the sensations of vision, taste, and smell are powerful signals which may induce appetite despite other signals of satiety. Taste information is carried via cranial nerves VII, IX, and X to the gustatory part of the NTS. These neurons then project to the medial parabrachial nucleus (in the pons), followed by projections to the ventral posteromedial nucleus of the thalamus, and then to the postcentral gyrus and insular cortex. Projections to the central nucleus of the amygdala and the LHA are also present, which may be responsible for the effects of taste sensation on appetite. There is cross-talk between peripheral metabolic signals and central pathways as leptin-deficient mice have a preference for sweet substances and leptin administration inhibits sweet taste sensation (Morley 1987; Kawai et al. 2000). CCK also reduces sucrose intake in fasted rats (Gibbs 1973).

Olfactory cues are first detected in the olfactory epithelium on the roof of the sinonasal passages. These primary sensory neurons project to the olfactory bulb, where second order neurons pass centrally via the olfactory tract. Axons in the olfactory tract terminate in numerous brain regions including the prepiriform area (primary olfactory cortex), amygdala, semilunar gyrus, ambient gyrus, septal (subcallosal) area, olfactory tubercle, and anterior olfactory nucleus. The olfactory system is the only sensory system which bypasses the thalamus en route to the CNS. Furthermore, the close association between the olfactory system and limbic regions (amygdala, septal area) provides a possible structural basis for the strong emotional responses invoked by olfactory cues. Olfactory information can also project to the hypothalamus, reticular formation, salivatory nuclei, and dorsal vagal nucleus via the medial forebrain bundle and the medullary striae of the thalamus. Again, it is clear that the gustatory and olfactory senses are strong modulators of appetite. However, the mechanisms and pathways whereby this modulation occurs are obscure.

67.6   Conclusions

Multiple steps are required in the central regulation of appetite and satiety behavior (Table 67.1). First, signals generated in the periphery are relayed to the brain. These signals are generated in response to short-term signals such as food intake into the gastrointestinal system. Long-term signals reflect the levels of energy storage in adipose tissue. Other signals are not homeostatic, but instead reflect non-homeostatic factors such as palatability and the hedonic response to food. These signals act on brain circuits including the NTS, arcuate hypothalamus, and mesolimbic reward system. The relative activation or inhibition of neuronal circuits results in appetite and satiety. The central control of appetite and satiety behavior is remarkably robust in most situations and for most organisms. Not until recent times of food abundance and relatively sedentary lifestyles are the mechanisms controlling appetite and satiety behavior becoming perturbed. Thus the basic understanding of the central regulation of feeding behavior under normal physiologic perturbation conditions provides a framework for elucidating the mechanisms underlying obesity and various disorders of energy homeostasis.

Table 67.1 Key central brain circuits in the regulation of appetite and satiety behavior

- Nucleus of the solitary tract (NTS)
  - Receives vagal afferents
  - Gut–brain axis (mechanical, cholecystokinin)
- Arcuate nucleus
  - Leptin signaling
  - Insulin signaling
  - Orexigenic peptides (NPY and AGRP)
  - Anorexic peptides (α-MSH and CART)
- Lateral hypothalamic area (LHA)
  - Catabolic pathway
  - Orexigenic peptides (MCH and orexins)
- Paraventricular nucleus (PVN)
  - Anabolic pathway
  - Anorexic peptides (CRH, TRH, OXY)
- Mesolimbic reward system, frontal neocortex, insular neocortex, ventral striatum
  - Ventral tegmental area, ventral striatum (nucleus accumbens), frontal neocortex, insular cortex, amygdala, hippocampus
  - Higher order processing such as hedonic response to food

Summary Points

- The central regulation of appetite and satiety behavior is one mechanism whereby an organism regulates its energy balance.
- The gastrointestinal tract sends short-term nutrient and humoral signals through the vagus nerve to the brainstem.
- Adipose tissue secretes leptin and other adipokines which serve as long-term hormonal signals of energy storage levels to the brain.
- Complex brain circuits such as the mesolimbic reward system integrate metabolic and nonhomeostatic signals to generate hedonic responses to food.
- Multiple brain circuits in the hypothalamus, other forebrain regions, and the brainstem integrate a variety of peripheral signals.
- In concert, numerous brain circuits are responsible for generating the feelings of appetite or satiety, which ultimately serve to regulate food intake.

Definitions and Explanations of Key Terms

Adipokine: Adipose-secreted hormones, many of which may regulate energy homeostasis. Although derived from the words adipose and cytokine, the term adipokine is generally used for any adipose-derived hormone, and not only adipose-derived cytokines (the latter specifically acting on the immune system).

Anorexigenic: Causing decreased feeding.

Appetite: Subjective desire to eat food.

Energy homeostasis: The processes whereby an organism regulates feeding behavior, energy storage, and energy expenditure to maintain a relatively constant metabolic profile. In environments in which food is in abundance, nonhomeostatic factors may overcome homeostatic factors, leading to obesity and other metabolic derangements.

> **Gut–brain axis:** Signals from the gastrointestinal system in response to food intake, transmitted to the brain via the autonomic nervous system or hormones.
> **Orexigenic:** Causing increased feeding.
> **Satiety:** Subjective feeling of adequate food intake.

Chapter 68
Role of the Gastrointestinal Tract in Peptide Hormone Release and Appetite

Joan Khoo, Christopher K. Rayner, Christine Feinle-Bisset, and Gary Wittert

Abbreviations

BBB	Blood–brain barrier
CB1	Cannabinoid-1
CCK	Cholecystokinin
CCK1R	Cholecystokin-1 receptor
CNS	Central nervous system
DPP-4	Dipeptidyl peptidase-4
GLP-1	Glucagon-like peptide-1
LCFA	Long-chain fatty acid
MCH-1	Melanin-concentrating hormone-1
OXM	Oxyntomodulin
PP	Pancreatic polypeptide
PYY	Peptide YY

68.1 Introduction

The gastrointestinal tract, in addition to its primary functions of digestion and absorption, plays an important part in the regulation of appetite, triggering processes that initiate food intake, and leading to satiation and satiety after meals. "Satiation" refers to the processes that terminate food intake (feeling of "fullness") and limit meal size, while "satiety" refers to the suppression of hunger in between meals that reduces the frequency of eating. The role of the vagus nerve in conveying signals that induce satiation has been known for decades, but there is increasing recognition of the importance of gut hormones in the regulation of food intake. Ingested food causes satiation by gastric distension and secretion of peptide hormones from the stomach and small intestine, which act locally on vagal nerve endings and in the brain to prevent the overconsumption of nutrients and maintain energy homeostasis. Vagal and hormonal signals also influence appetite regulation centers in the hindbrain and hypothalamus to control feeding behavior in a complex network of gut–brain interactions.

68.2 Responses of the Gastrointestinal Tract to Ingested Food

The gastrointestinal tract responds to a meal in three integrated and overlapping phases: cephalic, gastric, and intestinal, which are dependent on parasympathetic vagal nerve transmission (Camilleri 2006) (Fig. 68.1). In the cephalic phase, meal-induced stimuli and anticipation trigger gastrointestinal secretory and motor processes that aid digestion by gastric acid, pancreatic enzymes, and bile. Vagal signaling is integral to the cephalic phase: gustatory and other visceral afferents project to the nucleus tractus solitarius in the brainstem to activate these digestive processes via vagal efferents from motor nuclei in the brainstem, with acetylcholine, cholecystokinin, and gastrin being the main neurotransmitters. The cephalic phase constitutes approximately 50% of the prandial motor and secretory responses (Camilleri 2006). Subsequently, the gastric and intestinal phases are activated by transit of nutrients through the stomach and small intestine. The gastric phase involves relaxation of the proximal stomach, and load-dependent regulation of gastric emptying. During this process, solids empty in an overall linear pattern after an initial lag phase, while the emptying of liquids is dependent on caloric content and varies from an exponential to a linear pattern as the caloric content increases, with lipids having the greatest inhibitory effect (Ritter 2004). In response to meal ingestion, there is a switch from the cyclical migrating motor complex of the fasting state to intermittent irregular phasic contractions that characterize the fed state, which serve to slow transit of nutrients through the small intestine and facilitate mixing and absorption. The duration of this postprandial pattern is prolonged by increased caloric content (Camilleri 2006). Neural and hormonal signals are transmitted in the gastric and intestinal phases to slow transit food through the gastrointestinal tract and induce satiation. Impulses travel through networks of neurons (submucosal and myenteric nerve plexuses) collectively known as the enteric nervous system, which are present throughout the gastrointestinal tract, while gut hormones

Cephalic phase

VAGAL parasympathetic fibres in the brainstem transmit signals to mediate gut motility

Brainstem

Anticipation of meals and sensory stimuli trigger vagal impulses in the brain

FOOD

Gastric phase

VAGAL afferents in the gut convey information about distension and luminal nutrient type and content to the brain

Intestinal phase

➢ Gastric relaxation and accommodation
➢ Slowed gastric emptying
➢ Suppressed ghrelin secretion
➢ Increased leptin secretion

➢ Change to intermittent, irregular phasic contractions
  → slowing of intestinal transit
➢ Secretion of gut peptides (CCK, GLP-1, OXM, PYY)
  → satiation

Fig. 68.1 Responses of the gastrointestinal tract to a meal. This figure illustrates the neural and hormonal responses of the brain and gut to a meal. These responses facilitate digestion and nutrient absorption, and limit food intake (*CCK* cholecystokinin, *GLP-1* glucagon-like peptide-1, *OXM* oxyntomodulin, *PYY* peptide YY)

Table 68.1 Key features of neural and hormonal satiation signaling in the gastrointestinal tract

1. The *enteric nervous system* consists of submucosal and myenteric nerve plexuses in the stomach and intestine, which function as the "brain" of the gut.
2. *Vagal and spinal sensory afferents* in the stomach respond to stretch, volume and tension, and communicate with appetite centers in the brain.
3. *Enteroendocrine cells* (e.g., *I and L cells*) in the small intestine respond to nutrients in the intestinal lumen by secreting gut hormones which induce satiation
4. *Intestinal taste receptors* on apical surface of enterocytes detect chemical properties of "sweet" or "bitter" nutrients.

This table lists the components of neural and hormonal satiation signaling, which connect the gastrointestinal tract to the brain and limit feeding when nutrients are detected in the stomach and small intestine

are secreted from specialized gastric and intestinal mucosal cells in response to nutrients. The various forms of signaling will be discussed in subsequent sections (Table 68.1).

68.3 Satiation Signaling in the Gastrointestinal Tract

68.3.1 Gastric Satiation Signaling

Vagal signaling is central to the mediation of gastric satiation by distension of the stomach. The stomach wall contains receptors for tension, stretch, and volume, which relay signals to the brain through dense networks of vagal and spinal sensory afferents (Ritter 2004). Intramuscular arrays in the circular and longitudinal muscle layers, which serve as stretch and volume receptors for generating negative feedback from gastric distension, are capable of sustained impulse transmission during prolonged stretch in a full stomach during feeding, despite reduced gastric wall tension during accommodation (Berthoud 2008). Distension of the antrum, as compared to the proximal stomach, tends to provoke nausea and bloating (Ladabaum et al. 1998), and may explain the observation that satiation and satiety are directly related to antral width (Sturm et al. 2004), i.e. satiation is induced more readily by the presence of food in the distal stomach than the fundus.

68.3.2 Small Intestinal Satiation Signaling

The perception of gastric distension is greatly increased by concomitant intraduodenal lipid or carbohydrate infusions, inducing a sensation of "meal-like" fullness (Feinle et al. 1997). This highlights the importance of nutrients in the small intestine as a stimulus for terminating food intake. Infusion of nutrients directly into the small intestine rapidly reduces food intake due to satiation signals produced within the gut. Many of these signals, which include gut peptides secreted from enteroendocrine cells in the small intestine, slow nutrient emptying from the stomach and thus prolong gastric distension, but infusions of carbohydrates, amino acids, and fatty acids into the small intestines of rats in sham feeding experiments have shown that slowing of emptying is not necessary for satiation to occur (Fig. 68.2) (Ritter 2004).

There are four criteria that define a satiating factor (Geary 2004): (1) it is released in response to ingested nutrients; (2) infusion of physiological doses produces satiation and limits food intake; (3) cessation of eating occurs soon after secretion, and (4) blockade or absence of its receptor reverses the satiating effects and/or increases meal size. These criteria are satisfied by several gut hormones
Fig. 68.2 Sites of secretion of peptide hormones involved in appetite regulation and food intake in the gastrointestinal tract. This figure is an overview of the sites of release of gut hormones which regulate appetite

including, but not limited to, cholecystokinin, glucagon-like peptide-1, oxyntomodulin, peptide YY, and pancreatic polypeptide.

In response to nutrients, gut peptides are secreted from specialized enteroendocrine cells in the proximal and distal small intestine. These exert local and systemic effects by diffusing through interstitial fluid to stimulate vagal and spinal sensory nerve fibers in their vicinity, and may also circulate in the bloodstream and cross the blood–brain barrier to influence feeding and appetite directly or indirectly (Banks 2008). In the small intestine, gut peptide secretion and satiation is dependent on the caloric load (Pilichiewicz et al. 2007), macronutrient composition (Seimon et al. 2009), and the length of intestine exposed (Meyer et al. 1998). Digestion is required for nutrient–gut interactions, as shown by studies in which inhibition of lipase attenuated the satiating effect of oral fat ingestion in healthy subjects (O'Donovan et al. 2003). Within the small intestine, the site of contact with nutrients also influences peptide hormone secretion: the duodenum and jejunum release cholecystokinin (CCK), while glucagon-like peptide-1 (GLP-1), and peptide YY (PYY) are secreted predominantly in the distal small intestine and colon. These gut peptides are major satiation signals, acting both peripherally within the gastrointestinal tract, and in the appetite centers of the hindbrain and hypothalamus, to reduce food intake.

68.4 Gut Peptides Involved in Satiation Signaling

This section will briefly discuss cholecystokinin, gastric leptin, glucagon-like peptide-1, oxyntomodulin, peptide YY, pancreatic polypeptide, neuropeptide W, the endocannabinoids, and ghrelin (Table 68.2).

68.4.1 Cholecystokinin

Cholecystokinin (CCK), the first satiating gut peptide described, is secreted from I-cells in the duodenum and jejunum, primarily in response to the presence of luminal lipids (especially fatty acids) and proteins, with less stimulation by carbohydrate. CCK also regulates the digestion of fat

Table 68.2 Effects of peptide hormones secreted by the gastrointestinal tract and pancreas

Gut hormone	Site of secretion	Appetite	Other major effects
Cholecystokinin (CCK)	Duodenum, jejunum	↓	Slows gastric emptying
Gastric leptin	Stomach	↓ (↑ CCK secretion)	↑ biliary and pancreatic secretion
Ghrelin	Stomach	↑	↑ protein absorption
Neuropeptide W	Stomach	↓	↓ carbohydrate and fat absorption
Glucagon-like peptide-1 (GLP-1)	Distal small intestine, colon	↓	?appetite suppression, weight loss via effects in the brain
Oxyntomodulin (OXM)	Distal small intestine	↓	Accelerates gastric emptying
Peptide YY (PYY)	Distal ileum	↓	↑ insulin secretion in response to oral glucose load, weight loss
Pancreatic polypeptide	Pancreas	↓*	Weight loss

*Increases appetite when injected into the central nervous system of rodents

This table shows the effects of gut hormones on appetite and on processes in the gastrointestinal tract which aid digestion and absorption of nutrients

and protein in the small intestine by coordinating the delivery of nutrients with the secretion of pancreatic enzymes and bile salts in reflex pathways involving the vagus. The satiating effects of CCK are mediated via CCK1 (previously known as CCK-A) receptors (CCK1R), as evident from the increase in food intake in rats lacking CCK1R, and in humans given CCK1 receptor antagonists (Cummings and Overduin 2007). CCK1R are present in the hindbrain and hypothalamus, and on vagal afferents and efferents in the stomach, intestine, and pancreas. Injection of CCK into hypothalamic nuclei increases satiation in rodents by stimulating CCK1R in the hypothalamus and hindbrain, while administration of physiological doses of CCK in rodents and humans reduces meal size in a dose-dependent fashion (Little et al. 2005).

In humans, gastric distension augments the anorexigenic effects of exogenous CCK, suggesting that slowing of gastric emptying contributes to CCK-induced satiation (Kissileff et al. 2003). The vagus is important for CCK signaling, as vagotomy in rodents has been found to reduce the satiating effects of peripherally administered CCK (Moran et al. 1997). CCK may also influence the ability of vagal afferent neurons to respond to other neurohormonal signals through the expression of G-protein coupled receptors and regulation of the release of peptide neurotransmitters (Dockray 2009). When plasma CCK is low during fasting, expression of cannabinoid-1 (CB1) and melanin-concentrating hormone-1 (MCH-1) receptors, which are associated with stimulation of feeding, is increased. Conversely, postprandial release of CCK downregulates CB1 and MCH-1 receptors, but increases expression of Y2 receptors in gastric afferent neurons, which are stimulated by peptide YY, a satiating gut hormone (Dockray 2009). Although CCK reduces individual meal size, body weight does not change due to increased frequency of eating; furthermore, the anorexigenic effect is of short duration, being undetectable if CCK is injected more than 30 min before meals, and disappearing after 24 h of continuous infusion (Little et al. 2005). Hence, the importance of CCK in long-term body weight regulation appears modest.

68.4.2 Gastric Leptin

Although adipose tissue is known to be the primary source of the peptide hormone leptin, which reduces appetite and increases energy expenditure, chief cells in the gastric fundic mucosa of humans and rodents secrete leptin postprandially in response to vagal stimulation or hormonal factors (primarily CCK) (Guilmeau et al. 2004). In rats, gastric leptin binds to soluble leptin receptors in gastric juice to form high molecular weight complexes that are resistant to digestion by gastric acid and bind

to basolateral receptors in the small intestinal mucosa to exert paracrine effects in the gastrointestinal tract (Cammisotto and Bendayan 2007). Leptin stimulates intestinal secretion of CCK to form a positive feedback loop which slows gastric emptying, increases biliary and pancreatic secretion, and induces satiation (Guilmeau et al. 2004). Leptin also reduces the absorption of fat and carbohydrate in the jejunum (Cammissotto and Bendayan 2007), which, in addition to its central effects to suppress appetite by activation of satiety centers in the hypothalamus and hindbrain, serves to reduce caloric intake.

68.4.3 Glucagon-like Peptide-1

Glucagon-like peptide-1 (GLP-1) is derived from proglucagon, synthesized in L-cells predominantly located in the distal small intestine and colon, and is cosecreted with oxyntomodulin and peptide YY. The concentration of GLP-1 rises in response to the presence of lipids and carbohydrates in the small intestine, but its active metabolites GLP-1 (7–36) and GLP-1 (7–37) are rapidly inactivated by the enzyme dipeptidyl peptide 4 (DPP-4). Fat is the most potent secretagogue for GLP-1 (Feinle et al. 2003), followed by carbohydrate and protein hydrolysates (but not intact proteins). The mechanisms by which ingested nutrients stimulate GLP-1 secretion are not completely understood. In humans, direct infusion of glucose into the small intestine only results in GLP-1 release if glucose is allowed access beyond the proximal 60 cm (Little et al. 2006). Although a threshold load of glucose delivery of ~1.4 kcal/min to the small intestine has been suggested to be necessary to induce GLP 1 release, intraduodenal glucose infusions of 1.0 kcal/min have been shown to produce an early but transient rise in GLP-1 levels (Kuo et al. 2008), which is not seen with lipids, suggesting that lipids and glucose stimulate GLP-1 secretion by different mechanisms, or that GLP-1 release is delayed by the time required for intraluminal digestion of lipids. Possibly, the intestinal L-cell exposure to glucose stimulates the initial rise in GLP-1 secretion, and GLP-1 then slows further delivery of glucose downstream. Alternatively, this early transient release of GLP-1 could be due to a duodeno–jejunoileal "loop", in which glucose in the duodenum indirectly triggers distal GLP-1 release by neural or hormonal means, though the mediator of such a loop in humans is unclear at present.

The satiating effects of GLP-1 are mediated by receptors (GLP1R) which are present in the stomach, small intestine, colon, pancreatic islet cells, and brain (especially neurons in the hypothalamus around the satiety centers), as shown by the absence of the satiating effect of exogenous GLP-1 in GLP1R-knockout mice, and in rats and humans given the GLP1R antagonist, exendin 9–39 (Williams et al. 2009). GLP-1-induced satiation is also abolished by vagal transection or deafferentiation in rats (Abbott et al. 2005), underscoring the importance of the vagus in brain–gut communication for appetite suppression during feeding. Although intravenous infusions of physiological doses of GLP-1 (7–36) reduce food intake, its short half-life (1–2 min due to inactivation by DPP-4) necessitates continuous subcutaneous or intravenous administration for anorexigenic effects (Cummings and Overduin 2007) and renders native GLP-1 impractical for clinical use. GLP-1 also has an insulinotropic effect, and as one of the two known "incretin" hormones, plays an important role in many aspects of glucose metabolism. Long-acting GLP-1 analogs that are resistant to inactivation by DPP-4 (such as exenatide and liraglutide) were developed for the treatment of type 2 diabetes, but have also been shown to reduce appetite and weight (Drucker and Nauck 2006). Exogenous administration of GLP-1 also reduces gastroduodenal motility, increases gastric accommodation, and inhibits gastric and pancreatic secretion in a dose-dependent fashion (Drucker and Nauck 2006), which is likely to contribute to the satiating properties of GLP-1 by prolonging the duration of exposure of the small intestine to luminal nutrients.

68.4.4 Oxyntomodulin

Oxyntomodulin (OXM) is derived from proglucagon in L cells of the distal small intestine, and is cosecreted with GLP-1 and peptide YY, in proportion to the calorie content of ingested carbohydrates and fats (Cummings and Overduin 2007). Administration of OXM induces satiation in rodents (Dakin et al. 2004). Animal studies suggest that the satiating effects of OXM are likely to be exerted via GLP1R, since injection of the GLP1R antagonist, exendin 9–39, into the hypothalamus prevents intestinal OXM-induced satiation in rats (Dakin et al. 2004), and OXM does not affect feeding in GLP1R-knockout mice (Maida et al. 2008). The appetite-suppressing effects of OXM may be caused by reduction in secretion of ghrelin, an orexigenic hormone (Dakin et al. 2004; Cohen et al. 2003). Like GLP-1, OXM is inactivated by DPP-4 and has the capacity to stimulate insulin secretion (Maida et al. 2008).

68.4.5 Peptide YY and Pancreatic Polypeptide

Peptide YY (PYY) is a 36-amino acid peptide, which is co-secreted with GLP-1 by L-cells in the distal ileum in response to a nutrient load. Lipids are the most potent stimulus for PYY release, followed by carbohydrates and proteins (Pilichiewicz et al. 2007). Concentrations of PYY are low in the fasting state, but rise rapidly and in a biphasic pattern during feeding, with initial neural stimulation via cholinergic vagal afferents, followed by release in proportion to the caloric load, composition, and consistency of the food (Karra et al. 2009). In humans, postprandial PYY levels are positively correlated with satiety scores (Guo et al. 2006), suggesting a physiological role for PYY in appetite regulation. PYY is metabolized to the active form PYY (3–36) by the enzyme DPP-4, and binds to Y receptors in the G-protein coupled receptor superfamily in a variety of sites in the central nervous system (CNS), including the hindbrain, hypothalamus, and amygdala, which regulate satiation and energy balance, and to peripheral gastrointestinal vagal afferents. The satiating effect of intraperitoneal PYY injection is blocked by pharmacological Y2 receptor (Y2R) blockade and abolished in Y2R-knockout mice (Batterham et al. 2002), demonstrating the importance of Y2R activation for inhibiting feeding. There has been some inconsistency in data from different researchers as to the effects of intravenous administration of PYY (3–36) on appetite, and although plasma PYY concentrations in humans increase in proportion to the ingested calorie load, inhibition of food intake by exogenous PYY infusion is significant only at pharmacologic plasma concentrations of PYY (3–36), at which there is a tendency for nausea to occur (Degen et al. 2005).

Pancreatic polypeptide (PP), which shares structural features with PYY (3–36), is secreted from cells in the periphery of pancreatic islets in a biphasic manner (similar to PYY) in proportion to caloric load, under vagal nerve regulation. The effects of PP on appetite regulation are predominantly mediated by Y4, and, to a lesser extent, Y1 receptors (Cummings and Overduin 2007). In humans, peripheral PP administration results in acute and sustained (>24 h) reductions in appetite and food intake (Batterham et al. 2003). Previous reports that the anorexigenic effect of PP might be mediated by slowed gastric emptying were not reproduced in later studies which used human rather than bovine PP (Batterham et al. 2003).

68.4.6 Neuropeptide W

Neuropeptide W (NPW), a peptide hormone involved in the regulation of energy, thyroid, and adrenal homeostasis, was first discovered in the hypothalamus and brainstem of rodents, but has since

been demonstrated in rat, mouse, and human gastric antral mucosa (Caminos et al. 2008). NPW binds to the G-protein coupled receptors GPR7 and GPR8, and is thought to have a modulatory role in appetite regulation. Intracerebroventricular administration of NPW reduced food and water intake, reduced weight gain, and increased energy expenditure, suggesting that NPW is a catabolic signal in the brain (Mondal et al. 2003). Gastric NPW gene expression was decreased by fasting and restored with refeeding; moreover, increased feeding in pregnant rats is likely to be due to downregulation of NPW (Caminos et al. 2008). The role of NPW in humans remains to be established.

68.4.7 Ghrelin

Ghrelin, an acylated 28-amino acid peptide secreted by X/A cells in the stomach and duodenum, stimulates appetite and gastrointestinal motility (Cummings 2006). Plasma levels of ghrelin rise markedly just before expected meal times and are associated with an increase in meal frequency but not meal size. This preprandial surge is thought to be stimulated by the sympathetic nervous system as part of the cephalic phase of digestion, and can be entrained to regularly scheduled feeding (Mundinger et al. 2006), thereby suggesting a role in preparing for food intake and digestion. Endogenous ghrelin secretion is suppressed by food, with carbohydrates being more potent than proteins and lipids, but gastric distension or exposure of the stomach to nutrients is not required; rather, this negative feedback process is mediated by intestinal signaling and postabsorptive events such as increased plasma insulin, osmolarity of intestinal luminal contents, and nonvagal enteric neural signaling (Cummings 2006).

68.4.8 Endocannabinoids

The endocannabinoids are endogenous lipid mediators that regulate energy intake, primarily by activating cannabinoid receptors in the limbic system and hypothalamus to stimulate appetite. However, endocannabinoids also act to reduce excitatory transmission in the enteric nervous system, leading to slowing of gastric emptying and small intestinal transit (Izzo and Camilleri 2008). These effects on digestion and gut motility are mediated by CB1 receptors (CB1R) in cholinergic nerves in the myenteric and submucosal plexuses, circular and longitudinal muscle layers, and in crypt epithelial cells. Increased intestinal transit has been observed in rodents that are CB1-deficient or are administered the CB1-antagonist, rimonabant, while administration of CB1-agonists, or inhibitors of endocannabinoid inactivation, delay gastric emptying, slow small intestinal transit, and reduce phasic and tonic colonic motor responses to meal ingestion (Izzo and Camilleri 2008). The role of peripheral CB1R activation in humans remains unclear, though it is possible that endocannabinoid activation functions as an additional physiological "brake", in similar fashion to the slowing of gastrointestinal motility seen with GLP-1 and PYY.

68.5 Mechanisms of Nutrient Detection: Taste Receptors in the Gut

Until recently, the mechanisms of nutrient detection by the small intestine were almost completely unknown. There is now strong evidence that nutrient signaling can occur by stimulation of 'taste'

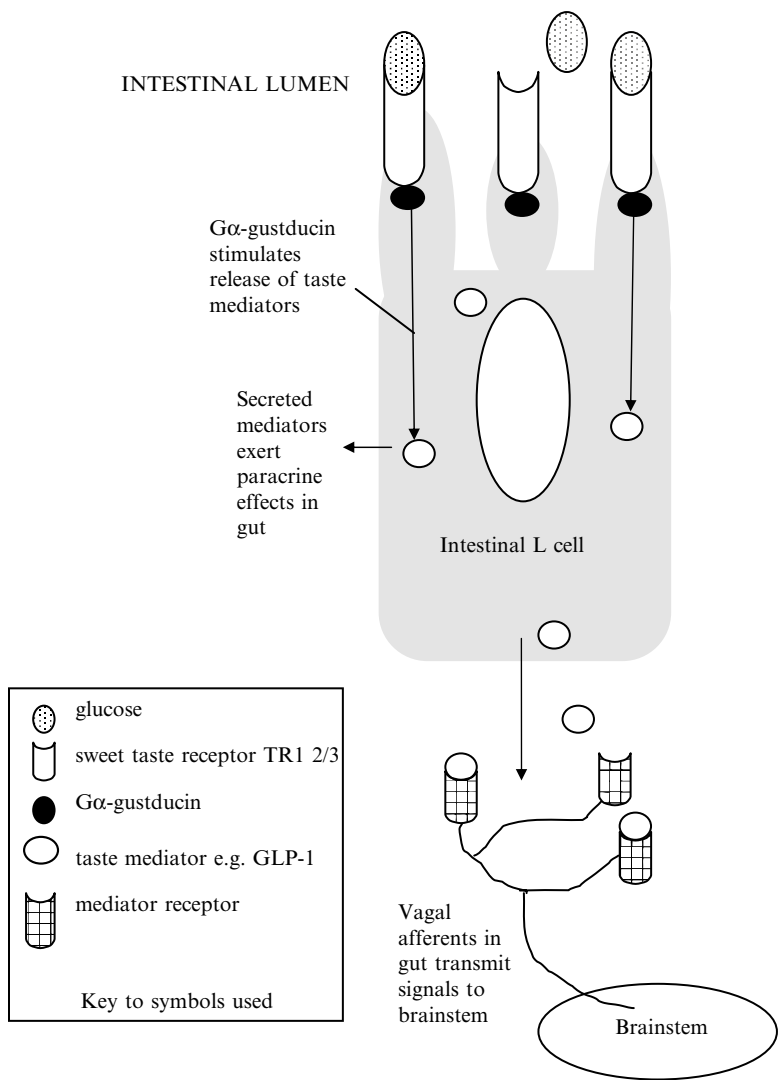
receptors on the apical microvilli of intestinal epithelial cells, which detect the chemical properties of food, analogous to taste-receptors on the tongue (Fig. 68.3). These might then induce the release of gut peptides such as GLP-1, PYY, and CCK, or mediators such as serotonin, from the basolateral surface of the cell to stimulate nearby vagal, enteric, and spinal afferents, or enter the circulation to exert central effects on appetite (Cummings and Overduin 2007). Examples of the small intestinal "taste" apparatus include the T1R2/T1R3 sweet taste receptor (Young et al. 2009), T2-family bitter taste receptors, and the taste-specific G protein, Gα-gustducin (Rozengurt 2006). While carbohydrate and protein could potentially be detected by the sweet and bitter taste receptors respectively, fatty acids can activate the G-protein-coupled receptors GPR120 and GPR119, a process that is linked to GLP-1 secretion in rats (Lauffer et al. 2009).


Fig. 68.3 Sensing of glucose in the small intestine by sweet taste receptors on L cells and mucosal vagal afferents to brainstem and hypothalamus. This figure illustrates the mechanisms by which intestinal sweet taste receptors detect ingested glucose and transmit sensory impulses via the vagus nerve to appetite centers in the brainstem. Diagram is not drawn to scale

68.6 Nonvagal Communication in the Gut–brain Axis

In addition to the importance of the vagus in mediating the effects of gut hormones, nonvagal mechanisms of gut–brain communication have been elucidated for ghrelin, CCK, PYY (3–36) and GLP-1. These include direct transfer of gut peptides across the blood–brain barrier (BBB) and alteration of endothelial cell function in the BBB (Banks 2008). Insulin, GLP-1, ghrelin, and pancreatic polypeptide are known to cross the BBB via specialized transporters and bind to receptors within the CNS. However, the central actions of these hormones may oppose their peripheral effects, such as with pancreatic polypeptide, which increases food intake in rats when injected intraventricularly, and reduces appetite when administered intraperitoneally (Asakawa et al. 2003), suggesting that central and peripheral Y4 receptors are differentially involved in appetite regulation. Insulin is a well-studied example of a hormone that influences appetite by altering endothelial function in the BBB: it increases the transport rate of the amino acid, tryptophan (which is required for the synthesis of serotonin), and thus stimulates feeding (Banks 2008). More studies are required to clarify the processes by which peripheral gut hormones exert their effects on appetite and metabolic regulatory centers in the hindbrain and hypothalamus.

68.7 The Ileal Brake

The negative feedback mechanisms, by which the transit of nutrients to the proximal small intestine stimulates the release of satiating gut peptides and vagal signaling to slow gastric emptying and reduce food intake (as discussed in the preceding sections), have been termed the "duodenal" and "jejunal" brakes; similarly, exposure of the ileum to nutrients inhibits proximal gastrointestinal motility and secretion to optimize nutrient digestion and absorption (Read et al. 1984). In particular, gastric and proximal intestinal motility in rats and dogs is markedly reduced by carbohydrate and fat infusions into isolated loops of ileum, but not duodenum, suggesting that passage of nutrients to the distal small intestine is necessary to generate strong inhibitory feedback (Maljaars et al. 2008), while the length of small intestine exposed to nutrient correlates with the degree of inhibition of motility induced by each class of macronutrient (Fig. 68.4) (Meyer 1998).

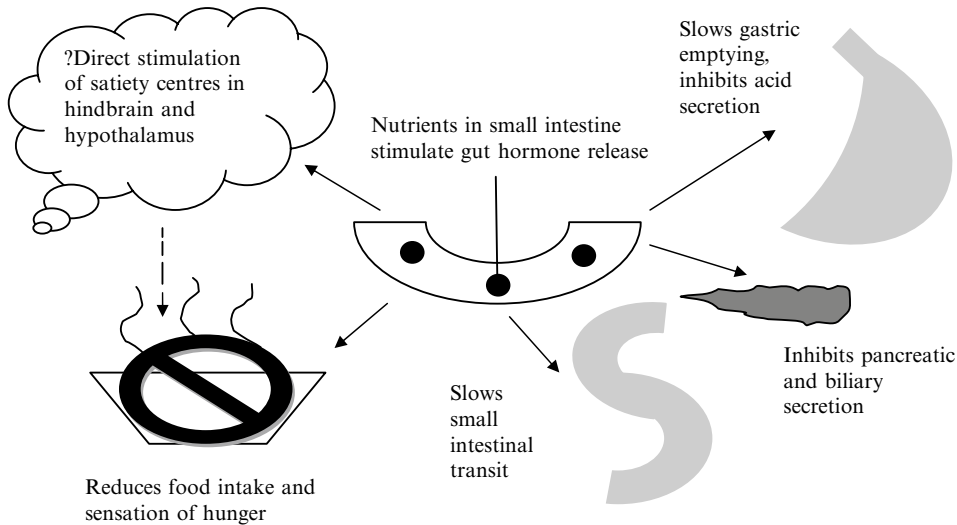
The chief mediators of the ileal brake are thought to be GLP-1 and PYY (Maljaars et al. 2008); as discussed earlier, these are stimulated by the presence of carbohydrates and lipids in the ileum and colon. Rats with a jejuno-ileal bypass, which leads to rapid exposure of the ileum to nutrients, exhibit raised concentrations of these gut hormones, in association with reduced food intake and weight loss, compared with sham-operated controls (le Roux et al. 2006). Transposition of an isolated segment of ileum to the jejunum, resulting in an intestinal tract of normal length but greater proximal density of enteroendocrine L-cells, produces an earlier and greater inhibitory response to feeding in rats, associated with reduced food intake and marked weight loss (Strader et al. 2005). In summary, there is strong evidence that activation of the ileal brake is an important inhibitory mechanism for food intake in animal models. Although there is a paucity of human studies, the ileal brake may be a potential target for appetite regulation and weight management. For example, rapid access of nutrients to the distal small intestine after Roux-en-Y gastric bypass surgery with concomitant release of "distal" gut peptides seems likely to contribute to the greater efficacy of this procedure over gastric banding in terms of weight loss (Morinigo et al. 2006).


Fig. 68.4 Effects of the ileal brake on appetite and gastrointestinal secretory and motor function. This figure is an overview of the processes involved in the ileal brake. The ileal brake is thought to limit nutrient intake by inhibiting gastrointestinal motility and secretion, and stimulating the brain to reduce appetite

68.8 The Gut–Brain–Liver Neural Axis

Neural circuits activated in the intestine in response to ingested nutrients, which connect the gut, brain, and liver, and contribute to the maintenance of glucose homeostasis by regulating insulin sensitivity, have recently been described in rats (Wang et al. 2008). A metabolite of long-chain fatty acids (LCFA), LCFA-CoA, formed from enzymatic cleavage of intraduodenally-infused triglycerides is detected by intestinal sensor cells, and a vagally mediated circuit through the nucleus tractus solitarius in the hindbrain leads to reduced glucose production in the liver. Interruption of this circuit by vagotomy or gut vagal deafferentiation abolishes the insulin-sensitizing effects of intestinal lipid infusion, but does not affect peripheral glucose metabolism. LCFA-CoA also activates satiety centers in the hypothalamus to reduce appetite, and CNS pathways that increase hepatic insulin sensitivity (Obici et al. 2003). Exposure of the small intestine to fatty acids thus stimulates counter-regulatory mechanisms in the brain, gut, and liver that prevent hyperglycemia and limit caloric intake. The presence of glucose in the small intestine similarly signals to reduce hepatic VLDL production (Lam et al. 2007). Circulating amino acids derived from ingested proteins, such as leucine, activate hypothalamic neurons involved in energy and nutrient sensing in the hypothalamus in rats via vagal afferents, and may also influence hepatic glucose production by stimulating amino acid sensors in the liver (Potier et al. 2009). The presence and importance of these elegant regulatory circuits in humans and their role in obesity and related metabolic disorders remain to be determined (Table 68.3).

68.9 Therapeutic Applications to Other Areas of Health and Disease

Strategies to modify secretion of peptide hormones in the stomach and small intestine may have a number of therapeutic applications. Antiobesity therapies targeted at gut hormones are in various

Table 68.3 Key features of the gut–brain–liver axis

1. Vagal afferent nerves in the small intestine respond to the presence of nutrients, such as long-chain fatty acids and amino acids.
2. These nerves connect to the brain and to the liver to form a circuit known as the gut–brain–liver axis.
3. Activation of this axis reduces appetite and hepatic insulin sensitivity through central effects, and reduces glucose and lipid production from the liver.
4. The presence of nutrients in the small intestine therefore stimulates the brain, gut, and liver to prevent hyperglycemia and reduce food intake.
5. Physical interruption of this circuit prevents lipids in the intestine from causing insulin sensitization, and leads to overproduction of hepatic glucose.

This table lists the key features of the gut–brain–liver axis, which serves as a counter-regulatory mechanism to prevent hyperglycemia and excessive calorie intake after feeding in rats

stages of development. In rodents, parenteral PYY (3–36) and Y2 receptor agonists are effective when used as monotherapy, or in combination with GLP-1 or leptin (Karra et al. 2009), for reducing food intake and weight. In healthy human subjects, orally active forms of GLP-1 and PYY were shown to increase plasma GLP-1 and PYY levels, and to reduce ghrelin, without major adverse effects (Beglinger et al. 2008), but there are no long-term data for the effects of these formulations on appetite and weight at present. The endocannabinoid CB1 receptor inverse agonist, rimonabant, was approved in 2006 by the European Agency for the Evaluation of Medical Products for weight reduction and improvement of metabolic profile in obesity, but was withdrawn in 2008 over concerns about the increased risk of depression and suicide. Bariatric surgical procedures in common use, such as Roux-en-Y gastric bypass, which lead to earlier exposure of the ileum to ingested nutrients, are associated with elevated postprandial levels of GLP-1 and PYY, and reduced ghrelin levels; GLP-1 and PYY concentrations rise progressively for months after bypass surgery, in association with sustained weight loss and rapid improvement of glycemic control (Vincent and le Roux 2008).

Long-acting GLP-1 analogs and pharmacological inhibitors of DPP-4, which utilize the insulinotropic effects of GLP-1 to lower blood glucose concentrations without the risk of hypoglycemia and, in the case of the GLP-1 agonists, with the benefit of modest weight reduction (Drucker and Nauck 2006), are potentially useful therapies for type 2 diabetes, especially in obese and elderly patients. Similarly, agonists of the small intestinal sweet taste or fatty-acid G-protein-coupled receptors could potentially be useful for augmenting endogenous GLP-1 release, although studies of the artificial sweetener, sucralose, in humans have not confirmed that it releases GLP-1, as reported for in vitro experiments, suggesting specific additional requirements of sugar-receptor binding (Ma et al. 2009).

Ghrelin, which increases gastric motility and energy storage through adipogenesis, in addition to its orexigenic effects, has been shown to increase dietary intake and functional status in peritoneal dialysis and cancer patients, as well as elderly patients with anorexia of aging (Davidson and Smith 2007). In critically ill patients with cardiac, renal, and hepatic failure, administration of ghrelin and ghrelin agonists improve appetite, reduce muscle and adipose tissue catabolism, and have anti-inflammatory effects (Kamiji and Inui 2008). Ghrelin receptor agonists have shown promise in treating gastroparesis by accelerating gastric emptying, and are currently in phase 1 trials in humans (Table 68.4) (Wargin et al. 2009).

Table 68.4   Therapeutic applications of gut hormones

Drug/procedure	Basis of action	Application
Rimonabant	Endocannabinoid CB1 receptor inverse agonist	Anti-obesity
Bariatric surgery e.g., gastric bypass	↑ endogenous GLP-1 and PYY production	Anti-obesity
GLP-1 analog e.g., exenatide, liraglutide	Activate GLP-1 receptors	Treatment of type 2 diabetes
DPP-4 inhibitor e.g., sitagliptin, vildagliptin	Inhibit degradation of GLP-1	Treatment of type 2 diabetes
Ghrelin, ghrelin receptor agonist e.g., TZP-101	Stimulate ghrelin receptors	Anorexia of cancer, critical illness and aging
		Gastroparesis

This table lists interventions which utilize the effects of gut hormones in the management of conditions such as obesity, type 2 diabetes mellitus, cachexia, and gastroparesis

Summary Points

- The gastrointestinal tract communicates with the brain to regulate appetite by neurohormonal signaling via the vagus nerve, and by gut hormones secreted in response to meals.
- "Gastric" satiation signaling is mediated by mechanical distension, particularly of the antrum, which stimulates vagal afferents, but requires concomitant 'intestinal' signals in order to be perceived as "meal-like" fullness.
- "Intestinal" satiation signaling by gut peptides is mediated by luminal exposure to nutrients, which is dependent on caloric load, macronutrient composition, and length of intestinal exposure.
- Satiating gut peptides, secreted by specialized cells in the small intestine and colon, include cholecystokinin (CCK), glucagon-like peptide-1 (GLP-1), oxyntomodulin, peptide YY (PYY), and neuropeptide W.
- These hormones act by slowing gastric emptying, and inhibiting appetite centers in the brainstem and hypothalamus.
- The stomach secretes leptin, which potentiates the effects of CCK, and ghrelin, which opposes the actions of the satiating gut peptides.
- Delivery of nutrients to the ileum inhibits secretion and motility in the stomach and proximal small intestine by the "ileal brake", which is mediated by GLP-1 and PYY.
- Nutrient detection in the small intestine appears to be mediated by "taste" receptors, analogous to those on the tongue, which detect macronutrients and are linked to secretion of peptide hormones such as GLP-1.
- Modulation of the gastrointestinal mechanisms involved in appetite regulation has potential therapeutic application to obesity, diabetes mellitus, nutrition in critically ill patients, and gastroparesis.

Glossary

Satiety: The suppression of hunger in between meals that reduces the frequency of eating.
Satiation: The processes that terminate feeding and limit meal size i.e. the feeling of "fullness" after ingestion of food.
Orexigenic: Appetite-stimulating (contrasts with *anorexigenic* = appetite suppressing)
Enteric nervous system: The network of neurons in the gastrointestinal tract (collected into submucosal and myenteric nerve plexuses), which control gut motility, secretion, and immune function.

Migrating motor complex(es): Waves of activity which pass down the intestines in regular cycles during fasting, and which facilitate transport of nutrients and other substances from proximal to distal parts of the gastrointestinal tract.

Enteroendocrine cells: Specialized cells in the gastrointestinal tract (e.g., L cells) that secrete hormones such as cholecystokinin, glucagon-like peptide-1, and peptide YY in response to luminal nutrients.

Incretin: An endocrine transmitter produced by the gastrointestinal tract which stimulates insulin secretion in response to postprandial hyperglycemia.

Ileal brake: Negative feedback mechanisms, by which the transit of nutrients to the ileum stimulates vagal signaling and the release of satiating gut peptides to inhibit gastric, duodenal, and jejunal motility and secretion.

Bariatric surgery: Surgical therapy for obesity, to restrict gastric capacity with intestinal malabsorption (e.g., Roux-en-Y gastric bypass) or without it (e.g., laparoscopic adjustable gastric banding).

Gastroparesis: A clinical disorder characterized by delayed gastric emptying, in the absence of mechanical obstruction, most frequently presenting with upper gastrointestinal symptoms such as nausea and vomiting.

Chapter 69
Manipulation of Diet to Alter Appetite

Joanne A. Harrold and Jason C.G. Halford

Abbreviations

AGRP   Agouti gene related peptide
AP   Area postrema
ARC   Arcuate nucleus
CART   Cocaine and amphetamine related transcript
CCK   Cholecystokinin
DMH   Dorsomedial hypothalamic nucleus
GLP-1   Glucagon-like peptide 1
g   Gram
kcal   Kilocalorie
LHA   Lateral hypothalamic area
Nac   Nucleus accumbens
NPY   Neuropeptide Y
NTS   Nucleus of the solitary tract
POMC   Pro-opiomelanocortin
PVN   Paraventricular nucleus
PYY   Peptide YY
VAS   Visual analogue scales
VMH   Ventromedial hypothalamic nucleus

69.1 Introduction

With enhanced prevalence of overweight and obesity, it is important to identify properties of food that promote increased energy intake and thus contribute to a positive energy balance. The effects of manipulating the macronutrient composition of the diet on appetite have been widely examined. More recently energy density and the portion size of foods have been identified as important environmental factors influencing appetite control.

Despite the considerable scientific input into this field, numerous anomalies and unanswered questions remain. For example, whilst it has become generally accepted that certain macronutrients exert

University of Liverpool, Liverpool, UK
e-mail: harrold@liverpool.ac.uk

stronger influences on postingestive appetite (per kcal consumed), e.g., protein verses fat, the number of studies demonstrating macronutrient-induced changes in subsequent ad libitum intake are more limited. Moreover, less satiating nutrients like fat paradoxically often provoke greater changes in biomarkers of appetite (gastrointestinal motility and gut peptide release), than their more satiating equivalents such as protein. Additionally, in experimental designs it is often not clear whether the incorporation of one nutrient, or the removal of another, drives any subsequent change in appetite, energy intake, or weight change. Finally, the heterogeneity of proteins, carbohydrates, fats, and fibers, and the consequent effects on sensory experience and energy density of food still provide clear obstacles to our ability to manipulate diet to control spontaneous appetite expression and manage body weight. These issues will be addressed in the chapter along with an examination of the nature of appetite expression, the structure of the appetite system, the consequences of energy restriction, the role of macronutrients, energy density, and portion size in appetite expression – and finally the implications of these for weight management.

69.2 Appetite Expression

Appetite can be defined as the tendency to seek and consume food. Typically, this consummatory behavior is characterized by discrete eating events (meals and snacks) which are under the control of a wealth of peripherally generated factors. Both episodic and tonic factors contribute to the control of feeding behavior (Halford and Blundell 2000). They differ in terms of their duration of effect. Episodic factors are generated by recent consumption and influence intake in the short term. Tonic factors provide influence over the long term and are generated by metabolism and the storage of energy. Both classes of peripheral factors provide input to hypothalamic CNS neurones which are key to the long-term control of body weight.

The regulatory components so far discussed (peripheral factors and hypothalamic CNS neurones) underpin the homeostatic expression of appetite. Their collective action maintains the body's energy stores. Eating is driven by need (hunger) as the energy stores are depleted. Once this need is met negative feedback signals are generated to bring the period of eating to an end (satiation). These signals ultimately lead to a state of satiety in which the hunger drive and eating behavior are inhibited (Blundell 1991). The satiety cascade depicts the events which stimulate eating along with the processes triggered by the ingestion of food which terminate intake (Fig. 69.1).

When food is freely available this homeostatic appetite system defends well against energy deficit. However, as demonstrated by the current obesity pandemic, defense against energy excess is less potent, resulting in an asymmetrical regulatory system more sensitive to under- than overconsumption. In turn, hedonic neuronal systems in the brain can stimulate overconsumption by signaling the sensory pleasure derived from food. Pairing the regulation of food intake with pleasure and reward in this way can lead to the less potent homeostatic energy-surplus defense mechanisms being overridden, promoting hyperphagia and obesity.

69.2.1 Episodic Factors

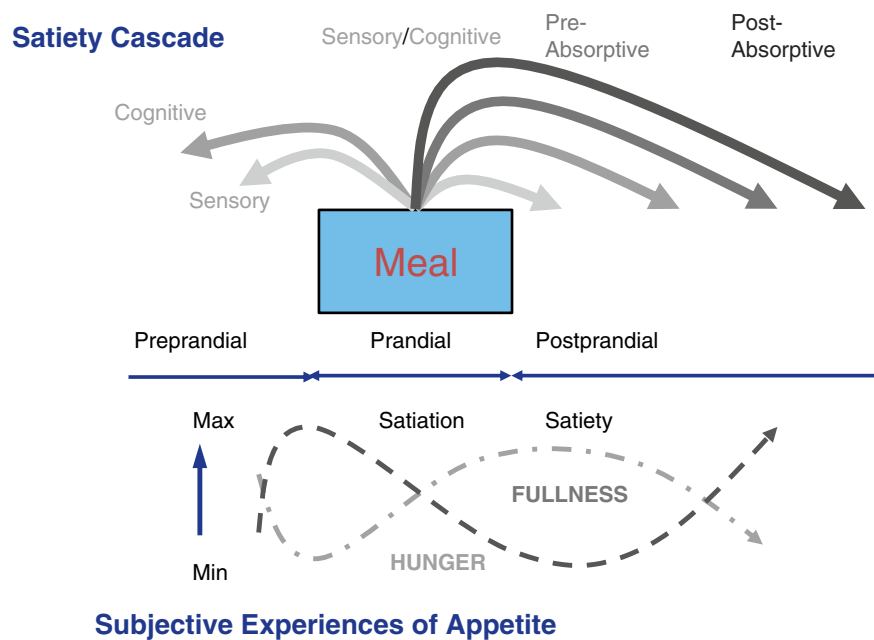
Episodic signals are predominantly generated by the gastrointestinal tract in response to the physical and/or chemical presence of food. As a consequence their levels tend to rise and fall in coordination with periods of eating. Many of these factors, including cholecystokinin (CCK) and glucagon-like peptide (GLP)-1, are sensitive to the presence of specific macronutrients (fats, protein, and carbohydrate). When released in response to macronutrients, they indicate the fullness of the stomach to the CNS and estimate the caloric content of the ingested food. Table 69.1 shows some key peripheral episodic signals as well as tonic and CNS regulatory factors.


Fig. 69.1 The satiety cascade demonstrates a series of behavioral and physiological events that stimulate eating, occur during food intake and follow food intake to inhibit further eating until the return of hunger signals

Table 69.1 Peripheral and central systems underpinning the expression of appetite

	Peripheral		Central	
	Episodic	Tonic	Homeostatic	Hedonic
Orexigenic	Ghrelin	Progesterone	NPY	Opioids
			Orexins (A and B)	Endocannabinoids
			MCH	Dopamine
			AgRP	
Anorexigenic	CCK	Leptin	Melanocortins	
	GLP-1	Estrogens	CART	
	PYY		5-HT	
	Amylin			
	Obestatin			

Major peripheral episodic and tonic signals along with CNS orexigenic and anorexigenic regulatory factors. Key: *CCK* cholecystokinin, *GLP-1* glucagon-like peptide-1, *PYY* peptide YY, *NPY* Neuropeptide Y, *MCH* melanin concentrating hormone, *AgRP* agouti-gene-related peptide, *CART* cocaine- and amphetamine-related transcript, *5-HT* serotonin

69.2.2 Tonic Factors

Appetite not only relates to daily food intake and eating behavior but must also respond to the long-term (tonic) energy status of the individual. Tonic signals arise from tissue stores, the metabolic status of which provides a signal to indicate the status of the stores and drive intake if energy reserves are low. Organs implicated in energy storage include the liver, pancreas, and adipose tissue. They secrete various circulatory factors known to act as potent determinants of food intake, e.g., leptin and insulin. In addition, there is evidence to suggest that metabolites produced by the metabolism of nutrients, e.g., adipsin and the interleukins, also play a role in influencing the long-term expression of appetite.

69.3 Structure of the Appetite System

The control of energy balance depends critically on the CNS. The brain integrates multiple biological signals in order to determine the energy requirement of the body and to modify the experience of hunger and initiate the relevant behavioral actions in response to this. The CNS regions that control energy homeostasis are accessible to numerous circulating hormones and other factors. Information reaches the CNS via three main routes:

1. The central control of appetite is guided by the peripheral signals already discussed. These include signals derived from receptors in the gut (mechanoreceptors and chemoreceptors) and from metabolic changes in the liver. They are sent via afferent vagal signals to the Nucleus of the Solitary Tract/Area Postrema (NTS/AP) complex in the brainstem.
2. Regulatory signals are also derived from receptors within the CNS, particularly the brainstem. These detect circulating levels of nutrients, metabolites, and other regulatory factors.
3. Specific substances, e.g. glucose and neurotransmitter precursors, have the ability to cross the blood–brain barrier and enter the brain. Here they alter neurochemical activity in key appetite-regulating sites.

Within the CNS itself are specific neuronal populations that recognize these signals and act in a network to integrate the multiple inputs, and help determine energy intake and expenditure. The primary location involved in the regulation of food intake in mammals is the hypothalamus (Fig. 69.2); others include the amygdala and nucleus accumbens of the forebrain and also structures in the brainstem.

69.3.1 Brainstem

The NTS/AP are adjacent areas in the medulla of the brainstem which are key sites for integration of various afferent signals. Vagally transmitted gustatory signals (including gastric distension and portal vein glucose levels) are relayed from the periphery. There is evidence to indicate that the levels of
Fig. 69.2 This image shows the relative positions of the key hypothalamic appetite regulating nuclei with respect to each other. Key: *DMH* dorsomedial hypothalamic nucleus, *PVN* paraventricular nucleus, *VMH* ventromedial hypothalamic nucleus, *ARC* arcuate nucleus, *LHA* lateral hypothalamic area, *ME* median eminence

circulating nutrients can also be detected by receptors located in these brainstem areas. Finally, afferent sensory information from the mouth, including taste, also converges on this region.

69.3.2 Hypothalamus

Hypothalamic nuclei play key roles in the control of hunger and satiety (Fig. 69.2). For example, injection of various substances into the paraventricular nucleus (PVN) influences intake (either increases or decreases it); lesions in this region result in hyperphagia (increased intake), reduced energy expenditure, and obesity (Shor-Posner et al. 1986). Other key hypothalamic sites include the Arcuate Nucleus (ARC), Dorsomedial Hypothalamic Nucleus (DMH), Lateral Hypothalamic Area (LHA), and the Ventromedial Hypothalamic Area (VMH). The ARC is readily accessible to peripherally generated signals (both episodic and tonic) indicating nutritional status. It contains functionally discrete populations of neurones including the orexigenic (stimulatory) neuropeptide Y and agouti-gene-related peptide (NPY-AgRP) containing neurones and the anorexigenic (inhibitory) pro-opiomelanocortin and cocaine and amphetamine-related transcript (POMC–CART) containing neurones. The ARC also has extensive reciprocal connections with the other hypothalamic appetite-regulating regions. In addition they receive afferent information via the NTS/AP.

69.3.3 Forebrain

Other key limbic sites identified as playing critical roles in appetite regulation include the Nucleus Accumbens (Nac) and Amygdala of the forebrain. These sites contain an extensive neural system that processes appetitive and rewarding aspects of food intake; palatability and pleasure are arguably the most powerful motivators of food intake. The Nac contains both dopaminergic and opiodergic neuronal pathways and thus acts as an interface between motivation and actual feeding behavior. Reciprocal connections have also been identified between the Nac and the LHA (Stratford et al. 1999). These connections offer a means of interaction between homeostatic and nonhomeostatic regulatory pathways. The amygdala is also an important component of reward circuitry, with several subnuclei of the amygdala influencing reward-related food intake.

Whilst this chapter provides only a brief overview of the complex CNS neuropeptide and neurotransmitter systems that integrate the numerous metabolic and gut signals that drive appetite, Lee and Ahima's chapter (Central regulation of appetite and satiety behavior) provides a more comprehensive review of current understanding in this field.

69.4 The Consequences of Energy Restriction

Fundamentally, to reduce body weight, individuals must reduce caloric intake and increase their energy expenditure. This principle is universally accepted as the only appropriate approach to weight control. However, theoretically whilst small adjustments to behavior should reverse weight gain, increasing levels of obesity clearly demonstrate that losing weight by reducing calorie intake and changing lifestyle remains difficult. Protective metabolic mechanisms which evolved to cope with periods of food shortage become reactivated during the self-imposed reduction in intake of dieting, thus making weight loss more difficult.

Reduced dietary energy intake has a number of positive effects in humans including lower cholesterol, fasting glucose, and blood pressure and improved memory. However, dietary restriction can also produce negative consequences, some of which are particularly relevant when the aim of the restriction period is the reduction of weight. Weight loss is characterized by numerous metabolic and/or endocrine adaptations which could in turn affect appetite in the reduced weight state. Weight loss has been shown to reduce sympathetic nervous system activity, plasma leptin, and insulin, all of which would normally act to inhibit food intake and energy expenditure. Furthermore, weight loss improves glycemic control resulting in reduced fasting glucose, which has been shown to trigger episodes of feeding (Campfield and Smith 1900).

69.4.1 Weight Loss and Appetite

The Minnesota experiment (Keys 1950), a clinical study performed at the University of Minnesota between November 1944 and December 1945, is a powerful indicator of the effects of caloric restriction on appetite. It consisted of a 12-week control phase during which the 36 male participants ate normally, a 24-week "semi-starvation" phase when participants were restricted to half of their normal daily intake and a 3–9-month rehabilitation phase during which the men were gradually refed. Although described as a semi-starvation phase it is important to note that the level of caloric restriction employed during this period of the study was comparable to that used currently to define "conservative" treatments for obesity. A number of physical and psychological changes were observed during this phase. In terms of attitude and behavior towards food, one of the most striking changes reported by the study participants was a considerable increase in preoccupation with food. Relentless thoughts of food and eating inhibited concentration on usual daily activities. Furthermore, participants reported serious difficulties in adhering to the diet when confronted with unlimited access to food. This was reflected during the refeeding phase by a loss of control over appetite demonstrated by the majority of the participants. Similar to preclinical studies, the Minnesota study also indicates the profound adaptive capacity of the body in terms of maintaining a relatively constant body weight. Although the participants regained their original weight plus approximately 10% during the refeeding period, this gradually declined to pre-experimental levels by the end of follow-up.

More recently, Doucet et al. (2000) have directly examined the impact of weight loss on appetite. In this study the impact of a standardized breakfast on subjective appetite scores (as measured by visual analog scales, VAS; Table 69.2) was measured in the control state, following a 15-week drug-treatment (fenfluramine) phase and after an additional 18-week low fat diet and exercise follow-up. Following both treatment phases, an increase in the fasting desire to eat, hunger and prospective consumption were observed, although the effect was greater following the low fat diet and exercise follow-up. These results suggest that weight loss is accompanied by an increase of baseline appetite.

Pasman, Saris, and Westerterp-Plantenga drew similar conclusions from their 1999 study. Following an initial weight loss induced over 2 months by a low calorie diet, hunger (as measured by the Three-Factor Eating Questionnaire) was found to be a significant predictor of weight regain over a 14-month period.

69.4.2 Weight Loss and Leptin

Given the appetite-suppressing effects of leptin, it has been speculated that lower leptin levels, occurring as a consequence of weight and specifically adipose tissue loss, may be responsible for stimulating appetite and thus limiting diet-induced weight loss in humans (Boden et al. 1996). Mars and

Table 69.2 Key features of Visual Analogue Scales (VAS)

1. Visual Analogue Scales (VAS) use self-report methodology to measure the motivation to eat.
2. VAS measure subjective appetite sensations and provide a quantifiable objective measure from these subjective sensations.
3. A series of experimental studies have demonstrated that VAS have within subject reliability and validity in experimental conditions.
4. VAS take the form of a 100 mm horizontal line, unbroken and unmarked and with the two extreme states (minimum and maximum) anchored at either end (Fig. 69.3).
5. VAS are flexible in that the questions and anchor labels can be altered to suit the manipulation being examined.
6. VAS are typically completed immediately before and after an eating episode and periodically at intervals (typically 1 h) between eating episodes, providing a diurnal profile of subjective appetite sensations.

This table lists the key features of visual analogue scales including the aspects they are designed to measure, the form they take, and the standard procedure via which they are administered

colleagues (2006) reported a positive correlation between self-reported appetite (assessed using a 10-point likert scale) and serum leptin levels during a 4-day diet containing 36% of estimated energy requirements. During the diet period leptin levels progressively fell by 39.4% and self-reported appetite increased. This suggests that falling leptin levels have an important role in restoring negative energy balances by stimulating appetite and signaling the need for increased food intake.

The relationship between appetite and plasma leptin has also been examined by Heini et al. (1998) who induced controlled weight loss in the form of a low calorie (800 kcal) diet for a 5-week period. During this period only changes in plasma leptin were found to be associated with appetite ratings such that higher leptin levels correlated with greater feelings of fullness.

Doucet et al. (2000) also identified a link between weight loss-induced changes in appetite and plasma leptin levels, with changes in fullness being reported to be associated with changes in fasting leptin levels, but only in their male participants. However, in this study, the most consistent predictor of weight loss-induced changes in appetite, in both men and women, was changes in fasting plasma cortisol levels. As glucocorticoids play a role in glucose homeostasis and weight loss reduces fasting glucose levels, it has been proposed that changes in cortisol may reflect an attempt to restore glucose levels by increasing energy intake.

To conclude, weight loss is always accompanied by a compensatory increase in appetite. Despite a need for greater understanding of the biological mechanisms underlying these changes in appetite, these human data concur strongly with anecdotal evidence from both dieters and clinicians that caloric restriction increases appetite. For human appetite control this has clear implications: (1) diet induced changes in appetite in turn make the process of controlling eating behavior difficult during the weight loss process and (2) the psychological consequences of these aversive appetite experiences predict post-treatment weight regain (consequences that may undermine further weight loss attempts).

69.5 The Influence of Macronutrient Composition on Appetite

In recent years interest has increased in the influence of food composition on energy intake and appetite.

69.5.1 Fats

For decades dietary fat has been considered a key contributor to the development of obesity. Obesity can reliably be induced in various animal models utilizing diets of 30% or more of energy from fat.

INSTRUCTIONS FOR PARTICIPANTS:
Please read each question and then put a mark through the line that best represents
how you are feeling in relation to that particular sensation at this moment.

EXAMPLE:

How **TIRED** do you feel **at this moment?**
Not at all   Extremely
tired   tired

PLEASE ANSWER THE FOLLOWING QUESTIONS:

How **HUNGRY** do you feel **at this moment**?

Not at all   Extremely
hungry   hungry

How **FULL** do you feel **at this moment**?
Not at all   Extremely
full   full

How **STRONG** is your desire to **eat at this moment**?
Not at all   Extremely
strong   strong

How **MUCH FOOD** do you feel you could eat **at this moment**?

None   A large
at all   amount

THANK YOU

Fig. 69.3 The commonly used questions to assess the motivation to eat and the appropriate anchor labels for each of these are incorporated into this example of a visual analogue scale. The questions assess subjective states and reflect the intensity of each state at the time of completion

Similarly, humans report higher caloric intake and higher BMI when consuming high fat compared to low fat diets (Ballard-Barbash et al. 1996).

The obesogenic properties of dietary fat are attributed to a phenomenon known as passive overconsumption. This refers to the unintentional ingestion of excess calories as a consequence of ineffective satiety signals thus undermining the normal regulation of food intake. Several

mechanisms are proposed for the stimulation of energy intake by energy dense foods, including high fat foods. Typically higher palatability ratings are assigned to energy dense foods (Nasser 2001) and palatability is positively associated with energy intake (McCrory et al. 2000). Additionally, energy dense foods tend to lack volume. Consequently, they can be rapidly consumed before satiety mechanisms such as stomach distension, which contribute to the feeling of fullness, can be activated.

Initially studies examining the influence of dietary fat on energy intake reported that reductions in fat content decreased energy intake even when palatability did not vary (Lissner et al. 1987; Kendall et al. 1991). In the study by Lissner and colleagues 24 women were exposed to three 2-week treatments in which 15–20%, 30–35%, or 40–45% of the energy was derived from fat. Compared to energy intake on the medium fat diet, subjects consumed an 11.3% deficit on the low fat diet and a 15.4% surplus on the high fat diet. However, whilst palatability was not a confounding variable in these studies, they were flawed by the inability to moderate fat content without altering energy density. It was thus impossible to attribute any observed changes in intake to one particular variable. Yet, it is possible to separate these effects by diluting food or by adding water-rich vegetables. When such approaches are employed to maintain energy density even large variations in the fat content of the diet (20–60%) had no significant impact on body weight (Stubbs et al. 1995; Saltzman et al. 1997; Rolls et al. 1999).

Despite this apparent lack of effect of fat content on energy intake, dietary fat remains a potential contributor to the obesity pandemic. Evidence indicates a potential genetic contribution to determining an individual's susceptibility to gain weight upon exposure to a high fat diet. Whilst normal weight subjects respond to increased fat intake with the enhanced oxidation of fats, this may not be the case for obese individuals. Some studies report an appropriate compensation for fat intake in obese individuals (Maffeis 1995) whilst others suggest that fat oxidation does not increase with intake in this population resulting in a vulnerability to weight gain (Thomas et al. 1992). Obese individuals also appear to differ from their lean counterparts in terms of preference for high fat foods (Reed et al. 1997). Obesity and preference for high fat foods are positively associated. Furthermore, it has been suggested that the disproportionally weak control over appetite offered by high fat foods is further weakened in obese individuals such that they are even less responsive to satiety signals triggered by fat intake.

To conclude, the apparent relationship between intake of dietary fat and obesity appears to be explained by the impact of enhanced fat content on energy density. However, not all individuals react equally to dietary fat, with genetics contributing to susceptibility to weight gain with fat intake. Particularly in susceptible individuals, the palatability of energy dense high fat foods stimulates passive and active overconsumption. Whilst advising people to moderate their dietary fat may assist in avoiding passive overconsumption, such advice will probably do little to overcome active overconsumption promoted by high palatability.

69.5.2 Carbohydrate

Total carbohydrate is composed of various nutrients with those of particular interest being sugars and fiber. As carbohydrates are less energy dense than fats and so result in lower intake when compared to higher fat diets (Kennedy and Bowman 2001) they appear to protect against overconsumption and the development of obesity. However, the different nutrient components of carbohydrate have quite different effects on energy intake.

69.5.2.1 Fiber

The link between dietary fiber and reduced appetite and energy intake is clearly established in the literature. Fibers possess distinct sensory, physiological, and metabolic properties which give rise to their effects on appetite and physiological responses to food. They may be distinguished by their solubility, viscosity, and fermentablity. Viscosity and fermentation in particular are likely to affect appetite through distinct within- and postmeal mechanisms. While most research emphasizes post-prandial mechanisms, viscous fibers may also affect satiation. Viscosity appears to be a key factor influencing slowing eating rate and the emergence of fullness during a meal (Mattes and Rothacker 2001). The effects of viscous fibers on appetite may also arise from postprandial delays in blood glucose response, prolonged gastric emptying, and altered intestinal transit times. Viscosity slows oral processing time, reducing intake by slowing the rate of ingestion and facilitating meal-generated satiating signals, alters palatability (Hoad et al. 2004), and may increase an individual's estimate of a food's satiating potency. Additionally, viscous fibers may increase sensations of fullness through delayed gastric emptying and/or increase in gastric volume "bulk." Increasing dietary fiber reduces postprandial glucose and insulin responses; particularly with insoluble fibers relating to their impact on glycaemic index of foods (Wolever 1990). Similarly, the literature indicates that various soluble fibers can alter the release of gut hormones, increasing glucagon-like peptide (GLP)-1 and peptide YY (PYY) and suppressing ghrelin release, providing potential mechanisms for the stimulation of satiety and later suppression of hunger (Adam and Westerterp-Plantenga 2005; Greenway et al. 2007). Another route by which (particularly nonviscous soluble) fibers may influence appetite is through microbial fermentation of fibers producing short-chain fatty acids (SCFA) in the proximal colon (Gibson et al. 1995). Increased availability of SCFA (acetate, propionate, and butyrate) may also stimulate GLP-1 and PYY release.

A systematic review of the available literature reveals 114 publications (117 studies) examining fiber manipulation and appetite in various experimental designs. Effects on appetite (hunger and satiety) are consistently reported (but only reach significance in 80 publications). Effects on intake are reported in a number of studies (Howarth et al. 2001) with intake being reduced upon consumption of high fiber regime, even when controlling for dietary fat, palatability, and energy density (Fig. 69.4.).
Fig. 69.4 Both protein and fibers have a documented role in appetite reduction by decreasing hunger and increasing fullness feelings, but not necessarily reducing food intake. However, when served as a breakfast meal and a mid-morning snack, a yoghurt enriched with protein and viscose fiber reduced energy intake (g and kcal) at an ad-libitum lunch compared to an equicaloric load of an unenriched yoghurt matched for taste and palatability. Results are expressed as mean ± SEM, $n= 24$ lean unrestrained female volunteers. $*p < 0.012$; $**p < 0.002$

69.5.2.2 Simple Carbohydrates

Links between carbohydrates and enhanced energy intake are established in studies employing refined and simple carbohydrates. Such carbohydrates are more rapidly absorbed into the circulation than other macronutrients or complex carbohydrates. This rapid glucose entry may prompt excess insulin release, consequently lowering blood sugar levels dramatically. According to glucostatic theory rapid falls in blood sugar will prompt a powerful hunger drive.

The general consensus from a review of 16 controlled experimental studies examining this concept is that high glycemic index foods (characterized by a high content of refined and simple carbohydrates) trigger the release of high insulin levels, promoting intake (Ludwig et al. 1999). As anticipated, intake of low glycemic index foods is associated with enhanced satiety and reduced intake (Ludwig et al. 1999). However, these findings remain controversial with methodological approaches being questioned and the short-term nature of the studies seen as a major limitation; studies investigating the long-term association between glycemic index and appetite have had inconsistent results (Vermunt et al. 2003; Raben et al. 2003).

To conclude, when considered as a whole, carbohydrates appear to reduce energy intake. However, not all carbohydrates are alike. Simple carbohydrates tend to promote overconsumption via an exaggerated insulin response. Conversely, fiber reduces energy intake, although the mechanism via which this is achieved depends on the nature and properties of the fiber employed.

69.5.3 Protein

It is generally accepted that proteins exert the greatest influence of the macronutrients on satiety (Blundell and Macdiarmid 1997). From this it can be predicted that elevated protein intake will impact upon appetite (increasing fullness and reducing hunger ratings) and reduce intake at the next meal (Fig. 69.4).

Halton and Hu (2004) provide a comprehensive review of controlled experimental studies investigating the predicted effects of high protein diets on appetite and intake. Of 14 studies examining protein's effects on appetite, 11 report that subjective ratings of satiety were significantly increased following a protein preload compared to at least one other macronutrient. However, many of these studies are methodologically flawed, with it being impossible to distinguish the influence of protein on appetite from other influences on satiety such as palatability, energy density and the reduction in the levels of other macronutrients resulting from elevation of protein levels. Of 15 studies examining the effect of protein on energy intake (Halton and Hu 2004), 8 found that energy intake was significantly decreased following higher protein preloads. However, in addition to the methodological problems identified above, the ecological validity of some of these studies can be questioned. For example, two were conducted in whole body calorimeter chambers, and two used anesthesia and/ or nose clips in order to remove taste of the protein preloads.

Despite some evidence to support an elevated satiating value of protein, other evidence points toward a potential contribution of elevated protein intake to the development of obesity. High protein diets are reported to induce hyperphagia in rodents (Rolland-Cachera et al. 1995). Furthermore, an association has been identified between high protein intake early in life and an increased risk of childhood obesity (Rolland-Cachera et al. 1995).

To conclude, there is evidence to suggest that high protein diets impact positively on appetite. However, reports of accompanying reductions in intake are inconsistent. Additionally, animal studies produce conflicting results, indicating an association between protein intake and the development

of obesity. Furthermore, similar relationships have been identified in humans when protein intake is elevated at critical times in development. It is possible that protein intake has a beneficial impact on appetite and intake over a specific range, with protein intake in excess of this maximum promoting the development of obesity.

Overall, a satiety hierarchy has been established amongst the macronutrients with protein > carbohydrate > fat. This hierarchy is established on the basis of differences in palatability and energy density of the macronutrients. Studies of the effects of macronutrients can be particularly misleading if they do not consider the energy density of the diet under investigation.

69.6 The Influence of Energy Density on Appetite

Energy density is the amount of energy (kilocalories or kilojoules) in a given amount of food (typically measured in grams, g). Thus, the energy density of a food is related to its macronutrient composition. Dietary fat and water exert the most significant impact on energy density. Dietary fat has a higher caloric density compared to protein or carbohydrate, whilst water contributes to the weight of a food without the addition of calories.

There is considerable evidence to indicate that the energy density of food, independent of macronutrient composition, is a key determinant of short-term energy intake in humans. From the results of controlled experimental studies and the examinations of self-reported intakes of free-living individuals, it would appear that individuals tend to consume a constant weight of food regardless of variation in energy density (Seagle et al. 1997). Consumption of energy dense foods will thus result in intake of additional calories. Bell and colleagues (1998) demonstrated this in a study manipulating energy density (low, medium, and high energy density conditions) within a given portion size. Over a 2-day period participants were served all of their meals (three per day). They ate a similar weight of food in all conditions despite the variation in energy density. Consequently intake was reduced by approximately 30% in the low energy dense condition compared to the high energy dense condition. However, ratings of fullness and satisfaction were not significantly altered despite reductions in energy intake. Importantly, ratings of palatability were also not altered by the modification to energy density.

69.6.1 Impact of Weight Status on Response to Energy Density of Foods

Rolls et al. (1999) confirmed this finding in lean and obese participants when manipulating the energy density of only a portion (50%) of the usual daily intake across a 4-day period. All participants reduced energy intake by approximately 16% when comparing low and high energy dense conditions. Ratings of hunger did not vary between diets. Nor was any compensation for reduced energy intake observed over the testing period.

Bell and Rolls (2001) also examined for lean and obese differences in the impact of varying energy density on intake. In this study the energy density of the main component of each meal (breakfast, lunch, and dinner) was manipulated across three percentages of dietary fat (25%, 35%, and 45%). Again, energy density was found to influence intake across all fat content in both lean and obese women, with approximately 20% lower energy intake in the low compared to the high energy-dense condition. Despite this, only small differences in hunger and fullness ratings were reported.

69.6.2 *Impact of Age on Response to Energy Density of Foods*

Whilst studies examining the impact of modifying energy density on intake have not identified a relationship with weight status there is evidence to indicate that the control of energy intake varies with age. It has been suggested that young children can respond to energy density of foods better than adults. This rationale is based on studies employing a preload design, with preschool children being found to compensate for increased energy density of preloads by reducing intake of a main course resulting in a constant total energy intake across both meals (Birch and Deysher 1985, 1986; Hetherington et al. 2000). However, these findings remain controversial as other preload studies report incomplete (both over- and under-) compensation (Birch et al. 1993; Cecil et al. 2005). Furthermore, ad libitum studies indicate that children, similar to adults, consume a consistent weight of food despite manipulations of energy density (Fisher et al. 2007; Leahy et al. 2008a) an effect found to persist beyond single meal studies to manipulation of the three daily meals consumed over a 2-day period (Leahy et al. 2008b)

Whilst dietary energy density impacts upon intake, it has been argued that decreases in energy intake associated with reductions in energy density will be shortlived with compensation occurring over time. This is based on the assumption that the weight of food consumed impacts initially upon pre-absorptive mechanisms associated with short-term satiety. However, it is not expected to have a persistent impact on post-absorptive mechanisms more orientated to reacting to the energy content of food. Few studies have tested this hypothesis. The influence of energy density independent of changes in macronutrient composition has been shown to persist for 4 days (Rolls et al. 1999) and 14 days (Stubbs et al. 1998) although the latter was an extremely small scale study recruiting six individuals.

To conclude, the consumption of low energy dense foods generally results in a reduction in energy intake with this effect being observed within a single meal and over a period of days. Whilst this finding has significance in terms of the development of dietary strategies for weight management, more long-term studies are required to identify whether changes in energy density can modulate intake in the long term or whether compensatory mechanisms limit the impact of this dietary manipulation on appetite.

69.7 The Influence of Portion Size on Appetite

The portion sizes of numerous foods have increased over recent years, occurring in parallel with the increased prevalence of obesity. Despite this, the average portions of food consumed by young children appear to have remained stable; suggesting that portion size appears to exert little influence over intake in this population (Westerterp-Plantenga 2004). This indicates that young children respond more to internal physiological intake cues such as hunger and satiety rather than food cues such as portion size. However, the observation that intake is increased with portion size in older children (Rolls et al. 2000) suggests that external factors appear to exert a greater influence in later years. It is possible that early eating experiences in children lead to the development of behaviors that result in them ignoring or overriding hunger and satiety signals. For example, it has been demonstrated that 4-year old children rewarded for clearing their plate increase energy intake (Birch et al. 1987). These learned responses along with heightened attention to food and environmental cues prompt overconsumption.

Adults respond in a similar way to older children with intake increasing with portion size. This effect has been observed with a variety of foods in both controlled laboratory environments (e.g.. Rolls et al. 2002) and the more naturalistic eating settings offered by cafeterias and restaurants (Dilberti et al. 2004). Observations of a lack of compensation for the increased intake at the next meal, an effect found to persist for 11 days (Rolls et al. 2007) indicate how this influence of portion size could potentially increase body weight.

Evidence from experimental studies suggest that this consistently observed increased intake with portion size in adults, as in older children, appears to relate to the ignoring or overriding of hunger and satiety signals. For example, in single meal studies it has been reported that fullness ratings do not increase despite the consumption of significantly greater portions of food (Rolls et al. 2002, 2004a). Furthermore, in studies with multiple meals, despite reporting enhanced feelings of fullness following consumption of larger portion size, compensation at the next or subsequent meals is not observed (Rolls et al. 2002, 2004a). It is possible that inappropriate eating behaviors learnt in childhood, e.g., eating in the absence of hunger, may persist into adulthood (Fisher and Birch 2002).

To conclude, both laboratory-based and free-living studies demonstrate that increasing the amount of food supplied as a snack or at a meal can lead to an increased intake. This effect applies to different types of food and is sustained beyond a single meal. Furthermore, the response to portion size is robustly demonstrated by individuals of various ages and body sizes. In fact, evidence suggests that cues indicating the amount of food consumed have a greater influence on intake than that offered by the energy density of the food consumed. Thus the "super size" portions offered in the modern eating environment place consumers at high risk of overconsumption and ultimately the development of overweight and obesity.

69.8 Combined Effects of Energy Density and Portion Size on Appetite

When both energy density and portion size are increased simultaneously within a meal, their effects are independent and additive in terms of increases in energy intake. Kral and colleagues (2004) demonstrated this relationship by manipulating energy density (high and low) across three portion sizes. They reported 56% greater energy consumption in the high energy-dense largest portion-size condition compared to the low energy-dense smallest portion-size condition.

By contrast, consumption of large portions can decrease energy intake across a meal if the food is of low energy density. For example, in a 7-week study of 33 women, Rolls et al. (2004b) demonstrated that consumption of a low energy-dense salad first course reduced intake at the main course, compared to consumption of no first course. Furthermore, whilst a small portion of the low energy-dense salad reduced intake by 7%, a large portion reduced intake by a greater extent (12%).

This additive effect of manipulations of energy density and portion size has been shown to persist beyond the single meal. In a 2-day study a 30% reduction in energy density was found to decrease daily intake by 23%, whilst a 25% reduction in portion size produced a 12% decrease in daily energy intake. These reductions in intake were not accompanied by significant differences in hunger and fullness ratings across the 2 days. However, longer term studies are required to determine whether these additive effects persist for extended periods. Such studies will need to consider the challenges faced by consumers, with low energy-dense foods often being more expensive than their high energy counterparts. This may impact upon the effectiveness and success of weight control strategies aimed at enhancing satiety and moderating intake through manipulation of a combination of energy density and portion size

69.9 Applications to Other Areas of Health and Disease

Irrespective of obesity the literature clearly demonstrates that childhood diet predicts adult health outcomes. Moreover, the role of body weight and more specifically abdominal fat mass

in obesity related disease is well understood. As epidemiologically studies have demonstrated the link between habitual diet and obesity, so they have also linked obesity to both the risk factors for (blood glucose and insulin, blood lipids and cholesterol, hypertension) and the occurrence of cardio metabolic disorders (diabetes, cardiovascular disease, and stroke) and other obesity related non-communicable diseases. Longitudinal data also clearly demonstrate that where the prevalence of obesity has spread, this has in time clearly been followed by increases in diabetes, and then cardiovascular diseases. However, even in the obese state, relatively small reductions in body mass appear to reduce both the risk factors for, and possible even the occurrence of obesity related disease. This strongly indicates effective changes in diet, reducing energy intake, and maintaining a negative energy balance, can yield positive health outcomes if sustained.

Summary

- A variety of nutritional scenarios exist (energy restriction, macronutrient composition, energy density, and portion size) whereby the manipulation of diet can lead to enhanced intake and the development of obesity.
- Variation in susceptibility to these different dietary inputs may be explained by genetics, adaptation, or nutrient-gene interactions.
- Energy restriction is always accompanied by a compensatory increase in appetite. This diet induced change in appetite in turn makes the process of controlling eating behavior difficult during the weight loss process.
- In terms of macronutrient composition, the heterogeneity of proteins, carbohydrates, and fats and the consequent effects on palatability and energy density provide obstacles to the manipulation of diet to control appetite.
- Increased intake promoted by an elevated dietary fat content can be explained by the impact of enhanced fat content on energy density.
- Fibers possess distinct sensory, physiological, and metabolic properties responsible for their reported effects on appetite (enhanced satiety) and physiological responses to food (reduced intake).
- Refined and simple carbohydrates are rapidly absorbed into the circulation producing an exaggerated insulin response. The resulting falls in blood sugar trigger hunger and promote overconsumption.
- High protein diets impact positively on appetite by enhancing satiety. However, an association between protein intake and the development of obesity has been demonstrated, particularly when protein intake is elevated at critical times in development.
- The energy density of food, independent of macronutrient composition, is a key determinant of short-term energy intake in humans. The consumption of low energy dense foods results in a reduction in energy intake.
- Increasing portion size can lead to an increased intake. This response to portion size applies to different types of food and is demonstrated by individuals of various ages and body sizes.
- The effects of energy density and portion size on intake are independent and additive.
- The manipulation of diet to alter appetite yields potential weight control strategies aimed at enhancing satiety and moderating intake.

Key Words

Energy density: The amount of energy (kilocalories or kilojoules) in a given weight of food (grams).

Energy intake: Total number of calories consumed daily.

Episodic factors: Peripheral signals generated by the recent consumption of food and which can influence intake in the short term, e.g., ghrelin and CCK.

Hedonic control: Reward based pathways that can override homeostatic regulation. They stimulate energy intake by increasing the desire to consume highly palatable foods.

Homeostatic control: The control of energy balance achieved by increasing the motivation to eat following depletion of the body's energy stores.

Hunger: The motivation to seek and consume food. It is often the initiator of a feeding event.

Hyperphagia: Increased appetite for and excessive intake of food.

Macronutrient: Nutrients (protein, carbohydrate, or fat) required by the body in relatively large amounts.

Palatability: A combination of attributes (taste, texture) of food which determine its acceptability and attractiveness for consumption.

Passive overconsumption: The unintentional ingestion of excess calories when signals for satiation do not function effectively to control meal size.

Satiety: The end point of the process of satiation. It begins at the end of one meal and continues until the start of the next, thus determining the intermeal interval. It is characterized by a lack of drive to consume as well as feelings of fullness.

Satiation: Begins within a meal and generates negative feedback signals designed to terminate food intake. In doing so satiation determines meal size.

Tonic factors: Peripheral signals generated by the metabolism and storage of energy which influence intake over the long term, e.g., leptin and insulin.

Chapter 70
Disinhibition, Appetite, and Weight Regulation in Adults

Eleanor J. Bryant

Abbreviations

BED	Binge eating disorder
BMI	Body mass index
BN	Bulimia nervosa
HD	High Disinhibition
HR	High Restraint
HDHR	High Disinhibition, high Restraint
HDLR	High Disinhibition, low Restraint
LDHR	Low Disinhibition, high Restraint
LDLR	Low Disinhibition, low Restraint
TEF	Thermic effect of food
TFEQ	Three Factor Eating Questionnaire
VLCD	Very low calorie diet
WHO	World Health Organisation

70.1 Introduction

The current rise in overweight and obesity in the Western world is associated with many health risks. Not only is the increase in body weight having an impact at an individual level, with increased risk of obesity related illnesses such as coronary heart disease (World Health Organization 2009), but it is also having an impact at a societal level. For example, the economic burden, with regard to the cost of health service, for treating obesity-related illness are estimated to be up to 6% of the total health care expenditure in the countries of the WHO's European Region (Knai et al. 2007), a cost which is expected to rise with the increase in prevalence of overweight and obesity.

It is clear that the susceptibility of some individuals to gain weight in an obesigenic environment (see list of definition) is an important issue. However, obesity and weight gain are not an inevitable consequence of living in an obesigenic environment; some individuals are more susceptible to weight

gain than others (Blundell et al. 2005). Susceptibility implies the presence of particular dispositions to create a positive energy balance. Here susceptibility refers to behavior (as opposed to metabolism), and is related to the tendency to increase energy intake (eating) or reduce energy expenditure (physical activity). Conversely, the obesigenic environment also increases the susceptibility of some individuals to develop disturbed eating behavior. The conflict between the obesigenic environment and societal demands to be lean can be argued to be responsible for the current trends for increased prevalence of eating disorders (Fairburn and Harrison 2003). Therefore, the identification of markers and eating behavior dispositions which are associated with an individual's susceptibility to weight gain, or to develop disturbed eating behavior, would be extremely useful.

Disinhibition, as measured by the Three Factor Eating Questionnaire (TFEQ: Stunkard and Messick 1985), is one factor which is becoming increasingly evident as a useful trait. It is not only associated with weight gain and obesity, but also with mediating variables, such as food choice, physical activity levels, and psychological and physical health. However, Disinhibition is also associated with disturbed eating behavior and eating disorders. The following sections will explore the relationship between disinhibition, eating behavior, appetite regulation, and weight in relation to the satiety cascade (Blundell 1991). It is probable that Disinhibition exerts its influence on the appetite regulation through both homeostatic and hedonic processes. Homeostatic regulation of appetite concerns the biological systems and processes in place which attempt to control our eating behavior, such as appetite related peptides. This system is primarily aimed at regulating energy balance. Whereas hedonic processes are related to the reward individuals gain from consuming food, and how this influences subsequent food intake. These systems interact to regulate appetite and food consumption (Lutter and Nestler 2009). Furthermore, an exploration of the usefulness of utilizing Disinhibition for predicting success at weight loss and managing Disinhibition within weight loss interventions will be addressed.

70.1.1 What Is Disinhibition?

Primarily, it is important to define exactly what is meant by Disinhibition. Trait Disinhibition is one of three eating behavior traits measured by the TFEQ (Stunkard and Messick 1985); these traits are Disinhibition, Restraint and Hunger. Restraint refers to concern over weight control and strategies which are adopted to restrict food intake or prevent overeating. For instance, avoiding fattening foods, eating small portions, and stopping eating before reaching satiation are strategies typically used to limit food intake. Disinhibition reflects a habitual tendency towards overeating and eating opportunistically in an obesigenic environment. This can include, eating in response to negative affect, overeating in the presence of others eating, overeating in response to the palatability of food, and not being able to resist temptation to eat. The factor of Hunger is concerned with the extent to which hunger feelings are perceived and the extent to which such feelings induce food intake. For example, feeling so hungry an individual finds it difficult to stop eating during a meal, eats more than three times per day, or feels so hungry that their stomach feels like a bottomless pit.

Further developments of the original TFEQ have been carried out, which have identified several subscales existing within the three factors. Bond et al. (2001), using factor analysis, identified that the three scales could be further broken down into several subscales; these are presented in Table 70.1. In addition, a more recent factor analysis of Disinhibition, revealed the existence of two subscales, which closely map onto those previously identified by Bond et al. (Niemeier

Table 70.1 Summary of key evidence of how Disinhibition influences the satiety cascade at each point of the satiety cascade

Eating phase	Hedonics vs. homeostasis	Influence of high Disinhibition
Cephalic phase	Hedonics	• Responsive to food cues. • Increased liking of food groups. • Eating in response to mood (reward from eating). • Personality factors (e.g. novelty seeking, extravagance, sensory stimulation, impulsiveness).
	Homeostasis	• Increased salivation.
Eating episode	Hedonics	• Responsive to the palatability of food. • Increased sensory sensitivity to the fat content of food. • Larger meal size.
	Homeostasis	• Decreased sensitivity to appetite related peptides (e.g. ghrelin & leptin). • Larger meal size.
Satiation	Hedonics	• Reduced alliesthetic response to food when sated.
	Homeostasis	• Reduced thermic effect of food. • Reduced satiety to high fat food.
Satiety	Hedonics	• Increased liking of food groups. • Increased wanting of high fat food. • Eating in response to mood. • Increased snacking.
	Homeostasis	• Eating in the absence of hunger. • Decreased sensitivity to appetite related peptides (e.g., ghrelin & leptin).

This table highlights the key mechanisms, both homeostatic and hedonic, through which Disinhibition influences the operational domain of the satiety cascade

et al. 2007). Despite the usefulness of these subscales, relatively few studies have examined the influence of these subscales, thus an in depth consideration of them is not included here.

Thus within this chapter, Disinhibition is considered as a trait which infers susceptibility to weight gain and eating disturbance. This chapter will regard Disinhibition as a general eating behavior trait as it is associated with an enduring set of characteristics which influence several aspects of an individual's life (Bryant et al. 2008). However, it is pertinent here to make a crucial distinction between trait Disinhibition and the term "disinhibition effect." The term "disinhibition effect" refers to transient episodes of overeating due to a weakening of Restraint. However, trait Disinhibition refers to a habitual tendency towards overeating, which is independent of Restraint. The focus of this chapter will be on trait Disinhibition, as a persistent set of characteristics associated with an individual's susceptibility to weight gain and disturbed eating behavior.

70.2 Disinhibition and Body Weight

Due to Disinhibition being characterised by a readiness to eat and a habitual tendency to eat opportunistically, it is not surprising that individuals characterised by a high level of Disinhibition are more susceptible to gain weight. This has been demonstrated in both cross-sectional and prospective studies. A positive association between BMI and Disinhibition scores has been

reported to exist across different BMI categories. For instance, individuals who are overweight and obese exhibit higher levels of Disinhibition (Provencher et al. 2003; Boschi et al. 2001). In addition, individuals within the lean BMI range (19–25 kg/m^2) are more likely to have higher BMIs than individuals with a low level of Disinhibition (Lawson et al. 1995; Bryant et al. 2010). Individuals with varying weight histories (e.g. where an individual was either overweight/obese as a child or adolescent or not), where formerly overweight/obese individuals maintained a higher Disinhibition score, despite a lower current weight (Bellisle et al. 2004), show how Disinhibition is also related to weight in the lower BMI categories. However, this raises an issue of causality: is Disinhibition driving the increase in weight or is it weight increase per se which drives up Disinhibition?

Similarly to the cross-sectional studies, two prospective studies showed how Disinhibition predicted weight gain over several years and predicted current BMI (Hays et al. 2002a), with the strongest predictor of weight gain being habitual susceptibility to Disinhibition (Hays and Roberts 2008). However, it should be noted that Drapeau et al. (2003) found that although changes in eating behavior traits were associated with changes in weight over 6 years; surprisingly, there was little difference between high- and low-Disinhibition individuals in their weight gain over this time period. This highlights the important issue that Disinhibition may not act in isolation, but frequently exerts its effect in interaction with the level of the TFEQ factors Restraint and Hunger. It has been suggested that when high Disinhibition is combined with a high level of Restraint, the relationship between Disinhibition and weight is weakened (Hays et al. 2002a, b 2004). Evidence for this suggestion comes from studies which demonstrate that a higher body weight is associated with a high Disinhibition coupled with a low Restraint. Conversely, when a high Disinhibition is associated with a high Restraint a somewhat lower body weight is evident (e.g. Dykes et al. 2004; Bryant et al. 2008, 2010). Therefore, to gain an accurate prediction of the influence of Disinhibition upon body weight, the other two TFEQ factors should be considered.

Given the evidence indicating a clear relationship between Disinhibition and weight, it is important to understand the mechanisms which may mediate or moderate this relationship. It is likely that Disinhibition influences both the homeostatic and hedonic control of eating, and that it is through these pathways which Disinhibition mediates appetite regulation and weight status. Thus the following sections examine evidence which may elucidate some of the mechanisms, both homeostatic and hedonic, linking Disinhibition and body weight.

70.3 Disinhibition and Food Intake Regulation

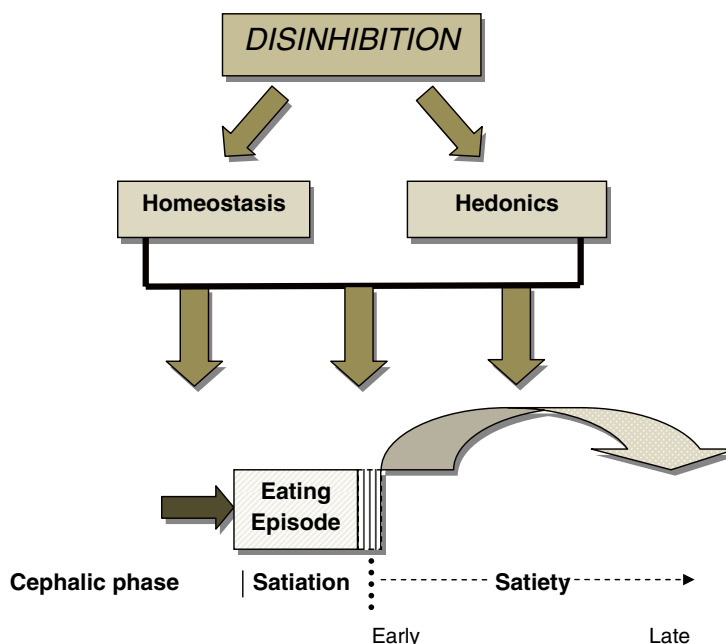
To examine the quality of food intake regulation in individuals with a high Disinhibition level the evidence can be considered within the framework of the satiety cascade (Blundell 1991). The satiety cascade details the temporal stages involved in appetite regulation, from cognitive processes to physiological and neurological processes involved in food intake from before food enters the mouth (cephalic phase), to the postabsorption stages of ingestion. This model is complex and a detailed account of all aspects of this model is beyond the scope of this chapter. Here, each temporal stage of the operational domain of the satiety cascade will be addressed, and evidence regarding food regulation in high Disinhibition individuals will be presented. Figure 70.1 presents a model outlining the role of Disinhibition in appetite regulation, through the homeostatic and hedonic processes. In addition, Table 70.2 summarises evidence relating to how Disinhibition influences appetite regulation at each temporal stage of food consumption.


Fig. 70.1 A schematic diagram outlining how Disinhibition could moderate satiety and satiation through homeostatic and hedonic processes. The model shows how Disinhibition (an enduring set of eating behavior characteristics) acts through both homeostatic and hedonic processes, to influence eating behavior at each stage of the operational domain of the satiety cascade. High Disinhibition individuals possess vulnerabilities (both hedonic and homeostatic) which facilitate a dysregulated appetite. These vulnerabilities exert their influence before eating (cephalic phase), during eating (satiation) and following a meal (satiety). Collectively these processes explain how HD individuals are more susceptible to weight gain and disturbed eating behavior

70.4 Meal Initiation

Inherent to the trait of Disinhibition is eating in response to habit and frequent overeating (Habitual Susceptibility), eating in response to emotion (Emotional Susceptibility and Internal Disinhibition), and eating in response to external cues (Situational Susceptibility and External Disinhibition). Eating episodes are not always driven by physiological appetite sensations, but rather psychological and external cues which could eventually lead to a dysregulated appetite response. Indeed, evidence suggests that eating episodes are not driven by feelings of hunger and fullness in obese participants with a high level of Disinhibition (Barkeling et al. 2007), thus other factors are contributing to the initiation of eating episodes. Therefore, what leads to the initiation of an eating episode? The following sections outline factors which could exacerbate the opportunistic eating pattern of individuals with a high level of Disinhibition.

70.4.1 Food Reward: Eating in Response to Negative Affect

The intensity of pleasure derived from eating and the amount food is liked could be a strong factor in the initiation of an eating episode. In terms of the hedonic dimension of food, individuals are likely to differ in the extent to which they derive pleasure from eating. Indeed, sensitivity to reward may reflect an innate characterological trait (Davis and Woodside 2002) which causes some individuals

Table 70.2 Subfactors of the original TFEQ factors

TFEQ factor	Subfactor	Definition
Bond et al. (2001)		
Restraint	*Strategic Dieting Behavior*	Specific behaviors which may be used to control weight (e.g. taking small helpings & stopping eating before being full).
	Attitude to Self Regulation	This assesses the individual's overall attitude to weight control and eating (e.g. counting calories & dieting to lose weight).
	Avoidance of Fattening Foods	This factor relates mainly to behavioral items (e.g. shopping for low calorie foods).
Disinhibition	*Habitual Susceptibility to Disinhibition*	This seems to be the core component, items loading on this factor relate to situations which may predispose an individual to recurrent episodes of overeating (e.g. binge eating and frequent weight fluctuations).
	Emotional Susceptibility	This describes situations where negative affect prompts an eating episode (e.g. eating when feeling down, anxious, or stressed).
	Situational Susceptibility	This factor is related to situations where environmental cues initiate an episode of eating (e.g. overeating when others do, and overeating in social occasions).
Hunger	*Internal Locus*	This refers to hunger which is interpreted and regulated internally (e.g. feeling so hungry their stomach feels like a bottomless pit).
	External Locus	This refers to hunger which is prompted by external cues (e.g. feeling hungry enough to eat when observing another person eating).
Niemeier et al. (2007)		
Disinhibition	*Internal*	This is related to eating episodes which are prompted by affect (e.g., eating in response to anxiety and feeling low).
	External	This factor refers to the influence external cues have on initiating eating episodes (e.g. the presence of others eating).

This table outlines the subfactors which have been indentified from the original Three factor Eating Questionnaire by two authors. These subfactors were derived using factor analysis, and they outline with more specificity what each factor measures

to seek reward from activities such as eating. Research has highlighted that genetically determined differences exist in dopamine availability in areas of the brain associated with reward, and that a lower availability is linked to a higher risk of addiction (Sabol et al. 1999). Some individuals are proposed to suffer from a deprivation of the brain's reward chemicals, an idea known as the "reward deficiency syndrome" (Blum and Nobel 1997). Here a person is likely to seek out compensatory behaviors as a way of self-medicating negative affective states (e.g. Carton et al. 1994: see list of definitions). On this basis, it is assumed that food can be used, in a similar fashion to addictive drugs, as a way to stimulate brain dopamine levels (Blundell et al. 2006). Therefore, it is hypothesized that individuals with a high level of Disinhibition may be particularly susceptible to the rewarding effects of consuming food, especially for alleviating negative affect.

Studies have demonstrated that high Disinhibition (HD) individuals do indeed eat in response to negative affect and stress (e.g. Weinstein et al. 1997; Haynes et al. 2003; Yeomans and Coughlan 2009). Interestingly, Haynes et al. (2003) reported that HD individuals were the most affected by a stress induction manipulation as they reported the highest levels of negative affect (& lowest positive affect) before taking part in the stress condition and were more responsive to the stress manipulation than the low Disinhibition (LD) individuals. This indicates that HD individuals may be more likely to eat in response to their emotional state as a way of self-medicating negative affect. Indeed, Carmody et al. (1995) suggested a relationship between aspects of coping and food intake among

overweight individuals. Their findings suggest that there are possible links between the experience and expression of emotions, dieting and eating behaviors, which can be influenced by Disinhibition.

The degree to which HD individuals eat in response to negative affect is moderated by Restraint. Both Haynes et al. (2003) and Yeomans and Coughlan (2009) have demonstrated that individuals with a high Disinhibition and low Restraint (HDLR) consumed the most food; high Disinhibition, high Restraint (HDHR) and low Disinhibition, low Restraint (LDLR) women increased their food consumption in response to stress and negative affect while the low Disinhibition, high Restraint (LDHR) women's intake remained unaffected by stress and negative affect.

These findings therefore suggest that HD individuals gain some reward from food consumption, as food intake can be initiated by negative affect and stress. In addition, the type of food that is usually chosen to alleviate negative mood is highfat and/or sugar (e.g. Oliver and Huon 2001). This poses a threat to maintaining energy balance and could lead these individuals to be susceptible to weight gain.

70.4.2 Hedonics: Disinhibition and Food Choice

A further hedonic aspect of food intake for high Disinhibition individuals is the degree of liking and wanting of food these individuals possess. A greater 'liking' for foods has been found to correlate positively with Disinhibition scores (Lahteenmaki and Tuorila 1995; Bryant et al. 2006) and a greater "wanting" of high fat foods has also been demonstrated experimentally in this group (Bryant et al. 2006). The level of liking and wanting HD individuals have for food is associated with actual intake. Individuals with high Disinhibition have been found to have a tendency to select more high fat foods, butter, high salt foods, sweet foods, ice-cream, sweets, fruit and vegetables, processed meat, coffee and sweet, carbonated drinks (Lahteenmaki and Tuorila 1995; Borg et al. 2004), whereas a negative correlation between Disinhibition and intake of some fruit and vegetables and high fibre bread has been documented (Borg et al. 2004). In addition, higher alcohol consumption has been reported by high Disinhibition women (Contento et al. 2005; Higgs and Eskenazi 2007) and men (Borg et al. 2004).

These studies clearly demonstrate that individuals with a high Disinhibition score are more likely to make less healthful food choices, which could have a detrimental influence on their body weight and general health. There is some evidence to suggest that mothers' Disinhibition scores were related to their own intake and their children's. Mothers' Disinhibition scores were positively correlated with their children's overall intake of calories, fat, cholesterol, protein, and sodium and correlated negatively with intake of some vegetables (Contento et al. 2005). This clearly raises issues for childhood weight management.

70.4.3 Responsivity to Food Cues

Disinhibition provides an indication of a person's higher responsiveness to cues to eat. This is illustrated well in the aforementioned studies where the hedonic aspect of food and reward gained from food could, at least in part, explain reasons for a HD individual's responsiveness. In addition, evidence revealed that HD individuals also have a tendency to show a heightened salivary response before food consumption (Brunstrom et al. 2004), suggesting that HD individuals have an increased biological, as well as psychological, response to food. It is important to note here that highly Restrained individuals in this study produced a stronger salivary response to food than the HD individuals. This highlights the importance of considering the influence of these eating behavior traits in combination, as the level of one trait may moderate the expression of the other.

Table 70.3 Summary of the influence of Disinhibition on meal initiation

1. HD individuals are likely to initiate an eating episode in the absence of hunger.
2. HD individuals show a heightened physiological response to food (increased salivary response).
3. HD individuals are likely to initiate an eating episode in response to their experience of negative affect.
4. HD individuals are responsive to the hedonic aspects (pleasure-derived) of eating food, making them more vulnerable to eat opportunistically.
5. HD individuals have a higher liking and wanting of food groups, particularly high fat, sweet foods.

This table summarises the key points from the section detailing the influence Disinhibition has on meal initiation, through both homeostatic and hedonic processes

Furthermore, in terms of HD individuals being responsive to cues to eat, evidence suggests that, in a sample of normal weight individuals, Disinhibition is associated with novelty seeking, impulsiveness and extravagance (Gendall et al. 1998; Yeomans et al. 2008). These traits are strongly associated with poor impulse control, excitability and the desire for sensory stimulation, thus it seems plausible that this combination of personality traits would be counterproductive to the maintenance of successful control over food intake and lead to a higher responsiveness to cues to eat. In support of this, Carmody et al. (1995) report that a high Disinhibition score is related to higher dietary helplessness.

In summary, the above sections give some indication of the factors which could lead to the opportunistic eating pattern expressed by HD individuals. They also highlight how HD individuals are susceptible to respond to a plethora of factors, other than their physiological drive, to initiate eating episodes. This not only increases their vulnerability toward overweight, but also towards problematic eating behaviors (e.g. binging) (Table 70.3).

70.5 During the Eating Episode: Homeostasis Versus Hedonics

70.5.1 Homeostasis

After the onset of an eating episode, HD individuals are vulnerable to a number of factors which make them more susceptible to overeating. These factors exert their influence during the meal and during meal cessation. Biologically, a number of systems and processes exist which attempt to control food intake and to terminate an eating episode. These processes include both tonic and episodic signals from the gastrointestinal tract, adipose tissue, and neurochemical processes. It is reasonable to purport that the dysregulated eating patterns displayed by high Disinhibition women could be influenced by differing levels of hunger or satiety related peptides. Two peptides which show a relationship with Disinhibition are ghrelin and leptin. Ghrelin levels are lower in obese than lean people and there is a negative relationship between BMI and ghrelin concentrations within an obese group (Schindler et al. 2004; Levin et al. 2004). However, St-Pierre et al. (2004) showed that ghrelin levels were not correlated with Disinhibition scores in a sample of lean women. Moreover, a positive relationship between leptin concentrations and Disinhibition in obese women, after controlling for BMI has also been demonstrated (Blundell et al. 2008). The significant relationship between Disinhibition scores and two peptides (ghrelin and leptin) known to play significant roles in energy homeostasis (Klok et al. 2007) suggest that the behavioral trait Disinhibition plays a role in the physiological processes of energy homeostasis. Therefore, it is possible that differing levels of, and sensitivity to, these peptides could contribute to the opportunistic and overeating behavior seen in HD individuals.

70.5.2 Hedonics

Alongside the homeostatic control over eating during a meal, the role of hedonics also influences eating behavior for HD individuals. This was well demonstrated in a study by Yeomans et al. (2004) where the palatability of food was manipulated. It was evident that HD individuals were highly responsive to the palatability of food, leading to a higher consumption. The responsivity of HD individuals to the palatability of the food was however moderated by the level Restraint: HDLR women were more responsive to the palatability of the food, as they consumed more food in the palatable than the bland condition. The HDHR and LDLR groups also increased their intake in the palatable condition, but LDHR did not increase intake in response to palatability.

The vulnerability of HD individuals to the palatability of foods could, in part, be as a result of the hedonic reward of food being closely linked to the sensory perceptions of food in the mouth; for many individuals this is the main drive to eat (Drenowski 1997). Support for this notion comes from a study by DelParigi et al. (2005) who demonstrated an abnormal brain response to the sensory experience of a liquid meal following a prolonged period of fasting, in a group of obese individuals, for whom Disinhibition was strongly correlated with BMI. A greater sensitivity to the fat content and/or texture of the liquid meal was apparent from an increased activity in the insular cortex (a sensory area). However, what the authors regarded as an abnormal brain response could actually be a normal brain response for HD individuals. This brain response could provide at least a partial explanation for the preference for sweet and high fat foods, shown in high Disinhibition individuals. As a result of this higher sensitivity, it is more likely that HD individuals will increase their food consumption and therefore their energy intake within a meal. This notion is supported by evidence which shows HD individuals do have a higher energy intake within meals (e.g. Lawson et al. 1995; Ouwens et al. 2003) and a higher vulnerability towards binging behavior (d'Amore et al. 2001).

70.5.3 Weak Satiation

HD individuals are susceptible to overeating due to experiencing a blunted response during the termination of a meal. A meal is usually terminated by feelings of fullness and reduced, perceived palatability of the food being consumed (alliesthesia: see list of definitions). It has, however, been demonstrated that individuals with a high level of Disinhibition display a blunted alliesthesia response following a meal, as they retain a higher liking and wanting of food, even in a sated state (Bryant 2006). This persistent vulnerability to the hedonic aspects of food, can lead to larger meal sizes and frequent episodes of overeating (e.g. Lawson et al. 1995), which will eventually result in weight gain.

Furthermore, Blundell et al. (2005) demonstrated that individuals who are susceptible to weight gain, and characterized by a high level of Disinhibition, show a weak satiety response to fatty meals and a strong hedonic attraction to palatable foods and to eating per se. This has been confirmed by Barkeling et al. (2007), who also found that obese women, with a high level of Disinhibition, also showed a weak satiety response to a high fat meal. This increases the likelihood of these individuals overconsuming during a meal, and entering positive energy balance.

Furthermore, Disinhibition has been shown to be associated with a metabolic process involved in energy balance. A blunted thermic effect of food (TEF) response has been demonstrated in HD individuals (Lawson et al. 1995). The TEF relates to the energy utilized for the digestion, absorption, and disposal of ingested nutrients. Some authors argue that a blunted TEF is associated with weight gain and obesity (see Granata and Brandon 2002 for a review). More importantly, however, TEF has been suggested to be associated with the satiating effect of food, whereby an increased TEF is associated

Table 70.4 Summary of the influence of Disinhibition during the eating episode

1. HD individuals may have differing levels of, and sensitivity to, appetite-related peptides which influence their control over eating.
2. HD individuals show a heightened response to the fat content of food, which could in part explain their higher energy intake within a meal.
3. HD individuals show a weakened alliesthetic response to food and blunted TEF, which could explain their weakened satiety response, leading to more frequent episodes of overeating.

This table is a summary of the homeostatic and hedonic processes through which Disinhibition influences food intake during an eating episode

with an increased satiation (Crovetti et al. 1997). Therefore, the blunted TEF response shown in high Disinhibition individuals could be related to their experience of a weaker satiety response to a meal (Table 70.4).

70.5.4 Satiety

Following a meal, HD individuals are susceptible to a number of factors which induce the initiation of the next eating episode more swiftly than other individuals. Once a meal has ended, a number of biological signals occur to stop an individual consuming more food until biologically necessary (the satiety cascade). In the postingestive stage, these signals (peptides and neural pathways) promote feelings of fullness and reduce feelings of hunger, whereas in the postabsorptive stage feelings of hunger will begin to return and the perception of fullness will decrease. Evidence indicates, however, that HD individuals have a reduced sensitivity to these signals, making them susceptible to opportunistic eating. Due to the differing levels of satiety peptides found in HD individuals (e.g. Schindler et al. 2004; Levin et al. 2004), a lack of sensitivity to these peptides can be hypothesized. This is particularly highlighted by a study in which obese individuals who reported that their eating episodes were unrelated to fluctuations in hunger and satiety (fullness), were characterized by a high Disinhibition (Barkeling et al. 2007). Eating in the absence of hunger is characteristic of opportunistic eaters, who show a readiness to eat.

The biological expression of Disinhibition is further supported by evidence which suggests that Disinhibition is, to some degree, genetically determined. Estimates of the genetic heritability of Disinhibition do however show large variation with ranges varying from 40%, to 45%, 17.5% and 0% (Steinle et al. 2002; Neale et al. 2003; Provencher et al. 2005; de Castro and Lilenfeld 2005). Authors have also suggested specific chromosomal locations for TFEQ eating behavior traits in proximity to genes encoding for peptides which control eating behavior and body weight. For instance, Bouchard et al. (2004) found four trait loci for Disinhibition and Hunger. A missense polymorphism (p.T73T) was significantly associated with Disinhibition and Hunger but not with Restraint. This variant is associated with body fat, where increased body weight and body fat were seen in individuals homozygous for T73T. On the chromosome areas related to Disinhibition and Hunger, the candidate genes identified were aryl-hydrocarbon receptor nuclear translator 2, which is known to be responsible for a monogenetic form of obesity (Michaud et al. 2000). Also associated was the thyroid hormone associated protein, which is known to modulate energy expenditure (al-Adsani et al. 1997), growth hormones 1 and 2 associated with metabolic syndrome, including abnormal obesity (Perusse et al. 2001) and also neuromedin B which modulates behaviors and food intake in many species (Oeffner et al. 2000; Johnston and Merali 1998).

Table 70.5 Summary of the influence of Disinhibition on satiety

1. HD individuals show a weaker satiety response, which can help to explain their opportunistic eating behavior.

2. HD individuals can continue to eat even in a sated state, leading to a higher energy intake. This can increase the vulnerability of these individuals entering positive energy balance.

3. Evidence suggests that Disinhibition is to some degree inherited and is associated with chromosomal loci in proximity to genes encoding for peptides which influence eating behavior and body weight.

This table provides a summary of the processes which Disinhibition influences food intake and appetite regulation during satiety

In addition, Steinle et al. (2002) have also proposed four regions of suggested linkage for Disinhibition and Hunger in proximity to leptin and plasminogen activator inhibitor (PAI-1) genes. PAI-1 plays a role in coronary heart disease and obese individuals may have higher concentrations along with those who have insulin resistance and type-II diabetes (Ito et al. 1996), whereas leptin exerts anorexigenic effects. Restraint on the other hand, was in proximity to genes encoding for glucagon-like peptide-1 (GLP-1), which is secreted following a meal, and stimulates the release of insulin, lowers blood glucose and decreases food intake (Flint et al. 1998). Therefore, chromosomal linkages for the TFEQ eating behaviors have been observed in proximity to some important genes which encode for peptides which influence eating behavior and body weight and could influence appetite regulation or dysregulation (as displayed in HD individuals). However, further research is required to confirm these genetic associations.

Taken together, the evidence outlined above describes an eating behavior trait, which at high levels leads to an individual to be susceptible to weight gain and overeating, through vulnerabilities in their eating behavior control. These vulnerabilities involve both hedonic and homeostatic processes, and contribute to HD individuals being more susceptible to initiate eating episodes in the absence of any homeostatic drive to eat, and continue to eat, even in a sated state (Tables 70.5 and 70.1).

70.6 Applications to Other Areas of Health and Diseases

Due to the intricate association of Disinhibition with eating behavior and body weight, there are obvious associations with health related issues. Not only has Disinhibition been implicated in weight gain and obesity, which is associated with a poorer physical and psychological health, it is also related to the level of success during weight loss interventions, and within eating disorders. The sections below will address the importance of managing Disinhibition levels within the management of weight and disordered eating.

70.6.1 Weight Loss and Weight Maintenance

There is a large body of evidence detailing the relationship of Disinhibition with weight loss in weight loss treatment programs. These treatment programs tend to look at administering low energy diets, dietary advice, behavioral treatment, and some prescribed physical activity. There is a consensus in the data that over the period of a weight loss regime, reductions in Disinhibition and Hunger and an increase in Restraint are associated with weight loss.

In studies which investigated weight loss with very low calorie diets (VLCD) (Foster et al. 1998; Westerterp-Plantenga et al. 1998; Karlsson et al. 1994; Pekkarinen et al. 1996; Foster et al. 1996;

LaPorte and Stunkard 1990; Wadden et al. 2004), all but one study (La Porte and Stunkard 1990) reported that over the duration of treatment, ranging from 10 to 120 weeks, Disinhibition and Hunger scores decreased, while Restraint scores increased. However, this change was not seen in all participants, for example Westerterp-Plantenga et al. (1998) in their 120 week dietary weight loss intervention, split their sample into successful weight maintenance (<50% of weight loss), partially successful (where <50% loss had occurred once, followed by some weight regain), and unsuccessful (a regain of >50% of weight lost). In the successful weight maintenance group there was a positive relationship between Disinhibition and Restraint and an increase in Restraint score. Whereas in the partially successful group, there was no correlation between Disinhibition and Restraint, yet in the unsuccessful group there was a negative correlation between Disinhibition and Restraint. This demonstrates how the relationship between Disinhibition and Restraint is complex and not always readily related to the success of weight loss and maintenance.

Further studies have explored the role of TFEQ factors in the relationship between a combination of diet and exercise on weight loss (Bjorvell et al. 1994; Clark et al. 1994; Richman et al. 1996; Fogelholm et al. 1999; Cuntz et al. 2001; Kiernan et al. 2001; Chaput et al. 2005). Again, there was a robust finding that following treatment, which ranged from 10 weeks to 1 year, Disinhibition and Hunger scores decreased and Restraint scores increased. Most of these studies also included behavioral therapy in their protocol, aimed at regulating eating behavior (Bjorvell et al. 1994; Clark et al. 1994; Richman et al. 1996; Fogelholm et al. 1999; Cuntz et al. 2001). The main aim of this behavior therapy varied between the studies: while most authors targeted the increase of Restraint, one group included decreasing Disinhibition in their therapy. Cuntz et al. found that Disinhibition could be reduced by enhancing self-control without increasing restrained eating. This was mainly achieved through the reduction of dysfunctional emotional influences on eating behavior, thus endorsing the use of behavioral therapy in obesity treatment, particularly for those with high Disinhibition scores.

Disinhibition has also been associated with weight loss maintenance. Two prospective studies found that individuals who had higher Disinhibition, were not as successful at weight loss, and found that higher Disinhibition was associated with weight regain (McGuire et al. 1999; Carmody et al. 1995). A further two prospective studies have identified that higher baseline Internal Disinhibition scores (a subscale of Disinhibition), are predictive of less successful weight loss and predictive of weight regain (Niemeier et al. 2007). Furthermore, Butryn et al. (2009) found that change in Internal Disinhibition was predictive of weight loss and weight loss maintenance, whereby the greater the decrease in Internal Disinhibition, the greater the loss in weight and the higher success in weight loss maintenance. This clearly shows that management of Disinhibition, particularly Internal Disinhibition, would be beneficial for improving weight loss.

However, recent evidence also suggests that a high Disinhibition level is associated with more successful weight loss (Bryant et al. 2009). Here an exercise only methodology was adopted with no additional behavioral or dietary intervention. Participants expended 500 kcal/day in a supervised exercise intervention for 12 weeks, Disinhibition, and particularly Internal Disinhibition, were found to predict better weight loss. Participants who had a higher baseline Disinhibition and experienced the greatest decrease in Disinhibition and Internal Disinhibition, also showed the greatest weight loss. Low attrition rates and the mandatory exercise sessions could explain why these data contradict previous findings. Therefore, structured and supervised weight loss intervention could benefit HD individuals, which has implications for the subsequent design and implementation of weight loss interventions. It is possible that HD individuals require a higher amount of external motivation and intervention structure to achieve optimal success within a weight loss program.

Furthermore, when weight is managed through gastric surgery (e.g. Karlsson et al. 1998; Burgmer et al. 2005), or through pharmacological treatment (e.g. Lejeune et al. 2003; McElroy et al. 2004; Hainer et al. 2004) a decrease in Disinhibition and Hunger and increase in Restraint scores are

Table 70.6 Summary of the influence of Disinhibition on weight loss:

1. A decrease in Disinhibition and Hunger and an increase in Restraint are seen with successful weight loss (through diet and behavioral interventions and through surgical and pharmacological treatment).

2. Some evidence suggests that a higher Disinhibition is related to less success at weight loss within a structured weight loss intervention.

3. High Disinhibition individuals are more vulnerable to regain weight they have lost following a weight loss intervention.

This table provides a summary of the key points relating to the influence Disinhibition has upon weight loss

observed. This highlights the influential role of these eating behavior traits within a variety of weight management interventions and the importance of considering these traits in relation to one another.

Therefore, two main conclusions can be drawn from these data: primarily Disinhibition scores tend to decrease as weight is lost. Secondly, Disinhibition appears to counteract body weight maintenance following weight loss (when the intervention is not highly structured) and favor weight gain. Further research examining more structured weight control interventions in HD individuals would be highly beneficial (Table 70.6).

70.6.2 Eating Disorders

Several studies have identified a relationship between TFEQ factors, eating disturbance and clinical eating disorders. These studies have tended to focus on Binge Eating Disorder (BED), but associations with bulimia nervosa (BN) have also been found. Disinhibition seems to play a key role in determining the severity of eating disturbances.

The evidence highlights a positive association between in both BED (e.g. Adami et al. 1995) and BN (e.g. Ardovini et al. 1999 see Bryant et al. (2008a, b) for a review) patients with Disinhibition. Perhaps one of the most interesting findings is that Disinhibition is associated with the severity of binge eating episodes (e.g. Ardovini et al.) and with a more problematic psychological health profile, including lower self esteem and higher neuroticism (Brown et al. 2006). Due to the relationship between Disinhibition and disordered eating behavior, it is proposed that the management of Disinhibition would be beneficial within eating disorder treatment.

It is, however, important to note that eating disorder pathology is also related to a (very) high Restraint score. Of particular interest is that evidence suggests the combination of a concurrent high Disinhibition and a high Restraint level, appears to dysregulate eating control in clinical (eating disordered) and nonclinical individuals. The conflict between the ardor to restrain intake (high Restraint) and the desire to eat (high Disinhibition), can lead to a cyclical pattern of food restriction and overeating. It is suggested, therefore, that a high Disinhibition (particularly when coupled with a high Restraint) could be used as a way to identify those who will be susceptible to disturbed eating behaviors and express high eating disorder symptomatology. Indeed, in a nonclinical sample of women a HDHR has been found to be associated with a higher vulnerability towards disturbed eating behavior (Lawson et al. 1995; Bryant et al. 2010). Furthermore, in a clinical sample, those with a HDHR have been shown to exhibit higher eating disorder pathology (Bryant 2006).

This evidence suggests that Disinhibition not only has the potential to be used as a psychomarker to predict for those more susceptible to disturbed eating behavior, but also that management of the Disinhibition trait could be utilized within eating disorder treatment to reduce disorder symptomatology and possibly to reduce relapse (Table 70.7).

Table 70.7 Summary of the influence of Disinhibition on eating disorder

1. A combination of a high Disinhibition and a high Restraint is related to eating disorder severity in a clinical sample and with eating disturbance in a nonclinical sample.

2. High levels of Disinhibition are associated with both BED and BN.

3. Management of Disinhibition levels could help to improve success within eating disorder treatment.

This table provides a summary of the key points of the influence Disinhibition has eating disorders

Table 70.8 Key points about Disinhibition

Key points

1. Disinhibition is a pervasive and dynamic eating behavior trait which influences an individual's body weight, food choice, and lifestyle choices.

2. The evidence suggests that high Disinhibition individuals are susceptible to a number of homeostatic and hedonic factors which facilitate a dysregulated appetite system. These influences exert their influence before, during and after a meal.

3. Evidence suggests high Disinhibition negatively impacts on weight loss in response to interventions and is associated with weight regain following weight loss. Therefore, Disinhibition management and intervention structure are important for optimum weight loss in this group of individuals.

4. Individuals with a high Disinhibition have a higher preference and intake of foods in general, but particularly high fat and sweet foods.

5. Disinhibition is related to disturbed eating behavior and eating disorders (e.g. BN and BED). High levels of Disinhibition are related to the severity of eating disorder pathology (e.g. binging severity).

6. Disinhibition does not act independently; a concurrent high level of other eating behavior traits (e.g., Restraint), moderate its influence. HDHR is associated with a more problematic eating behavior, higher levels of smoking, alcohol consumption and higher neuroticism. Whereas HDLR is associated with a higher body weight and increased sedentary behavior.

This table outlines the key messages within this chapter, including how trait Disinhibition is expressed, how Disinhibition is associated with other eating behavior issues such as eating disorders and food choice, and how Disinhibition influences weight loss

70.6.3 General Health

High levels of Disinhibition have been related to lower levels of general health, poor health behaviors (such as higher smoking rates and levels of alcohol consumption; Bryant et al. 2010), and adverse psychological symptoms (Kensinger et al. 1998). Cross-sectional studies have revealed that high levels of Disinhibition were associated with a lower health related quality of life (Marchesini et al. 2000), including a higher incidence of diseases associated with the metabolic syndrome (Hainer et al. 2006), whereby some of these associations have been shown to be independent of weight status (Hays et al. 2002b). Furthermore, high levels of Disinhibition have been found to be detrimental to glycaemic control in Type I and II diabetic patients (Balfour et al. 1993; Straub et al. 1996). It is probable that the opportunistic eating pattern and less healthy food choices of HD individuals can exacerbate any problems with maintaining glycaemic control in these individuals.

Thus it can be surmised that the association of high Disinhibition with lower levels of physical health could in part be due to their lower levels of physical activity, poorer quality diet, and higher adiposity. It is therefore apparent that trait Disinhibition is a pervasive trait, which not only influences eating behavior but has an overarching influence on the person as a whole (Table 70.8).

Summary

- Disinhibition is an influential, pervasive and dynamic eating behavior trait which exerts its influence to effect body weight, eating episode initiation, satiation and satiety.
- The mechanisms through which Disinhibition exerts its influence are both homeostatic and hedonic and serve to dysregulate an individual's eating pattern.
- Individuals with a high Disinhibition are characterized by a set of psychological and physiological traits which predispose that individual towards opportunistic eating, eating in response to negative affect (as opposed to physiological satiety signals), frequent eating episodes and overeating, and having a high preference and intake of high fat and sweet foods. All these factors can lead

---

Key Definitions

Alliesthesia: When an individual's ratings of an object (e.g., food) are sometimes pleasant, sometimes unpleasant, depending upon their internal state (e.g. being in a hungry or in a sated state).

Food cue: Any type of food associated signal can be considered as a food cue. For example, a food advertisement, the sight and/or smell of food (e.g., in a bakery or cafeteria), or simply talking about food.

Obesigenic: An environment which facilitates sedentary behavior and overconsumption due to the availability of energy dense foods. In essence, one which promotes a positive energy balance.

Negative affect: Experience of negative emotions (e.g., feeling low, or experiencing stress).

Satiety cascade: A model which summarizes the biopsychology of appetite regulation. It incorporates psychological, physiological, and neuronal elements of appetite control.

Satiation: Intrameal satiety. A point within a meal when an individual begins to experience feelings of fullness and less hunger, leading to the cessation of the eating episode.

Satiety: Postngestive satiety. The time interval in between eating episodes.

Taste test: An experimental procedure whereby participants rate the food for pleasantness and palatability; for example, when the primary focus is the amount of food being consumed. Usually, taste tests are carried out following a manipulation of mood, or following consumption of a preload, for instance.

---

an individual to be susceptible to weight gain, weight regain following weight loss, poor general health, and disturbed eating behavior.
- Disinhibition does not act in isolation; the levels of the other TFEQ factors moderate the influence of Disinhibition upon eating behavior and body weight. For instance, evidence highlighted how when a level of high Disinhibition was coupled with a high Restraint score, a problematic eating behavior profile was apparent (Bryant et al. 2010; Lawson et al. 1995), together with a higher alcohol consumption and a higher smoking rate (Bryant et al. 2010).
- When a high Disinhibition score was coupled with a low Restraint score, a higher sedentary behavior pattern emerged, alongside a higher susceptibility to weight gain (Bryant et al. 2010; Lawson et al. 1995).

- The utilization of strategies to manage high Disinhibition levels in weight management and eating disorder programmes, could prove to be useful in increasing their level of success.

Chapter 71
The Effects of Exercise on Appetite Control

Catia Martins, Denise Robertson, and Linda Morgan

Abbreviations

EB	Energy balance
EI	Energy intake
REI	Relative energy intake
EE	Energy expenditure
CCK	Cholecystokinin
TG	Total ghrelin
AC	Acylated ghrelin
DG	Desacyl ghrelin
PYY	Polypeptide YY
GLP-1	Glucagon-like peptide-1
PP	Pancreatic polypeptide
PA	Physical activity
AUC	Area under the curve
HEP	High-energy preload
LEP	Low-energy preload
VO_2max	Maximal oxygen consumption

71.1 Introduction

Obesity is a global epidemic with huge public health implications (World Health Organization 2006). Despite its complex etiology, it is widely accepted that obesity results from a state of long-term positive energy balance (EB), with energy intake (EI) exceeding energy expenditure (EE) (World Health Organization 2003). It has been suggested that a large reduction in PA levels, driven by dramatic changes in lifestyle, together with an inability of the organism to downregulate EI to a similar extent to match the reduced EE, are the dominant factors in promoting obesity in industrialized countries (Moore 2000). This uncoupling between EI and EE is likely to result from a breakdown in the normal mechanisms that regulate appetite and eating behavior.

Appetite is under the control of the brain, together with multiple hormonal and metabolic signals released by the periphery. The hypothalamus, in particular the arcuate nucleus, is constantly receiving and processing neural, metabolic, and endocrine signals from the periphery, enabling it to maintain energy homoeostasis by adjusting not only EI but also EE. Two types of peripheral signals can be described: firstly, episodic signals, which are periodically released, mainly from the gastrointestinal tract, in response to feeding or fasting, signaling the acute nutritional state; secondly, tonic signals, which are constantly released, mainly by the adipose tissue, in proportion to the amount of stored lipids, signaling the chronic nutritional state (Blundell 2006). To the first category of peripheral gastrointestinal signals belongs ghrelin, an orexigenic hormone released in response to fasting, and several satiety hormones such as glucagon-like peptide-1 (GLP-1), polypeptide YY (PYY), and pancreatic polypeptide (PP), which are released in response to feeding. The second category of peripheral signals includes leptin, released mainly by the adipose tissue, and insulin, released by the pancreas, whose secretion is directly proportional to the amount of body fat.

Apart from the potential for physical inactivity to deregulate the appetite-regulatory system, thus contributing to positive EB and obesity, it is also important to understand how exercise impacts on appetite control. When individuals start an exercise program, weight loss is neither inevitable nor consistent (King et al. 2008). This is probably related to the fact that in some individuals exercise upregulates hunger and food intake thus offsetting any beneficial impact exercise might have on EB (King et al. 2008). It is likely that the impact of exercise on EB and body weight is mediated through changes in the plasma levels of appetite-regulating hormones. In the face of current widespread levels of physical inactivity (Varo et al. 2003), it is extremely important to determine how both inactivity and exercise (short- and long-term) impact on appetite control. A better understanding of the role of exercise on appetite control will lead to more effective ways of incorporating exercise into weight management programs.

71.2 Effects of Exercise on the Coupling Between EI/EE and Energy Compensation

The impact of physical activity (PA) on the coupling between EI and EE has been extensively studied. EI and energy requirements seem to be very well coupled, but only for moderate-to-high levels of PA. At low levels of PA, however, EI and EE are uncoupled, so that a reduction in EE is not followed by a proportional reduction in EI, leading to a net positive EB and weight gain (Mayer et al. 1956). This clearly suggests first, that inactivity is linked to a disruption of the homeostatic mechanisms involved in appetite control and, second, that exercise has the ability to "fine tune" those physiological mechanisms. More recently, it has been shown that the adoption of a sedentary lifestyle is not followed, at least in the short- to medium-term, by a compensatory decrease in EI, with consequent positive EB (Murgatroyd et al. 1999; Stubbs et al. 2004).

Interestingly, inactivity seems to impair not only the coupling between EI and EE (as described above), but also short-term appetite control, usually described as "energy compensation." If this process is not tightly regulated it can lead to energy imbalance in the long-term. Energy compensation is measured using the "preload test meal paradigm." This paradigm has been systematically used in appetite research and consists of manipulating the energy content of a preload in order to alter EB and then investigating the homeostatic feedback control of appetite by measuring EI later on with an ad libitum test meal.

Cross-sectional studies have shown better accuracy in energy compensation in active versus sedentary normal-weight individuals, both acutely at a test meal (Long et al. 2002) and over the course of a day (van Walleghen et al. 2007). Whilst sedentary individuals are unable to adjust subsequent EI in response to preload energy manipulation, active individuals significantly decrease their EI following a high-energy preload (HEP) compared with after a low-energy preload (LEP) (Long et al. 2002; van Walleghen et al. 2007). These studies suggest that exercise improves short-term appetite control by leading to a more sensitive eating behavior in response to previous EI. Moreover, we have recently shown that a 6-week exercise program improves the sensitivity of compensation in response to previous EI, over a 24-h period, in normal-weight individuals (Martins et al. 2007b). Similar findings have been more recently observed after a 12-week exercise intervention in overweight/obese individuals (Fig. 71.1) (C. Martins, B. Kulseng, N.A. King, and J.E. Blundell, unpublished results).

The improvement in energy compensation observed in response to exercise is likely to result from changes at the level of the appetite regulatory system, in particular episodic signals released by the gastrointestinal tract in response to feeding. It can be hypothesized that, in a sedentary individual, there are no differences in the postprandial release of anorexigenic peptides (such as PYY and GLP-1) and/or suppression of orexigenic peptides (ghrelin) after high- and low-energy preloads (denoting an abnormal response), whereas after an exercise intervention the postprandial release of appetite hormones is sensitive to the energy content of the preload, resulting in an improved compensatory response. Although this is just hypothetical and research in this area is lacking, a large body of evidence has been accumulating regarding the impact of exercise on appetite regulating hormones.
Fig. 71.1 Effects of chronic exercise on energy compensation in overweight/obese individuals. Cumulative energy intake (EI) (kcal), for the rest of the day, after a high- (HEP) and low-energy preload (LEP), at baseline and end of a 12-week exercise intervention in all individuals ($n = 15$), men ($n = 8$), and women ($n = 7$) (C. Martins, B. Kulseng, N.A. King, and J.E. Blundell, unpublished results). Results are expressed as mean ± SEM. A 2-way ANOVA showed a significant effect of gender ($P < 0.01$) and an exercise*preload interaction ($P = 0.011$), but no effects of exercise, preload or other interactions. Histograms sharing the same symbol denote a trend towards significant differences between conditions: *$P = 0.030$, §$P = 0.047$. In men, ANOVA revealed also a significant exercise*preload interaction ($P = 0.027$), but no effect of preload or exercise. In woman no significant effects or interactions were observed on cumulative EI

71.3 Effects of Exercise on Appetite-Regulating Hormones

The impact of both acute and chronic exercise, on circulating levels of hormones involved in appetite control is an area that has received considerable attention over the last decades, particularly with respect to leptin and ghrelin.

71.3.1 Effects of Exercise on Leptin Plasma Levels

The effects of exercise on leptin plasma levels were extensively discussed in a review by Kraemer and collaborators (2002). They concluded that, in the absence of weight loss, no significant changes on fasting leptin plasma levels are observed in response to exercise (Kraemer et al. 2002). However, a significant reduction in plasma leptin levels was reported after an intense, prolonged exercise period (25 km swimming race) in highly trained individuals (Karamouzis et al. 2002) and also after a 1-year exercise intervention, even after adjusting for BMI and fat mass (Reseland et al. 2001). However, in the study where participants underwent a 25 km swimming race (Karamouzis et al. 2002), a huge negative EB was imposed and the subjects were not in a fasting state, therefore allowing the release of insulin, which is known to exert a negative feedback over leptin secretion. It has been proposed that an exercise intervention that improves insulin sensitivity would have the ability to alter leptin levels independently of any changes in fat mass, due to changes in insulin and cortisol levels, known modulators of leptin secretion (Considine 1997).

   Although acute exercise, when performed in the fed state, does not seem to impact on leptin plasma levels in normal weight individuals (Zoladz et al. 2005), extreme exercise (until exhaustion) in healthy normal-weight men was reported to significantly increase plasma leptin concentrations (Sliwowski et al. 2001).

71.3.2 Effects of Exercise on Gut Peptides

71.3.2.1 Acute Exercise

Effects of Acute Exercise on Ghrelin Plasma Levels

The majority of the studies show that total ghrelin (TG) plasma levels are unaffected by a single exercise session regardless of the exercise mode (running vs. cycling), intensity (50%, 70%, and 90% VO_2max), or metabolic state (fasting or postprandial) in normal-weight individuals (Dall et al. 2002; Kraemer et al. 2004a; Martins et al. 2007; Schmidt et al. 2004; Zoladz et al. 2005). There are a few studies, however, that report either a reduction or an increase in TG plasma levels in response to acute exercise. TG has been shown to be reduced for up to 2 h after the end of a maximal exercise test till exhaustion (Vestergaard et al. 2007), immediately and 15 min after moderate (80% maximal) resistance exercise with concentric, but not eccentric muscle contractions (Kraemer et al. 2004b), and immediately after a single bout of circuit resistance exercise (at 60% 1-RM) (Ghanbari-Niaki 2006). However, none of the three studies had a resting/control condition. In a study by Malkova and collaborators (2008), despite there being no difference in TG plasma levels between an exercise (cycling at 90% of the lactate threshold for a duration required to expend 200 kcal) and a control condition, when a meal was served 2 h after the end of exercise, postprandial TG plasma levels were

significantly lower after exercise compared with the control condition (Malkova et al. 2008). Moreover, several studies have reported an increase in TG in response to acute maximal exercise (6,000-m rowing ergometer test ~19 min) (Jürimäe et al. 2007), and prolonged moderate- to high-intensity rowing (~20 km/2 h) (Jürimäe et al. 2009), and cycling (3 h at 50% maximal aerobic power) (Christ et al. 2006) in elite athletes.

The above studies showing an increase in TG plasma levels in response to exercise have all been performed in elite athletes and involved high intensity and/or prolonged endurance training resulting in a large overall energy deficit (Christ et al. 2006; Jürimäe et al. 2007, 2009; Malkova et al. 2008). Studies that have not found any effect of acute exercise on TG plasma levels have included more sedentary individuals and employed exercise protocols using fewer muscle groups for shorter periods of time (Dall et al. 2002; Kraemer et al. 2004a; Martins et al. 2007; Schmidt et al. 2004; Zoladz et al. 2005) resulting, therefore, in limited negative EB. This suggests that changes in EB may drive the TG response; the TG concentration following exercise is therefore a direct result of exercise-induced EE and a threshold of energy imbalance may be needed for acute exercise to induce a compensatory increase in TG plasma levels. This is supported by the fact that TG plasma levels immediately after exercise were positively correlated with rowing distance during a 2-h training session (Jürimäe et al. 2009) and by the fact that when exercise is performed in EB (by upregulating food intake) no significant impact on fasting TG is observed (Hagobian et al. 2008).

Acylation of ghrelin is thought to be essential for ghrelin to bind to the growth hormone-secretagogue receptor and cross the blood–brain barrier and, therefore, to exert its effects on appetite control. For this reason, the isolated measurement of TG can mask important changes in AG. To date, relatively few studies have looked at the impact of acute exercise on AG plasma levels. One study investigated the impact of 1 h of vigorous treadmill running followed by 8 h of rest (exercise condition), performed in the fasting state, on the plasma levels of AG for a period of 9 h (with a meal being presented 3 h after the start of each trial) in normal-weight active men. The authors described a significant suppression in AG in the exercise compared with the control condition, which was sustained for up to 8 h after the end of the exercise session. Moreover, these suppressed levels of AG were shown to be correlated with suppressed hunger during the first 3 h of the exercise trial (Broom et al. 2007). A recent study by Broom and colleagues (2009) investigated the effects of resistance (90 min weight lifting session followed by 6.5 h rest) and aerobic (60 min run followed by 7 h rest) exercise (compared with a control condition of 8 h rest) performed in fasting, on hunger feelings and circulating levels of AG and PYY. Participants were fed a test meal 2 and 5 h into each trial. They reported a significant suppression of hunger during and shortly after resistance and aerobic exercise, a suppression of AG during resistance and aerobic exercise and a significant increased in PYY plasma levels during and after aerobic exercise (Broom et al. 2009). Moreover, a recent study showed that a cycling test to exhaustion suppressed AG plasma levels but did not affect TG, both in normal-weight and obese individuals, despite the latter achieving a lower exercise output and performance. The authors concluded that acute exercise has no impact on TG but suppresses AG plasma levels independently of adiposity and exercise performance (Marzullo et al. 2008). These studies suggest, not only that AG responds differently to acute exercise compared with TG, but also that AG may play a role in the suppression of appetite observed during and shortly after moderate- to high-intensity aerobic and resistance exercise, a phenomenon known as "exercise-induced anorexia."

Effects of Acute Exercise on Satiety Gut Peptides Plasma Levels

In contrast to the large number of studies investigating the impact of acute exercise on the orexigenic hormone ghrelin, only a few have looked at the effects of acute exercise on anorexigenic (satiety)

hormones, such as PYY, GLP-1, cholecystokinin (CCK), and PP, and the majority has been performed in normal-weight individuals (Table 71.1). The available evidence suggests that acute exercise increases fasting plasma levels of GLP-1 (O'Connor et al. 1995) and fasting and postprandial levels of CCK (Bailey et al. 2001; Sliwowski et al. 2001) and PP (Greenberg et al. 1986; O'Connor et al. 1995; Sliwowski et al. 2001; Sullivan et al. 1984). However, appetite was not the primary outcome in any of the previous studies and, therefore, appetite sensations and food intake in the postexercise period were not recorded.

We have recently investigated the effects of acute exercise on postprandial plasma levels of TG, PYY, GLP-1, and PP in normal-weight individuals. Participants were given a 500 kcal breakfast and 1 h later, cycled for 60 min, at 65% of their maximal heart rate or rested. A significant increase in postprandial plasma levels of PYY, GLP-1, and PP were observed, in the absence of significant changes in TG, suggesting that exercise triggers physiological changes in hormone secretion toward a more satiating state (Martins et al. 2007a).

All the studies previously described were run in normal-weight individuals. A recent study by Ueda and colleagues (2009) showed that exercise, performed 1 h after breakfast, lead to a significant transient increase in PYY and a significant sustained increase in GLP-1 plasma levels, compared

Table 71.1 Studies looking at the effect of acute exercise on satiety gut peptides

References	Subjects	Intervention	Outcome[a]
Hilsted et al. (1980)	Healthy men	Three hours of exercise (cycle ergometer) at 40% of VO_2max vs. resting	Sig.↑ in fasting PP plasma levels

Greenberg et al. (1986)	Nonobese healthy men and women	Forty-five min of exercise (cycle ergometer) at 50% VO_2max, 30 min after a 425 kcal breakfast vs. resting	Significant increase in postprandial plasma levels of PP
O'Connor et al. (1995)	Athletes (men and women)	Marathon running	Sig. ↑ in fasting GLP-1 and PP plasma levels
Bailey et al. (2001)	Physically active normal-weight men	Cycling test to exhaustion vs. resting	Sig. ↑ in fasting CCK plasma levels
Martins et al. (2007a)	Normal-weight men and women	Sixty minutes of exercise (cycle ergometer) at 65% max HR, 1 h after a 500 kcal breakfast vs. resting	Sig. ↑ in PYY, GLP-1 and PP plasma levels
Broom et al. (2009)	Physically active normal-weight men	Resistance exercise (90 min weight lifting) vs. aerobic exercise (60 min at 70% VO_2max) vs. resting (performed in fasting)	Sig. ↑ in PYY plasma levels during aerobic exercise
Ueda et al. (2009)	Normal-weight and obese men	Exercise (60 min at 50% VO_2max) performed 1 h after breakfast vs. resting	Sig. ↑ in PYY and GLP-1 plasma levels in both groups

The majority of the studies show that acute exercise increases the release of satiety gut peptides

Sig. significant, ↑ increase, ↓ reduction, *CCK* cholecystokinin, *PP* pancreatic polypeptide, *PYY* polypeptide YY, *GLP-1* glucose like peptide-1, *VO_2max* maximal oxygen uptake, *HR* heart rate

[a]In comparison with a control (resting) condition

with a resting condition, but no changes in TG, both in normal-weight and obese men (with no differences between groups). This pattern is identical to the findings previously reported by us in a mixed sample of normal-weight men and women (Martins et al. 2007a). For an overview on the effects of acute exercise on the plasma levels of hormones involved in appetite control, in both normal-weight and overweight/obese individuals, see Table 71.2.

Overall, the majority of the evidence suggests that acute exercise has a beneficial impact on the appetite regulatory system by increasing the release of satiety gut peptides and reducing the secretion of AG (Fig. 71.2).

71.3.2.2 Chronic Exercise

Studies on the impact of chronic exercise on appetite-regulating hormones are summarized in Table 71.3.

Table 71.2 Effects of acute exercise on appetite-regulating hormones in normal-weight and overweight/obese individuals

Gut hormones	Normal-weight	Overweight/obese
– TG	No change	NA
– AG	↓	NA
– GLP-1	↑ (fasting, postprandial)	↑ (postprandial)
– PYY	↑ (fasting, postprandial)	↑ (postprandial)
– PP	↑ (fasting and postprandial levels)	NA
– CCK	↑ (fasting)	NA

Acute exercise seems to have a neutral or negative impact (reduction) on hunger hormones (TG and AG) and a positive impact (increase) on satiety hormones (GLP_1, PYY, PP, and CCK)

NA not available, ↑ increase, ↓ reduction, *TG* total ghrelin, *AG* acylated ghrelin, *GLP-1* glucose like peptide-1, *PYY* polypeptide *YY*, *PP* pancreatic polypeptide, *CCK* cholecystokinin
Fig. 71.2 Effects of acute exercise on appetite-regulating hormones. Acute exercise has a beneficial impact on the appetite regulatory system by reducing the secretion of hunger hormones and increasing the secretion of satiety hormones. This, if sustained, can lead to negative EB in the long-term. *TG* total ghrelin, *AG* acylated ghrelin, *PYY* polypeptide YY, *GLP-1* glucagon like peptide-1, *PP* polypeptide YY, *EI* energy intake, *REI* relative energy intake, *EB* energy balance, ↑ increase, ↓ decrease, ↔ no change

Table 71.3 Studies looking at the effect of chronic exercise on appetite-regulating hormones

References	Subjects	Intervention	Outcome
Medium-term studies			
Mackelvie et al. (2007)	Normal-weight (NW) and overweight (OW) male adolescents	Five consecutive days of aerobic exercise (1 h/day)	No sig. change in body weight. No sig. change in fasting/postprandial TG or DG, but a sig. ↑ in fasting AG and postprandial AG AUC. The ↑ in fasting AG was sig. higher in NW compared with OW. DG AUC ↓ in NW but ↑ in OW
Chanoine et al. (2008)	Normal-weight and overweight male adolescents	Five consecutive days of aerobic exercise (1 h/day)	No sig. change in body weight. No sig. change in fasting GLP-1 plasma levels, but a sig. ↑ in GLP-1 response in the first 30 min postprandially, in both groups
Long-term studies (>2 weeks)			
Hurley et al. (1991)	Sedentary normal-weight men	Ten-week jogging program (20 min at 70% VO_2max, three times/week)	No sig. change in body weight, but sig. ↓ in % body fat. Slight ↑ in fasting and postprandial peak PP plasma levels
Bailey et al. (2001)	Physically active Normal-weight men	Four-week cycling program (three times/week with incremental duration and	No sig. change in body weight. No sig. change in fasting CCK plasma levels
Ravussin et al. (2001)	Seven pairs of monozygotic male twins (borderline overweigh)	Ninety-three days of exercise in a residential facility inducing a 53,000 kcal energy deficit	Sig. weight loss (average 5 kg). Trend toward an ↑ in fasting TG plasma levels
Leidy et al. (2004)	Normal-weight women	Three-month exercise intervention (five times/week) in negative EB or in EB (by providing extra calories to maintain body weight) vs. a control condition	Sig. ↑ in TG plasma levels in weight-loss exercisers (negative EB group – average weight loss 3.2 kg), but no difference in weight stable exercisers (EB group) or controls. Positive correlation between changes in TG and weight loss

Foster-Schubert et al. (2005)	Obese postmenopausal women	One-year exercise intervention (in the absence of dietary changes)	Sig. weight loss (average 1.4 kg) Sig. ↑ in fasting TG (positively correlated with weight loss)
Kim et al. (2008)	Overweight 11-year old boys	Twelve-week supervised exercise program (aerobic and resistance training, without energy restriction) vs. a control condition	Sig. ↓ in body weight (average 2 kg) compared with control No sig. change in fasting AG, but ↑ in DG and TG Weight loss was associated with increased DG
Jones et al. (in press)	Overweight sedentary adolescents	Eight months supervised exercise intervention (45 min, three times/week between 60–85% VO$_2$max)	No sig. change in body weight, but a sig. ↓ in % body fat Sig. ↑ in fasting PYY plasma levels No sig. change in fasting AG

Chronic exercise does not seem to have an independent effect on TG plasma levels, but exercise-induced weight loss may result in a compensatory increase in TG plasma levels. The impact of chronic exercise on AG seems to be dependent on body weight and a larger increase can be expected in normal-weight individuals. The few available studies on the impact of chronic exercise on satiety peptides seem to suggest an increase in their secretion

Sig. significant, ↑ increase, ↓ reduction, *TG* total ghrelin, *AG* acylated ghrelin, *DG* des-acyl ghrelin, *EI* energy intake, *EB* energy balance, *PP* pancreatic polypeptide, *PYY* polypeptide YY, *GLP-1* glucose like peptide-1, *VO₂max* maximal oxygen uptake, *NW* normal weight, *OW* overweight

Effects of Chronic Exercise on Ghrelin Plasma Levels

The effects of chronic exercise on TG plasma levels have been extensively studied. Foster-Schubert and colleagues (2005) showed that a 1-year exercise intervention (in the absence of dietary changes), leading to an average weight loss of 1.4 kg, resulted in a significant increase in fasting TG in obese postmenopausal women (Foster-Schubert et al. 2005). Moreover, they reported that the increase in fasting TG plasma levels was positively correlated with weight loss and that physical fitness per se did not appear to have an independent effect on TG independently of its impact on body weight. Ravussin and colleagues (2001), in a very elegant study, reported a trend toward an increase in fasting TG plasma levels after exercise-induced weight loss (average 5 kg) (Ravussin et al. 2001). This study was run under extremely controlled conditions in a research facility over a 93-day period where food intake was held constant and monitored over time and a 53.000 kcal energy deficit was induced through supervised exercise. The small sample size (seven pairs of borderline overweight monozygotic twins) may have prevented the detection of a significant change in TG in this study. In another well designed study, Leidy and colleagues (2004) compared the TG responses to a 3-month exercise intervention in normal-weight individuals, where participants were either in negative EB (by providing fewer calories than required to maintain body weight) or in EB (by providing extra calories to maintain body weight) versus a control condition. They reported a significant increase in TG plasma levels in the weight-loss exercisers (average weight loss of 3.2 kg), but no difference in the weight-stable exercisers or controls, and a significant positive correlation between changes in TG and changes in body weight (Leidy et al. 2004). Interestingly, they also reported that changes in body weight preceded changes in TG plasma levels. The above studies indicate first, that exercise does not have an independent effect on TG plasma levels in the absence of weight loss and second, that exercise-induced weight loss results in a compensatory increase in TG plasma levels, in both normal-weight and overweight/obese individuals, in order to up-regulate hunger and food intake and, therefore, restore EB.

However, changes in TG plasma levels in response to exercise provide limited information as to whether exercise leads to a stimulation or inhibition of appetite and food intake. Although desacyl ghrelin (DG) has traditionally been seen as devoid of any endocrine activities, recent studies suggest that the effects of ghrelin on EB are mediated through both AG and DG and that the latter induces a negative EB by reducing food intake and delaying gastric emptying in an inverse manner to AG (Soares and Leite-Moreira 2008). Therefore, the overall impact of exercise on appetite should be ascertained not only by changes in TG, but by relative changes in its components (AG and DG). Mackelvie and colleagues (2005) measured the impact of 5 days of supervised aerobic exercise on TG, AG, and DG plasma levels, in normal-weight and overweight male adolescents. They reported no change in TG or DG plasma levels, but a significant increase in fasting and postprandial AG and a positive correlation between changes in AG and markers of subjective appetite (Mackelvie et al. 2007). However, several interactions were reported so that the increase in AG observed with exercise was higher in the normal-weight group, both in fasting and postprandially, and exercise was associated with a decrease in postprandial DG in normal-weight, but an increase in overweight adolescents (Mackelvie et al. 2007). These preliminary results seems to suggest that the impact of chronic exercise on AG is body-weight dependent and that a larger increase may be expected in normal-weight, compared with overweight/obese individuals, in order to quickly restore EB and avoid weight loss.

Although the previous study suggests a limited effectiveness of exercise in inducing a sustained negative EB, particularly in the normal-weight group, since associated with an increase in AG plasma levels, it is limited by its short duration and the fact that EI was not controlled. A recent paper examined the impact of a 12-week supervised exercise program (without energy restriction), versus a control condition, on TG, AG, and DG in overweight children. The authors reported a significant

weight loss, no change in fasting AG plasma levels, but a significant increase in fasting TG and DG plasma levels after the exercise intervention (Kim et al. 2008). Based on the available evidence (Kim et al. 2008; Mackelvie et al. 2007) it can be hypothesized that as exercise duration increases, its impact on EB becomes more favorable by increasing DG without changing AG, thus creating an appetite inhibitory state which favors weight loss.

More importantly, weight loss in response to exercise was shown to be correlated not only with changes in TG but also with DG (much strongly and with higher significance level) and the increase in TG and DG observed after 12 weeks of exercise was also preceded by weight loss (Kim et al. 2008). This new evidence suggests that the increase in TG plasma levels reported by previous studies in response to exercise-induced weight loss (Foster-Schubert et al. 2005; Leidy et al. 2004) does not necessarily mean an increase in AG and is likely to reflect instead an increase in DG. Although more studies are needed in this area, the increase in TG reported after exercise-induced weight loss is unlikely to be part of a counter-regulatory mechanism to restore EB, particularly because chronic exercise has also been shown to increase the release of satiety peptides (see Section 71.3.2.2.2). In fact, the changes in appetite-regulating hormones following exercise are likely to, not only help in weight loss by inhibiting hunger/increasing satiety, but more importantly (since weight loss seems to precede the increase in DG) (Kim et al. 2008) prevent weight regain.

This argument is supported by the fact that high levels of PA have been shown to be a stronger predictor of long-term weight loss maintenance compared with dietary restriction (Catenacci et al. 2008), probably because diet-induced weight loss leads to counter-regulatory adaptations at the level of the appetite regulatory system which ultimately stimulate appetite and food intake (Doucet and Cameron 2007), which does not seem to occur is response to exercise. We propose that the critical role of exercise on long-term weight loss maintenance can, in fact, be attributed to an improved appetite control.

Effects of Chronic Exercise on Satiety Gut Peptides Plasma Levels

Evidence regarding the impact of chronic exercise on the plasma levels of satiety-gut peptides is relatively scarce. One study showed no change in fasting CCK plasma levels after a 4-week exercise program in active men (Bailey et al. 2001) and other a slight increase in both fasting and postprandial peak PP plasma levels, in previously sedentary men, after a 10-week exercise intervention (in the absence of weight loss) (Hurley et al. 1991). A recent study in normal-weight and overweight male adolescents measured fasting and postprandial GLP-1 plasma levels in response to five consecutive days of exercise (1 h/day). They reported no change in fasting GLP-1 but a significant increase in GLP-1 response in the first 30 min postprandially, independently of the weight group (Chanoine et al. 2008). Another recent investigation in overweight adolescents showed that an 8-month supervised exercise intervention (45 min, three times/week, between 60–85% VO_2max), in the absence of dietary restriction, increased fasting PYY plasma levels, and had no impact on AG. A significant reduction in fat mass (%) was observed with the exercise program, but no significant changes in body weight (Jones et al. 2009).

For an overview on the effects of chronic exercise, with and without weight loss, on the plasma levels of hormones involved in appetite control, see Table 71.4.

Overall, the available evidence seems to suggest that chronic exercise leads to changes in appetite-regulating hormones toward an appetite-inhibited state (Fig. 71.3). Unfortunately, no long-term studies have looked at the impact of exercise on the postprandial release of satiety-gut-peptides and how changes in these hormones correlate with changes in food intake and weight loss. More research is urgently needed in this area.

Table 71.4 Effects of chronic exercise, with or without weight loss, on appetite-regulating hormones

Gut hormones	Exercise with weight loss	Exercise without weight loss
– TG	↑ (fasting)	↔
– AG	↔ (fasting)	↑ (fasting and postprandial)[a]; ↔
– DG	↑ (fasting)	↓ in NW, ↑ in OW
– GLP-1	NA	↑ (postprandial)[b]
– PYY	NA	↑ (fasting)
– PP	NA	↑ (fasting and postprandial)

Chronic exercise alone increases TG but does not impact on AG. Chronic exercise with weight loss has no impact on TG, but may increase AG, and increases the release of satiety hormones (GLP-1, PYY, and PP)

NA not available, ↑ increase, ↓ reduction, ↔ no change, *NW* normal-weight, *OW* overweight

[a]Larger ↑ in NW compared with OW

[b]In the first 30 min postprandially
Fig. 71.3 Effects of chronic exercise on appetite-regulating hormones. Chronic exercise leads to changes in appetite-regulating hormones towards an appetite inhibited state. This can help to create a negative EB and, in the long-term, weight loss. *TG* total ghrelin, *AG* acylated ghrelin, *PYY* polypeptide YY, *GLP-1* glucagon like peptide-1, *PP* polypeptide YY, *EI* energy intake, *REI* relative energy intake, *EB* energy balance, ↑ increase, ↓ decrease, ↔ no change

71.3.3 Gender Differences in the Effects of Exercise on Appetite-Regulating Hormones

Several studies have suggested that gender may modulate the impact of exercise on the release of appetite regulating hormones. A training session consisting of 60–90 min of exercise at 80% VO_2max was reported to induce a significant reduction in TG plasma levels in male, but not female athletes (Sartorio et al. 2008). Although this study only measured TG (and not AG) and subjective feelings of appetite were not recorded, the suppression of TG during exercise in men, but not in women, can help to explain why the phenomenon of "exercise induced anorexia" is usually only experienced by men (Martins et al. 2008). More recently, Hagobian and colleagues (2009), using a crossover design, allocated overweight and obese men and women to three trials: (1) no exercise with subjects in EB, (2) 4 days of daily exercise with energy added to the baseline diet to maintain EB (EEB), and (3) 4 days of daily exercise without added energy to induce energy deficit (EED). In men, AG AUC was

not different between trials. In women, AG AUC was higher after the EED (+32%) and EEB (+25%) compared with the control condition. In men, but not in women, appetite was inhibited after EEB relative to EED and control (Hagobian et al. 2009). Another study also showed that serum leptin concentration decreased significantly in females after 12 weeks of aerobic exercise training (4 days/week, 30–45 min/day), but was not significantly reduced in males, despite no changes in fat mass after training in either group (Hickey et al. 1997). This suggests that exercise has the ability to down-regulate the production of leptin by the adipose tissue, in a gender-dependent manner.

The above studies suggest that exercise in women, but not in men, leads to changes in appetite-regulating hormones in a direction expected to stimulate appetite. This may help to explain why exercise has no effect on subsequent EI in men, whereas in women, an increase in EI is usually observed, either decreasing or abolishing the effects of exercise on EB (Stubbs et al. 2002a, b).

Although no study has investigated the differential effects of chronic long-term exercise on appetite-regulating hormones in men and women, the available evidence suggests an identical pattern to that already described for acute- and medium-term exercise. Long-term exercise was shown to increase TG in overweight postmenopausal women (Foster-Schubert et al. 2005) and young women (Leidy et al. 2004), but not in men (Ravussin et al. 2001), even though the exercise-induced energy deficit was much higher in the last study. Unfortunately all the studies on the impact of chronic exercise on AG and DG were done in males. Although a strong correlation seems to exist between TG and AG plasma levels, changes in one cannot be used to predict the other, and some studies have in fact reported changes in TG in the absence of changes in AG plasma levels or the other way around. Despite this limitation, the available data suggests that exercise has a more favorable impact on the release of appetite-regulating hormones in men compared with women and this can help to explain why exercise is a more successful strategy for weight loss in men (Donnelly et al. 2003).

71.4 Effects of Exercise on Appetite Sensations and Prospective Food Intake

71.4.1 Acute Exercise

The impact of acute exercise on hunger/fullness sensations and subsequent food intake is conflicting and seems to be dependent on the intensity and duration of exercise and on the time interval between exercise and meal intake. However, the majority of the evidence suggests that acute exercise has no impact or suppresses hunger and, although absolute EI after a bout of exercise is variable, a reduction in relative EI (REI) is usually observed (Martins et al. 2008). It was recently shown that while short-duration high-intensity (30 min/100 W = 170 kcal energy deficit) and low-intensity aerobic exercise (30 or 60 min at 50 W = 85–170 kcal energy deficit) have no effect on hunger sensations or EI at a test meal presented 15 min after the end of the exercise bout, long-duration low-intensity exercise (inducing 340 kcal energy deficit) significantly increases food intake without a concomitant increase in hunger levels (Erdmann et al. 2007). Interestingly, an increase in TG plasma levels was observed during low-intensity (for all durations: 30, 60, and 120 min), but not high-intensity exercise (Erdmann et al. 2007). This study suggests that the impact of acute exercise on food intake is probably dependent on the energy deficit induced by exercise and that TG is unlikely to be the only determinant in postexercise food intake.

Acute exercise (60 min at 50% VO_2max) has also been described to reduce EI and REI, at a test meal presented 1 h after the end of the exercise bout, when compared with a control condition, in the absence of changes in hunger, fullness, or desire to eat. Moreover, no change was observed in TG plasma levels in response to acute exercise, but a significant increase in PYY and GLP-1 was reported

(Ueda et al. 2009). In a recent study we reported a significant increase in absolute EI, but a reduction in REI, at a test meal presented 1 h after the end of an exercise bout (60 min at 65% max HR), compared with a control resting condition. Although a significant hunger suppression was observed during and shortly after exercise, no significant differences in hunger sensations, or circulating appetite-regulating hormones (TG, GLP-1, PYY, and PP) were observed between the exercise and the control leg, immediately before the buffet meal was presented (Martins et al. 2007a). It can be hypothesized that the increase in absolute EI observed in response to acute exercise was the result of cognitive factors such as the belief that exercise increases hunger or the common behavior of using food as reward for exercising. Although we reported an inverse temporal pattern, during and shortly after exercise between hunger feelings (which were suppressed) and PYY, GLP-1, and PP levels (which were increased), no significant correlations were observed between hunger feelings and the plasma levels of any of the satiety hormones measured (Martins et al. 2007a).

The previous studies suggest that changes in the plasma levels of appetite-related hormones following exercise underpin changes in the subjective measures of appetite (suppression of hunger) during the same period. However, the specific hormones involved in this phenomenon are unknown. Although changes in AG were shown to be correlated with hunger suppression in the postexercise recovery period in one study (Broom et al. 2007), others have found no correlations between suppressed hunger and AG (Broom et al. 2009), TG (Martins et al. 2007a), PYY (Broom et al. 2009; Martins et al. 2007a) or GLP-1 (Martins et al. 2007a) plasma levels. Appetite control is a complex process. It is likely that the impact of exercise on hunger feelings and prospective food consumption results from the combined action of both orexigenic and anorexigenic hormones, and not of the isolated action of a specific hormone, and other factors, both physiological and psychological, may also contribute to this process.

The effect of exercise timing, relative to meal consumption, on hunger feelings and appetite-regulating hormones was recently investigated by Cheng and colleagues (2009). They measured subjective feelings of hunger and plasma levels of PYY_{3-36} and TG in moderately active young men for a period of 7 h during three trials: (1) meal consumption, (2) exercise two hours after a meal, and (3) exercise 1 h before a meal, in random order using a crossover design. Exercise consisted of 50-min cycling at 60% VO_2max. They reported that exercise performed after a meal extended the appetite suppressant effect of food intake much more than when exercise was performed before a meal. Exercise, either before or after a meal, tended to increase PYY_{3-36} compared with meal consumption only (control trial). Only exercise performed before a meal increased TG plasma levels and this may help to explain the absence of a prolonged suppression of hunger in this trial (Cheng et al. 2009). However, other studies have shown no impact of acute exercise on TG plasma levels independently of the exercise bout being performed in the fasting (Dall et al. 2002; Kraemer et al. 2004a; Schmidt et al. 2004; Zoladz et al. 2005) or in the postprandial state (Martins et al. 2007a). More studies are needed in this area to clearly establish whether the impact of acute exercise on subjective feelings of appetite, prospective food intake and appetite-regulating hormones plasma levels is dependent upon the metabolic state (fasting vs. postprandial).

71.4.2 Chronic Exercise

In the long-term, very few studies have looked at the impact of chronic exercise, as the sole intervention, on motivation to eat. A significant increase in EI (corresponding to a partial 30% compensation relative to the energy deficit created by exercise) and a significant but small increase in hunger feelings has been described in women after 1 week of exercise (with either two or three 40 min

exercise session/day) (Stubbs et al. 2002b). However, no significant effects were observed on EI or subjective feelings of hunger/fullness after the same protocol in men (Stubbs et al. 2002a), suggesting that the impact of chronic exercise on appetite feelings and food intake is gender dependent. Unfortunately appetite-regulating hormones were not measured in these two studies. In a recent study, no significant changes in the sensations of hunger, desire to eat, or prospective food consumption, either in fasting or postprandially, were reported in normal-weight and overweight male adolescents after 5 days of supervised aerobic exercise, despite a tendency toward a decrease in fullness. Interestingly, the reduction in fullness 30 min after a meal was correlated with changes in AG. Another study consisting of a 6-week intervention of fixed, reduced dietary intake and 6 h a day of skill-based PA in obese children resident in a weight loss camp showed a significant increase in diurnal profiles of hunger and a reduction in fullness, together with a significantly lower suppression of hunger in response to a test meal at the end of the intervention (King et al. 2007). However, this intervention resulted in a substantial weight loss (8.4 kg) and consisted of both exercise and dietary restriction. Therefore, it is impossible to ascertain whether the increase in hunger was due to exercise or to diet.

A recent study consisting of a 12-week supervised exercise intervention in overweight/obese individuals showed that the impact of long-term exercise on subjective feelings of hunger and food intake is variable and can, at least to some extent, explain the magnitude of exercise-induced weight loss. King and colleagues (2008) reported that those who lost less weight than predicted after an exercise intervention (according to the energy expended during the exercise program) experienced an increase in hunger and EI, while those who lost more weight than predicted experienced no change in hunger feelings and a reduction in EI (King et al. 2008).

Despite the limited number of studies in this area, the available evidence seems to suggest that exercise has little or no impact on subjective feelings of hunger/fullness in the medium-term, in the absence of weight loss. However, in the long-term some individuals may experience an increase in hunger feelings which drives up food intake and offsets the magnitude of weight loss.

71.5 Conclusions and Future Directions

There is a large body of evidence supporting a beneficial role for exercise on appetite control. Acute exercise does not seem to impact on TG plasma levels, but increases the release of satiety hormones. Some studies also suggest that acute exercise may, in fact, suppress AG plasma levels, independently of body weight or exercise performance. However, there is some evidence for a compensatory increase in TG plasma levels in response to large volumes of acute exercise in athletes. This is likely to be a protective mechanism to prevent weight loss in athletes. Chronic exercise, per se, also does seem to increase TG plasma levels and there is some evidence for an increase in the release of satiety gut peptides.

The available findings clearly reinforce the importance of incorporating exercise in all weight management programs for several reasons. First, exercise improves the coupling between EI and EE in the long-term, so that changes in EE are quickly followed by proportional changes in EI in the opposite direction, thus ensuring the maintenance of a constant body weight over time. Second, exercise improves energy compensation, so that changes in EI at a particular meal are detected and compensated for at the following meal, leading to an improved appetite control in the short-term. Third, exercise does not seem to induce physiological adaptations at the level of the appetite regulatory system toward increased hunger or EI. However, the impact of exercise

on the release of appetite-regulating hormones is likely to be more favorable in men than in women.

The data discussed in this chapter is, nevertheless, limited by the fact that most studies on the impact of exercise on appetite-regulating hormones, have measured total hormone plasma levels and not their active components. More research is needed to clarify the impact of both, acute and chronic exercise, on the active components of the different hormones involved in appetite control and how that relates to changes in subjective feelings of appetite, food intake, and body weight.

71.6 Applications to Other Areas of Health and Disease

The more detailed evidence now available regarding the role exercise plays in appetite control is likely to contribute to the design of exercise programs that are more effective in creating an appetite suppressant environment and, therefore, in inducing a negative EB and weight loss. Moreover, a better understanding of the contribution that exercise-induced changes in the release of appetite-regulating hormones make on interindividual variation in exercise-induced weight loss will allow a better management of available resources by directing people to appropriate treatment regimes.

Apart from obesity management, other areas of research such as sports physiology and nutrition are likely to benefit from an increased knowledge in this area.

71.7 Key Facts on Exercise and Appetite Control (see Table 71.5)

Table 71.5 Key features on exercise and appetite control

1. Aerobic exercise consists of moderate intensity physical activity that requires the heart and lungs to work harder to meet the body's increased oxygen demand. Examples of aerobic exercise include running, swimming, and cycling.
2. Resistance exercise is any exercise where muscles contract against an external resistance with the objective of increasing strength, tone, mass, and/or muscular endurance. Is performed at high intensity and for very short periods of time.
3. Appetite is a range of parameters that can predict normal eating behavior, such as sensations of hunger and fullness, food preferences, and craving for certain foods.
4. Leptin is a hormone produced by fat cells, in proportion to body fat levels, which provides information to the brain about the state of energy stores. It plays a key role in long-term energy balance by reducing food and increasing energy expenditure.
4. Ghrelin is a hormone which increases hunger feelings and prompts us to eat.
5. GLP-1, PYY, PP, and CCK are satiety hormones that make us feel full and stop eating.

This table lists the key facts on exercise and appetite control including types of exercise, the basic concept of appetite, and the function of several hormones involved in appetite control

CCK cholecystokinin, *PYY* polypeptide YY, *GLP-1* glucagon like peptide-1, *PP* pancreatic polypeptide

Summary Points

- Exercise improves energy compensation, by leading to a more sensitive eating behavior in response to previous EI.
- Acute exercise does not change TG plasma levels, but may suppress AG and increase the release of satiety hormones (PYY, GLP-1, and PP). This is likely to underpin changes in subjective feelings of appetite during the same period.
- There is some evidence that resistance exercise may suppress TG but that if a large energy deficit is created by exercise, a compensatory increase in TG may occur, particularly in athletes.
- Chronic exercise per se independently of weight loss, does not increase TG plasma levels and seems to upregulate the release of satiety hormones, creating an appetite inhibitory state which favors weight loss and prevents weight regain.
- Exercise seems to have a more favorable impact on the release of appetite-regulating hormones in men compared with women.

Key Terms

Energy compensation: The ability to distinguish between two preloads (meals) with different energy content and to compensate for that afterward by eating more after a low-energy preload compared with after a high-energy preload. It is calculated as the difference in EI following preload consumption divided by the difference in preload energy content and expressed as a percentage.

"Exercise-induced anorexia": Suppression of hunger experienced during and shortly after exercise (particularly moderate- to high-intensity exercise).

VO$_2$max: The maximum capacity of an individual's body to transport and utilize oxygen during incremental exercise; it represents the physical fitness of an individual.

Lactate threshold: The exercise intensity at which lactic acid starts to accumulate in the bloodstream.

Relative energy intake: The difference between absolute EI at a test meal and the energy expended during exercise.

Chapter 72
Whey Protein and Satiety: Implications for Diet and Behavior

Sylvia M.S. Chung Chun Lam and Paul J. Moughan

Abbreviations

VAS	Visual analogue scales
GMP	Glycomacropeptide
BCAAs	Branched chain amino acids
β-lg	β-Lactoglobulin
α-la	α-Lactalbumin
BSA	Bovine serum albumin
Ig	Immunoglobulins
CCK	Cholecystokinin
GLP-1	Glucagon-like peptide-1
PYY	Peptide YY
DIT	Diet-induced thermogenesis

72.1 Introduction

In recent years, the prevalence of obesity and overweight has increased rapidly in various populations and across all age groups, but particularly among the young. Consequently, the risk of diseases associated with obesity such as type-2 diabetes, cardiovascular disease, hypertension, and stroke has also risen dramatically and this is a major health concern (Bjorntorp 2001).

The regulation of food intake has been the subject of intensive study driven by the need to understand the problem of overweight and obesity. It is well established that the satiating effect of foods is an important part of overall food intake regulation. Satiety is defined as the feeling of fullness and suppression of hunger feelings after a meal resulting from the ingestion of food. Foods that maximize satiety are promising as they help to reduce the amount of food consumed at the next eating episode and increase the time interval between two meals (Van Itallie and Vanderweele 1981; Kissileff and Van Itallie 1982; Blundell et al. 1996).

Various satiety-inducing food ingredients have been investigated (Kissileff et al. 1984; Rolls et al. 1990; Holt et al. 1995). It would appear that energy density (Stubbs et al. 2000) and fiber content

(Burton-Freeman 2000; Howarth et al. 2001) of a food are important factors modulating food intake and satiety. Consumption of low energy-dense foods and/or high-fiber foods is directly related to lower energy intake and increased satiety. Although there is some evidence that simple carbohydrate and fat may have an effect on satiety, there is increasing data indicating that protein is the most satiating macronutrient independent of its calorific value (Eisenstein et al. 2002; Anderson and Moore 2004; Halton and Hu 2004).

72.2 Dietary Protein, Food Intake, and Satiety

In many human studies protein appears to be more satiating than the other macronutrients (available carbohydrate, fat, or alcohol). Marmonier et al. (2000) convincingly demonstrated that a high-protein meal delayed the request for food for 60 min compared with 34 min for carbohydrate and 25 min for fat. Eisenstein et al. (2002) reviewed ten preload studies that included measurement of food intake as well as satiety ratings, and found that eight out of the ten studies showed a lower energy intake at the subsequent meal with a high protein preload than with a low protein preload. More direct evidence regarding the effect of high-protein meals in reducing food energy intake and increasing feelings of satiety comes from studies by Booth et al. (1970), Porrini et al. (1995), Poppitt et al. (1998), and Latner and Schwartz (1999) (see Table 72.1). In the study of Poppitt et al. (1998) where the satiating effect of the four dietary components (fat, carbohydrate, protein, and alcohol) was investigated, subjects reported feeling less hungry and more satiated throughout the study period and ate less food at lunch following a protein preload relative to the other macronutrients. In the Latner and Schwartz (1999) study, subjects consumed 31% more energy at dinner after a high-carbohydrate lunch and 20% more energy after a mixed carbohydrate and protein lunch compared to a high-protein lunch. The latter condition suppressed hunger more relative to the other two diets. Porrini et al. (1995) found that when twelve normal-weight men consumed a carbohydrate-rich meal, their subsequent food intake was higher versus consuming a protein-rich meal. Ratings of fullness and satiety were also increased after the high-protein preload compared to the high-carbohydrate preload. In a study of nine subjects who ate a protein-rich or a protein-poor lunch, Booth et al. (1970) found that energy intake at a meal 2–3 h later was lower after consumption of the protein-rich lunch compared to the low-protein lunch.

A few studies found suppression of food intake at a subsequent meal but no change in feelings of satiety after a high-protein meal (Table 72.1). Johnson and Vickers (1993) showed that a smaller amount of food and fewer calories were consumed after a high-protein meal compared with a high-carbohydrate or high-fat meal in 14 normal-weight subjects. However, there was no difference between carbohydrate and protein on feelings of satiety as both carbohydrate and protein were rated as more satiating than fat. Although Barkeling et al. (1990) did not find any change in subjective ratings of satiety between a high-protein meat casserole and a high-carbohydrate vegetarian casserole, they showed a decrease in food intake at the subsequent meal when subjects ate the high-protein meat casserole compared to when they ate the high-carbohydrate vegetarian casserole.

With respect to subjective ratings of satiety, studies by Stubbs et al. (1996), Vandewater and Vickers (1996), Crovetti et al. (1998), and Smeets et al. (2008) have shown that protein is more satiating than carbohydrate or fat (Table 72.1). Stubbs et al. (1996) reported that energy intake at a lunch test meal was similar for all the breakfast treatments but there was a greater suppression of the feeling of hunger after a high-protein meal compared to a meal high in carbohydrate or fat. Similar findings were observed by Crovetti et al. (1998) who studied intake at a test meal and satiety feelings by means of a satiety rating questionnaire in ten normal-weight women. There was no difference between the

Table 72.1 Compilation of recorded effects of dietary protein on food intake and subjective ratings of satiety in humans

References	Subjects	Diets	Measure	Results: food intake	Results: satiety
Barkeling et al. (1990)	Twenty normal-weight women	High-protein meat casserole (64.5 g P, 43% of E from P, 21% F, 36% C) High carbohydrate vegetarian casserole (15.5 g P, 10% of E from P, 21% F, 69% C)	Food intake 4 h after casserole lunch was measured using a universal eating monitor and subjective feelings of satiety were also rated.	Subjects consumed 12% fewer calories after the high-protein meal compared to the high-carbohydrate meal.	No change in subjective ratings between treatments.
Booth et al. (1970)	Nine normal-weight subjects (no further specification)	Protein-rich lunch Protein-poor lunch	Food intake 2–3 h after lunch	Energy intake was lower after consumption of the protein-rich lunch compared to the protein-poor lunch.	Not measured
Crovetti et al. (1998)	Ten normal-weight women	High-protein meal (68.1% of E from P, 19.2% F, 12.6% C) High carbohydrate meal (69.1% of E from C, 20.7% F, 10.1% P) High fat meal (70.1% of E from F, 21.3% C, 8.6% P)	Food intake 7 h later and satiety feelings were rated using a satiety rating questionnaire.	No difference on total test meal intake.	Subjects felt fuller after the high-protein meal over the 7 h test period than after the high carbohydrate or high fat meals.
De Graaf et al. (1992)	Twenty-nine normal-weight women	Ten liquid breakfasts: A zero condition (0.03 MJ) and the nine other preloads varied in energy levels (0.42, 1.05, and 1.67 MJ) and macronutrient content.	Food intake after breakfast was recorded in a diary. Satiety ratings were also assessed after consumption of breakfast.	No difference in energy intake for the remainder of the day.	The rated responses to satiety for the macronutrients did not differ.
Geliebter (1979)	Twelve normal-weight men	Protein load (egg albumin) Fat (corn oil) Carbohydrate (corn starch)	Test meal was presented 70 min after the preload and satiety ratings were measured.	No difference in energy intake during test meal.	Ratings of satiety did not differ.

(continued)

Table 72.1 (continued)

References	Subjects	Diets	Measure	Results: food intake	Results: satiety
Johnson and Vickers (1993)	Nine normal-weight women and six men	High-protein meal High-carbohydrate meal High-fat meal	A mini buffet lunch was served 90 min following the preload and subjects rated their hunger, stomach fullness, and prospective consumption 2 and 90 min after the preload.	A smaller amount of food and fewer calories were consumed after the high-protein meal compared to the high-carbohydrate or high-fat meals.	The high-carbohydrate and high-protein preloads decreased hunger and prospective consumption and increased stomach fullness more than the high-fat preload.
Latner and Schwartz (1999)	Twelve normal-weight women	High-Protein Lunch (80 g of whey protein, 71.5% of E from P) High Carbohydrate Lunch (113 g of polycose supplement 99% of E from C) Mixed Lunch (62 g C & 40 g P, 55.1% of E from C & 35.7% P)	Buffet-style dinner served 4.5 h after lunch consumption. Pre- and postmeal satiety ratings were assessed.	Thirty-one percent more energy was consumed at dinner following the high-carbohydrate lunch and 20% more following the mixed lunch than following the high-protein lunch.	Hunger was less in the high-protein condition than for the high-carbohydrate and mixed treatments. The mixed lunch also reduced hunger more than the high-carbohydrate lunch.
Poppitt et al. (1998)	Twelve normal-weight women	1 MJ baseline meal and drink to which 1MJ of carbohydrate, protein, fat and alcohol was added	Food intake 90 min after treatment and prior to, and at 30, 90, and 120 min, subjective feelings of hunger and satiety were measured.	Energy intake was statistically significantly lowest after the protein treatment relative to the other macronutrients.	Subjects reported feeling less hungry and more satiated throughout the test period on the protein meal compared to the other macronutrients.
Porrini et al. (1995)	Twelve normal-weight men	High-Protein meal (56% of E from P, 25% F, 19% C) High Carbohydrate meal (17% of E from P, 27% F, 56% C)	Food intake at an ad libitum meal was measured and subjects rated their feelings of satiety.	Subsequent food intake was lower for the high-protein meal compared with the high-carbohydrate meal.	Ratings of fullness and satiety were higher following ingestion of high-protein meal compared with the high-carbohydrate meal.
Raben et al. (2003)	Nineteen normal-weight women and 10 men	Breakfasts differed by percentage E contributed by each macronutrient: 1. P (32%) 2. C (65%) 3. F (65%) 4. Alcohol (23%)	Food intake 5 h after breakfast meals and subjective satiety ratings were measured before, after and every 30 min until 5 h after the test meals.	No difference in subsequent energy intake.	No difference in satiety sensations after the four meals.

Smeets et al. (2008)	Nineteen normal-weight women and 11 men	High-Protein lunch (25% of E from P, 45% C, 30% F) Adequate-Protein lunch (10% of E from P, 60% C, 30% F)	Satiety ratings were measured immediately, at 30, 60, 120, 180, and 240 min following the meal.	Not measured	The ratings for hunger and satiety were higher 30 and 120 min after the high-protein lunch than after the adequate-protein lunch.
Stubbs et al. (1996)	Six men	High-Protein breakfast (59% of E from P) High-Carbohydrate breakfast (18% of E from P) High-Fat breakfast (22% of E from P)	Energy intake at a test meal lunch and throughout the rest of the day was assessed and subjective hunger, fullness, and appetite was measured hourly.	Lunch and after lunch energy intakes were similar following all the breakfast treatments.	The high-protein breakfast produced greater suppression of hunger between breakfast and lunch and over 24 h than the High-Carbohydrate or High-Fat treatments.
Vozzo et al. (2003)	Sixteen normal-weight men	High-Protein yoghurt (29% of E from P, 44% C, 24% F) High-Carbohydrate yoghurt (60% of E from C, 24% F, 14% P) High-Fat yoghurt (40% of E from F, 14% P, 42% C)	Food intake for the remainder of the day (7 h) was measured. Subjective rating scales assessing hunger and fullness were used at 15 min intervals for the duration of the study.	Subsequent food intake least but statistically non-significantly after the High-Protein yoghurt than High-Carbohydrate and high-fat yoghurts.	No difference in ratings of satiety.

The weight of the evidence suggests that dietary protein induces satiety more strongly than available carbohydrate, fat, or alcohol in humans as indicated by objective and subjective measures. Meals high in protein decrease food intake at a subsequent meal and subjective ratings of satiety also showed that protein is more satiating than carbohydrate, fat, or alcohol

h hour, MJ megajoules, min minutes; E energy, P protein, C carbohydrate, F fat

diets on test meal intake but subjects felt fuller after the high-protein meal over the 7-h test period than after the high-carbohydrate or high-fat meals. In the Smeets et al. (2008) study, the visual analogue scales (VAS) for hunger and satiety were higher after the high-protein lunch than after the adequate-protein lunch. In addition, results from a study by Vandewater and Vickers (1996) showed that protein-rich meals produced a greater feeling of satiety. The high-protein versions of yoghurt or sandwich induced a greater decrease in hunger and increase in stomach fullness ratings than the low-protein versions.

Contrary to the above discussed results, however, Geliebter (1979), de Graaf et al. (1992), Raben et al. (2003), and Vozzo et al. (2003) found that protein did not affect food intake or subjective responses to satiety (Table 72.1). There was no difference in ratings of satiety and energy intake at a test meal presented 70 min after equicaloric loads of protein (egg albumin), fat (corn oil), and carbohydrate (corn starch) (Geliebter 1979). In the de Graaf et al. (1992) study, energy intake at a test meal, energy intake for the remainder of the day, and satiety feelings did not differ with preloads that varied in macronutrient content. Raben et al. (2003) showed no change in subsequent energy intake or satiety feelings after meals rich in one of the four macronutrients; protein, carbohydrate, fat, or alcohol. In the Vozzo et al. (2003) study, spontaneous food intake and ratings of satiety did not differ significantly after preloads high in protein, carbohydrate, or fat. Subsequent food intake tended to be suppressed 29% by the high-protein preload, 20% by the high-fat preload, and 17% by the high-carbohydrate preload.

Several trials have investigated the relationship between high dietary protein intake and reduced body weight as well as long-term weight maintenance as summarized in Table 72.2. In a 6-month study, Skov et al. (1999) compared the effects of diets varying in percentage energy from protein (25% vs. 12%) on body weight and body composition in 65 otherwise healthy overweight and obese subjects. Weight loss after 6 months was 5.1 kg in the low-protein group vs. 8.9 kg in the high-protein group and fat loss was 4.3 and 7.6 kg, respectively. Subjects spontaneously limited their food intake on the high-protein diet which may have been associated with an enhanced satiety of the high-protein diet. In another study, when 19 subjects increased the proportion of dietary energy supplied by protein from 15% to 30% for 12 weeks, they reported greater feelings of satiety, a larger decrease in spontaneous energy intake, and lost more body weight and body fat on the high-protein diet (Weigle et al. 2005). Layman et al. (2003) monitored the weight management progress of 24 overweight women, who were either on a carbohydrate to protein ratio of 3.5 (68 g protein/day) or a ratio of 1.4 (125 g protein/day). Participants in both groups lost 7–7.5 kg after 10 weeks but women on the low carbohydrate to protein ratio diet reported feeling more satiated compared to the women that were on the high carbohydrate to protein ratio diet. A 4-week study (Baba et al. 1999) of 13 obese hyperinsulinemic normoglycemic men on a hypoenergetic diet that provided 80% of their resting energy expenditure found that those who consumed a high-protein diet (45% protein, 25% carbohydrate, and 30% fat as a percentage of dietary energy) lost more weight (8.3 vs. 6.0 kg) compared to those who consumed a high carbohydrate diet (12% protein, 58% carbohydrate, and 30% fat).

The weight of the evidence suggests that protein is more satiating than the other macronutrients. Preload studies looking at differences in food intake at the subsequent meal and/or feelings of satiety report an increased satiety value of protein. However, some studies did not find any change in subsequent intake or subjective ratings of satiety. Discrepancies in observations from preload studies may be affected by preload volume and composition and the time interval between preload and test meal (Rolls and Hammer 1995). In a recent study by Bellissimo et al. (2007), when the time interval between preload and test meal was increased from 30 to 60 min, the effect of carbohydrate preload decreased whereas the effect of whey protein increased. Carbohydrates and proteins have different post-ingestional consequences. The satiating effect of protein may improve over time

Table 72.2 Summary of results of studies that investigated the long-term effects of high-protein diets in overweight and obese humans

References	Subjects	Diets	Duration	Effects
Baba et al. (1999)	Thirteen men	High-Protein diet (45% of E from P, 25% C, 30% F) Low-Protein diet (12% of E from P, 58% C, 30% F)	Four weeks	Greater weight loss with the High-Protein diet than with the Low-Protein, High-Carbohydrate diet.
Layman et al. (2003)	Twenty-four women	High-Protein diet, carbohydrate to protein ratio of 1.4 (125 g protein/day; 30% of E from P, 41% C, 29% F) Low-protein diet, carbohydrate to protein ratio of 3.5 (68 g protein/day; 16% of E from P, 58% C, 26% F)	Ten weeks	Decrease in body weight in both diets but the ratio of fat/lean loss was found to be greater in the High-Protein diet compared with the Low-Protein, High-Carbohydrate diet. Greater satiety with the High-Protein diet was demonstrated than with the Low-Protein diet.
Skov et al. (1999)	Sixty-five subjects; 19 women and 6 men on each treatment diet	High-protein diet (25% of E from P, 45% C, 30% F) Low-protein diet (12% of E from P, 58% C, 30% F)	Six months	Greater body weight loss and body fat loss with the High-Protein diet compared to the Low-Protein diet. Subjects also spontaneously reduced their total food intake on the High-Protein diet.
Weigle et al. (2005)	Sixteen women and 3 men	High-protein diet (30% of E from P, 50% C, 20% F) Low-protein diet (15% of E from P, 50% C, 35% F)	Twelve weeks	Decreased spontaneous energy intake, body weight, and body fat on the High-Protein diet. Subjects on the High-Protein diet also reduced their spontaneous energy intake and reported greater feelings of satiety.

The effects of high-protein intake on body weight and body composition in overweight and obese humans
E energy, *P* protein, *C* carbohydrate, *F* fat

(after 30 min) but the effect may become less precise as the duration to the next meal increases up to 3 h. The effect of the time interval between the ingestion of protein and subsequent food intake on the measurement of satiety appears to be critical and deserves more investigative attention. Nonetheless, consumption of high-protein meals in the long term may reduce body weight and body fat; effects that may be useful in the treatment of obesity. The short-term effects of protein on satiety may be an important factor.

72.3 Mechanism of Action of Protein on Satiety

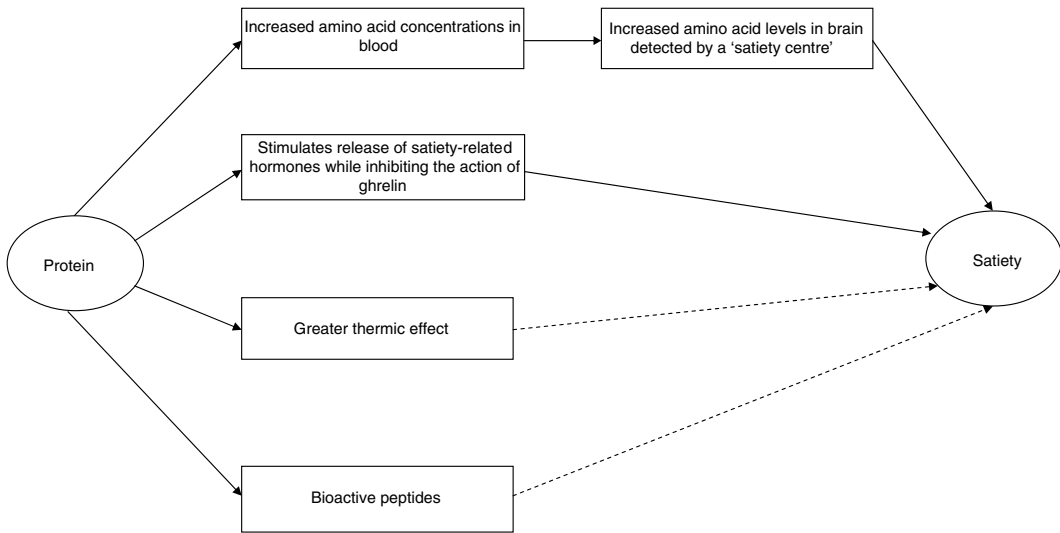
Dietary protein may influence food intake and satiety via a number of mechanisms. Firstly, higher dietary protein intakes influence the plasma concentrations of amino acids which in turn may influence satiety-related hormones. Proteins have a high thermic effect and bioactive peptides released during digestion in the gut may also play a role (Rutherfurd-Markwick and Moughan 2005; refer to Fig. 72.1).


Fig. 72.1 Mechanisms of action of dietary protein. This figure illustrates the mechanisms whereby dietary protein may exert its effect on satiety. Protein ingestion results in the release of amino acids and small peptides. The circulating levels of amino acids rapidly increase and this may contribute to satiety through increased amino acid concentrations in the brain. Amino acids may also stimulate the release of satiety-related hormones including cholecystokinin, glucagon-like peptide-1, and peptide YY while inhibiting the action of ghrelin, a hormone known to stimulate feeding. Part of the satiety effect of dietary protein may be due to the higher thermic effect of protein and the bioactive peptides released during protein digestion. → proven mechanism, --> probable mechanism

72.3.1 Amino Acids

The aminostatic hypothesis of feeding put forward by Mellinkoff et al. (1956) suggests that plasma amino acid concentration is inversely related to fluctuations in appetite. Studies in rats fed amino-acid-imbalanced diets indicate that low plasma concentrations of certain amino acids may lead to increases or decreases in food intake. The changes in plasma amino acid concentrations result in changes in amino acid concentrations in the brain, which are sensed by a "satiety centre" in the brain. The rise in plasma amino acids elicited by protein ingestion may assist in the suppression of food intake and the onset of satiety (Mellinkoff et al. 1956). Specific amino acids may have different effects on the satiety centre, which could explain differences among protein sources in inducing satiety.

72.3.2 Satiety Hormones

A number of studies show that dietary protein intake is correlated to the release of a number of satiety-related hormones such as cholecystokinin (CCK), glucagon-like peptide-1 (GLP-1), peptide YY (PYY) and to a decrease in ghrelin, a hormone known to stimulate feeding. In the study by Hall et al. (2003), the suppression of food intake by whey was shown to be associated with increases in CCK and GLP-1. Compared with whey or casein, carbohydrate consumption decreased ghrelin and increased CCK to a lesser extent (Bowen et al. 2006b). However, no difference in ghrelin, GLP-1, and PYY was found between a high-protein (25% of energy from protein) and an adequate-protein diet (10% of energy from protein) (Smeets et al. 2008). Further, in a metabolic trial in which the energy

from protein was increased from 10% to 30%, plasma ghrelin remained unchanged, but after dinner GLP-1 concentrations were higher on the high-protein diet compared with the adequate-protein diet (Lejeune et al. 2006).

72.3.3 Thermic Effect of Protein

The higher thermic effect of dietary protein may be partly responsible for its satiating effect. Consuming high-protein diets results in greater levels of heat production, partly related to increased energy expenditure, compared to carbohydrate and fat, which is referred to as the thermic effect of protein or diet-induced thermogenesis (DIT). Karst et al. (1984) studied the thermic effect of three protein sources (egg white, gelatine, and casein), two carbohydrates (starch and hydrolyzed starch), and two fats (sunflower oil and butter) in 12 healthy men for 6 h. While fat produced no observed thermic effect, the thermic effect of protein was three times larger than that of carbohydrate. A review of data from 19 trials revealed that for each 1% change in energy from protein, the thermic effect of the meal increased by 0.22% (Westerterp 2004). Crovetti et al. (1998) argued that the greater thermic effect of protein relative to carbohydrate or fat might be related to satiety. Similar conclusions were made by Westerterp-Plantenga et al. (1999), Lejeune et al. (2006), and Smeets et al. (2008). In the Westerterp-Plantenga et al. (1999) study, a high-protein meal (29% of energy from protein, 61% from carbohydrate and 10% from fat) increased DIT more than that for a high fat meal (9% of energy from protein, 30% from carbohydrate, and 61% from fat). They concluded that satiety assessed by VAS was associated with the thermic effect of the diets.

The higher thermic effect of protein is believed to be related to satiety and might explain at least in part why high-protein meals promote body weight loss. The role of dietary protein in body weight regulation and underlying mechanisms has been the subject of recent reviews (Halton and Hu 2004; Moughan 2008; Westerterp-Plantenga et al. 2009). High-protein diets seem to be effective in sustaining or increasing fat-free body mass. The preservation of a higher lean mass has an added energy cost and appears to have a significant effect on resting energy expenditure. Consumption of dietary protein above the required level will increase protein turnover by increasing protein synthesis and protein breakdown in the body. All of the processes associated with high-protein diets result in a lower metabolic efficiency of energy utilization that may contribute to weight loss.

72.4 Protein Source and Food Intake and Satiety

The source of dietary protein appears to be a factor in the suppression of food intake. Some evidence indicates that consumption of milk proteins, particularly whey protein may increase satiety in animals and humans.

72.4.1 Animal Studies

Studies in animals indicate that whey protein consumption may reduce food intake more than other protein sources. Yu et al. (2009) investigated the effects of whey, soy, and gluten proteins on inter-meal interval, meal number, meal size, and meal duration in male mice. Mice fed the whey protein

diet showed the greatest reduction in energy intake over seven days and gained less weight than those fed the other protein diets. The decrease in energy intake in mice fed the whey protein diet was attributed to a low meal number and a long intermeal interval rather than a decrease in meal size. Using obese minipigs, Ferrari et al. (2005) and Dunshea et al. (2007) compared the effects of whey or soy proteins on food intake and body weight. Both studies found that obese pigs fed the high whey protein diet reduced their food intake to a greater extent than pigs fed the high soy protein diet. Furthermore, pigs fed the high-protein diets experienced less weight and fat gain than pigs fed the low-protein diets, with the greater effect demonstrated by whey protein than soy protein.

72.4.2 Human Studies

The evidence regarding a stronger effect of whey protein compared to other protein sources on satiety in humans is limited (Table 72.3). In one study, food intake at a test meal 60 min later was reduced to a greater extent after consumption of whey protein than after soy protein or egg albumen (Anderson et al. 2004). In another study, although food intake at lunch 180 min after consumption of the treatments did not differ, whey protein had a greater effect in suppressing hunger than either casein or soy (Veldhorst et al. 2009a). Within milk protein types, Hall et al. (2003) reported that whey suppressed food intake at a buffet meal 90 min later more than casein. Subjective ratings of satiety were also greater following consumption of the whey preload.

However, not all studies have found whey to have an effect on food intake and satiety. In one study, Bowen et al. (2006b) investigated the role of whey and casein proteins, relative to lactose or glucose in energy intake and satiety and in a second study, Bowen et al. (2006a) compared the effects of whey, soy, gluten, and glucose. In both studies, energy intake at a buffet lunch 3 h later was 10% higher after the glucose treatment compared with all the other preloads. There was no difference in subjective ratings for hunger, satiety, emptiness, or desire to eat between the treatments. Although the researchers observed a greater reduction in food intake after consumption of the high-protein meals than the high carbohydrate meals, they did not find any significant effect of protein source (whey, soy, gluten, and casein). The time interval of 180 min between preload and test meal may have been too long for the effect of the different protein sources on food intake to be detected.

Several studies have compared the effect of different dietary proteins on satiety but it remains unclear whether whey protein has a stronger effect on satiety than other protein sources. There is evidence for an effect of whey protein, but the situation is not definitive.

72.5 Composition of Whey Protein

It is of interest to enquire as to what properties of whey protein could lead to the purported satiety effect. Is it related to the amino acid composition of whey, peptides released upon digestion or some other attribute?

Cow's milk contains approximately 3.3% protein, and milk proteins fall into two main categories: caseins and whey proteins, as illustrated in Fig. 72.2. Caseins represent ~80% while whey proteins represent the rest (~20%) of the total milk proteins (Walstra et al. 2006). During cheese making, whey is the soluble component of milk that is separated from the casein curd. For years, whey was considered as a waste product of the cheese making process but recently, whey has become a valuable ingredient in numerous food products, particularly in protein fortified products (Walzem et al. 2002).

Table 72.3 Compilation of research studies that investigated the effects of protein source on satiety in humans

References	Subjects	Treatments	Measure	Results: food intake	Results: satiety
Anderson et al. (2004)	Thirteen normal-weight men	Fifty grams of egg albumen, whey and soy protein were placed in sweet and flavored beverages in addition to water control.	Food intake 1 h after the treatments	Whey and soy protein decreased food intake relative to the control, whereas egg protein did not.	Not measured
Bowen et al. (2006a)	Seventy-two overweight men	Liquid preloads (1.1 MJ) containing 50 g whey, soy, gluten or glucose	An ad libitum buffet lunch was served 3 h after consuming the liquid breakfast and ratings of satiety were measured after preload consumption.	Energy intake after glucose was statistically significantly higher compared to the other preloads.	No effect of treatment on subjective ratings
Bowen et al. (2006b)	Nineteen over-weight men	Liquid breakfasts (1 MJ) consisting of 50 g of whey, 55 g of casein, 56 g of lactose or 50 g of glucose	An ad libitum buffet lunch was served 180 min after consuming the liquid breakfast and ratings of satiety were measured after preload consumption.	Energy intake after glucose was statistically significantly higher compared to the other preloads and there was no difference between protein sources.	Satiety ratings did not differ significantly between the four treatments.
Hall et al. (2003)	Eight lean women and 8 men	Liquid preloads (1,700 kJ) containing 48 g of whey or casein protein	A buffet meal was served 90 min after consumption of the preloads	The whey preload reduced energy intake at buffet meal by 829 kJ or 18% compared with the casein preload.	No difference in subjective satiety ratings.
Hall et al. (2003)	Eight lean women and 1 man	Liquid preloads (1,700 kJ) containing 48 g of whey or casein protein	A fixed lunch was offered at 42 g/kg 90 minutes after preload and ratings of hunger, satiety and desire to eat were measured.	Not measured	Greater fullness and reduced desire to eat followed the whey test meal over 180 minutes.

(continued)

Table 72.3 (continued)

References	Subjects	Treatments	Measure	Results: food intake	Results: satiety
Veldhorst et al. (2009a)	Fourteen normal-weight women and 11 men	Custard breakfasts with either casein, soy or whey protein at two different energy levels (Normal Protein, 10% of E from P, 55% C, 35% F or High Protein, 25% of E from P, 55% C, 20% F)	Satiety ratings were recorded for 4 h and an ad libitum lunch was offered 180 min after the preload.	No difference between protein source and protein concentration for food intake at lunch.	There was no difference in satiety ratings between protein sources when the protein level was high (25% P). At 10% P, whey decreased hunger compared to casein or soy.

Protein source may determine the satiating effect of protein, but the evidence from studies in humans is limited. Whey protein derived from milk has been suggested as a potential protein that may contribute more strongly than other protein sources to short-term satiety in humans

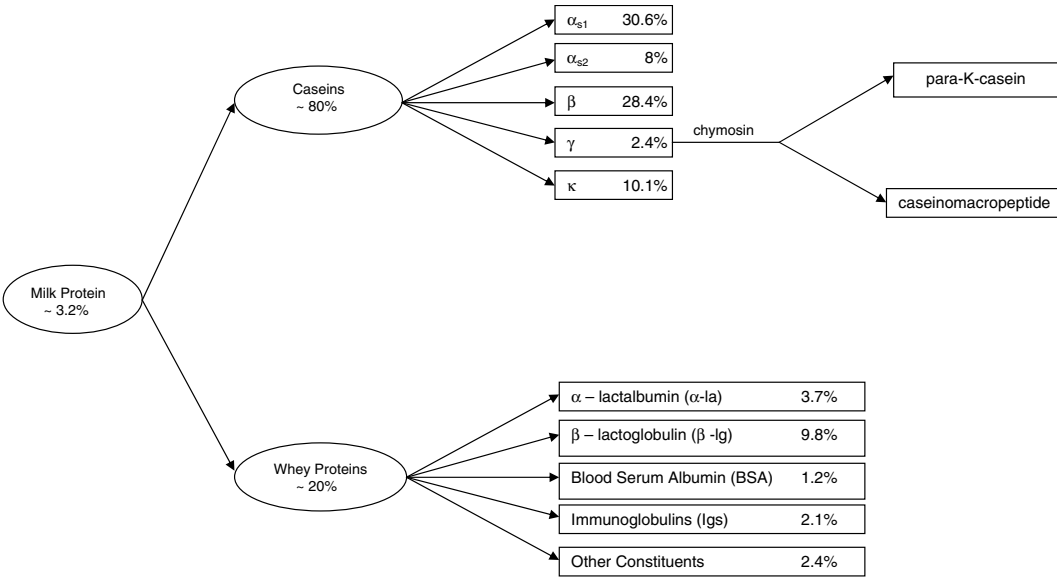
h hour, min minutes, MJ megajoules, kJ kilojoules, g grams, kg kilograms; E energy, P protein, C carbohydrate, F fat


Fig. 72.2 Protein composition of bovine milk. Bovine milk contains about 3.3% protein. The two major fractions of milk proteins are casein and whey protein, which comprise about 80% and 20% of the total milk proteins. Casein and whey protein are divided into other components. During cheese making, the enzyme chymosin breaks down κ-casein into para-κ-casein and caseinomacropeptide. The latter is water-soluble and becomes part of the whey fraction (Adapted from Walstra et al. 2006, with permission. ~ = approximately; α = alpha; β = beta; γ = gamma; κ = kappa)

The nutritive value of whey protein is related to its amino acid composition as well as the high bioavailability of these amino acids. Whey protein has a very high concentration of branched chain amino acids (BCAAs). These BCAAs are thought to be beneficial to athletes and individuals looking to achieve optimal lean muscle mass as they help to increase the bioavailability of carbohydrate in the muscles and prevent muscle protein breakdown during exercise (Walzem et al. 2002). The most important components of whey proteins are β-lactoglobulin (β-lg), α-lactalbumin (α-la), bovine serum albumin (BSA), and immunoglobulins (Ig). Other nitrogenous constituents include lactoferrin, lactoperoxidase, and many other bioactive factors and enzymes. They also contains caseinomacropeptide, a polypeptide of 64 amino acid residues, formed from the action of the enzyme chymosin on κ-casein. Glycomacropeptide (GMP), the glycosylated fragment of caseinomacropeptide has been shown to stimulate the secretion of the gut hormone cholecystokinin (CCK) (Beucher et al. 1994), which may induce satiety. Glycomacropeptide would appear to be a prime candidate for explaining a satiating effect of whey. Having said this, the empirical evidence for an effect of glyco-macropeptide on satiety is not overwhelming (refer to Table 72.4).

72.6 Effect of Glycomacropeptide on Food Intake and Satiety in Humans

Caseinomacropeptide, the unglycosylated form of GMP, at doses of 0.4 and 20 g did not show any effect on food intake or subjective ratings of satiety over 1 h in a clinical trial (Gustafson et al. 2001). In our own work and with a carefully controlled study, we did not find any difference in energy intake at a cafeteria meal offered 30 min after administration of whey preloads without GMP, or with naturally present GMP or with added GMP (Chung Chun Lam et al. 2009). However, Veldhorst et al. (2009b)

Table 72.4 Compilation of human studies assessing the effects of whey protein and glycomacropeptide on food intake and subjective ratings of satiety

References	Subjects	Diets	Measure	Results: food intake	Results: satiety
Burton-Freeman (2008)	Ten normal-weight men and 10 women	Preload milkshakes (1 MJ): 1. Whey; Whey Protein isolate (44% of E from P) 2. Whey-GMP; whey protein without GMP (44% P) 3. Control; low protein (2% P) 4. GMP; GMP isolate (3% P)	Food intake 75 min after the preloads and satiety ratings recorded before and after preload consumption	No difference between preloads for food intake at the lunch test meal.	Greater satiety with Whey and Whey-GMP preloads compared to the Control preload in women. However, no difference in satiety ratings observed in men. No difference between the GMP and control preloads on subjective satiety in participants.
Chung Chun Lam et al. (2009)	Thirty-one normal-weight women and 19 men	Preload milkshakes (1.3 MJ): 1 Whey; Whey Protein isolate (8.4 g GMP) 2. Whey + GMP; Whey with added GMP (24.2 g GMP) 3. Whey-GMP; Whey without any GMP 4. Carbohydrate (maltodextrin)	A buffet lunch was served 30 min after preload administration and ratings of satiety were measured before and after preload consumption.	Equal suppression of food intake by protein preloads compared with carbohydrate.	Whey induced a greater feeling of fullness immediately after consumption of the preload compared to the other treatments.
Gustafson et al. (2001)	Thirty-two normal-weight women and 20 men	Preloads (34 J) were prepared by dissolving 0.4 or 2.0 g of CMP in a noncaloric fruit-flavored beverage vehicle.	Food intake 1 h after consuming the beverage. Participants assessed their feelings of satiety pre- and post preload and test meal and every hour until bedtime on 100 mm VAS.	No difference in food intake during test meal.	No effect of treatment on subjective ratings of satiety.
Veldhorst et al. (2009b)	Fourteen normal-weight women and 11 men	Custard breakfasts (2.5 MJ) with either whey or whey without GMP at two different energy levels (Normal Protein, 10% of E from P, 55% C, 35% F or High Protein, 25% of E from P, 55% C, 20% F).	Satiety ratings were recorded for 4 h and an ad libitum lunch was offered 180 min after the preload.	Protein concentration did not have an effect on food intake at lunch. However, there was a greater reduction in energy intake after the Whey breakfast than after the breakfast with Whey without GMP.	There was no difference in satiety ratings between protein sources but satiety ratings were higher after the normal protein breakfasts than after the high-protein breakfasts.

The presence of glycomacropeptide may be a determinant of the satiating effect of whey protein but the limited evidence from studies in humans is not strong

MJ megajoules, min minutes, J joules, E energy; P protein, GMP glycomacropeptide, WPI whey protein isolate, SMP skim milk powder

found that the presence of GMP as part of whey protein in a breakfast meal reduced energy intake at lunch, 180 min later. To test the effects of a preload containing GMP alone on food intake, feelings of satiety, and CCK release, Burton-Freeman (2008) fed 20 adults either a low-protein preload, or a whey protein preload with GMP, or a whey protein preload without GMP, or a GMP preload. Test meal intake 75 min later, subjective satiety or CCK release was not affected by whey protein or GMP. Contradictory findings on the effect of GMP on satiety may be related to differences in the dose of whey protein used and the time interval between preload and test meal. Human trials looking at the long term effect of GMP and whey protein are limited. In a 12-month randomized trial, Keogh and Clifton (2008) compared the effects of GMP-enriched whey powder versus skim milk powder meal-replacements in 127 overweight and obese subjects. Subjects who consumed the GMP-enriched whey protein meal replacement had greater weight loss after 12 months than those who consumed skim milk meal-replacements (9.9 vs. 10.8 kg), but the difference was not statistically significant. The role of GMP on CCK release and CCK-mediated satiety requires further work.

72.7 Applications to Other Areas of Health and Disease

The need to understand the regulation of food intake and the termination of eating is essential to the understanding and effective treatment of obesity and eating disorders. Obese people or individuals with eating disorders such as anorexia nervosa, bulimia nervosa, or binge eating disorder may exhibit different hunger and satiety mechanisms compared to normal-weight people or people not suffering from eating disorders. Binge eating is a central characteristic of bulimia nervosa and binge eating disorder and is defined as the consumption of a very large amount of food until the person feels uncomfortably full (American Psychiatric Association 1994).

People with bulimia nervosa and binge-eating disorder exhibit distorted satiety responses and tend to overeat throughout the day (Rossiter et al. 1992) and during binge episodes (Yanovski et al. 1992). Individuals who binge-eat were found to consume a higher proportion of energy from fat and a lower percentage of intake from protein. Hetherington et al. (1994) showed that the percentage of dietary energy from protein intake during the day was lower for women with bulimia nervosa compared with controls. Similarly, women with binge-eating disorders ate a lower proportion of energy from protein than controls when asked to binge-eat (Yanovski et al. 1992). Consumption during binge episodes in subjects suffering from binge-eating disorders was shown to be high in carbohydrates but during non-binge days, a greater amount of protein was consumed (Rossiter et al. 1992). Protein intake may assist eating-disordered and obese individuals from overeating or binge-eating.

For individuals who binge-eat, the satiating effect of different macronutrients may be a factor in the loss of control over eating. There is strong evidence that protein, in comparison with other macronutrients, is more effective in promoting satiety and suppressing food intake (Table 72.5). Latner and Wilson (2004) investigated the effect of protein on binge eating, food intake at a test meal and rated satiety in subjects with bulimia nervosa or binge-eating disorder. Over the course of 2 weeks, eighteen women with bulimia nervosa or binge eating disorder ingested a high-protein or a high-carbohydrate supplement three times daily. Food intake at test meals was reduced and subjects felt less hungry and fuller after protein supplementation compared with carbohydrate supplementation. Subjects experienced less binge eating episodes during protein supplementation than during carbohydrate supplementation. Dietary protein may in part correct the satiety impairment in people with bulimia nervosa and binge eating disorders. The role of protein in inducing satiety and reducing binge eating episodes may have some implications for the long-term treatment of eating disorders.

Table 72.5 Key features of satiety

1. Satiety is defined as the feeling of fullness that determines the time interval between two meals (the intermeal interval) and the amount of food consumed at the next eating event.
2. Foods that increase satiety offer promise to encourage an individual to prolong the intermeal interval and reduce food intake. This is useful for the overweight and people on energy-restricted diets that have difficulty achieving satiety while complying with the energy restriction.
3. Many dietary factors affect satiety including the energy density, fiber content and macronutrient composition of a food. It is widely believed that protein is the most satiating macronutrient independent of its caloric value. Whey protein derived from milk may be more effective than other protein sources in inducing satiety.
4. Three main approaches used to measure satiety:
   ▪ The time taken to request food after a test meal.
   ▪ Rating scales are used to measure subjective feelings of satiety. The most common is the visual analogue scales which are usually 100 mm long lines labeled at each end with extremes of the subjective feeling.
   ▪ Food intake at a subsequent meal.

This table lists the key features underlying the concept of satiety including the definition of satiety, why satiety is important, the dietary factors affecting satiety and the measurement of satiety

Summary

- Satiety is related to the time interval between meals and the amount of food eaten at the next eating occasion.
- Dietary protein appears to be more satiating and suppresses food intake more than carbohydrate or fat**.**
- The effect of protein on food intake and satiety may be source-dependent with whey protein derived from milk, potentially having an effect on food intake suppression and increased satiety.
- Glycomacropeptide, found in whey protein, is a peptide claimed to induce satiety by stimulating the release of the hormone cholecystokinin involved in the control of food intake.
- The mechanisms of action of protein related to food intake suppression and satiety include increased secretion of satiety-related hormones, a greater thermic effect of protein, the plasma concentration of amino acids, and possibly bioactive peptides released during digestion.
- Dietary protein may play a role in the long-term treatment of eating disorders by promoting satiety and reducing binge-eating episodes.

Key Terms

Amino acids: The building blocks of proteins.

Binge eating: The uncontrollable consumption of an excessive amount of food.

Bioactive peptides: Peptides which are active either locally in the gut or systemically to impact on a range of physiological functions, including modifying nutrient absorption and excretion, immunoregulatory effects, and antihypertensive activity. Some are released from foods during digestion.

Branched chain amino acids: Three out of the nine essential amino acids that cannot be produced by the body. They are leucine, isoleucine, and valine.

Casein protein: The major fraction of milk protein comprising of 80% of the total protein.

Energy density: The energy content in kilojoules or Calories per unit of weight or volume.

Fiber: Plant materials which are resistant to digestion by alimentary enzymes.

Glycomacropeptide: The glycosylated fragment of caseinomacropeptide, a polypeptide of 64 amino acid residues. When milk is treated with the enzyme chymosin during the formation of

cheese curd, caseinomacropeptide is released from bovine kappa-casein and moves out of the curd with the whey fraction.

Peptide: Two or more amino acids chained together by a bond. Peptides can serve as messengers within the body such as enzymes, hormones, antibodies, and structural components.

Satiety: The feeling of fullness that occurs after eating a meal.

Visual analogue scales: A subjective measure of satiety. The scale is usually 100 or 150 mm long labeled at each end with extremes of the subjective feeling to be quantified.

Thermic effect of food or diet-induced thermogenesis: Levels of heat produced during the absorption and metabolism of ingested nutrients and partly related to energy expenditure.

Whey protein: The soluble component of milk that is separated from the casein curd during cheese making and represents 20% of the total milk protein.

General and Normative Aspects: Fatty Acids

Chapter 73
Dietary n-3 Polyunsaturated Fatty Acids and Brain Lipid Fatty Acid Composition

Gudrun V. Skuladottir

Abbreviations

ALA	α-Linolenic acid (18:3n-3)
DHA	Docosahexaenoic acid (22:6n-3)
DPA	Docosapentaenoic acid (22:5n-3)
EPA	Eicosapentaenoic acid (20:5n-3)
PC	Phosphatidylcholine
PE	Phosphatidylethanolamine
PI	Phosphatidylinositol
PL	Phospholipids
PS	Phosphatidylserine
PUFA	Polyunsaturated fatty acids
SM	Sphingomyeline

73.1 Introduction

In the mammalian brain, the major polyunsaturated fatty acids (PUFA) in neuronal membrane lipids are the n-3 PUFA docosahexaenoic acid (DHA, 22:6n-3) and the n-6 PUFA arachidonic acid (20:4n-6) (Sastry 1985). The main source of both these PUFA is the diet. The n-3 PUFA found in the diets are α-linolenic acid (ALA, 18:3n-3), eicosapentaenoic acid (EPA, 20:5n-3), and DHA, and the n-6 PUFA is linoleic acid (18:2n-6) and 20:4n-6. Metabolic studies on healthy humans have shown that in contrast to EPA, ALA is not efficiently converted to DHA. ALA is more rapidly oxidized than the 20- and 22-carbons n-3 PUFA, which decreases the availability of ALA for conversion to the EPA and DHA in liver (reviewed in Burdge and Calder 2005; Pawlosky et al. 2001). It has been suggested that the metabolism of n-3 PUFA in the brain depends both on the diet and the liver (Rapoport et al. 2007). The limited conversion of dietary ALA into EPA and DHA in the body might lead to an amount in brain lipids that is not sufficient to meet physiological needs.

Phospholipids (PL) are the fundamental building blocks of cell membranes, and the PL bilayers of the membrane form a stable barrier between two aqueous compartments and represent the basic structure of all biological membranes. The DHA and 20:4n-6 incorporated into the cell membrane PL of the central nervous system increase the fluidity of the membranes, which is an important feature for normal functioning of the central nervous system (reviewed in Horrocks and Farooqui 2004).

The ratio of n-6/n-3 PUFA in the human diet has changed from being ~1 in preagricultural times to 15–16.7:1 in the modern Western diet (Simopoulos 2006). This change is attributed both to increased intake of n-6 PUFA and to decreased intake of n-3 PUFA, particularly n-3 long chain (C ≥ 20) PUFA. The balance of the different types of dietary PUFA is important to fetal and postnatal development, and for beneficial health outcomes throughout life. In the present chapter an attempt is made to give an overview of the fatty acid composition in healthy mammalian brain lipids associated with balanced dietary n-6 PUFA and n-3 PUFA, gender, and aging.

73.2 n-3 Polyunsaturated Fatty Acids (PUFA)

PUFA are chains of 18 carbons or more in length, with hydrogens attached and with two or more double bonds between the carbons in the chain. PUFA are designated by the number of their carbons and double bonds. The location of the first carbon, where the first double bond appears, is counted from the methyl (n-) end of fatty acid. The n-3 PUFA have the first double bond at carbon number three, counted from the methyl end (Fig. 73.1): α-linolenic acid (ALA, 18:3n-3) with 18 carbons and three double bonds, and docosahexaenoic acid (DHA, 22:6n-3) with 22 carbons and six double bonds. PUFA with the first double bond at carbon number six from the methyl (n-) end are termed n-6 PUFA.
Fig. 73.1 Structure models of the n-3 polyunsaturated fatty acids (PUFA) α-linolenic acid (ALA, 18:3n-3) and its derivatives, the eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3). PUFA are designated by the number of their carbons and double bonds. The location of the first carbon, where the first double bond appears, is counted from the methyl (n-) end of fatty acid. The n-3 PUFA have the first double bond at carbon number three, counting from the methyl end. Neither carbon nor hydrogen is shown in the fatty acid chains

73.2.1 Essential Fatty Acids

The major PUFA in mammalian brain are the n-3 PUFA DHA and the n-6 PUFA arachidonic acid (20:4n-6). Mammals lack the necessary enzymes to synthesize the precursors ALA and linoleic acid (18:2n-6) of DHA and 20:4n-6 respectively. ALA is an essential nutrient for mammals in growth and development throughout the life span. Liver and brain of mammals have an enzyme system that desaturates and elongates ALA to make its longer-chain derivatives EPA and DHA. However, the liver is the primary site for essential fatty acid metabolism, where the first part of this pathway takes place in the endoplasmic reticulum and consists of sequential alternating elongation and desaturation steps catalyzed by fatty acid elongases and desaturases (Nakamura et al. 2001). The mechanism of the final conversion to DHA occurs via the so-called Sprecher pathway (Fig. 73.2) (Sprecher et al. 1995).

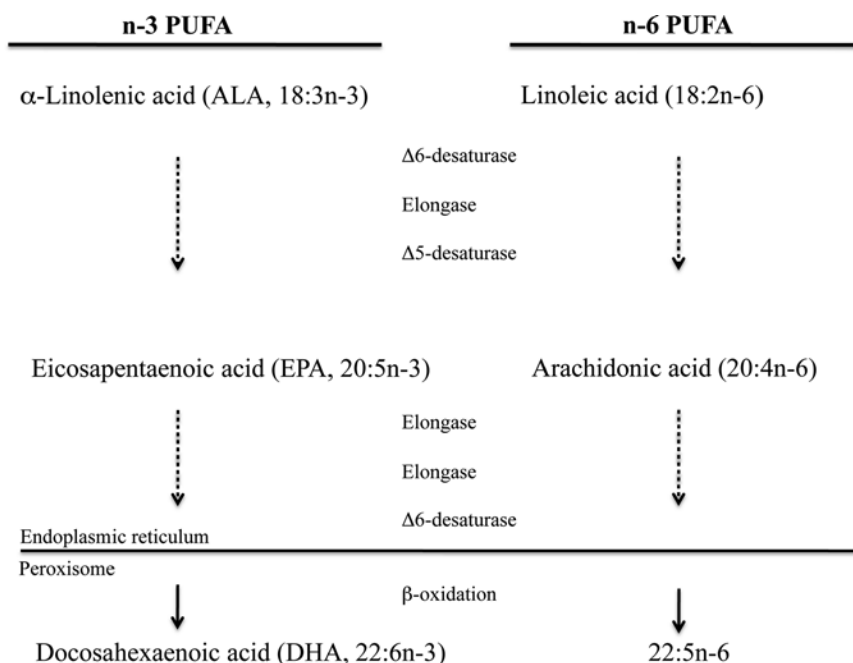
Both the precursors ALA and 18:2n-6 are essential fatty acids, since mammals have to obtain them from food. ALA is mainly found in green leafy vegetables, soybean, flax seed, and canola oil. Many studies indicate that the conversion of ALA to DHA is limited in the human body, and it is debated whether dietary ALA can fulfill the needs of the human body or whether dietary intake of preformed DHA is necessary. EPA and DHA are found in seafood. The solar energy (photosynthesis) and the necessary enzymes enable the phytoplankton to synthesize ALA, EPA, and DHA. These n-3 PUFA ascend the food chain, in zooplanktons, pelagic fish (such as herring, capelin, and tuna), and benthic fish (such as halibut and cod). Then n-3 PUFA ascend in the tissue of terrestrial animals when farmers manipulate animal feed in an attempt to increase n-3 PUFA content of meat, milk, and eggs (Fig. 73.3) (Enser et al. 1996; Kris-Etherton et al. 2000; Sanders, 2000). Specific 18:2n-6


Fig. 73.2 A schematic representation of the biosynthetic pathways for the n-3 polyunsaturated fatty acids (PUFA) and n-6 PUFA. The same enzyme system desaturates and elongates the essential n-3 PUFA and n-6 PUFA, α-linolenic acid (ALA, 18:3n-3) and linoleic acid (18:2n-6) to their longer chain derivatives: eicosapentaenoic acid (EPA, 20:5n-3), docosahexaenoic acid (DHA, 22:6n-3), and arachidonic acid (20:4n-6). Sprecher et al. (1995) re-evaluated the pathways for the biosynthesis of n-3 and n-6 PUFA and demonstrated that the final step for n-3 PUFA takes place in peroxisome, where C24:6n-3 is converted to DHA in one step of β-oxidation
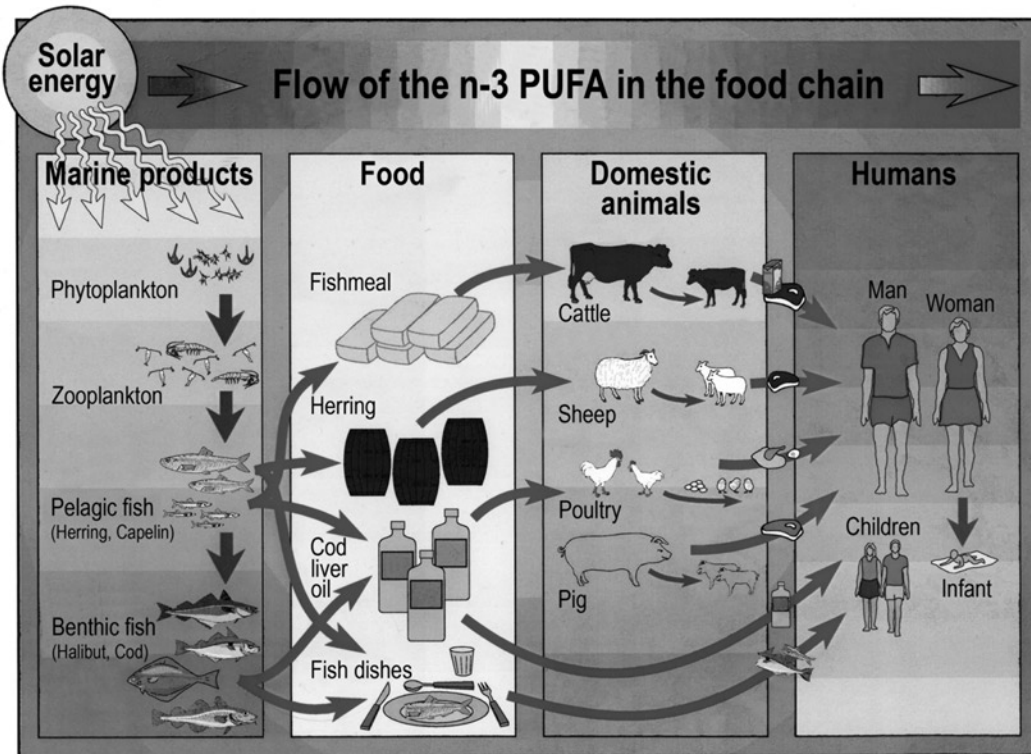

Fig. 73.3 A schematic flow of n-3 polyunsaturated fatty acids (PUFA) in the food chain. Marine products: The solar energy (photosynthesis) and the necessary enzymes enable the phytoplankton to synthesize α-linolenic acid (ALA, 18:3n-3), eicosapentaenoic acid (EPA, 20:5n-3), and docosahexaenoic acid (DHA, 22:6n-3). These n-3 PUFA ascend the food chain in zooplankton, pelagic fish (such as herring, capelin and tuna), and benthic fish (such as halibut and cod). Food: Marine products include: fishmeal produced from herring and capelin, cod liver oil, and fish. Domestic animals: Dietary n-3 PUFA of cattle, sheep, poultry, and pigs are reflected in blood, muscle, and other tissues of the domestic animals when farmers manipulate animal feed with fishmeal and/or fish oil in an attempt to increase n-3 PUFA content of meat, milk, and eggs. Humans: Dietary n-3 PUFA intake is reflected in blood plasma lipids and in cell membrane lipids of tissues and organs of the human body

deficiency does not seem to occur in the human body, since it is present in variable quantities in many plant oils. In the mammalian body, 18:2n-6 is converted to 20:4n-6 (Fig. 73.2) (Sprecher et al. 1995), and 20:4n-6 is also found in meat and eggs.

73.3 Brain DHA Sources

In humans, during growth, development, and aging, the brain DHA content is largely determined by dietary fatty acid composition. Most DHA accumulation in the brain takes place during brain development from the beginning of the last trimester of gestation to 2 years after birth (Dobbing and Sands 1979; Martinez 1992). Therefore, the supply of DHA has to be substantial in order to meet the demands of human growth during the last trimester of gestation and postnatal (Clandinin et al. 1980a,b). At birth, the DHA status in the human infant brain reflects maternal n-3 PUFA status during pregnancy (van Houwelingen et al. 1995). The DHA sources of neonates are DHA in adipose

tissue (Van Duyne and Havel 1959) and breast milk DHA or milk with preformed DHA (Makrides et al. 1994). Neonates that are not breast fed need a diet containing preformed DHA, since the DHA stores at birth will be used up within the first 2 months after birth (Farquharson et al. 1993). After weaning, the sources for DHA in brain membrane lipids are derived from the diet, from liver conversion of the respective dietary precursors ALA and EPA (Fig. 73.2), or from body stores (Spector 2001; Lefkowitz et al. 2005; Chen and Cunnane 1992).

73.4 Brain Lipids

In the mammalian brain, about 50% of the dry weight consists of lipids (Sastry 1985). A variety of complex lipids exist in the brain, and the composition and metabolism of these lipids change with development, age, and diet. Phospholipids (PL) are the major components of the neuronal membranes of the gray matter of the brain. PL is highly polar, with its two fatty acids being hydrophobic, and the water-soluble head group consisting of phosphorus and either choline, ethanolamine, inositol, or serine (Fig. 73.4). The PL classes are phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI), or phosphatidylserine (PS). This polar nature of PL confers on the property of forming bilayer membranes in aqueous media: the hydrophobic fatty acids face inward toward the core of the membrane, and the head groups face outward toward the water. The fatty acids of most natural PL have one or more double bonds, which introduce kinks into the hydrocarbon chains and make them difficult to pack together. The long hydrocarbon chains of the fatty acids therefore move freely in the interior of the membrane, the membrane itself is flexible, which is an important feature of the physical properties of all cell membranes.

The PL classes PC, PI, PS, PE, which contain two fatty acids each, and sphingomyeline (SM), which contains only one fatty acid, are asymmetrically distributed between the two leaflets of the membrane bilayer. It has been established that PC and PE are the major classes of PL in human brain, and that PS and PI make up the balance (Söderberg et al. 1991). The outer leaflet of the membrane consists mainly of PC and SM, whereas PE, PI, and PS are the predominant PL of the inner leaflet.
Fig. 73.4 A structural form of phospholipids (PL), the major components of cell membranes in gray matter of the brain. The three-carbon backbone glycerol has attached fatty acids at the first and second carbons. A phosphorus is attached to the third carbon, and a water-soluble head group consisting either of choline (phosphatidylcholine, PC), ethanolamine (phoshatidylethanolamine, PE), inositol (phosphatidylinositol, PI), or serine (phosphatidylserine, PS) is attached to the other side of the phosphorus

73.4.1 Fatty Acid Composition

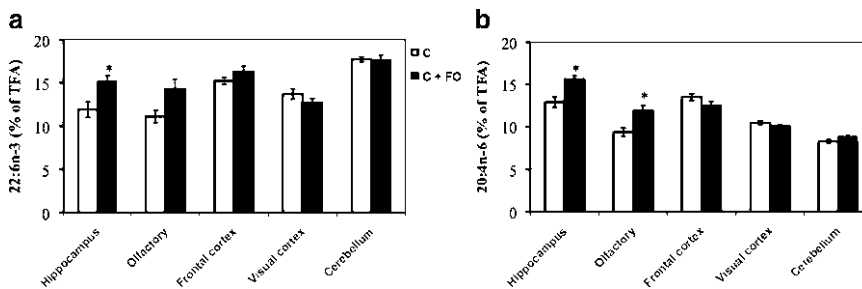
The brain PL of the grey matter are particularly rich in DHA and 20:4n-6. No ALA and only a trace amount of EPA are detected in brain PL. SM contains mostly saturated fatty acids and rarely 20:4n-6 and DHA. The analysis of fatty acid composition of human and animal brain lipids has been performed either in total lipids, total PL, or separate PL classes from whole brain or brain regions. In animals it has been demonstrated that the DHA levels in brain are different, both between regions (Chung et al. 2008; Levant et al. 2006; Xiao et al. 2005; Diau et al. 2005; Carrié et al. 2000) and between PL classes (Petursdottir et al. 2007; Söderberg et al. 1991). Chung et al. (2008) studied the fatty acid composition of total lipids in five brain regions from 4.7-month-old Sprague-Dawley rats fed a control diet. They demonstrated that the levels of DHA and 20:4n-6 in total lipids were region-specific, ranging from 11.1–17.7% and 8.3–13.5% of total fatty acids, respectively (Fig. 73.5). Petursdottir et al. (2007) studied the fatty acid composition of PC, PS, PI, and PE in hippocampus and amygdala in 4-month-old male senescence-accelerated prone mice (SAMP8) that were fed a control diet (Fig. 73.6). They found that both in hippocampus and amygdala, PS and PE contained the highest


Fig. 73.5 Effects of dietary n-3 polyunsaturated fatty acids (PUFA) on the levels (% of total fatty acids [TFA]) of docosahexaenoic acid (DHA, 22:6n-3) (**a**), and arachidonic acid (20:4n-6) (**b**) in total lipids of brain regions from 4.7-month-old male Sprague-Dawley rats. The rats were fed a control diet containing fish oil (C+FO group; dietary n-6 PUFA/n-3 PUFA = 0.13, where 23.7% EPA, 22:5n-3, and DHA were included), or a control diet (C group; dietary n-6 PUFA/n-3 PUFA = 8, where 1.8% EPA and DHA were included). Values are mean ± SEM, n = 9–11. *$P < 0.05$, compared to rats fed the control diet (Based on data from Chung et al. 2008)
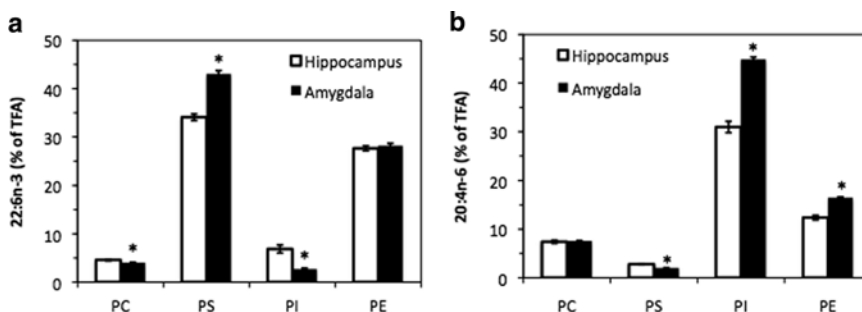

Fig. 73.6 The levels (% of total fatty acids [TFA]) of docosahexaenoic acid (DHA, 22:6n-3) (**a**) and arachidonic acid (20:4n-6) (**b**) in phosphatidylcholine (PC), phosphatidylserine (PS), phosphatidylinositol (PI), and phosphatidylethanolamine (PE) of hippocampus and amygdala from 4-month-old male senescence-accelerated prone mice (SAMP8). The mice were fed a control diet (n-6 PUFA/n-3 PUFA = 7.3) with trace amounts (0.6%) of EPA and DHA. Values are mean ± SEM, n = 8–10 preparations. *$P < 0.05$, compared to hippocampus (Based on data from Petursdottir et al. 2007)

levels of DHA (34.0% ± 0.69% and 43.03% ± 0.69%, 27.63% ± 0.51%, and 28.2% ± 0.48%, respectively) compared to the other PL classes, and that PI in amygdala contained the highest level (44.88% ± 0.49%) of 20:4n-6 compared to that in the hippocampus and the other PL classes. Furthermore, the level of DHA was higher in PS and lower in PI of the amygdala than in the hippocampus (43.03% ± 0.69% versus 34.0% ± 0.69%, 2.71% ± 0.2% and 6.87% ± 0.84%, respectively).

73.4.2 Dietary n-6/n-3 PUFA Ratio

As modern Western diet contains much more 18:2n-6 than ALA, most of the PUFA products in liver are 20:4n-6, since high levels of 18:2n-6 compete with ALA for the Δ6 desaturase (Fig. 73.2) (Rahm and Holman 1964). Nutritional interventional trial designed to determine whether in vivo conversion of dietary ALA is influenced by the 18:2n-6/ALA ratio or by the absolute amounts of 18:2n-6 or ALA in the human diet demonstrated that the dietary 18:2n-6/ALA ratio is not a determinant of the n-3 PUFA conversion (Goyens et al. 2006). It was reported that an increase in EPA synthesis can be obtained by lowering the amount of 18:2n-6 in the diet, whereas an increase in DHA synthesis is achieved by increasing the amount of dietary ALA. Recently, a study reported that higher DHA content was found in PE, PS, and PC of frontal cortex from piglets when fed a diet providing 1.1% energy from 18:2n-6 with a dietary 18:2n-6/ALA ratio close to 1 compared to that from piglets fed a diet providing 10.7% energy from 18:2n-6 with a dietary 18:2n-6/ALA ratio close to 10 (Novak et al. 2008). The elevated levels of DHA in PE, PS, and PC were compensated for by lower levels of 20:4n-6.

In rats and mice whose brains grow postnatally, studies have shown that diets, which are nutritionally adequate but differ in the fatty acid composition, can modify the fatty acid composition of the adult brain. When studying the dietary PUFA effect on fatty acid composition of these animal brain lipids, the control diet during development corresponded to the 18:2n-6/ALA ratio of 6–7 (Bourre et al. 1990). Chung et al. (2008) studied in rats the effect of fish oil supplementation (dietary n-6/n-3 PUFA ratio=0.13, with 23.7% total of EPA, 22:5n-3 and DHA) on the fatty acid composition of total lipids in five brain regions during development and adulthood. They found that the total lipids of hippocampus and olfactory bulb accumulated more DHA and 20:4n-6 in the fish oil supplemented rats than in those of the control rats (dietary n-6 PUFA/n-3 PUFA=7.97, with 1.8% total of EPA and DHA) (Fig. 73.5). The fish oil supplementation did not affect the total lipid levels of DHA and 20:4n-6 in frontal cortex, visual cortex, and cerebellum. However, studies have shown that dietary DHA competes with 20:4n-6 for incorporation into brain PL classes (Gamoh et al. 1999; Suzuki et al. 1998). A study on 10-month-old mice fed high-DHA diet for 8 weeks has demonstrated that PC, PI, and PE in hippocampus and amygdala contained higher DHA levels, and that PC, PS, PI, and PE contained lower 20:4n-6 levels than when mice were fed low-DHA diet (Fig. 73.7) (Petursdottir et al. 2008). The reason the DHA levels of PS in both hippocampus and amygdala were not affected by the high-DHA diet could be that PS contains the highest level of DHA compared to the other PL classes, and that an upper threshold for the incorporation of dietary n-3 PUFA has been reached (Venkatraman et al. 1992). The n-6/n-3 PUFA ratio was 0.1 (26% EPA and DHA included) and 7.4 (0.6% of EPA and DHA included) in the high-DHA diet and the low-DHA diet, respectively.

73.4.3 Gender

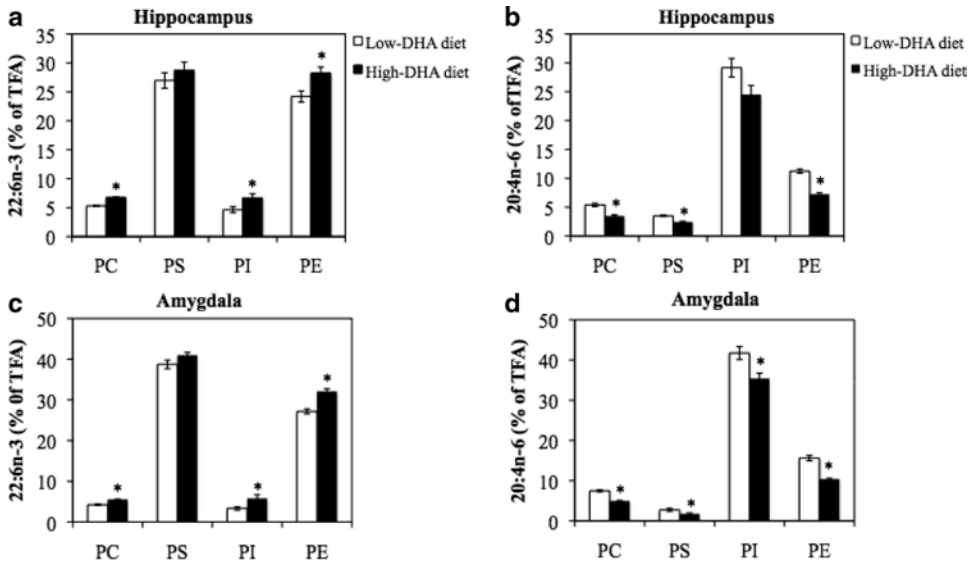
It has been suggested that gender has an important influence on DHA content of tissues, and this has been explained by the role of estrogen on DHA biosynthesis (Childs et al. 2008; Giltay et al. 2004). Studies have shown that when the dietary precursor ^{13}C labeled ALA is given to healthy adults,


Fig. 73.7 Effects of dietary n-3 polyunsaturated fatty acids (PUFA) on the levels (% of total fatty acids [TFA]) of docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (20:4n-6) in phosphatidylcholine (PC), phosphatidylserine (PS), phosphatidylinositol (PI), and phosphatidylethanolamine (PE) of hippocampus (**a** and **b**), and of amygdala (**c** and **d**) from 12-month-old male senescence-accelerated prone mice (SAMP8). The 10-month-old mice were fed low-DHA diet (n-6 PUFA/n-3 PUFA=7.4) for 8 weeks with trace amounts (0.6%) of EPA and DHA included, or a high-DHA diet (n-6 PUFA/n-3 PUFA = 0.1, where 26% EPA and DHA were included). Values are mean ± SEM, n = 8–10 preparations. *$P < 0.05$, compared to mice fed a low-DHA diet (Based on data from Petursdottir et al. 2008)

endogenous biosynthesis of DHA from ALA is higher in women than men (reviewed in Burdge and Calder, 2005; Pawlosky et al. 2003), and that women exhibit greater circulating plasma DHA than men under similar dietary conditions (Crowe et al. 2008; Bakewell et al. 2006; Giltay et al. 2004). Recently, preliminary data have shown that the AA/DHA ratio in postmortem prefrontal cortex from humans was greater in adolescent males than females irrespective of cause of death (McNamara et al. 2009). This preliminary data support the hypothesis of hormonal regulation of PUFA metabolism.

73.4.4 Aging

A direct comparison between data on age-related effects on brain lipid fatty acid composition is impossible, because the analysis of fatty acid composition in brain has been performed either in total lipids, total PL or in separate PL classes from whole brain or brain regions, and secondly, the n-6/n-3 PUFA ratio of the subjects diet might be variable throughout the life. And last but not at least, when studying age-related effects on lipid content and fatty acid composition of postmortem brain, one has to take in account the effects of postmortem storage conditions, such as time and temperature.

A study on the membrane lipid composition of frontal and temporal cortices and white matter in human subjects (20–100 years) who had died suddenly and unexpectedly demonstrated that total PL content began to decrease as early as ~20 years of age in both frontal and temporal cortices (Svennerholm et al. 1994). On the other hand, human study on normal subjects (33–92 years) reported that age had no influence on the fatty acid compositions of PE and PC from frontal gray matter, frontal white matter, hippocampus, and in the pons (Söderberg et al. 1991). Another study on

young (13–19 years) normal subjects reported that the 20:4n-6/DHA ratio in total lipids of frontal cortex was negatively correlated with age at death (McNamara et al. 2009). Rhesus monkeys fed the same control diet (18:2n-6/18:3n-3 ratio 53.1:7.7) as their mothers during pregnancy had higher levels of DHA and lower levels of 20:4n-6 and 22:5n-6 in frontal cortex PE and PS after two to three postnatal years than at birth (Anderson et al. 2005). Compared to 2-month-old male rats fed the control diet (18:2n-6/18:3n-3 ratio 18.2:3.0), the hippocampus of 18-month-old rats contained lower levels of DHA in PE and PS (Favreliére et al. 2003). This age-related decrease in DHA levels of PE and PS was replaced by the monounsaturated fatty acid oleic acid (18:1n-9) at 18 months. The levels of DHA and 18:1n-9 persisted at 21 months compared to 18-month-old rats. Human and animal studies on age-related changes in fatty acid composition in the brain lipids are inconsistent, and the main reason for this is probably the different PUFA composition of the subject diets. On the other hand, the data from these age-related studies on the fatty acid composition of brain lipids indicate that fatty acid analysis of PL classes, rather than total lipids, will produce more reliable data on the modification of fatty acids in cell membrane phospholipids during aging.

73.5 Applications to Other Areas of Health and Disease

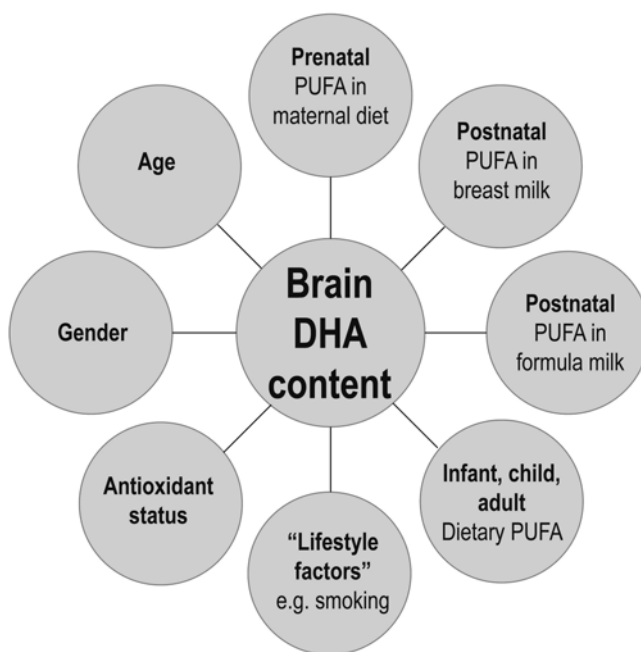
In mammals, DHA content in the brain is largely determined by type and content of dietary PUFA during growth, development, and aging (Fig. 73.8). Studies on dietary PUFA and PUFA in brain lipids associated with development and diseases indicate that dietary DHA is important for fetal and postnatal development (Innis 2009), and for health outcomes during aging (Calder and Yaqoob


Fig. 73.8 Key features on the factors that can affect docosahexaenoic acid (DHA, 22:6n-3) content in mammalian brain lipids. Brain DHA content can be affected by dietary fatty acid composition during intrauterine and extrauterine growth, development and aging, other lifestyle factors such as smoking, the antioxidant status in the body, gender, and aging

2009). Low DHA content in brain lipids has been linked to a variety of neurological disorders, such as impaired cognitive and sensory functions, psychiatric disorders, cardiovascular disease, diabetes, cancer, and degenerative diseases. Fortunately, several studies in young and aged animals have demonstrated that DHA deficiency in brain regions is reversible. However, due to the high content of DHA in brain relative to other organs, lipid peroxidation is thought to be one of the major outcomes of free radical-mediated injury to brain (Montine et al. 2002). Although healthy organisms possess an efficient antioxidant defense system, they might need nutritional compounds with antioxidant defense (such as lipoic acid, vitamin E, and vitamin C) to minimize lipid peroxidation in the body.

In summary, the data demonstrate that the n-3 PUFA content of lipids in mammalian brain regions is differently affected by type and content of dietary PUFA, gender, and age, which might contribute to changes in neuronal functions. Further studies are needed to estimate the dietary balance of n-3 and n-6 PUFA needed at different age stages to provide the conditions for normal neurological development and beneficial health outcomes.

Summary Points

- DHA is the major n-3 PUFA in neuronal membrane lipids in mammalian brain.
- DHA incorporated into cell membrane PL of the central nervous system increase the fluidity of membranes, which is an important feature for normal functioning of the central nervous system.
- Dietary n-3 PUFA are essential for mammals.
- Dietary n-3 PUFA maternal intake is especially important during gestation and breastfeeding for pre- and postnatal development of the offspring.
- DHA content of lipids in different brain regions is affected by dietary PUFA, gender and age.
- Relatively low DHA content in brain lipids is associated with disturbed neurological functions.

Definitions

α-Linolenic acid (ALA, 18:3n-3): An n-3 polyunsaturated fatty acid (PUFA) with 18 carbons and three double bonds. ALA is an essential fatty acid, and is mainly found in green leafy vegetables, soybean, flax seed, canola oil, and marine plants (phytoplankton). In animals, ALA is the precursor of the longer chain (C ≥ 20) n-3 PUFA eicosapentaenoic acid (EPA, 20:5n-3), docosapentaenoic acid (22:5n-3) and docosahexaenoic acid (DHA, 22:6n-3).

Arachidonic acid (20:4n-6): An n-6 polyunsaturated fatty acid (PUFA) with 20 carbons and four double bonds. It is found in meat and eggs. In animals, 20:4n-6 is synthesized from the linoleic acid (18:2n-6). The phospholipids (PL) of the grey matter in brain are particularly rich in 20:4n-6, as well as in DHA.

Docosahexaenoic acid (DHA, 22:6n-3): An n-3 polyunsaturated fatty acid (PUFA) with 22 carbons and six double bonds. DHA is mainly found in marine products. In animals, DHA is synthesized from α-linolenic acid (ALA, 18:3n-3) and eicosapentaenoic acid (EPA, 20:5n-3). DHA represents the longest and the most unsaturated fatty acid commonly found in biological systems.

Eicosapentaenoic acid (EPA, 20:5n-3): An n-3 polyunsaturated fatty acid (PUFA) with 20 carbons and five double bonds. EPA is mainly found in marine products. In animals, EPA is synthesized from α-linolenic acid (ALA, 18:3n-3).

Essential fatty acids: Animals lack the necessary enzymes to synthesize α-linolenic acid (ALA, 18:3n-3) and linoleic acid (18:2n-6) and have to obtain them from the diet. Those two fatty acids are essential because they are the precursors of the longer chain n-3 polyunsaturated fatty acid (PUFA) eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3), and the n-6 PUFA 20:4n-6, respectively. In humans, EPA and DHA are considered essential fatty acids, since the conversion of ALA to EPA and DHA is limited in the human body.

Linoleic acid (18:2n-6): An n-6 polyunsaturated fatty acid (PUFA) with 18 carbons and two double bonds. Linoleic acid is an essential fatty acid and is found in many plant oils. In animals, linoleic acid is converted into the longer chain n-6 PUFA arachidonic acid (20:4n-6).

Monounsaturated fatty acid: A monounsaturated fatty acid is a chain of carbons with hydrogens attached and only one double bond between the carbons in the chain. The most common monounsaturated fatty acid in mammals is oleic acid with eighteen carbons and the only double bond located at carbon number nine counted from the metyl (n-) end of the chain (18:1n-9).

Phospholipids (PL): PL are highly polar with two fatty acids being hydrophobic, and the water-soluble head group consisting of phosphorus and either choline, ethanolamine, inositol, or serine. The PL classes are phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI), or phosphatidylserine (PS). PL are the major components of the neuronal membranes of the gray matter of the brain, and they are particularly rich in docosahexaenoic acid (DHA, 22:6n-3) and 20:4n-6.

Polyunsaturated fatty acids (PUFA): PUFA are chains of 18 carbons or more in length with hydrogens attached and with two or more double bonds between the carbons in the chain. PUFA are designated by the number of their carbons and the location of the first carbon, where the first double bond appears in a position counting from the methyl (n-) end of the chain (e.g., 18:3n-3, 22:6n-3, 20:4n-6).

n-3 polyunsaturated fatty acids (PUFA): n-3 (or omega-3) PUFA have the first double bond located at carbon number three, counting from the methyl (n-) end of the chain. The essential n-3 PUFA, α-linolenic acid (ALA, 18:3n-3), is the precursor of the longer chain n-3 PUFA eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3).

n-6 polyunsaturated fatty acids (PUFA): n-6 (or omega-6) PUFA have the first double bond located at carbon number six, counted from the methyl (n-) end of the chain. The essential n-6 PUFA linoleic acid (18:2n-6) is the precursor of the arachidonic acid (20:4n-6).

Saturated fatty acid: Saturated fatty acid is a chain of carbons with hydrogens attached and with only single bonds between carbons in the chain. The most common saturated fatty acids in mammals are palmitic acid with 16 carbons (16:0) and stearic acid with 18 carbons (18:0).

Chapter 74
Mother–Child Long Chain Polyunsaturated Fatty Acid Relationships: Implications for Diet and Behavior

S.A. van Goor, D.A.J. Dijck-Brouwer, and F.A.J. Muskiet

Abbreviations

EFA	Essential fatty acids
LCP	Long chain polyunsaturated fatty acids
LA	Linoleic acid
ALA	Alpha-linolenic acid
FADS1	Fatty acid desaturase 1 (delta-5 desaturase)
FADS2	Fatty acid desaturase 2 (delta-6 desaturase)
AA	Arachidonic acid
EPA	Eicosapentaenoic acid
DHA	Docosahexaenoic acid
SAFA	Saturated fatty acids
MUFA	Monounsaturated fatty acids
PPAR	Peroxisome proliferator activated receptor
CVD	Cardiovascular disease
RCTs	Randomized controlled trials
RBC	Red blood cells
GDM	Gestational diabetes mellitus

74.1 Introduction

The maternal diet prior to conception and during pregnancy and lactation, as well as infant nutrition during early postnatal life, are important for child growth and development and for the maintenance of good health at adult age (Barker 2007). Dietary fat and especially its constituents, such as essential fatty acids (EFA; see Table 74.1) and fat soluble vitamins, are among the many nutrients that are involved. This chapter describes the role of EFA and their chain-elongated and desaturated metabolites, named long-chain polyunsaturated fatty acids (LCP, ≥20 carbon atoms and ≥3 methylene-interrupted cis-double bonds; see Table 74.2). After an introduction into the (patho)biochemistry and (patho)physiology of EFA we focus at the role of LCP during pregnancy and in early postnatal life and discuss the currently recommended LCP intakes by pregnant mothers and infants.

Table 74.1 Key facts of essential fatty acids, or EFAs

- EFA are fatty acids that cannot be synthesized within the human body.
- EFA are essential for the proper functioning of humans.
- EFA should be obtained from the diet to prevent disease.
- Linoleic acid (LA) and alpha-linolenic acid (ALA) are the parent EFA for humans.
- LA and ALA are obtained from vegetable oils; LA notably from safflower oil and sunflower oil and ALA from linseed oil and soy bean oil.
- EFA are used for energy generation but are also building blocks of membranes of all cells, thereby influencing the functions of membrane-bound receptors, transporters, ion channels, enzymes, and other membrane-dependent functions.
- LA is a building block of ceramides in our skin; ceramides function as barriers to limit water loss from our skin.
- LA can be stored in our adipose tissue.
- ALA is mostly degraded to acetyl-CoA for the generation of energy and for the synthesis of other fatty acids and cholesterol.
- ALA and LA are precursors of long-chain polyunsaturated fatty acids (LCP); they compete for the enzymes in the LCP synthetic pathway.

This table lists the key facts of Essential Fatty acids, including their function and sources

Table 74.2 Key facts of long-chain poly-unsaturated fatty acids or LCP

- LCP are fatty acids with at least 20 carbon atoms and at least 3 (methylene-interrupted *cis-*) double bonds.
- There are two LCP classes: the n-3 series (synthesized from ALA) and the n-6 series (synthesized from LA).
- The most important n-3 LCP are EPA (eicosapentaenoic acid) and DHA (docosahexaenoic acid); the most important n-6 LCP is arachidonic acid (AA).
- Endogenous EPA and notably DHA synthesis is considered insufficient.
- EPA and DHA can be obtained from the diet, notably from (fatty) fish.
- AA can be synthesized from LA with little difficulty.
- AA can also be obtained from the diet, notably from meat and eggs.
- AA, EPA, and DHA are precursors of eicosanoids, leukotrienes, neuroprotectins, and resolvins, which are hormone-like substances with a wide variety of actions.
- AA is an important building block of the brain, but also of all other organs. AA has functions in cell signal transduction and in the initiation and resolution of inflammatory processes.
- DHA is a building block of the brain, but also of all other organs. DHA in membranes is necessary for appropriate receptor functioning (e.g. in the retina), while EPA and DHA are important for the resolution of inflammatory processes.
- EPA and DHA are important for a healthy heart and blood vessels.
- High EPA+DHA intake from fish is beneficial for brain development, and the prevention of cardiovascular disease, depression, and other psychiatric diseases in which low-grade inflammation may be a common denominator.

This table lists the key facts of long-chain poly-unsaturated fatty acids or LCP, including their function and sources

74.2 EFA and LCP Dietary Origins and Synthesis

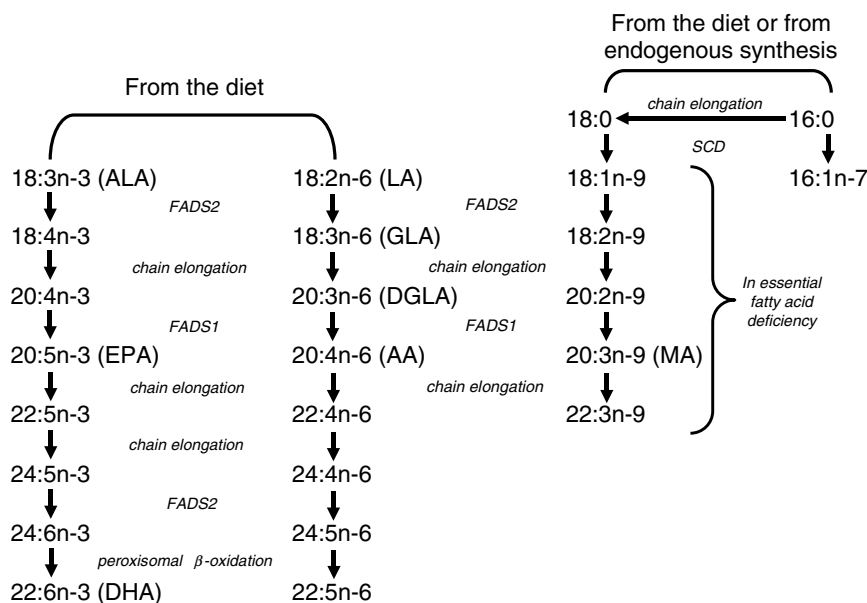
Linoleic acid (18:2n-6, LA, precursor of the so called omega-6 or n-6-series fatty acids) and alpha-linolenic acid (18:3n-3, ALA, precursor of the omega-3 or n-3-series) are the parent EFA for humans. They can be converted into LCP by microsomal desaturation by delta-6 and delta-5 desaturase (also referred to as FADS2 and FADS1, respectively), microsomal chain elongation and peroxisomal chain shortening (Fig. 74.1). Both LA and ALA are predominantly derived from vegetable oils. Important LCP are arachidonic acid (20:4n-6, AA) from LA, and eicosapentaenoic acid (20:5n-3, EPA) and docosahexaenoic acid (22:6n-3, DHA) from ALA. Synthesis of DHA from ALA is limited in humans and DHA is therefore considered to be conditionally essential (Muskiet et al. 2004). "Conditionally essential" refers to the necessity of a dietary source at circumstances during which


Fig. 74.1 Pathways of fatty acid chain elongation and desaturation. ALA and LA are the parent EFA for humans, and can be converted into LCP by microsomal desaturation by FADS2 and FADS1, microsomal chain elongation, and peroxisomal chain shortening. *ALA* alpha-linolenic acid, *LA* linoleic acid, *GLA* gamma-linolenic acid, *DGLA* dihomo-gamma-linolenic acid, *EPA* eicosapentaenoic acid, *AA* arachidonic acid, *MA* Mead acid, *DHA* docosahexaenoic acid, *FADS1* fatty acid desaturase 1, delta-5 desaturase, *FADS2* fatty acid desaturase 2, delta-6 desaturase, *SCD* stearoyl-CoA desaturase, delta-9 desaturase

the need exceeds endogenous synthesis. Meat, eggs, and poultry are rich sources of AA, while EPA and DHA are derived notably from fish, especially fatty fish.

The order of substrate affinity of FADS2 is ALA>LA>oleic acid (18:1n-9). Consequently, deficiency of parent EFA (i.e., of both LA and ALA) gives rise to the accumulation of Mead acid (20:3n-9), because of the action of the chain elongation/desaturation system on the competing oleic acid (Fig. 74.1). The sharing of the elongating and desaturating enzymes by n-6 and n-3 fatty acids causes these fatty acids to compete for conversion into the various LCP. The n-3 and n-6 fatty acids also compete in many other processes, such as transport, beta-oxidation, incorporation into lipids, release from lipids, conversion into highly active metabolites, and binding to receptors. The regulation of LCP synthesis is complex and notably targets FADS1 and FADS2. Both enzymes are widely expressed in human tissues with the highest contents in liver. The liver seems the major origin of endogenously synthesized LCP from LA and ALA. Dietary LCP downregulate LCP synthesis by negative feedback inhibition (Nakamura and Nara 2004). Insulin stimulates the expression of both enzymes, while it also stimulates expression of delta-9 desaturase (stearoyl-CoA desaturase) (Jump 2008). The latter is the third important desaturase that is notably associated with de novo fatty acid synthesis and is, e.g., induced in adipose tissue during insulin resistance. The strong feedback control of LCP on LCP synthesis predicts that the dietary supply of either LCPn-6 or LCPn-3 may shut off synthesis of both LCP series (Nakamura and Nara 2004). This seems especially important in the context of our currently high intake of LA from vegetable oils, which inhibits the synthesis of EPA from ALA (Angela Liou and Innis 2009). The complex interrelationships between the two EFA series put emphasis on the need of dietary "n-3/n-6 balance" to reach "homeostasis." The dietary composition producing this balance is as yet unknown, but it may be postulated that this balance is part of our Paleolithic diet on which our genes have evolved (Muskiet et al. 2006).

74.3 EFA and LCP (Patho)Biochemistry and (Patho)Physiology

Most of the dietary LA and ALA is used for energy generation, converted to other compounds or used for structural purposes. LA especially, can be stored to reach high levels in adipose tissue. LA and LCP (especially AA, EPA, and DHA) are the building blocks of the membrane phospholipids of all cells. They contribute to the membrane's physico-chemical properties and thereby to the functions of membrane-bound receptors, transporters, ion channels, enzymes, and other membrane-bound biochemical processes, such as those involved in signaling pathways. LA also acts as building block of ceramides in the skin and thereby contributes to the skin's barrier function. In contrast to LA, ALA gets stored in our body to only a limited extent. ALA is largely degraded to acetyl-CoA for the generation of energy or de novo synthesis of saturated fatty acids (SAFA), monounsaturated fatty acids (MUFA), and cholesterol.

Brain dry weight contains about 6% AA and 8% DHA, whereas brain levels of LA and ALA are low. DHA and AA are notably located in the synaptosomes, where AA is of special importance as a second messenger in (synaptic) signal transduction, and DHA provides the needed membrane fluidity for appropriate neurotransmitter receptor activity. DHA's role in neurodevelopment has been grouped into effects on gene expression, monoaminergic neurotransmission, protection against apoptotic cell death, and neurite outgrowth from the cell body (Innis 2007a). LCP are precursors of eicosanoids, resolvins, and protectins, which are highly potent metabolites that are involved in various signaling processes. The eicosanoids from EPA are believed to be less potent than those of AA. Eicosanoids from AA are widely considered to be proinflammatory, whereas those from EPA are weakly inflammatory or even anti-inflammatory. This must however be viewed upon as a generalization, since newly identified mediators of AA are not only involved in the initiation, but also in the resolution of inflammatory reactions (Serhan and Chiang 2008). Brain regions differ in AA and DHA contents at different ages, which may imply age- and region-specific regulation. Especially the membrane lipids of the visual elements of the infant retina contain high amounts of DHA and AA (Makrides et al. 1994), whereas at a later age, the retina contains a high amount of DHA but not AA. In nonhuman primates, brain grey matter contains the highest amounts of DHA as well as AA (Diau et al. 2005).

Together with their eicosanoid products and other fatty acids, LCP are firmly implicated in gene expression. For example, dietary LCP are ligands of peroxisome proliferator-activated receptors (PPARs). PPARs are among our bodily "lipid sensors" and, importantly, they constitute a link between lipid and glucose metabolism and inflammation (Jump 2008). They are also involved in growth and development. Because of their strategic role in many metabolic and signaling routes PPARs are logical targets for drugs. For instance, the fibrates for serum triglyceride lowering are agonists of PPAR-alpha, while the insulin sensitivity increasing properties of the thiazolidinediones (glitazones) are based on their agonistic action towards PPAR-gamma. In addition, PPARs are also likely to constitute a link between dietary fatty acids and one-carbon metabolism and thereby epigenetics, since folic acid supplementation of dietary protein-restricted pregnant rats corrected the overexpression of the PPAR-alpha gene in the fetal liver (Lillycrop et al. 2008). Folic acid-stimulated methylation of CpG dinucleotides in the PPAR-alpha gene promoter was found to be the underlying mechanism. These methylation patterns persisted into adulthood (Lillycrop et al. 2008) and were passed on to the next generation (Burdge et al. 2007). Modifiable PPAR-alpha expression by maternal dietary protein and folic acid might be expected to confer different sensitivities of the offspring to PPAR-alpha natural ligands, such as the LCP and their metabolites. Little is as yet known on the influence of nutrient–nutrient interaction in (patho)biochemistry and (patho)physiology, including the many possible interactions of different nutrients with LCP.

Clinically apparent EFA deficiency (i.e., of both n-6 and n-3 fatty acids) in Western countries is rare. The sporadic cases are mostly based on heritable or acquired diseases that cause, or are accompanied by, poor gastrointestinal fat absorption. A-betalipoproteinemia, cystic fibrosis, and chronic intestinal disorders causing malabsorption (e.g., Crohn's disease) are examples of such diseases. Growth retardation, reproductive failure, fatty liver, and a dry scaly skin that is characterized by augmented transdermal water loss are attributed to n-6 fatty acid shortage. Deficiency of n-3 fatty acids is related to dysfunction of the central nervous system, including cognitive dysfunction and impaired vision. Imbalances between AA, EPA, and DHA may change the ratio between their eicosanoids, resolvins, and protectins with concomitant pathophysiological effects, such as those associated with chronic low grade inflammation (Serhan and Chiang 2008). Higher intakes of EPA and DHA from fish are firmly implicated in cardiovascular and neuro-psychiatric health benefits. It is nowadays widely recognized that insulin resistance and its sequelae associated with the metabolic syndrome (such as diabetes type 2, cardiovascular disease (CVD), certain pregnancy complications and cancer types), neurodegenerative disorders (like Alzheimer's and Parkinson's disease), and depression may find a common origin in a state of chronic low-grade inflammation that is intimately related to the current high dietary intakes of SAFA, *trans* fatty acids, and n-6 fatty acids, and the low intakes of n-3-fatty acids, notably those abundant in fish (Warnberg et al. 2009). The presently advised dietary intake of about 450 mg LCPn-3/day confers virtually maximum antiarrhythmic effects, but is below the estimated dosages that confer maximum benefits for other CVD risk factors responding favorably to fish oil, such as hypertension, dyslipidemia, and thrombosis (Mozaffarian and Rimm 2006), suggesting that each of the many LCPn-3 functions has its own optimal intake and that the function least sensitive to dietary intervention may define the requirement.

Low perinatal frontal cortex DHA accretion is associated with suboptimal development of the dopaminergic system and is therefore considered to be a risk factor for attention-deficit/hyperactivity disorder (ADHD) and schizophrenia. There is good evidence to show that DHA is accrued in rodent, primate, and human brain during active periods of perinatal cortical maturation, and that DHA plays an important role in neuronal differentiation, synaptogenesis, and synaptic function (McNamara and Carlson 2006). Low intake of EPA and DHA is implicated in the high incidence of depression in Western countries and there is a strong inverse correlation between national dietary fish intakes and rates of postpartum depression (Hibbeln 2002). Randomized controlled trials (RCTs; see Table 74.3 for explanation) with LCPn-3, especially EPA, have shown favorable outcomes in depression (Ross et al. 2007).

74.4 LCP in Pregnancy

74.4.1 Maternal and Fetal LCP Metabolism and Transplacental Transport

Fetal EFA/LCP status is dependent on maternal EFA/LCP status and on fetal LCP synthesis from transplacentally transferred parent EFA. Several human studies demonstrated relationships between maternal and fetal EFA/LCP status in compartments such as red blood cells (RBC) and plasma (Al et al. 1990, 1995; Rump et al. 2001; Vlaardingerbroek and Hornstra 2004). Differences in maternal dietary DHA and AA ratios were shown to influence offspring brain LCP composition (van Goor et al. 2008a; Wainwright et al. 1997), while maternal erythrocyte LCP content was shown to correlate with fetal brain LCP content (van Goor et al. 2008a) (Fig. 74.2), at least in mice. Although, in general, conversion of ALA to EPA and especially to DHA is low in humans, women show a higher

Table 74.3 Key facts of randomized controlled trials or RCT

- An RCT is a scientific experiment of high standards that is most commonly used for testing the efficacy or effectiveness of a healthcare service (such as nursing) or health technologies (such as drugs, nutrients, medical devices or surgery).
- RCTs involve the random allocation of different interventions (treatments or conditions) to subjects.
- A Placebo-controlled study is a way of testing a medical therapy in which, in addition to a group of subjects that receives the treatment to be evaluated, a separate control group receives "placebo" treatment which is specifically designed to have no real effect.
- The purpose of the placebo group is to account for "placebo effects," which are effects from treatment that are not caused by the treatment itself. Such effects may originate from the knowledge of who receives real treatment, attention from health care professionals, and the expectations that the real treatment is effective by those who conduct the study. Without a placebo group for comparison there is no proof of "causality," that is, it is not possible to know whether the real treatment had any effect.
- If the RCT is double-blinded, patients and investigators are unaware of which treatment (real or placebo) is given to an individual patient.
- As long as the numbers of subjects are sufficient, randomization is an effective method for balancing confounding factors between treatment groups.

This table lists the key facts of randomized controlled trials
Fig. 74.2 Correlations between maternal erythrocyte LCP, and maternal and fetal brain LCP. Maternal erythrocyte DHA and AA correlates with fetal brain DHA and AA in mice. *AA* arachidonic acid, *DHA* docosahexaenoic acid. Diets varying in parent essential fatty acids (EFA), AA and DHA were administered from day 3 prior to conception till day 15 of pregnancy at which samples were taken (Adapted from van Goor et al. (2008a) with permission from Elsevier (modified figure))

conversion compared to men. A possible explanation may lay in the action of estrogen, and it is possible that the increasing estrogen concentrations upregulate ALA conversion during pregnancy (Burdge 2006). This higher efficiency in women might be important, but is unlikely to compensate fully for the fetal and newborn needs. Transplacental fatty acid transport is selective for LCP, as concluded from the relatively higher LCP contents in the fetal circulation, compared with maternal circulation, while the transfer of LA and ALA is nonselective. The underlying mechanism of LCP transplacental transfer, causing what is called "biomagnification" (Crawford et al. 1976) (Fig. 74.3), is probably by a combination of many mechanisms, including selective hydrolysis of LCP from
Fig. 74.3 Essential fatty acid contents (g/100 g fatty acids) in maternal plasma lipids (*left*) and cord plasma lipids (*right*). The higher DHA and AA in fetal lipids compared to maternal lipids has been named "biomagnification." ■ Linoleic acid; □ arachidonic acid (AA); docosahexaenoic acid (DHA); *TG* triglycerides, *PL* phospholipids, *CE* cholesterol esters (Adapted from Innis (2005) with permission from Elsevier)

maternal triglycerides, increasing maternal free fatty acids with advancing gestation in combination with higher fetal albumin, placental fatty acid binding proteins and fatty acid transfer proteins, and the trapping of the transferred LCP in the fetal circulation by albumin and alpha-fetoprotein or by esterification to lipids (Duttaroy 2009). The placenta contains both FADS1 and FADS2 activities which suggests that placental LCP synthesis may contribute to fetal LCP status, although the extent to which this occurs is unknown (Innis 2005). The outcome of the various mechanisms is that fatty acids are transferred from mother to child with an order of preference of DHA>AA>ALA>LA (Duttaroy 2009).

There is reasonable evidence to show that in Western countries, the maternal body becomes somewhat depleted from LCP, notably DHA, during pregnancy and subsequent breastfeeding. The following characteristics of LCP physiology have been derived from the courses of the plasma phospholipids and RBC fatty acid compositions during pregnancy in Western countries: maternal AA increases in early pregnancy and subsequently falls below prepregnancy levels, DHA increases in early pregnancy and subsequently decreases but remains above prepregnancy levels, the EFA/non-EFA ratio [(sum n-3 + sum n-6)/(sum n-7 + sum n-9)] decreases while the DHA deficiency index (22:5n-6/22:4n-6) increases with gestational age. Maternal and fetal LCP (notably DHA) status is correlated, normalization of maternal DHA status after delivery is retarded by breastfeeding, and maternal plasma DHA is higher in primigravidae than multigravidae (Hornstra 2000).

In general, EPA + DHA intakes in Western countries are low compared to the recommendation to consume about 450 mg LCP n-3/day. An EFA deficiency initiated three days prior to conception in female mice, caused biochemical signs of DHA depletion in maternal brain, but severely impaired accretion of DHA in the fetal brain. This implies that, at least in mice, the growing fetal brain is more sensitive to low LCP status than maternal brain (van Goor et al. 2008a), as illustrated by the steeper slopes of the relation between maternal erythrocyte LCP and fetal brain LCP, compared to the relations between maternal erythrocyte LCP and maternal brain LCP (Fig. 74.2). Extreme models with long term ALA-deficiency in female rats showed that maternal brain DHA is vulnerable to depletion, which becomes aggravated by pregnancy and lactation and affects specific brain regions differently (Levant et al. 2008). Thus, because of the high fetal demands, it seems likely that the marginal LCP status in Western countries causes maternal brain to lose LCP, notably DHA, during pregnancy, while declining brain DHA is associated with increasing AA turnover and neuroinflammation (Orr and Bazinet 2008). Declining maternal DHA status was suggested to be involved in the compromised

selective attention, which is a key component of cognition, during pregnancy (de Groot et al. 2004) and although unproven in RCTs with LCPn-3 (Ross et al. 2007), a relation between declining maternal DHA status and postpartum depression was observed (Hibbeln 2002).

Positive as well as negative associations between fish intake and fetal growth have been observed. A meta-analysis of LCPn-3 supplementation studies during pregnancy indicated an increased length of gestation (1.57 days) and a trend towards an increased head circumference (0.26 cm). Supplementation did not influence the percentage of preterm deliveries, the rate of low-birth-weight infants, the rate of preeclampsia or eclampsia, and birth weight and birth length (Szajewska et al. 2006).

Both maternal and fetal LCP status are compromised by gestational diabetes mellitus (GDM), types 1 and 2 diabetes mellitus, and preeclampsia. This might be of growing importance because affluent countries experience increasing prevalence of overweight and obesity in pregnancy, while a high maternal BMI is a well established risk factor for GDM, diabetes mellitus type 2, preeclampsia and fetal defects. Umbilical vessels at term (Muskiet et al. 2006) and erythrocytes of newborns up to 0.2 years (Fokkema et al. 2002) contain relatively high amounts of Mead acid. Umbilical arteries contain higher Mead acid than umbilical veins. Both in the umbilical artery and umbilical vein, Mead acid correlates inversely with AA and LA levels, and positively with oleic acid levels, suggesting that the intrauterine environment is characterized by low EFA status. The abundant intrauterine synthesis of Mead acid is a consequence of the high de novo synthesis of oleic acid from the ample glucose that crosses the placenta in the third trimester (Fig. 74.4). In contrast, relatively little maternal LA becomes trapped in the fetal circulation. The resulting high fetal oleic acid/LA ratio directs fetal FADS2 to synthesize Mead acid from oleic acid (Fig. 74.1), at the expense of AA synthesis from LA. Compromised glucose homeostasis in maternal diabetes mellitus and GDM may cause higher transplacental glucose flux with concomitantly increased fetal de novo fatty acid synthesis, while the insulin resistance in both (gestational) diabetes and preeclampsia may cause increased de novo fatty acid synthesis in the maternal liver with subsequent transfer of these de novo synthesized fatty acids to the fetus. The outcome is a fetal state of "relative EFA/LCP deficiency," rather than an absolute deficiency, with as yet unknown consequences.

Taken together, it seems that both maternal and fetal DHA status and to a lesser extent AA status are at risk in current Western societies because of the low maternal intake of fish and the increasing prevalence of maternal insulin resistance and compromised glucose homeostasis. The crucial importance of the fetal LCP status seems, however, clear from the well established fetal preference of LCP, notably DHA, as compared with their parent EFA precursors, while there is ample evidence that the DHA and AA intakes from our ancient diet have been much higher compared with contemporary intakes (Muskiet et al. 2006).

74.4.2 *LCP in Pregnancy and Neurodevelopment*

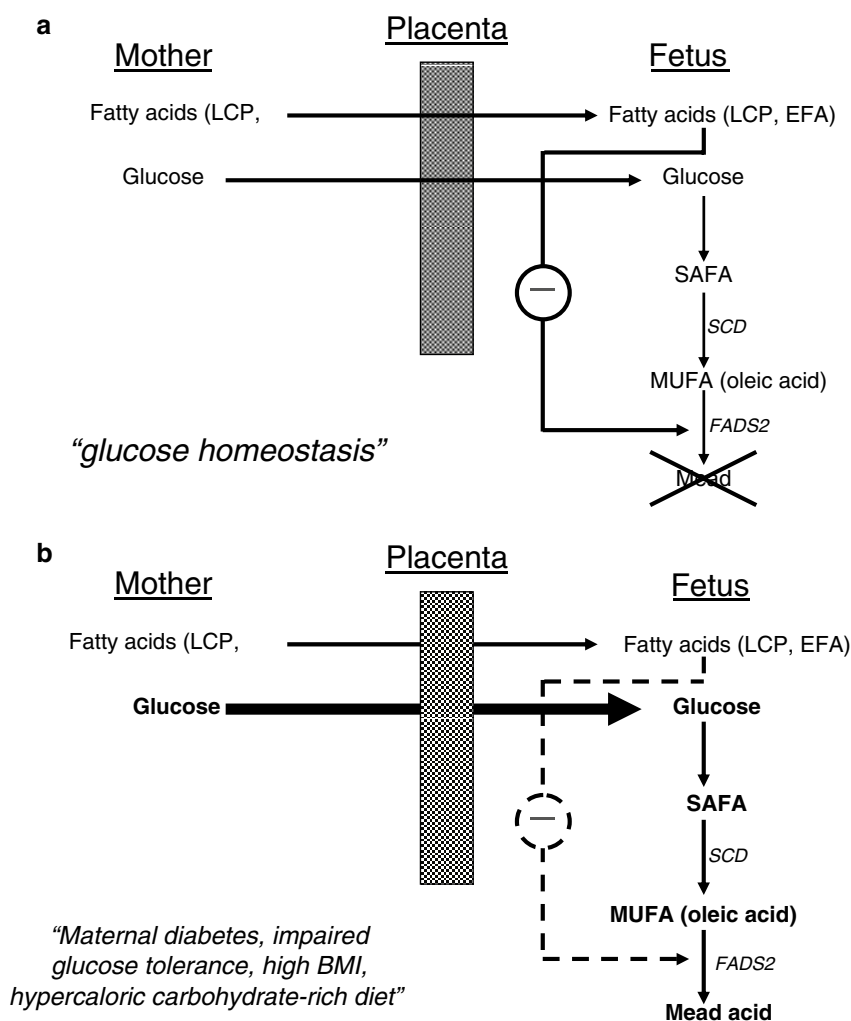
Several studies indicated the importance of DHA in pregnancy and neurodevelopment. A large observational study showed that 6 months to 8 years old children from mothers with seafood consumption below 340 g/week had lower verbal IQ and an increased risk of suboptimal outcomes for prosocial behavior, fine motor skills, communication and social development scores, compared with children from mothers eating more than 340 g/week (Hibbeln et al. 2007). A higher cord plasma DHA was associated with a more optimal cognitive development at 6 months and at 11 months, and a higher cord plasma DHA/AA was associated with a more optimal visual development at 6 months, cognitive development at 6 months, and motor development at 11 months (Jacobson et al. 2008).


Fig. 74.4 Fetal essential fatty acid (EFA) and long chain polyunsaturated fatty acid (LCP) status at "normal" (**a**) and augmented (**b**) transplacental glucose transport. Increased transplacental glucose fluxes may occur in maternal diabetes, impaired glucose tolerance, high body mass index (BMI), and a hypercaloric carbohydrate-rich diet. Increased de novo synthesis of fatty acids from glucose in the fetus by stearoyl-CoA desaturase (SCD, delta-9 desaturase) causes augmented accretion of saturated (SAFA) and monounsaturated (MUFA) fatty acids, notably 16:0, 16:1n-7, and 18:1n-9 (oleic acid). Oleic acid may compete with linoleic acid for fetal delta-6 desaturase (FADS2) causing formation of Mead acid (20:3n-9) at the expense of the synthesis of arachidonic acid (20:4n-6) from linoleic acid. Accretion of de novo synthesized fat gives rise to dilution of fetal EFA and LCP status, causing a state of 'relative' EFA/LCP deficiency, rather than absolute deficiency (Adapted from Muskiet et al. (2006) with permission from Elsevier)

Umbilical cord plasma DHA was also associated with lower internalizing problem behavior at 7 years (Krabbendam et al. 2007), whereas AA showed no significant relations. Others showed that maternal plasma phospholipid DHA was related to more mature sleep patterns in their neonates, while the n-6/n-3 ratio was negatively associated (Cheruku et al. 2002). Infants of mothers with high RBC DHA performed better on psychophysiological measures (4, 6, and 8 months) and on free play attention and distractibility paradigms (12 and 18 months) (Colombo et al. 2004), while maternal DHA intake during pregnancy was associated with better stereo acuity of their children at 3.5 years

(Williams et al. 2001). Also, AA was found to be important to neurodevelopment. For instance, a positive association was found between umbilical vessel DHA as well as AA and the neurological optimality score at 2 weeks (Dijck-Brouwer et al. 2005), and between umbilical venous AA and general movement quality at 3 months (Bouwstra et al. 2006b) and the neurological optimality score at 18 months (Bouwstra et al. 2006a). Maternal AA intake during pregnancy was related to shorter brainstem auditory-evoked potentials of their infants at 1 month (Parra-Cabrera et al. 2007). Another study revealed no relation between umbilical blood DHA or AA status with child cognition at 4 years (Ghys et al. 2002) and 7 years (Bakker et al. 2003). Taken together, these studies indicate the importance of not only DHA during pregnancy, but also of AA and the DHA/AA balance.

Maternal DHA supplementation studies during pregnancy or during pregnancy and subsequent lactation with doses ranging from 200 to 3,300 mg DHA/day resulted in improved visual acuity at 4 months (Judge et al. 2007a), enhanced problem solving at 9 months (Judge et al. 2007b), improved eye–hand coordination at 2.5 years (Dunstan et al. 2006) or a higher IQ at 4 years (Helland et al. 2003), whereas other developmental parameters showed no benefits (Hadders-Algra 2008). Some studies showing no effect, reported associations similar to those noted in observational studies (Hadders-Algra 2008). The positive effects of maternal DHA supplementation may first become expressed after early infancy, but the discrepancy may also relate to a complex interplay between a ceiling effect in the dose–outcome relationship, benefits to those with suboptimal baseline status only, and interindividual differences in developmental potential (Innis and Friesen 2008). A high variety in developmental tests, differing in functional background, has been employed in the various studies. Various brain regions differ in fatty acid composition, which may imply region-specific regulation of brain LCP contents. It might therefore be that DHA supplementation influences some brain regions, but not all, and thereby fails to influence the outcomes of each of the various tests. In addition, the relation between DHA status and neurodevelopment may be nonlinear.

Preliminary data from our group indicate a U-shaped relation between especially the erythrocyte DHA/AA ratio and the quality of general movements as a parameter of brain development. U- or bell-shaped curves similar to ours were also reported by others. Variation in rat brain DHA content by dietary means caused sex-specific alterations in locomotor activity, with males being most affected notably at postadolescent age. The observed DHA intake-effect curve proved bell-shaped, with both low and high DHA intakes giving rise to lower locomotor activities compared with control and medium low DHA intakes (Levant et al. 2006). Although uncommented by the authors, a U-shaped relation was shown between cord plasma phospholipid DHA and the Bayley Scales Psychomotor Development Index (PDI) at 11 months in breastfed Inuit infants with high DHA intakes living in the Arctic region (Jacobson et al. 2008). In addition, excess as well as deficient n-3 fatty acid intakes during pregnancy and lactation cause impaired neural transmission in rats (Church et al. 2008). In human infants, negative associations between higher DHA intakes and verbal skills have been reported (Lauritzen et al. 2005; Scott et al. 1998). U-shaped dose–response curves are not uncommon (Calabrese and Baldwin 2003). Of these, the effect of alcohol consumption on CVD risk is probably best known, while also micronutrient dose–response curves are classical examples (Hayes 2008). The pathophysiological effects in U-shaped curves in the descending (i.e., deficient) and ascending (i.e., toxicological) parts usually reflect different underlying mechanisms leading to the common denominator of "unfavorable effects." It is possible that the descending and ascending parts of U-shaped dose–response curves of DHA or the DHA/AA ratio in neurodevelopment indicate different neurodevelopmental trajectories in which the descending part indicates DHA shortage, while the effects in the ascending part may not necessarily be unfavorable in the long term.

74.5 LCP in Early Postnatal Life

74.5.1 Importance of LCP in Neonatal Nutrition

Generally, breastfeeding is associated with better brain development, at least partly because breast-feeding is related to socioeconomic background. A higher socioeconomic background is associated with better brain development, and it is known that mothers with a higher socioeconomic status tend to breastfeed their children more frequently compared to those with a lower socioeconomic background. In addition, the nutrient composition of breast milk is also widely presumed to be superior for brain development, compared to that of infant formula. For example, important brain constituents such as LCP are available in breast milk, whereas many formulas up till now do not provide LCP. Numerous studies have shown a decline of DHA and AA in plasma and RBC of children receiving infant formula without preformed LCP, as compared to breastfed counterparts. A few autopsy studies on brain LCP levels have been conducted (Clandinin et al, 1980a, b; Farquharson et al. 1992; Jamieson et al. 1999; Makrides et al. 1994; Martinez and Mougan 1998). Infants receiving formula without DHA and AA had lower DHA in brain, but their AA was normal or somewhat higher. Brain DHA levels increased with age in breastfed infants, which was largely an effect of length of feeding, while the accretion of AA was dependent on age but not diet (Makrides et al. 1994). The lower DHA in frontal cortex phosphatidylethanolamine, with concomitantly higher AA, 22:4n-6 and 22:5n-6, suggested low DHA status with compensatory chain elongation/desaturation of n-6 fatty acids (Innis 2003). In other words, the occasionally higher AA and consistently lower DHA in the brain of formula-fed infants seem rather caused by DHA shortage with corresponding dominance of LCPn-6 synthesis, notably of 22:5n-6, than by competition of DHA and AA for incorporation. The consequences in humans are as yet unclear, but the decrease in brain DHA in animals is accompanied by altered developmental parameters (Innis 2003).

Brain accretion of DHA and AA primarily occurs during the last trimester of pregnancy and the first year of life (Clandinin et al. 1980b). Consequently, prematures are likely to benefit most from postnatal DHA and AA supplementation. However, a Cochrane meta-analysis based on RCT with relatively mature and healthy preterm infants showed: (i) that most studies did not find differences in visual acuity over the first year; (ii) that there was no effect on neurodevelopment at 12 or 18 months; and (iii) that there were no effects on growth (weight, length, or head circumference) at 12 and 18 months. It was concluded that there are no clear long-term benefits for infants receiving formula supplemented with LCP and that there is no evidence that formulas with LCPn-3 and LCPn-6 impair the growth of preterm infants (Simmer et al. 2008b). In a recent study, mothers of preterm infants were supplemented with DHA from enrolment until term corrected age in order to achieve a 1 wt% DHA in their milk. Compared to controls receiving milk with 0.3 wt% DHA, infants receiving milk with 1 wt% DHA showed improved visual evoked potential acuity at 4 months corrected age, although not at 2 months (Smithers et al. 2008), and improved Bayley Scales of Infant Development-Mental Development scores at 18 months corrected age in girls only (Makrides et al. 2009).

A Cochrane meta-analysis on postnatal LCP supplementation with term infants showed: (i) that data for visual acuity up to 3 years are inconsistent; (ii) that there are no benefits on mental or psychomotor developments through the first 2 years; and (iii) that there are neither beneficial nor harmful effects on growth through the first three years of life. The final conclusion was that there are no beneficial effects of LCP supplementation of formula milk on visual, physical, and neurodevelopmental outcomes for infants born at term, and that LCP supplementation cannot be recommended on the basis of current evidence (Simmer et al. 2008a).

In contrast to the inconsistency of human studies, animal experiments with induced DHA deficiency have shown consistent abnormalities in various cognitive and behavioral tests, while also the beneficial effects of DHA in other human life stages (e.g., in CVD and neuro-psychiatric diseases) cannot be ignored. It was suggested that differences in sensitivity of global tests and of tests targeted at more specific neural domains may account for the mixed results of the currently completed RCTs. Other possible explanations include inadequate amounts of supplemental DHA in formulas, poor study quality, the ability of term infants receiving formulas without LCP to synthesize their own DHA, an absence of cognitive deficits when differences in brain concentrations of DHA are small because of brain plasticity (i.e., the ability of the brain to adapt), or the inability of the performance tests to detect subtle differences in performance resulting from relatively small differences in brain concentrations of DHA (McCann and Ames 2005). Also of importance might be that in the majority of studies neurodevelopmental outcome was assessed at 6–24 months, which is an age of "latency" in the expression of neurological dysfunction (Hadders-Algra et al. 2007).

74.6 Recommendations for Infant Formula

Despite inconsistent beneficial results of LCP supplementation of formula, many recommendations for infant formula have been issued by various nutritional boards and advisory committees. These recommendations are based on studies with LCP contents as encountered in breast milk of mothers living in Western countries. This approach does not take into account that milk DHA and to a lesser extent AA are highly variable among different countries with different dietary habits (Kuipers et al. 2007) (Fig. 74.5). Western mothers have low intakes of ALA, a high dietary LA/ALA ratio and a limited consumption of fish, which relates to CVD, postpartum depression, and suboptimal neurodevelopment as outlined earlier. Criticizing their diet in relation to these conditions is inherent to criticizing the milk content of DHA and AA (and other fatty acids), since both milk DHA and AA are to a large extent dependent on long-term dietary habits, with the majority of the LCP deriving from maternal stores (van Goor et al. 2009).

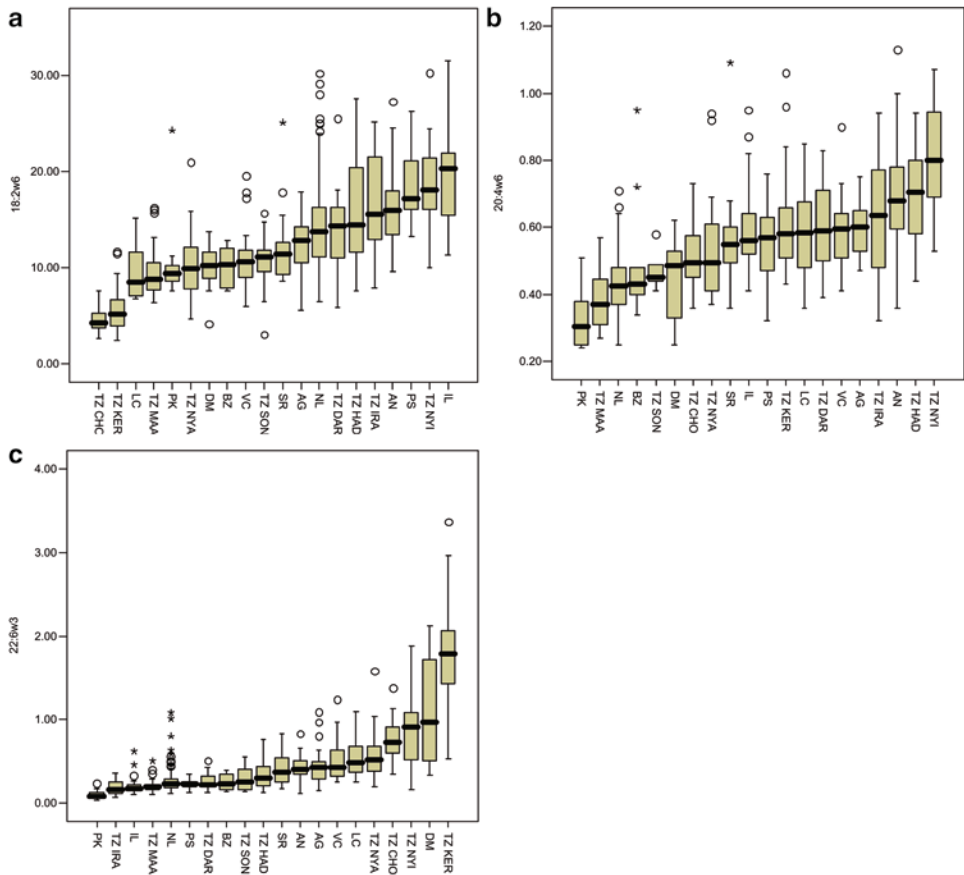
In view of their derivation from Western observations, it is not surprising that the current recommendations for DHA in infant formula are inconsistent with the human milk DHA contents of women who have lifetime dietary DHA intakes according to current recommendations for adults or those for pregnant and lactating women (van Goor et al. 2008b). For instance, the recent guidelines for the LCP contents of infant formulas, as endorsed by the World Association of Perinatal Medicine, the Early Nutrition Academy and the Child Health Foundation recommend to add at least 0.2 g DHA/100 g fatty acids (0.2 wt%) to formula for term infants. DHA should not exceed 0.5 wt% and the minimum amount of AA should be equivalent to DHA (Koletzko et al. 2008). The basis of this recommendation is that at least 0.2 wt% DHA is necessary to achieve benefits on functional endpoints, but that systematic evaluation of levels above 0.5 wt% DHA has not been published. The recommendations acknowledge that "breast is best," that pregnant and lactating women should aim at dietary intakes of at least 200 mg DHA/day, and that higher intakes up to 1 g DHA and 2.7 g LCPn-3 have been studied without significant adverse effects. This new advice on formula DHA is not in line with current recommendations for the general public to consume 450 mg LCPn-3/day (about 170 mg DHA) or with the recommendations of the International Society for the Study of Fatty Acids and Lipids (ISSFAL) to consume 300 mg DHA/day during pregnancy and lactation (ISSFAL 2009). Women adhering to these recommendations will have mature milk DHA contents ranging from 0.43–0.79 wt%, but likely above 0.5 wt% (van Goor et al. 2008b) (Fig. 74.6). We constructed dose–response curves for the mature milk DHA contents of women with known lifetime DHA


Fig. 74.5 Linoleic acid (LA, panel **a**), arachidonic acid (AA, panel **b**), and docosahexaenoic acid (DHA, panel **c**) in the milk of Tanzanian tribes and locations, as compared with countries in our world data set. Data [in wt%] are indicated as box plots, showing medians [black bar], interquartile range [box length], minimum and maximum of the sample or smallest and largest values inside a 1.5 box length distance from the end of the box [crossbars at the far ends of whiskers], values between 1.5 and 3 box lengths from either end of the box [outliers, indicated by *], and values >3 box lengths from either end of the box [extremes, indicated by *]. *AG* Antigua, *BZ* Belize, *DM* Dominica, *IL* Jerusalem–Israel, *LC* St. Lucia, *AN* Curaçao–Netherlands Antilles, *NL* The Netherlands, *PK* Pakistan–Islamabad, *PS* Jerusalem–Palestine, *SR* Surinam, *TZ-CHO* Chole, *TZ-DAR* Dar-es-Salaam, *TZ-HAD* Hadzabe, *TZ-IRA* Iraq, *TZ-KER* Kerewe, *TZ-MAA* Maasai, *TZ-NYA* Nyakius, *TZ-NYI* Nyarimba, *TZ-SON* Sonjo, *VC* St. Vincent (Adapted from Kuipers et al. (2007) with permission from Elsevier)

intakes (Innis 2007b) and for milk of women who were supplemented with various DHA dosages for 12 weeks (Makrides et al. 1996). The estimate from women with lifetime intakes indicates that a recommendation of 170 mg DHA/day corresponds with 0.43 wt% DHA in mature milk and that this figure increases up to 0.79 wt% DHA if the women would comply with the consumption of 300 mg DHA/day during pregnancy and lactation. The slope of the dose–response curve for a short-time supplementation is less steep compared with that of a lifetime intake, probably because milk DHA derives mostly from maternal stores that are unlikely to reach an equilibrium in 12 weeks.

DHA has been found to reach the highest contents in milk from traditionally eating Tanzanian populations living along the shores of the Indian Ocean (i.e., Chole) and freshwater lakes (i.e., Kerewe and Nyakius) (Fig. 74.5). Their milk AA was in the median range whereas their milk LA was among the lowest. Especially the milk fatty acid composition from Chole was suggested to closely reflect the diet on which *Homo sapiens* has evolved. Their milk DHA content of 0.73 wt% is
Fig. 74.6 Dose–response curves for dietary DHA and mature milk DHA. Data are depicted for a lifetime DHA intake and a 12 weeks supplementation. The estimated lifetime curve (Innis 2007b) shows that the current recommendation of 170 mg DHA/day (450 mg LCPn-3) for adults results in 0.43 wt% DHA in mature milk. Milk of women complying with the recommendation of 300 mg DHA/day during pregnancy and lactation will have a milk DHA content in between 0.43% and 0.79 wt%. The supplementation curve (Makrides et al. 1996) is less steep compared to the lifetime curve, probably because milk DHA derives mostly from maternal stores that will not reach equilibrium during 12 weeks supplementation

at the upper range of the milk DHA of women complying to lifetime intakes of 170–300 mg DHA/ day (Fig. 74.6). Whether this composition supports optimal homeostasis is currently unknown. However, the apparent lack of adverse effects in the children living in Tanzanian land–water ecosystems, seems to argue against the validity of recommendations that are solely based on the milk composition of Western mothers (Kuipers et al. 2007).

74.7 Epilog

Western diets are characterized by low fish intakes and consequently low DHA and EPA intakes. Maternal dietary LCP status is correlated with fetal and neonatal brain LCP status, which implies that also the fetal and neonatal DHA status in Western countries is low. In addition, the increasing incidence of maternal insulin resistance and compromised glucose homeostasis may cause a state of relative fetal EFA/LCP deficiency. It is generally accepted that both DHA and AA are important for brain development and that the members of the LCPn-3 and LCPn-6 families exhibit as yet incompletely understood relationships of competition, but also of collaboration and synergy (Horrobin et al. 2002; Orr and Bazinet 2008). Taken together, this raises the question whether the current Western EFA/LCP status of the fetus and newborn is optimal.

Apart from our currently low dietary LCPn-3 intake, we have also decreased our ALA intake, while our LA intake has increased 2–3-fold. At present, both high intakes of LCPn-3 and LA are advocated to diminish the risk of cardiovascular disease, which translates into a recommended intake of 450 mg EPA + DHA per day and of 5–10 energy% LA (about 17 and 12 g/day for men

and women) (Harris et al. 2009), respectively. The problem with the LA recommendation is that such high LA intakes have never occurred in the past (Kuipers et al. 2007) and that the resulting EFA/LCP status may impose new challenges to our health. For instance, a high LA intake is known to inhibit the synthesis of 20:3n-6 and EPA (Angela Liou and Innis 2009) which, together with AA and DHA, are precursors of eicosanoids, resolvins, and protectins. These signaling molecules are involved in both the initiation and resolution of inflammatory reactions (Serhan and Chiang 2008). The recommended higher intake of EPA + DHA may on its turn inhibit the conversion of LA to AA by feedback inhibition and thereby increase our dependence on a dietary AA source. Whatever the underlying mechanisms, it has become clear that plasma phospholipid LA contents correlate positively with the AA/20:3n-6 and AA/EPA ratios (Liou and Innis 2009), suggesting that a higher LA intake contributes to the chronic low grade inflammation that is characteristic for the current Western lifestyle, while a higher EPA + DHA intake may be favorable.

It should be noted that RCTs show only small effects on brain development at best, whereas association studies indicate clear relations between LCP status and neurodevelopment. Since cognitive development is related to socioeconomic status and DHA status might be no more than a proxy for socioeconomic background, healthy lifestyle factors, or both (Hibbeln et al. 2007), the genuine lesson here might be that RCTs with single ("magic bullet") nutrients are unlikely to provide us with the proper information to restore the homeostasis on which our genes have evolved. RCTs basically ignore the many possible interactions with other nutrients and the many changes in our lifestyle that have occurred, while they usually rely on dose choices from poorly investigated dose–response relations. Heterodimerization of nuclear receptors, that each require the binding of a certain nutrient or one of its metabolites, is illustrative for the many poorly understood nutrient–nutrient interactions (Nakamura and Nara 2004). It is therefore possible that the only genuine overall conclusion from the negative meta-analyses on LCP supplementation and neurological development might be that "no evidence of effect is not evidence of no effect" and that we are still distant from the definition of a balanced diet and a healthy lifestyle in general.

It seems that the current recommendations based on the milk LCP contents of Western mothers are likely to create a vicious circle: low LCP intakes by Western mothers cause low LCP contents in their breast milk and, correspondingly, low recommendations for infant formulas, while both the consumption of LCP-poor breast milk and formula will cause maintenance of low infant LCP status. The sole reliance on RCTs for "evidence-based" therapies in patient care and recommendations in health care are increasingly criticized (Rawlins 2008). Combinations of intervention studies, observational studies, historical data, knowledge of underlying mechanisms, toxicological considerations, and others might add to the strength of a recommendation and each of these pieces of evidence cannot contribute by introducing standardized weight factors that are compiled from a consensus hierarchy of scientific strength. For instance, higher intakes of EPA and DHA in the past, positive outcomes of RCTs with fish oil in CVD (Lee et al. 2008) and of EPA in depression (Ross et al. 2007), and knowledge of the underlying (patho)physiological mechanisms in inflammation, gene expression, and others, are together strong arguments for LCPn-3 recommendations for adults and consequently for all humans across the life cycle, infants included.

We conclude that, given the difficulty to prove beneficial effects of LCP in infants, current recommendations for pregnancy and early infancy are not to be based on negative meta-analyses and also not on data of milk from mothers with Western lifestyles. While more attention should be paid to the interaction of other nutrients with LCP, such as the interaction between folate and LCP, until further notice, a combination of data from milk of mothers eating traditional diets from the land–water ecosystem, and milk from mothers adhering to evidence-based recommended LCP intakes for adults may constitute the basis for LCP recommendations for infants.

Summary Points

- The maternal diet prior to conception and during pregnancy and lactation, as well as infant nutrition during early life, are important for child growth and development
- The long-chain polyunsaturated fatty acids (LCP), docosahexaenoic acid (DHA), and arachidonic acid (AA) are important for brain development.
- The positive meta-analyses of RCTs with LCPn-3 in cardiovascular disease and depression add to the contention that LCPn-3 is important across the entire life cycle.
- The DHA contents of infant formula should not be based on DHA contents in breast milk from mothers living in Western countries, since these mothers have low fish intakes.
- Studies on the relation between LCP status and brain development are positive, while meta-analyses of RCTs with prenatal as well as postnatal LCP supplementation are inconclusive.
- No evidence of LCP effects is not evidence of no effects.
- RCTs with single nutrients ignore the many possible interactions with other nutrients. Their outcomes are therefore unlikely to provide the proper information to restore the homeostasis on which our genes have evolved.
- Milk from mothers eating traditional diets from the land–water ecosystem and mothers adhering to evidence based recommended LCP intakes, may set the basis for LCP recommendations for infants.

Definitions of Key Terms

Essential fatty acids: EFA, fatty acids that cannot be synthesized and must be obtained from the diet to prevent deficiency disease. "Conditionally essential" refers to the necessity of a dietary source at circumstances during which the need exceeds endogenous synthesis.
Long chain polyunsaturated fatty acids: LCP, fatty acids with 20 or more carbon atoms, and 3 or more methylene-interrupted double-bonds in the *cis* configuration.
DHA, **docosahexaenoic acid:** an important LCP that is considered conditionally essential since its synthesis from precursors is limited. DHA is an important structural component of membrane phospholipids, a modulator of gene expression, and a precursor of resolvins and (neuro) protectins.
AA, **arachidonic acid:** an important LCP. AA is an important structural component of membrane phospholipids and a precursor of eicosanoids and resolvins.
Relative EFA/LCP deficiency: a deficiency of EFA/LCP that is not caused by low absolute amounts, but rather by an increase of other fatty acids, causing EFA/LCP dilution.

Key areas of this chapter

Essential fatty acids (EFA) and long chain polyunsaturated fatty acids (LCP)
    EFA and LCP metabolism
    EFA and LCP function
LCP in pregnancy
    Maternal and fetal LCP metabolism and transplacental transport
    LCP during pregnancy and neurodevelopment
LCP in early postnatal life
    Importance of LCP in neonatal nutrition
Recommendations for pregnant women and newborns
Epilog

Chapter 75
Genetic Markers, Weight Reduction, and Behavioral Changes in Lifestyle

Thomas Reinehr and Anke Hinney

Abbreviations

BMI	Body mass index
BMR	Basal metabolic rate
ENPP1	Nucleotid pyrophosphatase/phosphodiesterase-1 gene
FTO	Fat mass and obesity associated gene
INSIG2	Insulin-induced gene 2
MC4R	Melanocortin 4 receptor gene
POMC	Pro-opiomelanocortin gene
SDS-BMI	Standard deviation of BMI
TCF7L2	Transcription factor 7-like-2 gene

75.1 Introduction

The prevalence of obesity is increasing in adults and children worldwide caused by changes in lifestyle and environment (Ebbeling et al. 2002). Since obesity is associated with increased morbidity and mortality, effective preventive and therapeutic approaches are urgently needed. Already, obese children suffer from features of metabolic syndromes such as dyslipidemia, impaired glucose tolerance, and hypertension (I'Allemand et al. 2008), which all lead to atherosclerosis (Reinehr et al. 2006b). Early vascular changes as demonstrated by increased intima-media thickness have already been reported in obese children and were reversible after weight loss. Additionally, childhood obesity affects both the children's quality of life and social integration (Ebbeling 2002). Furthermore, obese children tend to become obese adults (Ebbeling 2002). In conclusion, early intervention in obese children seems necessary.

Guidelines concerning treatment of childhood obesity recommend long-term outpatient training programs for both children and parents consisting of a combination of physical exercise, nutrition education, and behavior therapy, although few programs have been run or evaluated (Ebbeling 2002; http: and www.a-g-a.de/Leitlinie.pdf 2008; Summerbell 2007).

Furthermore, the effect of lifestyle intervention varied widely between different studies. Probably, a different degree of motivation, socioeconomic status, and/or genetic background may influence the outcome. In the following chapter these potential influence factors are discussed after introducing the training program Obeldicks, which is an example of a long-lasting successful lifestyle intervention in obese children and adolescents (Reinehr et al. 2005).

75.1.1 Lifestyle Intervention "Obeldicks"

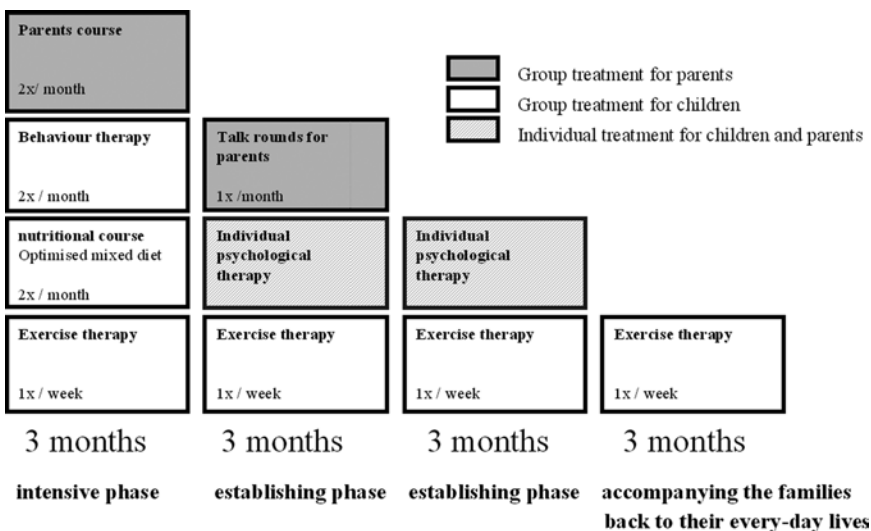
Obeldicks, a lifestyle intervention program addresses obese children and adolescents aged 8–14 years. Briefly, this outpatient intervention program is based on physical activity, nutrition education, and behavior therapy, including the individual psychological care of the child and his or her family (Reinehr et al. 2005, 2006a). An interdisciplinary team of pediatricians, diet-assistants, psychologists, and exercise physiologists is responsible for the training. The children are divided into groups according to their sex and age. The 1-year training program is divided into three phases (see Fig. 75.1): In the intensive phase (3 months), the children take part in the nutritional course and in the eating-behavior course in six group-sessions each lasting for 1.5 h. At the same time, the parents are invited to attend six parents' evenings. In the establishing phase (6 months), individual psychological family therapy is provided (30 min/month). In the last phase of the program, accompanying the families back to their everyday lives (3 months), further individual care is possible, if and when necessary. The exercise therapy takes place once a week during the whole year through and consists of ball games, jogging, trampoline jumping, and instructions in physical exercise as part of everyday life and in a reduction in the amount of time spent watching television. The nutritional course is based on the prevention concept of the "Optimized mixed diet." Here the present scientific recommendations are translated into food-based dietary guidelines, while also considering the dietary habits of children and families in Germany. In contrast to the present-day diet of children in Germany with a fat content of 38% of energy intake, 13% proteins, and 49% carbohydrates including 14% sugar (Kersting et al. 1998), the "Optimized mixed diet" is both fat and sugar reduced and contains 30%


Fig. 75.1 Structure of the lifestyle intervention "Obeldicks." Components of the lifestyle intervention Obeldicks

fat, 15% proteins, and 55% carbohydrates including 5% sugar. The children follow a "traffic-light system" when selecting their food. In this system, the foods and drinks available in Germany are separated according to their fat and sugar contents into "red = stop," "orange = consider the amount," and "green = o.k. when hungry or thirsty." Three-day weighed dietary records demonstrated a reduction of the mean energy content of 1,459 (standard deviation (SD) 379) kcal per day before intervention to a median of 1,250 (SD 299) kcal per day at the end of intervention and a reduction of percentage fat from 36.3 (SD 5.0)% to 30.4 (SD 7.1)% (17). Furthermore, we have demonstrated an increase of physical activity during intervention (Reinehr et al 2005; Sousa et al 2009).

75.1.1.1 Long-Term Outcome After Intervention

More than 1,000 children and adolescents participated in this lifestyle intervention program, and in contrast to a control group, demonstrated long-term success (Reinehr et al. 2005). The success rate based on the "intention-to-treat" approach was 79% with a dropout rate of 17%. The mean reduction of SDS-BMI was 0.40, approximately a mean reduction of 2 kg/m² in BMI. A subgroup of 227 children was evaluated three years after the end of the intervention (Reinehr et al. 2007). In these children the mean SDS-BMI reduction was greater as compared to end of intervention (see Fig. 75.2).

Long-term multidisciplinary lifestyle interventions for children and their parents based on nutrition, exercise, and behavior therapy can lead to long-term weight loss. However, it is unclear which children profit from this intervention.

The achieved weight loss was clinically relevant as demonstrated by a decrease of blood pressure, triglycerides, impaired glucose tolerance, and prevalence of metabolic syndrome in contrast to a control group (Reinehr et al. 2006a) (Fig. 75.3). Furthermore, the intima-media thickness as a predictive factor for atherosclerosis decreased (Wunsch et al. 2006). The achieved weight loss was also relevant from the perspective of the participants as demonstrated by improved quality of life (Reinehr et al. 2005).
Fig. 75.2 Degree of overweight as standard deviation score of BMI (SDS-BMI) in a 4-year follow-up of 227 participants in the lifestyle intervention program Obeldicks (intention-to-treat analysis, data as mean and 95% confidence interval) (adapted from Reinehr et al. 2007). The participants in the lifestyle intervention program Obeldicks reduced their extent of overweight and this achieved weight loss was sustained over 3 years
Fig. 75.3 Change of prevalence of the metabolic syndrome and its components in 288 obese children with lifestyle intervention and 186 obese children without lifestyle intervention in the course of 1 year (*p*-value derived from paired *t*-test; *perc.* percentile; *chol.* cholesterol, *sys* systolic, *dia* diastolic, *BP* blood pressure, *MetS* Metabolic syndrome). Participating in the lifestyle intervention program Obeldicks was associated with a reduction in the prevalence of metabolic syndrome in contrast to a control group

The achieved weight loss in lifestyle intervention for obese children even when only small is sufficient to improve the cardiovascular risk factor profile.

75.1.2 Motivation and Socioeconomic Status

The motivation and willingness to change dietary habitual intake and exercise habits are very likely decisive for success in lifestyle intervention (Ebbeling et al. 2002; http: and www.a-g-a.de/Leitlinie.pdf 2008; Summerbell 2007). Subjective estimates of the degree of motivation shown by the children

and their families are only of limited use. The desire to decrease weight does not always correspond with the willingness to change behavior. A questionnaire on the degree of motivation before the treatment showed that those obese children who were extremely well-motivated achieved worse results (Kirschenbaum et al. 1984).

Therefore, it is still not clear how the obese children's motivation to reduce weight can be proven. Suggestions have been a previous weight reduction, payment for the treatment by the patient himself, or psychological tests. It is problematic to demand weight reduction before the treatment since the children and their families want to take part in the training for the very reason that they are not able to achieve weight reduction on their own. Furthermore, there is the danger that weight loss is achieved due to a short-term hypocaloric diet which then leads to the yo-yo effect. If the parents have to pay for their children's training this would mean that the lower social classes (where obesity is more often found (Gortmaker et al. 1993)) would be unable to take part in the intervention. One disadvantage of using psychological tests to determine the degree of motivation is the necessarily long time and number of personnel involved. Studies on adults showed that psychological tests could not predict the rate of success after schooling (Fontaine et al. 1997).

To identify potential prediction factors for therapy success, we characterized the participants in our outpatient training "Obeldicks" and their families at the beginning of the treatment according to their dietary and physical habits, somatic characteristics, socioeconomic status, and the quality of their 3-day-weighes records (Reinehr et al. 2003).

The children who successfully reduced weight through the Obeldicks program differed from the unsuccessful children in the following ways (see Table 75.1): their mothers had a slightly higher BMI, they lived more seldom in single parent families, they had more often participated in therapy trials to reduce weight, and they had more often taken part in the exercise groups for the obese offered at the clinic before beginning of the training. Multiple logistic regression analysis showed that the previous participation in the exercise groups for the obese was an independent factor that was the strongest predictor for success in the training (Reinehr et al. 2003).

Therefore, families' motivation to change lifestyle during a training program and success in a lifestyle intervention may be predicted by participation in exercise groups before the beginning of the intervention.

In our experience an advantage of exercise groups for obese children before intervention is that the families are confronted with the difficulties involved when attending training regularly (time expenditure, means of transport, caring for other family members). Furthermore, these obese children can make contact with other obese children who have already finished their training and who can report on what they experienced. The children usually enjoy the exercise therapy which is often not the case for them when doing school sports. Conventional sport clubs are often unsuitable for obese children since they strive to achieve high sporting results. The difficulties for obese children being accepted within a conventional sports club can be estimated by the fact that no child in our sample actually became a member of such a club.

In our sample, the somatic characteristics of participants and their families (age, sex, and weight status) had no influence on the success of the treatment corresponding to other studies (Golan et al. 1998), while some others report on a better success rate with younger children, and a negative correlation between the success of the treatment and the degree of overweight (Epstein et al. 1990). Obesity in the parents has been described as a negative predictor of success (Epstein et al. 1990). Beside genetic influence factors, obese parents are said to have worse control over their children's nutrition, have less physical exercise, and are thus negative role models (Fogelholm et al. 1999).

The family's socioeconomic status (level of education of the children and their parents, working mother, marital status) had no influence on the success of the treatment in our sample. However, there was a tendency, though not significant, that children from single-parent families who were also

Table 75.1 Characteristics of successful and unsuccessful participants at the beginning of training program

Data as median and range, *: Chi-square-test, **: Mann-Whitney *U* test, *SDS-BMI* Standard deviation Score of Body Mass Index (Reinehr et al. 2003) in Germany, Grundschule is a primary school for all children in the first 4 years of school and Gesamtschule includes all types of secondary schools (Hauptschule, Realschule, and Gymnasium). Hauptschule refers to the lowest level of school education among the secondary schools compared to Realschuleand Gymnasium. Hochschulreife means qualification for university

Demonstrating that participating in sports groups predicts success in the lifestyle intervention Obeldicks in contrast to all other analyzed parameters

cared for by other people apart from their parents, had difficulties in losing weight. Another study, though on much smaller numbers, also showed that children from malfunctioning families had worse results (Kirschenbaum et al. 1984). If children regularly have meals elsewhere than in their family the chances of success decrease (Epstein et al. 1990). Strict adhesion to nutrition and dietary and exercise rules is made more difficult if different people like home helps, day care nurses, or grandparents are all responsible for the child.

In our sample, the quality of dietary recording as indicators of self-reflection and motivation demonstrated no association with the success of the intervention. We used several indices for quality of dietary recording:

- Number of recorded days.
- The quality of recording by percentage of weighed versus estimated food items per record.
- The validity of reported energy intake. For that purpose, the ratio of reported energy intake (EI) and predicted basal metabolic rate (BMR) was used. BMR was calculated using equations of Schofield (Schofield 1985), including measured height and weight of the individuals.
- Percentage of valid records was calculated based on sex and age-dependent cut-offs for EI/BMR calculated for children to identify underreporting (Sichert-Hellertet al. 1998). In both groups (successful and nonsuccessful participants) the percentage of nonplausible dietary records was high. In the ongoing observational DONALD-Study (DOrtmund Nutritional and Anthropometric Longitudinally Designed Study), conducted in the neighborhood at the Research Institute of Child Nutrition Dortmund, using the same recording method, only 5% of dietary records from normal weight children were identified as nonplausible (Sichert-Hellert et al. 1998). However, it is well known, that underreporting increases with increasing overweight (Golan et al. 1998; Sichert-Hellertet al. 1998).

Negative predictive factors of success in lifestyle interventions in children are

- Single-parent families
- Age >14 years
- Extreme obesity
- Obese parents

Since obesity in parents seems to influence the outcome in a lifestyle intervention program, genetic background may influence the success in lifestyle intervention.

75.1.3 Genetic Background

Twin studies clearly demonstrated a genetic predisposition in obesity (Hebebrand et al. 2001, 2003). The initially detected (until 2009) human genetic variants associated with polygenic obesity in multiple studies are summarized in Table 75.2. These variants have a relatively small effect size, but they are frequent and thus relevant in a substantial number of obese individuals. In 2009 the number of polygenic variants increased to 17 (Hinney and Hebebrand 2009); additionally, there is a small number of

Table 75.2 Variants with a polygenic effect on the human body weight detected until 2009 (adapted from Hinney and Hebebrand 2009)

Nearest gene	SNP	Approx. frequency of the risk allele (risk allele)	Sample size in the original publication	Effect on BMI in the original publication	Reference
INSIG2	rs7566605	37% (C)	9,881	+1.0 kg/m² for CC genotype	Herbert et al. (2006)
FTO	rs9939609	40% (A)	38,759	+0.40 kg/m² per A allele	Dina et al. (2007)
MC4R	rs2229616 (Val103Ile)	2% (103I)	7,713	−0.48 kg/m² per 103I allele	Geller et al. (2004)

Demonstrating the frequencies and effects on BMI of different SNPs

monogenic forms of obesity. The latter is characterized by a major effect of the respective mutation on the development of obesity. However, the frequency of these mutations is (extremely) low and can thus only explain the obese phenotype in a small fraction of obese individuals.

75.1.3.1 MC4R Mutations and Polymorphisms

Studies in mice and humans have pointed out the critical importance of the central melanocortinergic pathway in the control of energy homeostasis and, in particular, the pivotal role of the melanocortin 4 receptor gene (*MC4R*) (Hinney et al. 2006). Previous studies in humans have shown that the prevalence of functionally relevant *MC4R* mutations ranges from 0.5% to 5.8% in obese children and adolescents ascertained for molecular genetic studies (Hinney et al. 2006). More than 90 different obesity-associated mutations in the *MC4R*, most of which are nonsynonymous mutations leading to either total or partial loss of function, have so far been reported (Hinney et al. 2006; Tao and Segaloff 2003). The phenotype of carriers with mutations leading to a reduced receptor function considerably varies in their effect on body weight (Hinney et al. 2006). These mutations within the coding region are assumed to have a major effect on body weight, averaging approximately 4.5 and 9 kg/m² in adult males and females, respectively (Dempfle et al. 2004). Interestingly, two nonsynonymous polymorphisms, Val103Ile and Ile251Leu, that occur in 1–3% of the examined populations, respectively, are both associated with a slightly decreased BMI (Geller et al. 2004; Heid et al. 2008).

Recently, two genome-wide association studies (GWAS) showed that two variants located downstream of the *MC4R* are associated with obesity and related traits (Chambers et al. 2008; Loos et al. 2008). The C-allele of rs17782313 was associated with obesity as detected in more than 60,000 individuals (adults and children) of European descent (Loos et al. 2008). Each copy of this allele conferred odds of approximately 1.30 for severe childhood obesity. Chambers et al. (2008) showed that the variant rs12970134 was additionally associated with waist circumference and insulin resistance (Chambers et al. 2008).

75.1.3.2 FTO Polymorphisms

Several studies have demonstrated an association between variants in the "fat mass and obesity associated gene" (*FTO)* and obesity in both adults and children (Dina et al. 2007; Hinney et al. 2007; Muller et al. 2008). The biological function of *FTO* is largely unknown. However, *FTO* is expressed in multiple tissues throughout the brain and the periphery with high expression in the pituitary and adrenal glands and the hypothalamus. It has thus been suggested that *FTO* might play a role in the hypothalamic–pituitary–adrenal axis. Recently, a knockout mouse model for *Fto* showed that lack of *Fto* protects from obesity (Fischer et al. 2009). *FTO* knockout mice showed postnatal growth retardation and a significant reduction in adipose tissue and lean body mass. The leanness of *Fto*-deficient mice developed as a consequence of increased energy expenditure and systemic sympathetic activation, despite decreased spontaneous locomotor activity and relative hyperphagia. In summary, these data show that *FTO* is functionally involved in energy homeostasis by the control of energy expenditure (Fischer et al. 2009). Additionally, it was shown that *FTO* mRNA levels were reduced by 60% in the arcuate nucleus of wild-type mice following food deprivation, and that this decrease of *Fto* mRNA was independent of the fasting-induced decrease of leptin levels (Gerken et al. 2007). Further analyses revealed that *FTO* shares sequence motifs with Fe(II)- and 2oxoglutarate (2OG)-dependent oxygenases and that murine *FTO* catalyzes the Fe(II)- and 2OG-dependent demethylation of 3-methylthymine in single stranded DNA with concomitant production of succinate, formaldehyde, and carbon dioxide. Localization of *FTO* to

the nucleus in transfected cells is consistent with this potential role of *FTO* in nucleic acid demethylation. Additionally, allelic variation of *FTO* has been shown to be associated with a reduced cerebrocortical insulin effect on beta activity. It is therefore possible that impaired cerebrocortical insulin response at least partly accounts for the implication of *FTO* variants on obesity (Tschritter et al. 2007).

75.1.3.3 INSIG2 Polymorphism

An SNP located ~10 kb upstream of the insulin-induced gene-2 *INSIG2* (rs7566605) was shown to be associated with increased obesity risk for CC-homozygotes in a cross-sectional study of adults and children (Herbert et al. 2006). However, the influence of this SNP on obesity risk is uncertain: It has been genotyped in another 25,166 individuals of different ethnic backgrounds (Rosskopf et al. 2007). In 8,197 of these, an association with obesity could not be detected. However, a meta-analysis of case-control and family-based approaches comprising 16,969 individuals confirmed an association of rs7566605 and obesity (Lyon et al. 2007).

The mechanisms by which *INSIG2* influences body weight are unclear. *INSIG2* encodes a protein of the endoplasmic reticulum (ER) that blocks proteolytic activation of sterol regulatory element binding proteins and membrane-bound transcription factors that activate synthesis of cholesterol and fatty acids in animal cells. These proteins also restrict lipogenesis in mature adipocytes and block differentiation of preadipocytes (Gong et al. 2006).

75.1.3.4 Other Mutations and Polymorphisms Associated with Obesity

The extremely rare autosomal recessive genetic disorders leptin or leptin receptor deficiency, and loss of function mutations in the pro-opiomelanocortin gene (*POMC*) are well-established monogenic causes of obesity (Hinney and Hebebrand 2009). Moreover, several polymorphisms are discussed to influence the weight status such as, for example, variants in nucleotid pyrophosphatase/phosphodiesterase-1 gene (*ENPP1*) or the transcription factor 7 like-2 gene *(TCF7L2)* (Bottcher et al. 2006; Grant et al. 2006). The relevance of these variants is unclear and large confirmation studies are lacking so far. Variations in *TCF7L2* also contribute to insulin sensitivity and resistance. *TCF7L2* encodes a transcription factor and thereby regulates blood glucose homeostasis through regulation of proglucagon gene expression. The single nucleotide polymorphism (SNP) rs7903146 in *TCF7L2* is associated with an increased risk of type 2 diabetes mellitus and a slightly reduced risk for obesity.

75.2 Impact of Genetic Variants on Outcome of a Lifestyle Intervention

If all of the above mentioned genetic variants and mutations had an impact on body weight, one might speculate that they may influence the success in a lifestyle intervention program. Therefore, we analyzed the genetic background concerning mutations and/or variants in *MC4R*, *INSIG2*, *FTO*, and *TCF7L2* in the participants of the lifestyle intervention program Obeldicks and correlated them to the achieved weight loss.

The degree of overweight reduction in relation to genetic variants is demonstrated in Table 75.3 and Figs. 75.4 and 75.5. We did not find an increased risk for dropping out of lifestyle interventions for carriers of the obesity risk alleles of the polymorphisms in *INSIG2*, *TCF7L2*, and *FTO*, or *MC4R* mutations.

In concordance with a small previous report comprising four children with *MC4R* mutations (Hainerova et al. 2007), our children with *MC4R* mutations that lead to a reduced receptor function

Demonstrating the effect of different genetic variants on the degree of overweight reduction in the lifestyle intervention program Obeldicks
Fig. 75.4 Decrease of BMI-SDS (mean and standard deviation of the mean) in children with *MC4R* mutations that leads to a reduced receptor function (group A) and age- and gender- matched children without *MC4R* mutations (group B) at the end of a 1-year lifestyle intervention and 1 year after end of intervention compared to baseline BMI-SDS, *$p < 0.05$ (adapted from Reinehr et al. 2009a). Children with MC4R mutations were able to lose weight in the lifestyle intervention but failed to sustain this weight loss after the end of intervention

decreased their weight at the end of the intervention (Reinehr et al. 2009a). However, 1-year after the end of the lifestyle intervention, children with these *MC4R* mutations demonstrated a similar degree of overweight as at baseline, while children without these mutations had sustained their degree of weight loss (see Fig. 75.4) (Reinehr et al. 2009a). These findings support the impact of *MC4R* mutations on weight status. Since carriers of the *MC4R* mutations can lose body weight but have difficulties in maintaining this weight loss, longterm lifestyle interventions seem to be necessary for these children.

   MC4R-deficient obese children can lose weight in a lifestyle intervention but have great difficulties in maintaining weight loss.
Fig. 75.5 INSIG2: rs7566605 genotypes and change of weight status (SDS-BMI) compared to baseline in 293 children after participation in the 1-year intervention based on an intention-to-treat analysis (data as median and interquartile range) (adapted from Reinehr et al. 2008b). CC carrier in *INSIG2* demonstrated a significant lower overweight reduction as compared to the wildtype or heterozygotes

Homozygotes for the C-allele of rs7566605, located approximately 10 kb upstream of *INSIG2*, showed a slightly increased risk to become obese. After the 1-year obesity intervention, children with the CC-genotype had reduced their BMI-SDS to a lower extent than obese children with GC- or GG-genotypes (recessive model P = 0.007) (Reinehr et al. 2008b). However, we have to keep in mind that it is unlikely that rs7566605, located 10 kb upstream of the transcriptional start site of the gene, is itself functional, but rather a variant elsewhere within the gene (Smith et al. 2007).

CC-homozygotes at SNP rs7566605 in the vicinity of *INSIG2* lost less weight in this lifestyle intervention. However, the effect was very moderate and replication studies are necessary to prove if a causal correlation really exists.

Children homozygous for the obesity risk-A-allele in *FTO* lost weight in the intervention, but to a lesser extent than children heterozygous or homozygous for the wildtype allele, while there was no significant difference with respect to SDS-BMI (Reinehr et al. 2009b). After adjusting for age, gender, baseline BMI, and the analyzed gene polymorphisms, this quantitative association between A-alleles in *FTO* and BMI change was not significant. Also, TT-carriers in *TCF7L2* did not differ in their overweight reduction as compared to heterozygotes or the wildtype carriers (Reinehr et al. 2008a).

Polygenic mechanisms are relevant in obesity; we therefore analyzed potentially aggravating effects of obesity risk alleles on weight loss. Our data revealed that obese children with a combination of the *INSIG2* CC-genotype and the *FTO* AA-genotype had no decrease of BMI and SDS-BMI within the Obeldicks lifestyle intervention (Reinehr et al. 2009b). The interaction term between the allele frequencies was significant ($p = 0.02$ for BMI as response and $p = 0.003$ for SDS as response variable (Reinehr et al. 2009b). One previous study in adults showed that homozygosity for both polymorphisms in *FTO* and *INSIG2* as well as the combination of *FTO/INSIG2* homozygosity/

heterozygosity leads to increased BMI (Chu et al. 2008). Conversely, yet another study showed no interaction between *INSIG2*, *MC4R* mutations, and *FTO* (Andreasen et al. 2008).

Since the combination of *INSIG2* CC-genotype and *FTO* AA-genotype was significantly associated with the lowest degree of overweight reduction, this finding suggests that the effects of *INSIG2* and *FTO* aggravate each other. Therefore, this finding provides a hint toward gene–gene interactions for weight loss during a lifestyle intervention program lasting 1 year.

Some important limitations of our studies have to be considered. First, the mechanisms of the genetic variants that influence overweight reduction are unclear. It is also possible that an interaction between polymorphism, mutations, and environmental factors such as diet may influence the change of weight status. Obesity occurs due to gene–gene and gene–environment interactions that vary across individuals. However, dietary records in obese children are difficult to interpret due to underreporting. Furthermore, our study only considered one polymorphism per gene; but especially for *FTO* the a priori evidence is so compelling that the analysis of a single SNP can be viewed as sufficient for an initial analysis (Hinney et al. 2007; Muller et al. 2008). With regard to the validity of our findings and the moderate study size, subsequent replication studies are necessary. However, longitudinal studies in overweight children undergoing a lifestyle intervention are difficult to perform and data are currently scarce.

Apart from the potential influence of genetic markers on the degree of weight loss, genetic polymorphisms may influence the improvement of cardiovascular risk factors in weight loss. In our study samples, most genetic variants such as *INSIG2, FTO,* or *MC4R* mutations did not influence the change of cardiovascular risk factor profile and insulin resistance (Reinehr et al. 2008b, 2009a, b). However, the T-allele at rs7903146 in *TCF7L2* was associated with a significant negative dosage effect per allele on the improvement of insulin resistance and sensitivity indices such as HOMA-IR and QUICKI after the lifestyle intervention independently of degree of weight loss, age, and gender (Reinehr et al. 2008a). Linear regression with gender, age, puberty, insulin, and glucose levels at baseline, as well as change of BMI-SDS as covariates, demonstrated a significant relationship between genotypes of rs7903146 and changes of HOMA-IR, HOMA-B%, and QUICKI (Table 75.4). The estimated effects adjusted for age, gender, pubertal stage, and change of BMI-SDS were +0.68 ± 0.01 for HOMA-IR per additional T-allele and −0.010 ± 0.004 for QUICKI per additional T-allele. However, the variance explained by these models was low (only 6.5% for HOMA-IR and 6.8% for QUICKI).

This finding is in line with the study of Florez and colleagues (Florez et al. 2006) demonstrating in a longitudinal study that the T-allele at rs7903146 is associated with impaired β-cell function. Further experimental and longitudinal studies are necessary to clarify the role of the *TCF7L2* gene variants in the progression to type 2 diabetes mellitus in humans.

Genetic background also influences changes in cardiovascular risk factors in lifestyle intervention programs independent of change in weight status.

Table 75.4 Tests for association of *rs7903146* in *TCF7L2* with changes of BMI-SDS, insulin, glucose, HOMA-IR, HOMA-B%, and QUICKI in the course of a 1 year lifestyle intervention in 236 overweight children

	Homozygous CC	Heterozygous TC	Homozygous TT	*p*-value
Number	121	97	18	–
Change of BMI-SDS	−0.30 ± 0.03	−0.28 ± 0.03	−0.33 ± 0.08	0.999
Change of glucose [mmol/l]	+0.04 ± 0.05	−0.04 ± 0.05	+0.10 ± 0.08	0.441
Change of insulin [mU/l]	−2.9 ± 1.3	+0.64 ± 1.4	+3.5 ± 2.6	0.014
Change of QUICKI	+0.008 ± 0.003	+0.002 ± 0.004	−0.020 ± 0.013	0.001

Data as mean and SE except *: median and interquartile range since variable is not normally distributed; *p*-values derived from linear regression analyses under allele-dosage model adjusted for gender, age, pubertal stage, baseline insulin and glucose levels, as well as change of weight status (BMI-SDS) except for change of BMI-SDS (adapted from Reinehr et al. 2008a)

The TT carriers in *TCF7L2* demonstrated a significantly lower improvement of insulin resistance as compared to the wildtype, and heterozygous carries independently of overweight reduction

75.3 Applications to Other Areas of Health and Disease

Lifestyle intervention is effective in motivated obese children to reduce weight and improve the cardiovascular risk factor profile. Therefore, whenever possible all diseases related to obesity should be treated with lifestyle intervention in this age group. Since genetic variations influence outcome with respect to both overweight reduction and improvement of cardiovascular risk factors, unsuccessful children should not be blamed. Putting together genetic research and clinical intervention studies represents a new promising field to prove the impact of genetic variants on body weight and to understand the different outcomes

Summary points

- Guidelines concerning treatment of childhood obesity recommend long-term outpatient training programs for both children and parents consisting of a combination of physical exercise, nutrition education, and behavior therapy, although few programs have been run or evaluated.
- Long-term multidisciplinary lifestyle interventions for children and their parents based on nutrition, exercise, and behavior therapy can lead to long-term weight loss.
- The families' motivation to change lifestyle during a training program and success in lifestyle intervention may be predicted by participation in exercise groups before the beginning of the intervention.
- Negative predictive factors of success in lifestyle interventions in children are single parent families, age >14 years, extreme obesity, obese parents.
- The achieved weight loss in lifestyle intervention for obese children is only small but sufficient to improve the cardiovascular risk factor profile.
- *MC4R*-deficient obese children can lose weight in a lifestyle intervention but have great difficulties in maintaining their weight loss.
- CC-homozygotes at SNP rs7566605 in the vicinity of *INSIG2* lost less weight in this lifestyle intervention.
- The effects of *INSIG2* and *FTO* on the effect of a lifestyle intervention seem to aggravate each other (gene–gene interactions)
- Genetic background also influences the changes in cardiovascular risk factors in lifestyle intervention independent of change in weight status.

Definitions

Socioeconomic status: Social class depending on income and education of an individual
Somatic characteristics: Weight, height, body circumferences of individuals
Genetic predisposition: Genetic part of the variance of a given phenotype or disease, usually determined by heritability estimates derived from, e.g., twin studies.
Polygenic: The combined action of alleles of more than one gene leads to a phenotype/disease. Body weight is an example of a polygenic trait. Presumably, the effect sizes of most gene variants predisposing to obesity are quite small (polygenic inheritance).
Mutation: The original human genetic definition is "**g**enetic variants (heritable changes in the nucleotide sequence in a gene or a chromosome) that occur in *less* than 1% of the normal population." Some authors suggest that "mutation" should relate to variants that are causal for/associated with a phenotype/disease. For this definition it is important that reference to the caused/associated phenotype/disease is given.

Polymorphism: Again the original human genetic definition is "**g**enetic variants that occur in *more* than 1% of the normal population." Some authors suggest that "polymorphism" should relate to variants that are *not* causal for/associated with a phenotype/disease. For this definition it is important that reference to the analyzed phenotype/disease is given. However, for complex traits this definition might not be useful.

Key Features of Single Nucleotide Polymorphisms (SNPs)

1. Single nucleotide polymorphisms (SNPs) are DNA sequence variations that occur when a single nucleotide (A, T, C, or G) in the genome sequence is altered.
2. Frequency of the minor allele above 1% in the general, unselected population.
3. SNPs make up approximately 90% of all human genetic variation.
4. They occur every 100–300 bases along the three billion base human genome.
5. SNPs can occur in coding (gene) and noncoding regions of the genome.
6. Many SNPs have no (direct) effect on function, but could predispose individuals to disease or influence their response to a drug.
7. A total of 6,573,789 validated SNPs in introns, exons, and intergenic regions can currently be found in the database (*dbSNP web query for build 129:Apr 14, 2008*).
8. Approximately 100,000–300,000 SNPs are presumed to be related to disease (associated to a phenotype).
9. SNPs are valuable for biomedical research and for developing pharmaceutical products or medical diagnostics.

Key Facts of Obeldicks

1. Lifestyle Intervention for obese children and adolescents aged 6–15 years
2. One-year intervention based on physical activity, nutrition education, and behavior therapy, including the individual psychological care of the child and his or her family.
3. An interdisciplinary team of pediatricians, diet-assistants, psychologists, and exercise physiologists is responsible for the training.
4. The children are divided into groups according to their sex and age.
5. The 1-year training program is divided into three phases:

   • In the intensive phase (3 months), the children take part in the nutritional course and in the eating-behavior course in six group-sessions each lasting for 1.5 h. At the same time, the parents are invited to attend six parents' evenings.
   • In the establishing phase (6 months), individual psychological family therapy is provided (30 min/month).
   • In the last phase of the program (accompanying the families back to their everyday lives) (3 months), further individual care is possible, if and when necessary.

• The exercise therapy takes place once a week during the whole year through and consists of ball games, jogging, trampoline jumping, and instructions in physical exercise as part of everyday life and in reduction of the amount of time spent watching television.
• The nutritional course is based on the prevention concept of the "Optimized mixed diet." Here the present scientific recommendations are translated into food-based dietary guidelines.

Chapter 76
The Role of Gene Polymorphisms in Susceptibility to Anorexia Nervosa and Bulimia Nervosa

Palmiero Monteleone and Mario Maj

Abbreviations

5-HT	Serotonin
5-HTT	Serotonin Transporter
AN	Anorexia Nervosa
ANBP	Anorexia Nervosa Binge-Eating/Purging Subtype
ANR	Anorexia Nervosa restricting Subtype
BDNF	Brain-Derived Neurotrophic Factor
BMI	Body Mass Index
BN	Bulimia Nervosa
BNNP	Bulimia Nervosa Nonurging Subtype
BNP	Bulimia Nervosa Purging Subtype
BW	Body Weight
CLOCK	Circadian Locomotor Output Cycles Kaput
COMT	Cathecol-O-Methyltransferase
DAT	Dopamine Transporter
ED	Eating Disorder
FAAH	Fatty Acid Amide Hydrolase
KCNN3	Small-Conductance Calcium-Activated Potassium Channel-3
MAOA	Monoamino Oxydase A
NAAA	N-Acylethanolamine-Hydrolyzing Acid Amidase
NET	Noradrenaline Transporter
NPY	Neuropeptide Y
SNP	Single Nucleotide Polymorphism
SSRI	Selective Serotonin Reuptake Inhibitor
TPH-1	Tryptophan-Hydroxylase-1
UCP	Uncoupling Protein
VNTR	Variable Number of Tandem Repeats

76.1 Introduction

Anorexia nervosa (AN) and bulimia nervosa (BN) are eating disorders (EDs) characterized by pathological concerns about body weight (BW) and body shape and abnormal patterns of feeding behavior and energy expenditure. Specifically, AN is characterized by the obsessive fear of being fat and the voluntary pursuit of thinness; despite increasing emaciation and a BW below the 85% of the ideal, individuals with AN are dissatisfied with the perceived size and shape of their body, and engage in unhealthy behaviors to perpetuate BW loss or prevent BW gain. In the Diagnostic and Statistical Manual of Mental Disorders – IV edition (American Psychiatric Association 1990), AN is classified into two subtypes: AN binge-eating/purging subtype (ANBP), where patients engage in binge-purging behaviors, and AN-restricting subtype (ANR), where patients exclusively restrict their food intake. BN is characterized by recurrent episodes of uncontrolled binge eating coupled with inappropriate compensatory behaviors, such as vomiting, laxative abuse, food restriction, and/ or excessive exercising, in order to prevent BW gain, because of the patient's pathological fear of becoming fat. Similarly to AN, BN is classified into two subtypes: BN purging subtype (BNP), where patients provoke vomiting, abuse laxatives and/or diuretics as compensatory behaviors, and BN nonpurging subtype (BNNP), where patients engage in excessive exercise and/or food restriction to prevent BW gain.

The etiopathogenesis of EDs is thought to be multifactorial with psychological, social, and biological factors being allegedly involved, although the exact role played by each of them is not yet completely known. At present, it is widely accepted that genetic factors are responsible for the transmission of a biological vulnerability to the disorders, as clearly demonstrated by epidemiological, family, and molecular genetic studies.

Molecular genetic studies aiming to identify chromosomal regions and genes of vulnerability in EDs use two methodologies: linkage and association (i.e., case–control or within family) designs.

Linkage study is an approach without an a priori hypothesis for the genes possibly involved in the disease. By screening the whole human genome with genetic markers in a cohort of affected families, it examines the transmission and segregation of polymorphic markers to identify chromosomal regions rather than specific genes likely linked to the disorder. This strategy needs a large recruitment of families including probands and affected and unaffected relatives, which represents a major limitation for rare disorders such as EDs.

Association study uses a different approach based on a priori hypotheses, which rely on biochemical, physiological, or pharmacological evidence suggesting the involvement of specific endogenous substances in the etiopathogenesis of a disorder; therefore, the genes involved in the physiology of those substances are identified as "candidate genes" contributing to the heritable susceptibility to the disorder. Association study compares the frequency of polymorphic alleles and genotypes between two groups, controls and patients (Table 76.1). A higher or a lower frequency in patients would suggest that the gene may be associated to the disorder with predisposition or protection, respectively. A disadvantage of this design is the risk of yielding false positive results due to population stratification. However, an association study can also be performed in family trios (affected proband and both biological parents) by using the transmission disequilibrium test (TDT). In this design, the transmission versus nontransmission of marker alleles to affected offspring is compared. This method eliminates population stratification effects completely.

The purpose of this review is to critically appraise the extant literature on association studies of candidate gene polymorphisms in AN and/or BN.

Table 76.1 Key features of polymorphisms.

- A single-nucleotide polymorphism (SNP) is a DNA sequence variation occurring when a single nucleotide in the genome differs between members of a species (or between paired chromosomes in an individual). In this case two *alleles* are identified: the wild type allele and the polymorphic (or mutant) allele.
- SNPs may fall within coding sequences of genes, noncoding regions of genes, or in the intergenic regions between genes.
- SNPs within a coding sequence will not necessarily change the amino acid sequence of the protein that is produced, due to degeneracy of the genetic code. A SNP in which both alleles lead to the same polypeptide sequence is termed *synonymous.*
- An SNP which induces a different polypeptide sequence is termed *nonsynonymous*. The nonsynonymous SNP leads to changes in protein structure and/or function.
- SNPs that are not in protein-coding regions may still have consequences for gene splicing, transcription factor binding, or the sequence of noncoding RNA.
- The greatest importance of SNPs in biomedical research is for comparing regions of the genome between cohorts (such as with matched cohorts with and without a disease) in order to identify polymorphic variants of genes that could be involved in the genetic susceptibility to human disease.
- There are variations between human populations; so an SNP allele that is common in one geographical or ethnic group may be much rarer in another.
- The nomenclature for SNPs can be confusing: several variations can exist for an individual SNP and consensus has not yet been achieved.

76.2 Central Regulators of Eating Behavior

In the last 20 years, central neurotransmitters, hormones, and peptides have been identified to regulate eating behavior and, in some cases, psychopathological dimensions associated to EDs (Monteleone et al. 2008). Regulators of feeding that have been of interest for the genetics of AN and BN include central neurotransmitters and peptides such as serotonin (5-HT), dopamine (DA), noradrenaline (NA), endocannabinoids, opioids, the brain-derived neurotrophic factor (BDNF), neuropeptide Y (NPY), and the agouti-related protein. Therefore, the genes involved in the biosynthesis and/or degradation of those substances and their receptors have been selected as candidate genes, and mutations, variations, and polymorphisms of those genes appear of particular interest, especially if they affect either the protein structure/function or expression.

76.2.1 Serotonin

Genes coding the 5-HT transporter (5-HTT) protein, 5-HT receptors, and the biosynthetic enzyme tryptophan hydroxylase-1 have received a great deal of interest in association studies, since 5HT has been shown to be involved in the modulation of both food ingestion and psychopathological traits associated with EDs, such as depression, anxiety, impulsivity, and obsession (Lucki 1998). Moreover, 5-HT has been supposed to modulate harm avoidance, a human personality dimension that is disturbed in ED patients (Cloninger et al. 1993).

76.2.1.1 Serotonin Transporter

The human *5-HTT* gene is located on chromosome 17q11.1–17q.12. A polymorphism in the promoter region of the *5-HTT* gene (*5-HTTLPR*) has been described (Heils et al. 1999). It consists of a

44-base pair deletion (short or S variant) or insertion (long or L variant), which is endowed with functional consequences as the S form is associated with a lower transcriptional activity and a reduced 5-HT reuptake efficiency than the L isoform (Greenberg et al. 1999). A nominal association of the S allele with AN has been detected in two studies (Fumeron et al. 2001; Matsushita et al. 2004), but not confirmed in five others (Hinney et al. 1997a; Di Bella et al. 2000; Sundaramurthy et al. 2000; Urwin et al. 2003a; Rybakowski et al. 2006) (Table 76.2). In particular, the positive study of Matsushita et al. (2004) reported that the S allele was more frequent in AN patients who had a stable AN diagnosis for at least 3 years. A meta-analysis including four of the cited association studies concluded that the S allele of the *5-HTTLPR* polymorphism may represent a moderate but significant risk factor for AN (Gorwood 2004).

As for BN, one study showed a positive association between the S allele of the *5-HTTLPR* polymorphism and BN (Di Bella et al. 2000), one other found a higher frequency of the L allele in BN female patients (Monteleone et al. 2006a), and two studies did not report any significant association (Lauzurica et al. 2003; Matsushita et al 2004) (Table 76.3).

The possibility that the *5-HTTLPR* polymorphism is not directly associated with EDs, but linked to phenotypic aspects of AN and BN has been also explored. Indeed, the S allele was found to be associated with comorbid borderline personality disorder, affective instability, and insecure attachment in women with binge-purging syndromes (Steiger et al. 2005), and to higher levels of drive for thinness and body dissatisfaction in patients with AN and BN (Frieling et al. 2006). Moreover, two studies found that BN patients carrying at least one S allele had lower values of BMI and body fat mass and higher levels of harm avoidance and anxiety than those with the LL genotype (Monteleone et al. 2006a; Ribasès et al. 2008).

The 5-HTT represents the prime target of Selective Serotonin Reuptake Inhibitors (SSRIs) and the S allele of the 5-*HTTLPR* has been associated with poorer SSRI response in major depression (Serretti and Artioli, 2004). Similarly, one study showed that the S form of the 5-*HTTLPR* was associated with a poorer outcome of SSRI therapy in BN women undergoing a 12-week naturalistic treatment with different SSRIs plus nutritional counselling (Monteleone et al. 2005a). Indeed, as compared to patients with LL genotype, bulimic subjects carrying at least one copy of the S allele had a 23.33-fold reduced probability of a response (defined as a >50% decrease in the weekly frequency of binge-purging episodes) and a 10.66-fold decrease in the probability of remission (defined as a complete absence of binge-purging episodes). These results disagree with those of Erzegovesi et al. (2004) who found no association between the 5-*HTTLPR* polymorphism ant treatment outcome in BN individuals undergoing a 6-week treatment with one of four different SSRIs or placebo plus a standardized intensive cognitive behavioral treatment program. However, in this study, the efficacy of drug treatment was evaluated as the percent improvement in the Yale-Brown-Cornell Eating Disorders Scale, which assesses food-related obsessions and compulsions and does not provide any specific measure of bulimic symptomatology. Therefore, differences in the study designs, duration of SSRI treatments, and measurements of the outcome may explain the inconsistency between the two studies. In line with Monteleone et al.'s results (2005a), Steiger et al. (2008) found that women with bulimia-spectrum EDs carrying the 5-HTTLPR low functional allele (or the low function allele of the -1438G/A SNP of the $5\text{-}HT_{2A}$ receptor gene) showed smaller reduction in binge-eating and anxiety symptomatology after a multimodal intervention strategy.

It has been recently shown that the L allele consists of two main different variants, one of which has the same activity as the S allele (Nakamura et al. 2000); hence, studies taking into account the 5-*HTTLPR* triallelic model need to be performed to clarify the role of 5-*HTTLPR* polymorphism in the genetic susceptibility to EDs and in the response prediction in BN.

This table lists published association studies of polymorphic variants of genes involved in the physiology of central regulators (neurotransmitters, neuropeptides and neurohormones) of feeding and energy homeostasis in anorexia nervosa

AN anorexia nervosa, *ANR* anorexia nervosa restricted subtype, *ANBP* anorexia nervosa binge-purging subtype, *5-HT* serotonin, *NS* not significant, *S* significant, *VNTR* variable number of tandem repeats, *ARVCF* armadillo repeat gene deleted in velocardiofacial syndrome, *MAOA-uVNTR* MAOA-upstream variable number of tandem repeats

76.2.1.2 Serotonin Receptors

5-HT_{2A} and 5-HT_{2C} receptors play a role in the serotonergic control of appetite, and polymorphisms of genes coding these two receptors have been identified. The -1438G/A polymorphism in the promoter region of the 5-HT_{2A} receptor gene is of particular interest, since functional activity of the promoter and 5-HT_{2A} receptor activation have been reported to be lower for the G allele and higher for the A allele (Shimizu et al. 2003; Parsons et al. 2004). A significantly higher frequency of both the AA genotype and the A allele of the -1438G/A polymorphism was found in AN by some studies (Collier et al. 1997; Collier 1999; Sorbi et al. 1998; Enoch et al. 1998; Nacmias et al. 1999; Ricca et al. 2002, 2004), but not confirmed by others (Hinney et al. 1997b; Campbell et al. 1998; Ziegler and Görg, 1999; Ando et al. 2001a; Nishiguchi et al. 2001; Kipman et al. 2002; Gorwood et al. 2002; Rybakowski et al. 2006) (Table 76.2). Four of the positive studies, all of the same research group (Sorbi et al. 1998; Nacmias et al. 1999; Ricca et al. 2002, 2004), reported that the -1438G/A polymorphism was specifically associated to ANR subtype. The A allele has been reported to be linked with some AN-related phenotypic traits such as an older age at onset, higher levels of weight

This table lists published association studies of polymorphic variants of genes involved in the physiology of central regulators (neurotransmitters, neuropeptides, and neurohormones) of feeding and energy homeostasis in bulimia nervosa

BNNP bulimia nervosa nonpurging subtype, *5-HT* serotonin, *NS* not significant, *S* significant, *VNTR* variable number of tandem repeats

and shape concerns and total Eating Disorder Examination scores, lower levels of harm avoidance, and reward dependence (Kipman et al. 2002; Gorwood et al. 2002; Ricca et al. 2004; Rybakowski et al. 2006).

Three studies reported a significant association of the -1438G/A polymorphism of the promoter of the *5-HT$_{2A}$* receptor gene with BN (Nishiguchi et al. 2001; Ricca et al. 2002, 2004), whereas five others did not (Enoch et al. 1998; Ziegler and Görge 1999; Fuentes et al. 2004; Bruce et al. 2005) (Table 76.3). One of the positive studies performed in an Asian population (Nishiguchi et al. 2001) found a nominal association between BN and the GG genotype/G allele instead of the AA genotype/A allele as observed in the other two studies (Ricca et al. 2002, 2004). Interestingly, the GG genotype and the G allele were more frequent in the group with binge-purging phenotype (ANBP and BNNP), and BN patients with GG genotype were characterized by blunted prolactin response to meta-chlorophenylpiperazine and higher levels of impulsivity (Bruce et al. 2005), which suggests a reduced serotonergic activity of the wild type allele. Therefore, the higher 5-HT$_{2A}$ receptor activity associated to the A allele, could result in a potentiation of the anorectic 5-HT signal explaining the above-reported association of this allele with ANR and with reduced levels of harm avoidance, whereas the G allele could sustain binge eating behavior in BN because of lower 5-HT$_{2A}$ receptor activity.

The Thr25Asn, His452Tyr, 102T/C, and 516T/C SNPs of the *5-HT$_{2A}$* receptor gene were found not significantly associated with both AN and BN (Hinney et al. 1997b; Nacmias et al. 1999) (Tables 76.2 and 76.3).

The Ser23 allele of the Cys23Ser SNP of the *5HT2C* receptor gene is associated with a higher 5-HT$_{2C}$ receptor expression (Sodhi et al. 1999), and two out of three studies (Nacmias et al. 1999; Westberg et al. 2002; Hu et al. 2003) reported higher frequencies of the Ser23Ser genotype and the Ser23 allele in Caucasian AN patients (Table 76.2). Furthermore, in the study of Hu et al. (2003), including also 43 AN trios, the TDT showed a preferential transmission of the Ser23 allele, which was also associated with lower BMI. Therefore, the putative enhanced activity of 5-HT$_{2C}$ receptors in carriers of Ser23 allele would sustain the restrictive behavior of AN patients and could explain the lower BMI. Recently, a higher frequency of the Ser23 allele has been found also in teenage girls reporting weight loss but not affected by AN (Westberg et al. 2002), which suggests that this SNP might be not specifically associated with AN, but with a general proneness of young women to experience weight loss through reducing food intake. No association between the Cys23Ser SNP of the *5-HT$_{2C}$* receptor gene and BN has been detected (Nacmias et al. 1999; Burnet et al. 1999) (Table 76.3).

Some SNPs and the haplotypes -1123T>C/1080C>T and 1080C>T/2190A>G of the *5-HT$_{1D\beta}$* receptor gene were found significantly associated with AN or ANR (Bergen et al. 2003; Brown et al.

2007) (Table 76.2). These associations are intriguing, since the *5-HT$_{1D\beta}$* receptor gene is positioned under an observed linkage peak on chromosome 1 for ANR (Grice et al. 2002; Bergen et al. 2003). Therefore, the *5-HT$_{1D\beta}$* receptor gene certainly is worth of further investigation. The G861C SNP of the *5-HT$_{1D\beta}$* receptor gene has been investigated in BN patients (Levitan et al. 2001, 2006) (Table 76.3); although no significant association emerged between this SNP and BN, bulimic individuals with GG genotype had a minimum lifetime BMI significantly lower than GC and CC genotypes and a more severe comorbid obsessive-compulsive disorder.

No significant association has been detected between the Pro279Leu SNP of *5-HT$_7$* receptor gene and AN (Hinney et al. 1999a).

76.2.1.3 Serotonin Biosynthetic Enzyme

The A218C SNP of the *tryptophan-hydroxylase-1* (*TPH-1*) gene is endowed with functional effects, since the A allele has been found to be associated with lower cerebrospinal fluid 5-hydroxyindolacetic acid levels in healthy volunteers (Jonsson et al. 1997). Although no significant association was found between the A218C SNP of the *TPH*-1 gene and BN (Table 76.3), BN women with the AA genotype displayed a more severe bulimic symptomatology (as measured by the weekly frequency of binge-purging episodes and the Bulimia Investigation Test Edinburgh) and higher levels of harm avoidance as compared to AC and CC genotypes (Monteleone et al. 2007). Therefore, it could be hypothesized that BN individuals with the A variant of the *TPH*-1 A218C SNP have reduced concentrations of 5-HT at their central synapses, which would represent a vulnerability factor for binge eating behavior and higher harm avoidance.

No significant association between the Y1095C SNP of the *TPH-1* gene and AN was reported in a small sample study (Han et al. 1999) (Table 76.2).

76.2.2 Dopamine

Dopaminergic neurotransmission modulates feeding, thinking processes, motor activity, reward-motivated and drug-seeking behaviors. AN and BN patients, aside from their well-known disturbances of eating behavior, exhibit physical hyperactivity, distortion of thinking and body image, and obsessive–compulsive behaviors. Therefore, genes of dopamine transmission are candidate genes in EDs.

76.2.2.1 Dopamine Transporter

The dopamine transporter (DAT) protein is a critical regulator of synaptic dopamine. The *DAT1* gene, encoding the DAT protein, is polymorphic, and in most human beings occurs with greatest frequency in the 9- and 10-repeat forms. The 10-repeat variable number of tandem repeats (VNTR) polymorphism has been shown to be associated with an approximately 50% increase of DAT binding sites as compared to the 9-repeat allele (vanNess et al. 2005). One study investigated the VNTR polymorphism of the *DAT1* gene in small groups of ANBP and BN patients and found a higher frequency of short alleles (seven and nine repeats) as compared to long alleles (10 and 11 repeats) in ANBP but not in BN (Shinohara et al. 2004) (Tables 76.2 and 76.3).

76.2.2.2 Dopamine Receptors

Bergen et al. (2005) tested seven SNPs within the dopamine D2 receptor gene (*DRD2*) and found significant associations of the 725bp3'G>T and 10620C>T SNPs with ANBP (Table 76.2). Moreover, the haplotype Indel+939C>T was significantly associated with both AN and ANR; the haplotypes Indel +957C>T and 939C>T+725bp3'G>T were significantly associated with AN, and the haplotype 939C>T+10520C>T was significantly associated with ANR. Another variant of the *DRD2* gene is represented by the polymorphic Taq1A restriction endonuclease site that has been shown to reduce D2 receptor synthesis (Laakso et al. 2005). No association between the *DRD2* Taq1A polymorphism and AN or BN was detected in a very small sample of patients, including also obese individuals (Nisoli et al. 2007) (Tables 76.2 and 76.3), although it was found significantly associated with the Eating Disorder Inventory Subitems that characterize the drive for thinness and ineffectiveness, which suggests a possible role of this polymorphism in ED-related phenotypic traits.

SNPs of the dopamine D3 (*DRD3*) and D4 (*DRD4*) receptor genes have been investigated for association with AN and results were generally negative (Bruins-Slot et al. 1998; Hinney et al. 1999b; Bachner-Melman et al. 2007) (Table 76.2). A functional polymorphism of the *DRD4* gene is represented by the D4prC(521)T, where the C allele has been found to be responsible for less transcriptional activity of the *DRD4* gene (Okuyama et al. 2000). The recent study of Bachner-Melmam et al. (2007), who explored five SNPs of the *DRD4* gene, showed that the C allele of the D4pr C(521) T SNP was preferentially transmitted to AN individuals and that the D4pr C(521)T SNP, the D4pr 120 repeat, and several two, three, four, and five locus haplotypes were significantly associated with AN (with some differences between ANR and ANBP) and with the socially proscribed perfectionism subscale and/or the self-oriented perfectionism subscale of the Children and Adolescent Perfectionism Scale in AN. These findings suggest a possible involvement of *DRD4* gene in ED-related phenotypic traits such as perfectionism.

76.2.3 Noradrenaline

Decreased levels of norepinephrine have been detected in the blood and cerebrospinal fluid of long-term weight-restored patients with AN (Kaye et al. 1985), which supports an involvement of noradrenergic transmission in AN. A repeat polymorphism in the promoter region of the norepinephrine transporter (*NET*) gene (NETpPR), characterized by a 4bp deletion (NETpPR-S4) or insertion (NETpPR-L4), has been characterized. This polymorphism results in an alteration of a potential transcription factor binding site. In a sample of 101 AN Australian trios, including 14 ANBP trios and 87 ANR trios, a higher frequency of L4/L4 genotype and L4 allele was found in ANR patients. Moreover, the TDT showed a preferential transmission of the NETpPR-L4 allele from L4/S4 heterozygous parents to their ANR children (Urwin et al. 2002). This finding was not confirmed in a subsequent study (Hu et al. 2007) (Table 76.2).

In humans, the beta-3 adrenoceptor is primarily expressed in visceral fat and its activation by catecholamines promotes lipolysis. Recently, the Trp64Arg SNP of the beta-3 adrenergic receptor has been suggested to be a predisposing factor for abdominal obesity and metabolic alterations, especially in women (Kurabayashi et al. 1996); therefore, this SNP has been considered to be of interest also in EDs. However, no association between the Trp64Arg SNP of the *beta-3 adrenergic receptor* gene and AN or BN has been detected (Hinney et al. 1997c; Miyasaka et al. 2006) (Tables 76.2 and 76.3).

76.2.4 Monoamine Degrading Enzymes

Catechol-O-methyltransferase (COMT) and monoamine oxidase A (MAOA) are the two main enzymes involved in the degradation of brain monoamines. An SNP at position 472 (472G/A) of the *COMT* gene creates an amino acid change (158 Val>Met) leading to two forms of the mature protein: the 158Val protein is provided of high enzymatic activity, which is about 4 times greater than the 158Met protein (Lachman et al 1996). A nominal association of the ValVal genotype and the Val allele with AN has been shown in two studies (Frisch et al. 2001; Micolajczyk et al. 2006) but has not been confirmed in a large case-control study of individuals from six European countries (Gabrovsek et al. 2004) (Table 76.2). Similarly, a preferential transmission of the Val allele was detected in a sample of 66 ANR trios (Michaelovsky et al. 2005), but not confirmed in a larger study including 372 AN trios (Gabrovsek et al. 2004). Moreover, four SNPs of the COMT gene other than the Val158Met SNP were investigated together with two SNPs in the adjacent *armadillo repeat gene deleted in velocardiofacial syndrome* (*ARVCF*) gene, and the haplotype COMT-186C-408G-472G-ARVFC-659C-524T was identified as a "risk haplotype," whereas the haplotype COMT-186T-408C-472A-ARVFC659T-524C was identified as a "protective haplotype" for AN (Michaekowsky et al. 2005) (Table 76.2). Moreover, the TDT showed a preferential transmission of the C allele of the 408C/G and of the T allele of the 524T/C SNPs. Finally, the Met allele of the 158 Val>Met SNP of the COMT gene was found to be associated with ED-related phenotypic traits, such as higher scores on the subscales bulimia, ineffectiveness, interoceptive awareness, maturity fears, and impulse regulation of the Eating Disorder Inventory (Frieling et al. 2006).

The promoter of the *MAOA* gene has a functional MAOA-upstream VNTR (MAOA-uVNTR) polymorphism, which consists of 3 (3-allele) or 4 (4-allele) copies of a 30-bp sequence, or rarely 2 (2-allele) or three copies plus the first 18-bp of the same 30-bp sequence (3a-allele), or five copies (5-allele). The 3a-allele and 4-allele (MAOA-L) are transcribed more efficiently than the shorter 3-allele (MAOA-S) (Sabol et al. 1998). One study found no significant association between the MAOA-uVNTR polymorphism and AN (Urwin et al. 2003b) (Table 76.2). No study has been performed to assess specifically the association of SNPs of the *COMT* and *MAOA* genes with BN. Only Mikolajczyk et al. (2006) reported no significant association between the 472G/A SNP of the *COMT* gene and BN in a study including only 28 BN individuals.

76.2.5 Epistasis

Epistasis, that is gene–gene interaction, between the *5-HTTLPR* polymorphism and polymorphisms of the *NET* or the *MAOA* gene have been investigated in AN. No significant interaction between *5-HTTLPR* and a polymorphism within the *NET* gene promoter polymorphic region was found in a sample of 106 Australian trios (Urwin et al. 2003a). On the contrary, the same research group detected a significant synergistic epistatic interaction between the *5-HTTLPR* and a polymorphism in the *MAOA* gene, since the risk of developing AN was up to eight times greater that the risk imposed by the *MAOA* gene variant alone when the MAOA variant was transmitted together with the *5-HTTLPR* SS genotype (Urwin and Nunn 2005). Finally, an epistatic interaction between the MAOA-uVNTR and the NETpPR polymorphisms was identified, since receiving a MAOA-L allele was found to more than double the risk for developing ANR, conditional on an individual also being a NETpPR-L4 homozygote (Urwin et al. 2003b).

76.2.6 Brain-Derived Neurotrophic Factor

It has been widely demonstrated that BDNF has a role in the regulation of eating behavior, acting as a satiety factor in the experimental animal (Tsuchida et al. 2001). Moreover, in symptomatic patients with AN or BN, circulating levels of BDNF have been detected to be decreased (Monteleone et al. 2004, 2005b) and only partially restored after body weight rehabilitation in AN (Nakazato et al. 2006). The Val66Met (196G/A) SNP of the *BDNF* gene, which has an effect on the intracellular processing and secretion of BDNF, has been assessed for association with AN yielding somewhat conflicting, yet generally, promising results. Indeed, a small study and a large case-control study of individuals from five European countries showed that ANR and ANBP individuals had a higher frequency of the AA genotype and the A allele of the Val66Met (196G/A) SNP of the *BDNF* gene (Ribasès et al. 2003, 2004), and that patients carrying at least one copy of the A allele had lower values of lifetime minimum BMI (Table 76.2). In a subsequent study (Ribasès et al. 2005a) including 359 family trios recruited from seven European countries, the previously reported higher frequency of the AA/AG genotypes and the A allele in ANR was confirmed, but no preferential transmission of the A or G allele was detected, although in trios with ANR the A allele was transmitted with a significant lower minimum BMI than the G allele. An association between the Val66Met SNP and ANR or AN was reported by two further independent research groups (Koizumi et al. 2004; Dmitrzak-Weglarz et al. 2007). Three studies, instead, provided negative results (Friedel et al. 2005; Rybakowski et al. 2007; Dardennes et al. 2007); however, in one of them AN patients with the A allele of the Val66Met SNP had higher levels of harm avoidance than GG homozygotes (Rybakowski et al. 2007), suggesting an association between this SNP and personality traits in AN (Table 76.2).

As for BN, Ribasès et al. (2004) found a higher frequency of the AA/AG genotype and the A allele of the Val66Met SNP in 389 BN individuals recruited from three European countries, but this was not confirmed in their subsequent family trios study (Ribasès et al. 2005a) and in a small study including only 70 BN patients (Ribasès et al. 2003). Negative findings were also reported by Koizumi et al. (2004) in a sample of 118 BN patients; however, when patients were stratified into BNP and BNNP subtypes, a significantly higher frequency of the AG genotype was detected in BNP patients while the A allele was significantly associated with BNNP subtype (Table 76.3). Monteleone et al. (2006b) assessed the association of the Val66Met SNP with both BN and binge eating disorder, and results were negative; however, patients carrying the AA genotype displayed a higher severity of binge-eating (assessed by the weekly frequency of bingeing and the Bulimia Investigation Test Edinburgh symptom and total scores), which suggests a possible involvement of this SNP in the susceptibility to the aberrant eating behavior.

A second common SNP of the *BDNF* gene is represented by the -270C/T SNP. No significant association between the -270 C/T SNP and AN was founded in five studies (Ribasès et al. 2003, 2004, 2005a; Koizumi et al. 2004; Dardennes et al. 2007) (Table 76.2). However, in a study including 359 AN trios recruited from seven European countries and investigating also the Val66Met SNP, it was found that the -270C/T/Met66 haplotype was preferentially transmitted to the affected ANR offspring (Ribasès et al. 2005a) while Rybakowski et al. (2007) reported that AN patients with the T allele had higher levels of persistence and harm avoidance than CC homozygotes.

No significant association of the -270C/T SNP with BN has been detected (Ribasès et al. 2003, 2004, 2005a); however, BN individuals carrying the T allele exhibited an earlier age at onset of weight loss and higher maximum BMI (Ribasès et al. 2004) (Table 76.3).

Very recently, epistasis between the *BDNF* gene and the *DRD4* gene has been assessed in a sample of 162 female probands with BN (Kaplan et al. 2008). Probands carrying both the hypofunctional 7R allele of *DRD4* gene and the Met allele of *BDNF* gene had significantly higher maximum BMI than probands in the other gene–gene interaction groups.

76.2.6.1 BDNF Receptor

SNPs of the *NTRK2* gene, which encodes a BDNF receptor, have been investigated for association with AN and BN in a study that screened the entire NTRK2 gene and identified 14 SNPS (Ribasès et al. 2005b). The -69C >G SNP was found nominally associated with ANBP and the IVS13+40G>A and the IVS17+125T>C SNPs were found significantly associated with BN, whereas no significant association emerged between the IVS2+40C>T, IVS18+13G>A and 2784–2785insC with both AN and BN (Tables 76.2 and 76.3). Moreover, a strong association was detected between the C-A-insC haplotype and ANBP. Finally, BN patients carrying the C-A-insC haplotype showed higher scores in the harm avoidance dimension of the personality. These results need replication.

76.2.7 Neuropeptide Y and the Agouti-Related Protein

NPY is a highly potent stimulator of hunger in the hypothalamus, where it is co-secreted with another potent orexigenic peptide, the agouti-related protein, which is an inverse agonist at melanocortinergic receptors where melanocortins derived from proopiomelanocortin act as anorexigenic agonists. NPY exerts its effects in the regulation of food ingestion mainly through NPY 1 and NPY 5 receptors. No significant associations between SNPs of *NPY Y$_1$* and *Y$_5$* receptor genes and AN were detected in one study (Rosenkranz et al. 1998a), whereas the G760A and G526A, but not the C659T SNP of the *agouti-related protein* gene were found nominally associated to AN (Vink et al. 2001) (Table 76.2). The 760A and 526A alleles were in complete linkage disequilibrium and the mutant allele was preferentially transmitted to ANBP offspring in a family trios study (Dardennes et al. 2007). Finally, it was found that AN individuals carrying the mutant allele had a younger age at onset and lower sense of interpersonal distrust (Dardennes et al. 2007).

76.2.8 Opioids and Endocannabinoids

Opioid peptides and endocannabinoids have been demonstrated to be involved in the control of both quantitative and hedonic/rewarding aspects of food choice and consumption. In particular, endocannabinoids, such as anandamide and 2-arachidonylglycerol, control food intake at two levels. First, they tonically reinforce the motivation to find and consume food with a high incentive value, possibly by interacting with the mesolimbic pathway involved in reward mechanisms. Second, they are activated "on demand" in the hypothalamus after short-term food deprivation and transiently regulate the levels and/or action of other orexigenic and anorectic mediators to modulate appetite (Matias and Di Marzo 2007). Alterations in circulating levels of anadamide and opioid peptides have been detected in ED patients (Brambilla et al. 1991; Monteleone et al. 2005c); so the investigation of genes involved in the physiology of those substances seems to be promising in EDs.

Bergen et al. (2003) found that the 47821A>G SNP and the haplotypes 8214T>C/47821A>G and 80A>G/8214T>C/23340A>G/47821T>G/51502A>T of the *OPRD1* gene were associated to AN. Recently, Brown et al. (2007) found three other SNPs of the *OPRD1* gene to be associated with both ANR and/or ANBP (Table 76.2). It is of note that the *OPRD1* gene is positioned under the observed linkage peak on chromosome 1 for ANR close to the *5HTR1D* gene (Grice et al. 2002; Bergen et al. 2003).

Polymorphisms of the endocannabinoid CB1 receptor gene (*CNR1*) and of the gene coding the fatty acid amide hydrolase (FAAH) and the N-acylethanolamine-hydrolyzing acid amidase (NAAA), the major degrading enzymes of endogenous cannabinoids, have been studied for association with AN (Table 76.2). Specifically, it was demonstrated that the 13-repeat allele of the (AAT)n triplet repeat polymorphism of the *CNR1* gene was preferentially transmitted in ANBP patients while the 14-repeat allele was preferentially transmitted in the ANR group (Siegfried et al. 2004), but this was not confirmed in a larger study showing also no significant association or transmission of different SNPs of *CNR1*, *FAAH*, and *NAAA* genes with AN in 91 German AN trios (Muller et al. 2008).

76.3 Peripheral Regulators of Eating Behavior

A number of substances secreted by the gut, the pancreas, and the adipose tissue have been identified and characterized as modulators of food intake and/or energy expenditure. Alterations in circulating levels of those substances and/or change in their secretory responses to physiological stimuli have been detected in both AN and BN patients (Monteleone et al. 2008). At the moment, there are no conclusive data as to whether secretory alterations of feeding regulatory substances precede the appearance of an ED or are the consequence of the nutritional changes occurring with the disorder. However, it has been suggested, although not proved, that even if those alterations are secondary phenomena disappearing after the recovery from the ED, they may hypothetically contribute to the maintenance of both aberrant eating behaviors and/or other symptomatic changes, thus affecting the course and the outcome of the ED. Therefore, genetic association studies have been performed to evaluate the role of polymorphic variants of genes coding ghrelin, cholecystokinin, leptin, and their receptors, as well as adiponectin and resistin in the genetic susceptibility to AN and/or BN.

No significant associations between the Arg51Gln and/or the Gln90Leu SNPs of the *ghrelin* gene with AN have been reported in four independent studies (Ando et al. 2006; Cellini et al. 2006; Dardennes et al. 2007; Monteleone et al. 2006c) (Table 76.4); the Leu72Met SNP, instead, was found associated with ANBP in a family trios study reporting a preferential transmission of the Met allele and of the haplotype 90Gln/72Met to ANBP offspring (Dardennes et al. 2007). However, two case-control studies and a large family trios study did not confirm those results (Ando et al. 2006; Cellini et al. 2006; Monteleone et al. 2006c) (Table 76.4). No significant association was found between the Arg51Gln and the Gln90Leu SNPs of the *ghrelin* gene and BN (Cellini et al. 2006; Monteleone et al. 2006c), although the haplothype Gln90/Leu72/Arg51 was detected preferentially transmitted to BN offspring (Cellini et al. 2006). Similar negative findings were reported for the Leu72Arg SNP in two different BN samples (Cellini et al. 2006; Monteleone et al. 2006c) (Table 76.5). Ando et al. (2006), instead, reported a nominal association of the Leu72Met and 3056T>C SNPs with BNP and a higher frequency in this group of the haplotype Met72/3056C. Finally, the 171T/C SNP of the *ghrelin receptor* gene was found associated with BN, but not with AN in a Japanese population (Miyasaka et al. 2006).

Only the rs11129946 SNP of the *cholecystokinin* gene was found nominally associated with AN in a single study (de Krom et al. 2006) (Table 76.4). No associations were found between SNPs of the *cholecystokinin-A receptor*, *leptin*, *leptin receptor*, *adiponectin*, and *resistin* genes with AN and/or BN in single small case–control studies (Hinney et. 1998; Quinton et al. 2004; Dolinkova et al. 2006; Miyasaka et al. 2006) (Tables 76.3 and 76.4). The only interesting finding that emerged from those studies was that AN patients carrying the minor T allele of the 276G>T SNP of the *adiponectin* gene had increased cholesterol levels (Dolinkova et al. 2006), which might help to explain hypercholesterolemia of underweight AN patients.

76.4 Other Candidate Genes

Other genes that have been supposed to be likely involved in the biological vulnerability to EDs are those coding uncoupling proteins (UCP), tumor necrosis factor-α, estrogen receptors, phospholipase A2, the small-conductance calcium-activated potassium channel-3 (KCNN3), and the circadian locomotor output cycles kaput (CLOCK).

UCP2 and UCP3 are ubiquitous proteins promoting thermogenesis and modulating metabolic adaptation during fasting. Allele 13 of the microsatellite marker D11S911 of the *UCP2/UCP3* gene was found associated with AN in one study (Campbell et al. 1999), but this was not confirmed by another research group (Hu et al. 2002). One study performed in an Asian population reported no

association between the -866G>A SNPs of the *UCP2* gene and the -55cT SNP of the *UCP3* gene with AN (Ando et al. 2004) (Table 76.6).

Tumor necrosis factor-α is a cytokine that decreases the activity of lipogenic enzymes including the intracellular phospholipase A2 enzyme and induces lipolysis-promoting cachexia. Four SNPs of the *tumor necrosis factor-α* gene and the intPla polymorphism of the *Phospholipase A2* gene were found not associated with AN in two case–control studies (Ando et al. 2001b; Slopien et al. 2004) (Table 76.6).

EDs occur predominantly in women with a female to male ratio of 9:1. This female predominance suggests a role for sex hormones, especially estrogens, in the etiopathogenesis of AN and BN. The genes coding estrogen receptor type 1 (*ESR1*) and estrogen receptor type 2 (*ESR2*) have been analyzed for their putative association with AN and BN. The 1082G>A SNP but not the 1730A>G SNP of the *ESR2* gene has been found nominally associated with AN in two independent case-control studies (Rosenkranz et al. 1998; Eastwood et al. 2002) (Table 76.6). The 1730A>G SNP of the *ESR2* gene, instead, has been found nominally associated with BN in one study (Nilsson et al. 2004), but not in another one (Rosenkranz et al. 1998) (Table 76.7). Finally, a statistically significant higher frequency of the mutant A allele of the ERβcx+56G>A polymorphism of the *ESR2* gene has been detected in a small sample of BN individuals including also patients with partial syndrome BN (Nilsson et al. 2004). No association of polymorphisms of the *ESR1* gene with AN was detected in a single case–control study (Eastwood et al. 2002).

The KCNN3 regulates ion flow through the NMDA-glutamate receptor and dampens neuronal excitability. An association between the CAG repeat polymorphism of the *KCNN3* gene and AN has

been recently investigated in two studies by the same group (Koronyo-Hamaoui et al. 2002, 2004) (Table 76.6). Patients with AN were more likely than controls to manifest genotypes with alleles longer than 19 CAG repeats (L alleles). The TDT showed a preferential transmission of the L alleles to AN offspring. Moreover, AN patients with comorbid obsessive-compulsive disorder had a higher frequency of L repeats than those without an obsessive–compulsive disorder (Koronyo-Hamaoui et al. 2004).

Feeding is subjected to circadian regulation; therefore, changes in the components of the endogenous oscillator regulating circadian rhythms may be involved in disordered rhythmicity of eating

behavior as it occurs in EDs. Although several genes have been identified in the endogenous machinery modulating circadian rhythms, to date only the *CLOCK* gene has been investigated in EDs. No significant associations of the 3111T/C SNP of the *CLOCK* gene with AN or BN has emerged (Table 76.7); however, AN and BN subjects with at least one copy of the C allele exhibited a minimum past BW significantly lower than those with the T/T genotype, which suggests a possible involvement of the *CLOCK* gene in the regulation of BW (Tortorella et al. 2007).

76.5 Concluding Remarks

It is evident from the above that genetic association studies of AN and BN are in an early phase. Although in the last 10 years, polymorphic variants of different candidate genes have been assessed for an association with AN and BN, results have been often inconsistent. There are several reasons that may explain at least part of such an inconsistency. First of all, the majority of association studies has been performed on small subject samples (often in groups of less than 100 subjects) and suffered from insufficient statistical power and lack of correction for multiple testing. Second, differences in the ethnicity of populations included and the use of different criteria to diagnose AN and BN may further contribute to the discrepancies among the studies. Third, genetic heterogeneity and population stratification may provide false positive results. Furthermore, EDs have a high rate of comorbidity with other psychiatric conditions, including affective, anxiety, and personality disorders, which may further contribute to the clinical heterogeneity of studied samples and may partially account for current discrepant results. Finally, the effects of environmental risk factors on gene expression have been so far completely neglected in genetic association studies on EDs. Life events, nutrition, cultural, and social risk factors by acting through epigenetic mechanisms may influence the activation and/or deactivation of genes and modify the risk of developing an ED. As outlined by Moffitt et al. (2005), discrepancies among association studies may be the result of still unknown gene x environmental interactions, in which genes have a susceptibility role for an ED only in those patients who are exposed to those putative environmental risk factors.

Nonetheless, some intriguing conclusions can be drawn across association studies in AN and BN. The -1438G/A SNP of the *5-HT*$_{2A}$ receptor gene and the Val66Met SNP of the *BDNF* gene have been

found quite consistently although not specifically linked to ANR and/or to phenotypic traits associated with the disorder in large sample studies. Therefore, the *5-HT*$_{2A}$ receptor gene and the *BDNF* gene are promising candidates for genetic influences on AN. The second intriguing finding is that in both AN and BN SNPs have been found frequently associated with ED-related phenotypic traits rather that to the full syndromes as currently categorized in DSM-IV. Although these results need replication and confirmation in larger studies, they underline the importance of focusing on more homogeneous subgroups, either relying on specific ED traits or identifying endophenotypes. For instance, six quantitative phenotypic traits (obsessionality, age at menarche, anxiety, lifetime minimum BMI, concern over mistake, and food-related obsessions) have been characterized as specific traits to be used for both linkage analyses and association studies (Bulik et al. 2005), and future researches should consider them. An endophenotype, instead, is a measurable trait that may be physical (neurophysiological, biochemical, neuroanatomical), cognitive, or neuropsychological and that is associated with the related illness, is heritable, and primarily state-independent. The identification of endophenotypes in EDs will help to identify more homogenous subgroups of patients in order to reduce the potential obscuring effects of focusing on currently categorized complex syndromes.

It is clear that the genetics of EDs needs more and larger association studies with adequate sample sizes. To pursue this goal, multicenter collaborative studies should be encouraged. Moreover, a promising area for future research is to examine gene–gene interactions in light of the fact that biological susceptibility to EDs has a multigenic nature. Epistatic studies have produced some interesting findings, but the results are still too preliminary to draw any significant conclusion.

In summary, genetic association studies of EDs have produced a plethora of data but little conclusive knowledge. We are hopeful that, in the future, a more homogeneous characterization of clinical phenotypes and the promotion of multicenter collaborative studies will help to identify the genes likely involved in the heritable transmission of biological vulnerability to these serious and debilitating conditions.

76.6 Applications to Other Area of Health and Disease

Anorexia nervosa and bulimia nervosa are psychiatric disorders with physical consequences that often may threat the survival of the patients. The etiology of these conditions is not know, but it is commonly believed that a genetic predisposition to the disorders is transmitted to vulnerable individuals and may interact with personality and environmental risk factors to generate anorexia or bulimia nervosa. Some phenotypic aspects, such as low body weight, bingeing behavior and personality dimensions, seems to be more strictly associated with polymorphic gene variants. Moreover, preliminary evidence has been provided that polymorphisms of certain candidate genes may predict the outcome to treatments. Putting together genetic research and clinical intervention studies will help clinicians to improve the outcome of anorexia and bulimia nervosa and to organize adequate prevention.

Summary Points

- Epidemiological, family and molecular genetic studies suggest a strong genetic component in anorexia nervosa and bulimia nervosa.
- Association studies of candidate genes indicate the *5-HT*$_{2A}$ receptor gene and the *BDNF* gene as promising candidates for genetic susceptibility to AN.
- Association studies of candidate genes have provided inconsistent results in BN.

- The following reasons may explain at least part of discrepancies among the studies: a) the majority of studies has been performed on small subject samples and suffered from insufficient statistical power and lack of correction for multiple testing, b) different ethnic populations have been studied; c) different criteria to diagnose AN and BN have been used; d) genetic heterogeneity and population stratification could provide false positive results; e) comorbidity of AN and BN with other psychiatric conditions has been not taken into account; f) the interaction gene-environment has been completely neglected.
- Several intriguing associations have emerged between polymorphisms of candidate genes and eating disorder-related phenotypic traits.
- In the future, the identification of endophenotypes and the promotion of multicenter collaborative studies will lead to more consistent results.

Key Terms

Binge eating: An episode of binge eating is characterized by both of the following:
- o Eating, in a fixed period of time, an amount of food that is definitely larger than most people would eat under similar circumstances.
- o A lack of control over eating during the episode: a feeling that one cannot stop eating or control what or how much one is eating.

Candidate gene: gene coding a protein that is likely involved in the etiopathogenesis of a disease as supported by clinical, biochemical and other research data.

Compensatory behaviors: acts by which the person tries to compensate for the effects of overeating. Examples of such acts are purging (induced *vomiting* or *laxative* abuse), *fasting*, and heavy exercising.

Eating-disorder related phenotypic traits: clinical symptoms or personality characteristics that are typical of patients with anorexia nervosa or bulimia nervosa.

Epistasis: is the *interaction* between genes. Epistasis takes place when the effects of one *gene* are modified by one or several other genes.

Single-nucleotide polymorphism: is a *DNA sequence* variation occurring when a single *nucleotide* in the *genome* differs between members of a species (or between paired chromosomes in an individual). In this case two *alleles* are identified: the wild type allele and the polymorphic (or mutant) allele.

Chapter 77
Changes in Brain Gene Expression in Nutrient Deficiencies: An Example with Iron

Erica L. Unger, Narasimha Hegde, and James R. Connor

Abbreviations

CSF	Cerebrospinal fluid
IF	Interstitial fluid
Tim-2	T-cell immunoglobulin and mucin domain-containing protein 2
IRP	Iron regulatory protein
IRE	Iron responsive element
UTR	Untranslated region
mTOR	Mammalian target of rapamycin
CamK2a	Calcium/calmodulin-dependent protein kinase II alpha
BDNF	Brain derived neurotrophic factor
ARA	Arachidonic acid
MBP	Myelin basic protein
MOG	Myelin-oligodendrocyte glycoprotein
MAL	Myelin and lymphocyte protein
MOBP	Myelin-associated oligodendrocytic basic protein
PMP22	Peripheral myelin protein 22
PLP	Proteolipid protein
DAT	Dopamine transporter
GABA	Gamma-aminobutyric acid
GAT1	Gamma-aminobutyric acid transporter type 1
VMAT2	Vesicular monoamine transporter 2
trkB	Tyrosine kinase B

77.1 Introduction

Iron is an indispensable element in biological systems and is responsible for the function of many prosthetic groups, including heme and iron–sulfur clusters. Cellular iron uptake, distribution, and export must be tightly regulated, as iron deficiency impairs the function of many proteins, and excess

iron can oxidize and damage the protein, nucleic acid, and lipid content of the cell. A well-regulated feedback control functions to enhance iron absorption when the body is deficient and to limit excessive iron accumulation when iron is abundant. Major sites of iron regulation are the doudenum where dietary iron is absorbed, the bone marrow where red blood cells are produced, the liver where most excess iron is stored, and the spleen and reticuloendothelial system where red blood cells are catabolized and iron is extracted for reuse. The importance of iron homeostasis becomes clear when one considers that iron deficiency anemia is the most widespread nutritional disorder affecting over 30% of the world's population, and that iron overload can lead to diabetes and heart disease and is a contributing factor to neurodegenerative diseases. The proper distribution and sequestering of iron is a challenging task at both the cellular and organismic levels due to the involvement of many organs and their differential requirement for iron that differs by age and sex. In the brain, iron is required for a multitude of cellular processes; thus it is the organ most vulnerable to iron deficiency during critical periods of development, particularly during the last trimester of fetal life and during the period of brain growth spurt and differentiation. This chapter will discuss iron regulation in the brain and changes in gene expression in the condition of iron deficiency.

77.2 Iron Transport in the Brain

Iron is required as a cofactor in central nervous system metabolic processes such as oxygen transport, neurotransmitter production, nitric oxide metabolism, and oxidative phosphorylation (Ponka 2004). The neuronal need for iron is obvious considering the fact that about 20% of the oxygen consumption of the body relies on mitochondrial respiration in the brain. During development, embryonic and dividing neurons require iron to support the activity of the enzyme ribonucleotide reductase, which is critical for DNA replication. Further, the role of iron in neuroectodermal development was demonstrated by mutating the gene encoding the transferrin receptor, which provides transferrin-bound iron to the brain, resulting in nonviable embryos with severe malfunctions of the central nervous system (Levy et al. 1999).

Evidence over the last 2 decades suggests that mechanisms of iron transport across the blood–brain barrier involve a transferrin–transferrin receptor pathway. (Bradbury 1997; Malecki et al. 1999; Burdo and Connor 2003). Uptake of transferrin-bound iron by transferrin receptor-mediated endocytosis from the blood into the cerebral endothelial cells is similar to iron uptake by other cell types. This process involves binding, endocytosis, acidification, and dissociation, and finally translocation of iron across the endosomal membrane via a process that may involve divalent metal transporter 1 (Fleming et al. 1997). A second proposed mechanism of iron transport across the abluminal membrane involves astrocytes, through their endfoot processes on the capillary endothelium (Malecki et al. 1999; Oshiro et al. 2000). A small portion of transferrin–iron complex is also known to cross the blood–brain barrier by receptor-mediated transcytosis (Moos and Morgan 1998). In addition to these pathways, it has been proposed that the lactoferrin receptor-lactoferrin and glycosylphosphatidylinositol (GPI)- anchored p97-secreted pathways may play a role in iron transport across the blood–brain barrier (Faucheux et al. 1995).

When iron has been transported across the blood–brain barrier, it binds to transferrin that is secreted from the oligodendrocytes and epithelial cells of the choroid plexus (Bradbury 1997). Transferrin in cerebrospinal fluid (CSF) and interstitial fluid (IF) is fully saturated with iron under normal conditions, and several experiments suggest that the iron concentration exceeds that of the binding capacity of transferrin in the CSF and IF. The nontransferrin-bound iron in the brain is likely associated with citrate, ascorbate, albumin, lactoferrin, and secreted p97. The presence of nontransferrin-bound iron in brain extracellular fluids and the absence of transferrin receptors in astrocytes, oligodendricytes, and microglia show that glia acquire iron via mechanisms independent

of transferrin/transferrin receptor mediation (Moos 1996; Moos and Morgan 1998). For instance, oligodendrocytes express T-cell immunoglobulin and mucin domain-containing protein 2 (Tim-2), which binds and internalizes the iron storage protein H-ferritin. This interaction is likely the main mechanism for iron acquisition into oligodendrocytes (Todorich et al. 2008).

77.3 Iron Homeostasis

Given the fact that iron requirements far exceed the gastrointestinal absorption capacity, iron utilized on a daily basis is continuously recycled from internal storage. This process is regulated by the hepatocyte-derived peptide hepcidin, which maintains systemic iron homeostasis by regulating gastrointestinal iron absorption and iron release from reticuloendothelial stores via the plasma membrane iron exporter ferroportin (Nemeth et al. 2004). Ceruloplasmin maintains a rate of plasma iron oxidation sufficient for the continued release of this essential metal from the storage site (Harris et al. 1998). Iron levels in the blood are not static and are known to fluctuate with the diurnal cycle, which has been attributed to fluctuating iron release from reticuloendothelial cells (Scales et al. 1988; Uchida et al. 1983). The rationale for variations in plasma iron relative to fluctuations in tissue needs for iron is interesting but not elucidated by current theories of iron requirements.

Brain iron accounts for less than 2% of the total body iron content. Iron content in the brain is highest in basal ganglia, with substantia nigra, red nucleus, and hippocampus also having significant iron contents (Hill and Switzer 1984; Morris et al. 1992). Similar to peripheral iron levels, regional brain iron levels fluctuate with the diurnal cycle, with as much as 30% differences in ventral midbrain (substantia nigra/ventral tegmentum) iron between the light and dark phases of the diurnal cycle in several inbred strains of mice (Unger et al. 2009). This flux in iron levels has not yet been attributed to specific cell types and the mechanisms surrounding this observation remain unknown. This is a paradigm shifting observation that establishes a dynamic state of iron flux rather than the static concepts that are entrenched in the literature to date (Dallman and Spirito 1977).

In the developing brain, iron uptake is greatest during the prenatal period when the brain is undergoing rapid growth. Iron deficiency in infancy is now known to inhibit cognitive development and alter affective behavior. Iron supplementation is ineffective in correcting many of these deficits (Lozoff 2007; Lozoff et al. 2000; Pinero et al. 2001). Similar to humans, rodents that were iron deficient during gestation and early postnatal life show similar deficits in cognition and attention after iron repletion. Thus, an understanding of the effects of early iron deficiency on brain structure and function and of the inability of the brain to correct iron content during postnatal iron repletion has critical implications.

Iron regulatory proteins: Regulation of iron metabolism occurs through iron regulatory proteins (IRPs) and iron-responsive elements (IREs). IRP1 and IRP2 register cytosolic iron concentrations and posttranscriptionally regulate expression of iron metabolism genes. These two proteins are ubiquitously expressed mammalian members of the aconitase gene family (Gruer et al. 1997), and bind to IRE with high affinity when intracellular iron levels are low. The IRE is a highly conserved nucleotide hairpin (IRP binding regions) located in the untranslated region (UTR) in mRNAs encoding specific proteins of iron metabolism (Henderson et al. 1994). Among the genes known to take part in iron homeostasis, the mRNA for ferritin, ferroportin, and HIF2alpha contain IREs in the 5′ untranslated region while transferrin receptor 1 and DMT1 mRNA contain IREs in the 3′ untranslated regions. In states of iron depletion, each IRP responds by binding to IREs. When the IRE is located in the 3′ UTR, the binding of IRPs to IRE stabilizes the mRNA, and hence more protein is translated (Haile 1999). Alternatively, by binding to a single IRE located in the 5′ UTR of mRNA, the IRP prevents translation. In cells that are iron-repleted, IRPs do not bind IREs, and ferritin and other transcripts that have an IRE in the 5′UTR are freely translated (Klausner et al. 1993).

77.4 Effect of Dietary Iron on Gene Expression in the Brain

77.4.1 Iron Regulatory Proteins

Abnormal amounts of iron in the brain have been documented in a number of age-related neurode-generative disorders including Alzheimer's (Bishop et al. 2002; Connor et al. 1992a, b 1995) and Parkinson's diseases (Kaur and Andersen 2004). It is generally accepted that this excess iron catalyzes the formation of reactive oxygen species and induces oxidative damage to which the brain is sensitive (Robb and Connor 1998). Iron deficiency-related research conducted to date suggests that dietary iron deficiency during critical periods of development also adversely affects brain function (Beard et al. 2002, 2003a; Felt et al. 2006; Felt and Lozoff 1996). Although a large body of literature is available that focuses on dietary iron deficiency and cognitive and behavioral deficits, only recently have studies focused on gene expression profiling in the brain during prenatal and postnatal iron deficiency (Carlson et al. 2007; Clardy et al. 2006; Liu et al. 2007).

Alterations in gene expression of the iron transporter transferrin in brain in response to iron deficiency has been observed in several rodent models. Iron deficiency from early gestation to postnatal day 21 produces a downregulation in transferrin gene expression (Clardy et al. 2006), which was also observed in a postweaning animal model where iron deficiency continued for six weeks (Han et al. 2003 #184). These studies further indicate that transferrin receptor and divalent metal transporter 1 are upregulated by gestational/lactational iron deficiency, while transferrin receptor gene expression is not changed by postnatal iron deficiency (Carlson et al. 2007; Clardy et al. 2006; Han et al. 2003; Siddappa et al. 2002). In pre and postnatal models of iron deficiency, transferrin protein levels in the brain and periphery are typically upregulated, which is an indication that transferrin protein could be acquired from sources outside the brain (Clardy et al. 2006; Crowe and Morgan 1992; Han et al. 2003). In contrast to the previously mentioned studies, iron deficiency during gestation and during the first week of lactation followed by 1 week of iron repletion increases transferrin mRNA levels in hippocampus (Carlson et al. 2007). Oligodendrocytes are the predominant source of transferrin mRNA in the brain, suggesting that transferrin mRNA production by oligodendrocytes may be upregulated by small periods of adequate iron during early postanal life.

77.4.2 Energy Metabolism and Cell Growth

Since iron homeostasis is coupled to energy metabolism, it is expected that dietary iron deficiency would bring about changes in the expression pattern of genes involved in energy metabolism and cellular growth. Mammalian target of rapamycin (mTOR) is a serine/threonine protein kinase that integrates several pathways to regulate cell growth, differentiation and survival. Importantly, the expression of genes in the mTOR signaling cascade including *Fkbp 1a*, *Gltscr 2*, *Ddit4*, *and Tsc2* are altered in hippocampus from gestational and early lactational iron-deficient rats (Carlson et al. 2007). A significant upregulation of the gene *Slc2a1*, the major brain glucose (energy) transporter, is observed in this same animal model (Carlson et al. 2007). Altered regulation of genes involved in energy metabolism and cell growth suggests that neural dendritic growth and synaptic transmission may be affected by iron deficiency. Iron deficiency also induced an upregulation in the hippocampal expression of the calcium/calmodulin-dependent protein kinase II alpha (CamK2a) gene, which is regulated by brain derived neurotrophic factor (BDNF) through the mTOR pathway, further implies an altered density of glutamatergic synapses and changes in synaptic plasticity (Schratt et al. 2004).

These specific neuronal changes may underlie some of the disturbed spatial recognition and learning abilities in the iron-deficient animal models.

Genes involved in the cell division cycle are also responsive to iron depletion. Microarray analyses of the whole brain from rats that are iron deficient during early gestation until weaning show more than a 1-fold increase in the cyclin B1, cyclin D1, cyclin L, and cyclin-dependent kinase four genes, indicating that iron deficiency affects the cell cycle progression during this period. To date, there is no evidence as to which cell type(s) show more active cycling after this period of iron deficiency. Studies using isolated hippocampal cells cultured in iron-depleted conditions show altered mRNA levels of *Bs69*, *Pdcd5*, *Anapc8*, and *Ruvbl2* (Liu et al. 2007). These proteins function during cell cycle arrest and can lead to apoptotic events in the brain. The direct relationship, if any, between iron status of cells and cell cycle activity is not known. Does iron status drive cell division or is iron only important for the cell to meet metabolic needs during division? One possible direct mechanism is through IRP2 which has a phosphorylation site, Ser157, that is phosphorylated by cyclin-dependent kinase/cyclin B1 during G(2)M. Thus phosphorylation of this site provides a mechanism by which ferritin and transferrin receptor production can be regulated during the cell cycle (Wallander et al. 2008).

Microarray analyses of whole brain (Clardy et al. 2006) and hippocampus (Carlson et al. 2007) suggest that several genes involved in cellular signal transduction mechanisms are altered by prenatal/lactational iron deficiency. Both of these studies have reported nearly a 3-fold increase (highest among all the genes represented in the array) in the expression of arachidonate 12-lipoxygenase and arachidonate 15-lipoxygenase. These enzymes belong to the family of oxydoreductases and are iron-dependent. 12/15-lipoxygenases are the major source of oxidative stress during pathological conditions including Alzheimer's disease (Pratico et al. 2004), which suggests that upregulation of these two enzymes could be indicative of brain oxidative stress induced by dietary iron deficiency. Arachidonate 12-lipoxygenase and arachidonate 15-lipoxygenase also participate in arachidonic acid (ARA) metabolism. ARA is a polyunsaturated fatty acid that is present in the phospholipids of membranes and is abundant in the brain (Rapoport 2008). Functions of arachidonic acid in the brain include maintaining hippocampal cell membrane fluidity (Fukaya et al. 2007), protecting the brain from oxidative stress by activating perioxisomal proliferator-activated receptors (Wang et al. 2006), and activating syntaxin-3 that is involved in neuron growth and repair (Darios and Davletov 2006). The involvement of ARA in cellular signaling as a lipid second messenger and as an inflammatory intermediate has been well documented (Darios and Davletov 2006; Abe et al. 1992). It is worth mentioning at this point that upregulation of these oxydoreductases in the ARA pathway are a good indication of altered lipid synthesis during developmental iron deficiency. The brain has to depend on de novo synthesis of lipids and cholesterols for structural changes such as dendritic growth, synapse formation, and myelination, which reach their peak during early postnatal life (Brody et al. 1987). Changes in the structural composition of the brain are likely to alter many processes including synaptic neurotransmission between and within brain regions and cause potentially irreparable behavioral deficits.

77.4.3 Myelin-Related Genes

Oligodendrocytes produce myelin in the CNS and are the most robustly iron stained cells in the healthy adult brain (Benkovic and Connor 1993; Todorich et al. 2009). A deficiency in iron increases the latency of auditory brain stem responses in human infants, an indirect indication of hypomyelination (Roncagliolo et al. 1998). Moreover, gestational and lactational iron deficiency in rodents reduces myelin formation in the spinal cord and the presence of integral myelin proteins proteolipid protein and myelin basic protein isoforms in whole brain homogenates (Ortiz et al. 2004; Yu et al. 1986).

Table 77.1 Myelin-related genes downregulated by early iron deficiency in whole brain

Name	Known or proposed function
Myelin basic protein	Myelin compaction and stability
Myelin-oligodendrocyte glycoprotein	Myelin stability, maintenance
Myelin and lymphocyte protein	Myelin biogenesis, stabilization
Myelin-associated oligodendrocyte basic protein	Myelin sheath maintenance
Peripheral myelin protein 22	Myelin compaction
Proteolipid protein	Myelin compaction, oligodendrocyte maturation

Myelin is a fatty insulating sheath that is wrapped around the nerve process termed the axon. Mylein increases the speed at which signals are conducted within the brain. A reduction in myelin associated genes suggests that the myelin content of the brain is reduced, thus affecting the transmission of signals

Further, hindbrain CNPase and myelin basic protein levels, indicators of reduced myelin production, are reduced in rats only exposed to postweaning iron deficiency, indicating that sufficient iron is required by oligodendrocytes for maintenance of myelin even after the period of peak myelination from P8-P12 (Beard et al. 2003b).The question of whether these changes in myelination are due to posttranslational events in iron deficiency or whether gene expression is also altered was examined as part of a study that investigated gene responses to gestational and early postnatal iron deficiency in rats (Clardy et al. 2006). This model of early iron deficiency showed a downregulation of myelin basic protein (MBP) and myelin-oligodendrocyte glycoprotein (MOG) that are important in myelin stability, myelin and lymphocyte protein (MAL) that is involved in myelin biogenesis, and myelin-associated oligodendrocytic basic protein (MOBP) that may be important in myelin sheath maintenance. Other downregulated genes include peripheral myelin protein 22 (PMP22), proteolipid protein (PLP), fibroblast growth factor, and chimerin 2. The decrease in myelin-related gene expression is consistent with a delay in oligodendrocyte maturation or with a reduced number of oligodendrocytes in the iron-deficient brain (Clardy et al. 2006).

Importantly, iron supplementation from weaning until 6 months of age can correct the deficits in whole brain myelin gene expression (Clardy et al. 2006). Despite this normalization of gene expression, myelin deficits remain at 6 months of age, indicating that there is a critical time point during which iron is required for proper myelination in adulthood (Ortiz et al. 2004). Given these recent findings, future studies aimed at investigating the critical period during which iron supplementation is required for proper myelination are warranted. The peak period of myelination is P8-P12 in the rat, but the question remains as to how late in postnatal life that iron supplementation can begin to have proper myelin production (Table 77.1).

77.5 Iron Deficiency and Neurotransmitter Systems

77.5.1 Dopamine

Extensive studies during the last several decades have indicated that iron deficiency has deleterious effects on the dopamine neurotransmitter system. The nigrostriatal dopamine pathway that regulates movement and the mesolimbic pathway that mediates the reinforcing effects of drug addiction appear to be the most affected regions of the brain (Beard 2003; Beard et al. 2003a; Erikson et al. 2000; Pinero et al. 2001; Youdim et al. 1984; Youdim). The 12 transmembrane domain protein, the dopamine transporter (DAT), serves as a key regulator of dopamine neurotransmission and is encoded by the Slc6A3 gene. Importantly, the solute carrier (Slc) gene family encodes membrane transport

Table 77.2 Genes affected by iron deficiency that encode neurotransmitter transporters and receptors

Name	Period of ID	Brain region(s)
Upregulated genes		
Norepinephrine transporter	P21 – P63	Globus pallidus
GABA transporter type 1	P21 – P63	Substantia nigra
Serotonin transporter	G5 – P21	Whole brain
Vesicular monoamine transporter 2	G5 – P21	Whole brain
Downregulated genes		
Dopamine receptor 1A	G5 – P21	Whole brain
Norepinephrine transporter	P21 – P63	Locus ceruleus, substantia nigra, cerebellum
Norepinephrine alpha2 receptor	P21 – P63	Locus ceruleus, cerebellum
GABAA receptor delta	G5 – P21	Whole brain
GABAA receptor alpha6	G5 – P21	Whole brain
GABAA receptor	P21 – P63	Substantia nigra
GABAB receptor	P21 – P63	Substantia nigra

Many neurotransmitter systems including dopamine, serotonin, norepinephrine and GABA are altered by iron deficiency. The timing (postnatal versus gestational) and the extent of iron deficiency are likely important factors in producing these outcomes. Further, the effect of iron deficiency on the brain is region dependent, i.e. all brain regions are not affected equally by iron deficiency

Period of iron deficiency (ID); *G* gestational day; *P* postnatal day

proteins that regulate neurotransmitter and nutrient transport, and deficits in the expression of these genes have serious health implications. In most rodent models of iron deficiency, regional DAT protein expression is downregulated, but the limited studies to date do not indicate that there is a similar change in Slc6A3 gene expression (Carlson et al. 2007; Clardy et al. 2006). The protein levels of two subtypes of dopamine receptors, D1 and D2, are also affected by iron deficiency, although only a downregulation in dopamine receptor 1A has been described in whole brain. Gene expression of DAT and dopamine receptor subtypes have not been evaluated in brain regions that typically show the largest reductions in DAT protein (i.e., striatum and nucleus accumbens). Thus, studies evaluating dopamine-related gene expression within these regions are necessary to conclude that changes in protein levels are a consequence of posttranslational modifications and/or changes in gene expression in the iron-deficient brain (Table 77.2).

77.5.2 Norepinephrine

There is a large body of literature that implicates norepinephrine in the modulation of attention, memory, emotion, and drug addiction. Deficits in these behaviors have been linked to iron deficiency in humans and rodents (Unger et al. 2007; Lozoff et al. 2006; Lozoff and Brittenham 1987; Lozoff et al. 1991, 2007). Norepinephrine cell bodies project from the locus coeruleus in the pons to diverse regions in the forebrain (cortex, caudate putamen, and hippocampus) or to the hindbrain cerebellum. Regulation of norepinephrine signaling occurs via the norepinephrine transporter, a member of the Slc6 family of transporters that has a similar structure to the previously mentioned dopamine transporter, and two distinct classes of receptors, alpha and beta, that are further divided into subtypes. Iron depletion in the brain typically reduces regional norepinephrine transporter protein expression and intracellular and extracellular norepinephrine levels in striatum (Anderson et al. 2009; Beard et al. 2006b; Bianco et al. 2009).

Two studies have specifically investigated the effects of iron deficiency on norepinephrine transporter and receptor mRNA levels in the brain using a postweaning animal model (iron deficient from

postnatal day 21 to day 63). Iron deficiency causes a downregulation of norepinephrine transporter mRNA in locus ceruleus, substantia nigra, and cerebellum and produces an upregulation in globus pallidus compared to iron-sufficient rats (Anderson et al. 2009; Beard et al. 2006b). Likewise, alpha2 receptor expression is reduced in locus ceruleus and cerebellum. These changes in the norepinephrine neurotransmitter system are not surprising given the extensive changes in the dopamine system in iron deficiency and the anatomical connections between the dopaminergic and noradrenergic systems. There is mounting evidence that the locus ceruleus can mediate dopamine release in the nucleus accumbens via direct and indirect projections to the ventral tegmental area, and that dopamine afferents in the locus ceruleus originate in the ventral tegmental area (Guiard et al. 2008). These projections allow a communication between neurotransmitter systems that together modulate cognition, attention, affect, drug addiction, and many other behaviors. As research into the gene expression profile of iron deficiency continues, elucidating the response of key genes involved in these pathways will become increasingly important to understand the persistent effects associated with iron deficiency.

77.5.3 Serotonin

The serotonin neurotransmitter system is widely known for its involvement in anxiety- and depression-related disorders. Slc6a4 encodes the serotonin transporter, which moves serotonin into the presynaptic neuron to terminate the serotonin signal, and is the site of action of many antidepressant/antianxiety drugs. Gestational and early postnatal iron deficiency causes an upregulation of Slc6a4 in whole brain (Clardy et al. 2006). Several postweaning models of iron deficiency have indicated that regional serotonin transporter protein levels are reduced, which creates a potential disconnect between gene and protein data (Beard 2003; Burhans et al. 2005). It is likely that the effects of pre- versus postweaning iron deficiency on the serotonin neurotransmitter system are quite diverse. A more in depth study investigating regional serotonin-related gene expression during iron deficiency will facilitate our knowledge as to the impact of iron regulation on the serotonin neurotransmitter system, and perhaps offer clues as to the relationship between iron deficiency, serotonin, and affective disorders.

77.5.4 GABA

Gamma-aminobutyric acid (GABA) is the most abundant inhibitory neurotransmitter in the adult mammalian central nervous system. Similar to monoamine neurotransmitters, the action of GABA is terminated by uptake via a membrane transporter protein and transmitted via distinct transmembrane receptors. The GABA neurotransmitter system has 4 known subtypes of transporters named type 1 (GAT1), type 2, type 3, and type 4 GABA transporters that are located on neurons and glia (Beleboni et al. 2004). The receptors are divided into two classes, metabotropic and ionotropic receptors. GABAB receptors are metabotropic and characterized by their ability to produce a slow inhibitory response through activation of G proteins (G-protein coupled receptors) and subsequent opening of ion channels. GABAA and GABAC ionotropic receptors are directly coupled to transmembrane ion channels (ligand gated ion channels) and produce fast responses. An understanding of the effect of iron deficiency on the GABA neurotransmitter system has become increasingly important because of behavioral abnormalities that are characteristic of deficits in dopamine/GABA interactions in the substantia nigra, striatum, and nucleus accumbens (Beard et al. 2006a; Erikson et al. 2000, 2001;

Pinero et al. 2001). These brain regions have proven to be sensitive to iron loss and to dopamine system dysregulation in iron deficiency (Beard et al. 2007; Erikson et al. 1997; Unger et al. 2007).

GABA-related gene expression in iron deficiency has been investigated in gestational and postweaning animal models. Microarray analysis of whole brain from rats that were deficient in iron from gestational day 5 to postnatal day 21 indicates that GABAA receptor delta and GABAA receptor alpha 6 are downregulated after early iron deficiency (Clardy et al. 2006). Since this study was performed with whole brain samples, we are unable to pinpoint these changes to distinct brain regions. Importantly, it appears likely that long-term iron repletion can correct this deficit since 5 months of iron supplementation did restore whole brain GABA receptor mRNA to control levels.

Iron deficiency begun at postnatal day 21 and continuing for 6 weeks reduces substantia nigra GABAA and GABAB receptor expression compared to iron sufficient rats, with other regions including caudate and cerebellum not being significantly affected (Anderson et al. 2008). GAT-1 mRNA expression was increased 3-fold in substantia nigra, again with little affect in other brain regions. Protein concentrations of GAT-1 were decreased and GABAA were increased in the iron-deficient substantia nigra suggesting that the gene response is a mechanism aimed at maintaining normal levels of these proteins or that there is a change in transcription efficiency. There are GABAergic striatal neurons that project to the substantia nigra (striatonigral neurons) that act to inhibit dopaminergic output from the dopamine call body containing substantia nigra. Given the consistent changes in GABA gene and protein expression in the substantia nigra, this provides a mechanism by which GABA may be involved in regulating dopamine and the related behaviors observed in iron deficiency.

77.5.5 Other Transporters

Two additional solute carrier genes that are important in the regulation of neurotransmitter signaling, Slc18a2 and Slc7a1 are upregulated by gestational/lactational iron deficiency (Clardy et al. 2006). Slc18a2, or vesicular monoamine transporter 2 (VMAT2), accumulates cytosolic monoamines including dopamine, serotonin, and norepinephrine into synaptic vesicles via an ATP dependent mechanism for release into the synapse. As noted previously, neurotransmitter system functioning is compromised in iron deficiency, and altered VMAT2 expression may contribute to the observed deficits in iron-deficient rodents. The gene encoding Slc7a1, or cationic amino acid transporter 1, is also upregulated in the same iron deficiency model and is responsible for arginine, lysine, ornithine, and histidine transport in the brain. Its role in arginine transport has implications for cell proliferation and for the production of nitric oxide that is necessary for many biological processes and has detrimental effects if not present at appropriate levels (Lameu et al. 2009). The altered expression of these transporter genes further indicates that proper movement of molecules and ions in the iron-deficient brain cannot be maintained.

77.6 Iron Deficiency and Neurotrophic Factors

Neurotrophic factors are a family of proteins that promote the growth and maintenance of developing neurons and the survival of mature neurons. Probably the best studied class of neurotophic factors are the neurotrophins, that include brain derived neurotrophic factor (BDNF) and nerve growth factor (NGF) among others. Perinatal iron deficiency from gestational day 2 to postnatal day 7 reduces levels of BDNF transcript III and BDNF transcript IV mRNA at postnatal days 7, 15, and 30, and these effects persist through postnatal day 65 (Tran et al. 2008, 2009). The gene expression of the

primary binding site of BDNF, tyrosine kinase B (trkB) receptor, is also reduced at P65. The BDNF signaling mechanism has several downstream targets including the activity-dependent immediate early transcription factors that assist in the regulation of neurite outgrowth and synaptic plasticity. Similar to BDNF, these transcriptional targets, early-growth-response-gene 1 (ERG1) and 2 (ERG2), cfos, and 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMGCR), are reduced at P65. The literature suggests that a reduction in the expression of BDNF and activity dependent immediate early transcription factors in hippocampus can result in a loss of neuronal plasticity. Indeed, early iron deficiency in rats does produce long-term changes in the morphology of dendrites and alters synaptic function in the CA1 area of the hippocampal dendrites (Jorgenson et al. 2003, 2005).

These studies illustrate that perinatal iron deficiency reduces the action of BDNF through early adult life and perhaps throughout the lifespan. Importantly, peak import of iron into the hippocampus occurs between postnatal day 5 and postnatal day 15 (Siddappa et al. 2002), and dramatic changes in gene expression in the rat hippocampus occur during the first 2 weeks of postnatal life (Stead et al. 2006). This period also encompasses the stage of maximal neuron growth and differentiation. Detrimental neurochemical and behavioral outcomes resulting from altered BDNF gene expression have been revealed in several mouse models and include deficits in maintenance of long term potentiation (Barco et al. 2005; Patterson et al. 1996), learning (Gorski et al. 2003; Monteggia et al. 2004) and affective behaviors (MacQueen et al. 2001). These findings may have direct relevance to the prolonged and irreversible losses in hippocampal-based learning and memory functioning and emotional responses that have been observed in human infants with iron deficiency and iron-deficient rodent models (Felt et al. 2006; Lozoff 2007; Lozoff et al. 2006).

77.7 Applications to Other Areas of Health and Disease – Alzheimer's Disease

Dysregulation of iron homeostasis has been implicated in several disease states including Parkinson's and Alzheimer's diseases (Connor et al. 1992a, b). An upregulation of several genes known to be implicated in the etiology in Alzheimer's disease has been observed in the developing hippocampus of mice that were iron deficient during gestation and early lactation (Carlson et al. 2007). These genes include connective tissue growth factor, fibronectin 1, cystatin C, cathepsin B, cathepsin S, amyloid beta precursor-like protein 1, amyloid beta precursor protein-binding familyB member 1, clusterin, and NDRG2. These data suggest there could be iron deficiency in the Alzheimer's brain despite the reported increase in iron. The latter concept may not be contradictory; much of the elevated iron in the Alzheimer's disease brain may be bound to plaques and thus, not bioavailable (Connor et al. 1992a; Meadowcroft et al. 2009). Moreover, there is a similar pattern of expression in genes associated with oxidative stress in the hippocampus of iron-deficient rodents and brains from Alzheimer's patients. These data suggest that we should re-evalute the interpretation of some of these data to consider that iron deficiency could generate a gene/protein profile of oxidative stress

Summary Points

- The brain is the organ most vulnerable to iron deficiency during critical periods of development that include the stage of brain growth spurt and differentiation.
- Genes that are altered by brain iron deficiency are integral to processes including signal transduction, myelin formation, cell growth, energy metabolism, and neurotransmitter signaling.

- While the expression level of some genes can be corrected with iron supplementation, other genes may not be responsive to iron treatment strategies.
- Timing of iron deficiency is an important factor when considering treatment intervention strategies. Critical to this idea is to determine the point in development when iron supplementation is required such that the negative behavioral effects associated with early iron deficiency do not persist through adulthood.
- The novel concept that iron deficiency may generate a stress profile in the brain similar that that observed in Alzheimer's Disease is an area that warrants future studies.

Definitions of Key Terms and Words

Iron deficiency anemia: is a late stage of iron depletion characterized by low plasma iron levels, a low serum transferrin saturation, elevated transferrin receptor levels and low serum ferritin concentrations.

Transferrin: is a glycoprotein that binds ferric iron for transport to target tissues.

The **transferrin receptor:** is a carrier protein that binds transferrin for movement of iron across membranes. Transferrin receptor levels are regulated by iron content in the body via iron regulatory proteins and iron response elements.

An **oligodendrocyte:** in a type of glial cell located within the central nervous system that is responsible for myelination of axon processes.

Oxidative stress: is a condition defined by elevated levels of reactive oxygen species, including peroxidases and free radicals, which the body is not able to eliminate efficiently.

Dopamine: is an inhibitory neurotransmitter synthesized from the amino acid tyrosine. This neurotransmitter is the precursor of the neurotransmitter norepinephrine.

Dopamine transporter: is a 12 transmembrane domain protein that transports dopamine from the extracellular space into the cytoplasm of a presynaptic neuron.

Brain-derived neurotrophic factor: is a member of the neurotrophin family of growth factors that supports neuron growth and survival.

Key Points of Iron Deficiency

- The World Health Organization (WHO) recognizes iron deficiency as the most common and widespread nutrient disorder in the world. Iron deficiency is currently the only nutrient deficiency that is prevalent in both nonindustrialized and industrialized countries, where it is prevalent in mainly women and children.
- Iron deficiency is believed to be the most common cause of anemia, which afflicts more than two billion people worldwide. Anemia is a condition in which the number of red blood cells in the body is reduced or the ability of the red blood cells to carry oxygen is diminished and cannot meet the body's needs.
- Iron deficiency in infancy has been consistently associated with adverse changes in development and in behavior, including impaired motor skills and increased fearfulness and unhappiness. Many of these behavioral outcomes continue to be observed for years after iron status has been improved in these children.
- Iron deficiency anemia can have a significant impact on an individual's work capacity by causing severe fatigue and producing affective difficulties, decreased attention, and reduced cognitive abilities. These negative outcomes can have an economical impact, particularly in regions where iron deficiency anemia is rampant.
- There is considerable evidence that iron plays an important role in many processes in the brain including neurotransmitter metabolism, myelin formation, and brain energy metabolism. These physiological consequences have been linked to the behavioral and development observations in iron deficiency.

LiCl	Lithium chloride
WD	Water deprivation

78.1 Introduction

Taste perception, food ingestion behaviors, and social behaviors are intimately linked together in mammals. The search for comestible food is one of the principal behavioral drives for animals. Transmission of information related to food has a critical importance in strongly socially organized species. Accurate social perception – necessary to maintain hierarchical rankings and satisfying group cohesion – is by essence multimodal. If the influence of smell on interindividual communication is obvious, the involvement of taste-related information in the regulation of interindividual interaction appears somehow less direct. It is however not necessarily less important. In addition, these links are pertinent – and can be actualized – not only in normal physiological situations, but also in pathological ones.

Philogenetical and ecological considerations can explain why the gustatory modality deserves a particular treatment, compared to other sensory modalities. Taste and smell are the only two sensory modalities using chemodetection directed toward external stimuli; they thus are the heirs of the most archaic forms of perception. Taste-dependent learning differs from other forms of associative (classical or instrumental) learning in a critical point: the time interval separating the conditioned stimulus

from the unconditioned stimulus (the interstimulus interval or ISI). Whereas in most cases the two stimuli must appear almost together in time in order to be correctly associated, taste-dependent learning tolerates incredibly long ISI, up to several hours. This is due in part to the fact that, in contrast to the vast majority of negative reinforcers, ingestion-induced malaises (which unfortunately represents one of the main ecological outcomes of taste experience) usually require some time to develop. Stimuli that are less closely associated with food (such as auditory, visual, or tactile cues) are not able to support the same long intervals than taste (Garcia et al. 1968). In the context of conditioning, socially oriented behavioral sequences represent conditioned responses much longer than the ones classically observed for other forms of learning. Thus, the very long ISI of taste-dependent learning could support associations with social behaviors.

In this text, we will focus on the alteration to social behavior which can be induced by presentation of a taste. We will describe whether presentation of taste can induce direct social withdrawal, how taste presented by a conspecific can socially transmit food-related information, and how taste can reactivate off-line negative emotional states to trigger marked social withdrawal. The implications of these findings for human eating disorders will be extensively discussed, as well as some promising topics such as the influence of sexual hormones and the exploration of alterations in hedonism.

78.2 Food Ingestion and Social Withdrawal

The search for food is one of the most basic motivational drives of animal behaviors. Indeed, the capacity of survival of the individual is a direct function of the amount of food which can be found – and successfully ingested. However, one of the inherent problems of ingestive behavior is the risk of absorbing toxic or poisonous food. But luckily enough for animals, toxic food does not necessarily have a lethal effect. In most cases, the ingestion of toxic food only translates into transient malaise, often characterized by visceral pain. If the toxicity is averred, the individual won't be able to efficiently react to challenging situations. Thus, intoxicated animals should, through their behavior, avoid encountering predators – even more than in normal conditions. One of the best ways not to be captured by a predator is for the individual to avoid being in the same location than other potential preys, i.e., other conspecifics.

However, the increased vulnerability to predators does not represent the only risk for poisoned individuals. In the context of social organization, the maintenance of hierarchized ranking is a dynamic process. Animals sickened by inadapted food are likely to be unable to fight to maintain their hierarchical position regarding their subordinates. After ingesting poisonous food, the animal may well survive, but to fully avoid subsequent problems, the process should not be accompanied by a loss of social status within the hierarchy. In the context of social groups based on hierarchical organization, weakened animals should thus not only avoid encountering predators, but also avoid encountering conspecifics (Fig. 78.1).

Isolation periods following toxic food ingestion could thus rely on at least two evolutionary justifications: first, directed toward nonconspecific – to avoid predators while unable to defend efficiently – second, directed toward conspecifics – to avoid losing social status in a highly hierarchized context. Worthy of note is that this global social withdrawal following food poisoning is very close to the general sickness-associated social isolation (Bluthé et al. 1991; Dantzer 2001). In the case of unknown food – i.e., food with "new" taste – postingestion social withdrawal may therefore represent a natural predisposition of ecological significance (Fig. 78.1). By actively avoiding unnecessary social contacts, the individual may secure recently acquired food and avoid putative risks linked to postingestion. This direct effect represents a first level of food related taste-triggered social withdrawal in animals.

Fig. 78.1 Social withdrawal provoked by poisoning. After ingestion of poisonous or toxic food, the animal (white animal) will experience delayed noxious effects (such as visceral pain), and will adapt its social behavior in order to actively decrease its social interactions with conspecifics (grey animal)
78.3 Socially Transmitted Food Preference

The social withdrawal triggered by absorption of toxic food represents a direct effect which can be associated with taste perception. Surprisingly, the effect that tastes can have on social behaviors go much further: in addition to effects on the social behavior of the animal which actually ate the food, passive information carried following food ingestion can trigger massive effect on the social behavior of other conspecifics as well (Galef and Wigmore 1983; Clipperton et al. 2008). Indeed, the taste of food attached to the animal can also carry information which will be socially transmitted to conspecifics (Galef and Wigmore 1983; Valsecchi and Galef 1989). This social transmission of information related to taste takes advantage of the fact that taste and smell can persist long time after their original cause (in this case, the food) disappeared.

Once an animal has eaten something, the smell of the food will stay on body parts surrounding the mouth. Actually, even the taste of the ingested food will stay and could be detected if another conspecific would be able to lick these body areas. While saying that may at first glance sound surprising, it is not. Indeed, most mammals do have interactions bringing into play these specific zones. For instance, in the case of rodents, whiskers represent one of the main organs used to investigate the world (Brecht et al. 1997). This also includes social interindividual exploratory behaviors – such as sniffing or grooming the partner (Guitton et al. 2008).

There are thus possibilities for direct exchange of taste related information between two animals during the process of social interactions. Generally speaking, alterations of perception can trigger clear modifications of social behavior. For instance, the occurrence of tinnitus – perception of sound in the absence of auditory stimulation – triggers in mice the full spectrum of social alterations

(Guitton 2009). As for other sensory modalities, such links exist between taste and social behavior, as it has been described here above. But, in contrast to other sensory information, taste can be directly transmitted from one individual to another. Due to the possibility of direct transmission of taste information between two individuals after physical contact, a same taste can elicit a second order, indirect effect in an individual which was not at first exposed to the original food.

As we mentioned above, one of the inherent problems of ingestive behavior is the risk to consume poisonous or toxic food. A major advantage for animals to live in a social context is the possibility for any given member of the group to use the experience of others. Taste information related to food can be transmitted without having to experience the real ingestion process; in contrast, effects of the food can be inferred by assessing the physical state of the "demonstrator" conspecific (Fig. 78.2). Thus, emerged the mechanism of social acquired food preference referred to as socially transmitted food preference (Galef and Wigmore 1983; Valsecchi and Galef 1989). The logic of this particular form of social learning is based on the principle that if an individual survived after ingesting a given food, then this food should not be so bad to eat (Fig. 78.2). On the other hand, for this mechanism to correctly work, if a newly ingested food is toxic, it is crucial for the poisoned individual not only to avoid taking it again, but also to transmit this information to its conspecifics by not letting them validate the food as putatively good by assessing its presence ("taste") on him. The obvious ecological advantage of acquiring food preferences from conspecifics is the possibility to somehow "bypass" the danger linked to the potential ingestion of toxic food (Galef and Wigmore 1983; Valsecchi and Galef 1989).

Thus, in addition to the two first ecological justifications underlying social withdrawal following the ingestion of toxic food, a third one would be not to transmit to other conspecifics the false information of the relative safety of the ingested food. Social withdrawal observed after the ingestion of toxic
Fig. 78.2 Socially transmitted food preference. (**a**) When an animal is confronted with unknown food, it will hesitate before eating it (neophobia), since the new food may be potentially dangerous. (**b**) If a conspecific (white animal) has already eaten this food and "presents" the taste on its whiskers, the animal which was not confronted with the food (grey animal) will display a marked preference for this food when it encounters it. Indeed, the animal will "infer" from the fact that the demonstrator is still alive that the food can be ingested safely. This form of socially acquired knowledge is referred as socially transmitted food preference

food can therefore have at least three ecological reasons. As we will discuss below, the combination of these three postulated causes is highly interesting in the context of the ontogeny of food disorders observed in humans.

What we just discussed however only represents the most obvious part of taste-triggered social withdrawal. Indeed, in this case, the signals – both the taste (either directly from food, or indirectly via presentation of the taste by a conspecific) and the effects of food ingestion (either direct if the animal ate the food, or indirect if the animal is assessing the state of its conspecific) – are "on-line." But can taste trigger alterations of social behaviors if stimuli are not present, in other words "off-line" (Guitton et al. 2008)? The next paragraph will attempt to answer this question by examining how taste exposure and association with emotional states can produce long-term effects on social behaviors.

78.4 Taste-Dependent Social Withdrawal

Up to now, the effects described here where only "on-line" effects, meaning effects observed when the two stimuli (the taste and the effects of food) are still salient. The relationship between on-line taste information of social behavior is obvious, either in the case of immediate taste distress-provoked social withdrawal with direct taste detection and effect of the food, or in the case of immediate taste-dependent social learning with indirect presentation of the taste via a conspecific and evaluation of the health status of the individual. But in addition to these responses, taste can also trigger massive alterations of social behavior when the reinforcer is not there, i.e., when the original stimuli are "off-line" (Guitton et al. 2008).

When an animal is first exposed to a poisonous food, the odds that this animal will ingest this food if presented again are rather low. Indeed, the animal is likely to avoid it (Garcia et al. 1966; Berman and Dudai 2001; Guitton and Dudai 2004). This taste-dependent learning, in which the subject associates a conditioned stimulus (the taste) with a delayed unconditioned stimulus (visceral pain) is called a conditioned taste aversion (CTA, for a classical protocol used to induce CTA in rats, see Fig. 78.3) (Garcia et al. 1966; Bures et al. 1998). Following such a conditioning, the conditioned response will be a massive aversion for the food displaying the same taste. In the case of a classical CTA (while the new taste is associated with clear-cut visceral pain), there is no real need to engram the information necessary to trigger complex social withdrawal next time the taste will be presented, since once the taste will be recognized anew, the corresponding food will not be eaten again. And indeed, if animals present a CTA for a given taste, a subsequent presentation of this taste will not trigger any modification of their social behavior (Guitton et al. 2008). They will clearly avoid the food, but no further social effect will be observed (Fig. 78.4). However, the situation is drastically different if the food did not provoke massive visceral pain, but rather elicited a diffuse and vague emotional state. Anxiety and anxiety-like state result from situations that represent either real or imaginary danger for the individual (Marks 1987; LeDoux 1998). In contrast to visceral pain, anxiety is a rather diffuse internal state. But can anxiety act as unconditioned stimulus in the context of taste-dependent learning? This question was addressed using pharmacological tools to experimentally induce anxiety-like state in rats (Guitton and Dudai 2004). For instance, metachlorophenylpiperazine (mCPP), a serotoninergic agent acting as a 5-HT2C receptor agonist, is known to be able to provoke, both in humans and animals, anxiety-like state when injected (Bilkei-Gorzo et al. 1998; Guitton and Dudai 2004). Delayed anxiety provoked by intraperitoneal injection of mCPP was able to be specifically associated with taste information by rats, and this association was strong enough to be detected by behavioral measurements as a CTA (Guitton and Dudai 2004).
Fig. 78.3 A classical protocol to induce a CTA. Here is exemplified a "classical" protocol which can be used to induce conditioned taste aversion (CTA) in rats. During the time course of the protocol, animals are under water deprivation (WD), meaning that their access to water is restrained to 10 min per day (except the first day, for which the time allowed to access water is 30 min). At Day 4 (Conditioning), animals are allowed to drink a solution with a new taste instead of water for 10 min. About 15–45 min after the offset of the drinking period, animals are exposed to an agent inducing visceral pain (classically, a single intraperitoneal injection of LiCl, 0.15M, 2% of body weight). Three days after the conditioning (Day 7, Test), animals are given free choice between water and the conditioned taste during their 10 min daily drinking period. Conditioned animals are expected to massively display a behavioral preference toward water over the taste associated with visceral pain

Using a combination of anxiety-induced CTA (using mCPP injections as inductor of anxiety-like state) and social interaction measurements, we recently reported that taste-dependent conditioning procedure can trigger a marked impairment in social behavior – corresponding to a massive and active social withdrawal, or a "sociophobia" (Fig. 78.4) – in response to the conditioned taste (Guitton et al. 2008). When compared to control animals (or animals subjected to a classical CTA with visceral pain as unconditioned stimulus), animals treated with mCPP completely diverged concerning their behavioral outcomes when presented anew with the conditioned taste. Animals for which taste was initially paired with delayed anxiety presented a drastic decrease of the social events they displayed compared to any of the other experimental groups (Guitton et al. 2008). The number of behavioral escapes stayed very low for experimental animals whatever the group, except for the animals initially conditioned with mCPP-induced anxiety. In a phenotyping point of view, the modifications observed for the escape responses are of major importance to explain the deterioration of social interactions, since they confirm an active participation of the treated animal. Thus, the decrease of the number of social events was definitively not merely passive, but rather an active phenomenon. Therefore, this decrease of social interactions was really isomorphic to a social withdrawal (Guitton et al. 2008). The abnormal (anti)social behavior displayed by these animals is likely to affect the behavior of their naïve partner. And that is what actually occurred. Indeed, naïve partners strongly increased their following behaviors, mirroring the evolution of the escape behaviors
Fig. 78.4 Taste-dependent sociophobia. (**a**) Consumption of food does usually not induce any alteration of social behavior. (**b**) If an animal experiences the taste of a new food and is subjected later on to visceral pain (for instance using LiCl injection), the association of these two stimuli will produce a conditioned taste aversion (CTA). Such association will result in a strong avoidance of the conditioned taste (and so, food). However, if the animal eats this food again (which is unlikely to happen, discontinued arrow), the perception of this taste will not induce any modification of social behavior. (**c**) However, if the animal experiences a new taste followed by a delayed negative emotional state (such as anxiety-like state), the association will be more diffuse and the behavioral outcomes will be totally different. First, the animal may still want to eat the target food. However, after ingesting it, social behavior will be drastically affected. Indeed, the animal will actively avoid social contact (social withdrawal)

observed in mCPP-treated animals. However, since they were receiving less social inputs, naïve partners were ultimately also decreasing slightly their social activity in response to the sociophobic behavior displayed by mCPP-treated animals (Guitton et al. 2008) (Fig. 78.5). This behavioral response observed once the taste was presented again was clearly not a generalized avoidance, since almost no reduction in approach behavior of the spout, or in consumption was observed, translating the fact that anxiety was able to produce only a limited CTA (Guitton and Dudai 2004; Guitton et al. 2008). Furthermore, taste–anxiety associations are not generalized (Fig. 78.6): only the taste on which the association has been made can trigger social withdrawal, other tastes being unable to do so (Guitton et al. 2008).

Thus, if anxiety-like states have a relatively low power to induce CTA, this taste–emotion association has remarkable outcomes at the social behavior level (Guitton et al. 2008). The retrieval-induced "sociophobic" state lingers long after a single exposure to the nonreinforced taste. By predicting the unconditioned stimulus (which is in this case a purely emotional state), the gustatory cue appears to trigger a persistent emotional and social response. And that could be happening in the case of human beings. Indeed, taste could get associated with the emergence of a feeling, even unrelated. Since taste-dependent conditioning tolerates long ISI, the emotional feeling could well be associated with the taste. The association of taste with delayed negative internal states could generate conditioned response different from taste aversion, such as in this case active social withdrawal. It is clear that such forms of memory of association may contribute to the ontogenesis, reinforcement, and symptoms of some types of taste- and food-related disorders. The further association of a taste with social withdrawal might represent a conditioned augmentation of the natural predisposition of social withdrawal following ingestion of new food described in the beginning of this text.
Fig. 78.5 Social interactions and social withdrawal. (**a**) Social interactions are active processes in which each of the two animals exhibits social behavior. In other words, there are interactions because each animal displays and initiates social events directed toward its partner – the events can be elicited either originally, or in response to the previous event emitted by the partner. (**b**) If one of the animal does not respond to the social stimuli sent by its partner (for instance, in the case of social withdrawal), there are no "interactions." So, the social dialog evolves toward a monolog. Finally, the partner will lose interest in the social communication with the unresponding animal, and will in turn also decrease the number of social behaviors emitted
Fig. 78.6 Taste specificity in association leading to taste-dependent sociophobia. (**a**) Associations able to lead to a taste-dependent sociophobia (association between a new taste and a negative emotional state) are not generalized. Only the taste on which was made the association can potentially trigger alterations of social behavior such as social withdrawal. (**b**) In contrast, if another taste is presented to the animal, no alterations of social behavior will be assessed

78.5 Relevance for Human Eating Disorders

As we suggested above, this last effect of taste-triggered social withdrawal, described in animals, has significant implications for the understanding of ontogenesis and maintenance of human food disorders. Even if clearly based on abnormal and in adapted behaviors triggered by altered perception of food or food-related

elements (including body image – anorexic patients commonly present distortions in the perception of the size and shape of their own body), the social component of anorexia or bulimia is obvious and cannot be denied (Klein and Walsh 2004). According to current definitions, anorexia could be characterized by social withdrawal triggered by food consumption itself, or by the fact (averred or inferred) that others know that food was ingested. Numerous physiological, psychological, and social alterations are associated with eating disorders, and deciphering which are the factors predisposing or accelerating the apparition of the disorder is far to be an easy task (Klein and Walsh 2004). The ontogenesis of eating disorders is likely to be multifactorial, with massive interactions between internal (biological or psychological) and external (social or environmental) risk factors (Walsh and Devlin 1998; Klein and Walsh 2004).

Links between food disorders and alterations of social behavior clearly exist (Kaye et al. 2004; Guitton et al. 2008). Indeed, clinical studies demonstrated that both anorexia and bulimia nervosa present a significant comorbidity with social phobia (Kaye et al. 2004). A study performed during the Second World War on healthy conscientious war objectors showed that starvation provoked in humans increased irritability and diminished social interest (Franklin et al. 1948). Irritability is also one of the psychological symptoms frequently reported by anorexic patients in the acutely underweight state (Kaye 1997). Thus, progressive weight loss facilitates social avoidance. But since decrease of social interactions also oftenly triggers further weight loss, these two elements may well draw a vicious circle. Furthermore, food disorders have a strong co-occurrence with anxiety (Godart et al. 2000; Klein and Walsh 2004), with the onset of anxiety states often preceding the onset of anorexia or bulimia nervosa (Deep et al. 1995; Bulik et al. 1997; Godart et al. 2000). These privileged relations between negative emotions, taste perception, and social behavior may well represent a key element in the processes at the origin of food disorders. In this view, the taste–anxiety–sociophobia association described above may be highly relevant to eating disorders (Guitton et al. 2008).

Psychological stress may play some role in the initiation of the disorder. However, it is important to note that despite the high frequency of anxiety and mood alterations, purely antidepressant medications generally fail to help during the acutely underweight state of anorexia (Jones et al. 1991), suggesting that anxiety plays a role of reinforcer rather than being the real origin of the disorder. In the case of bulimia, negative emotions (such as feelings of anxiety, rejection, frustration, or low mood) often precede binges, which seem to become learned responses to negative emotional states (Abraham and Beumont 1982; Heatherton and Baumeoster 1991; Klein and Walsh 2004). A striking characteristic of eating disorders is the high persistence of disordered eating and/or abnormal dieting behavior once it has begun (Klein and Walsh 2004). This long-term persistence also strongly echoes the notion of strong association assessed in the particular form of memory that is a CTA (Bures et al. 1998; Berman and Dudai 2001; Guitton and Dudai 2004; Guitton et al. 2008).

Finally, in CTA, the context actualized when the subject tasted the food has also been shown to be able to act as a cue to elicit latter taste aversion (Desmedt et al. 2003), echoing the importance of the contextual environment in food disorders. In conclusion, association between food perception system and social behavior, and particularly the possibility of delayed social withdrawal triggered by taste, may be highly relevant for eating disorders (Table 78.1). An interesting possibility could be to consider anorexia as an epiphenomenon of social disturbance triggered by taste and food perception systems.

78.6 Influence of the Sex

In humans, eating disorders clearly affect disproportionately women (Klein and Walsh 2004), with a lifetime prevalence among women estimated at 1–3% for bulimia nervosa and at 0.5–2% for anorexia nervosa (Kendler et al. 1991; Favaro et al. 2003; Klein and Walsh 2004). Cultural reasons

Table 78.1 Key features of taste-dependent sociophobia

1. Social withdrawal occurs when an animal actively decreases the emission of social behaviors directed toward partners.
2. The regulation of social interactions and social ranking is dependent on sensory information.
3. Taste information related to food has clear ecological significance and can induce marked alterations of social behavior.
4. Social withdrawal can be triggered in mammals after association between taste and visceral pain or after retrieval of association between taste and negative emotional state.
5. The understanding of the links between taste and social behavior (especially taste-dependent social withdrawal) has significant implications for the understanding of ontogenesis and maintenance of human food disorders.
6. Eating disorders are associated with numerous physiological, psychological, and social alterations.
7. Anorexia and bulimia nervosa present a significant comorbidity with social phobia.
8. Anorexia may be characterized by social withdrawal triggered by food consumption, or by the fact (averred or inferred) that others know that food was ingested.

This table lists the key facts of taste-dependent sociophobia, including basic concept of social withdrawal, and how taste-dependent sociophobia evidenced in animals can be relevant for human food disorders

have often been mentioned to explain this situation. However, when considered with a sociobiological point-of-view – meaning, when considering that social behaviors are grounded by biological mechanisms – these sex-dependent differences observed in humans can find some elements of explanation at the molecular level. Indeed, estrogens are known to be able to modulate social learning. Both estrogen receptors alpha and beta have been demonstrated to be necessary for optimal social recognition in mice (Imwalle et al. 2002; Choleris et al. 2003, 2006).

This role of estrogens in social learning is particularly true for the social transmission of food preferences, and has been demonstrated using mice at various phases of the estrous cycle (Sánchez-Andrade et al. 2005; Clipperton et al. 2008). When tested immediately after socially acquired preference, the preference for the "unknown" food from which the taste was presented by a conspecific lasted longer in females in diestrus or proestrus females, than in females in estrus or ovariectomized (Clipperton et al. 2008). In addition to this effect on acquisition phase and short-term behavioral expression of this taste-dependent social learning, there is also an effect on the maintenance phase. Indeed, when compared to females in estrus or ovariectomized, females in proestrus and diestrus display a prolonged preference for the food targeted by the socially modulated taste-transmission (Clipperton et al. 2008). Finally, only mice in proestus clearly show a massive food preference when tested 24 h after the exposition to the taste through a conspecific having eaten the target food (Sánchez-Andrade et al. 2005).

A recent pharmacological study performed on animal model investigated more deeply the molecular basis of this modulation of taste-related social learning by estrogens, by focusing on the effects of selective agonists of the estrogen receptors (ERs) on socially transmitted food preferences. This study unveiled a differential role of ER alpha and ER beta in the acquisition and maintenance of socially transmitted food preference (Clipperton et al. 2008). When treated with the ER alpha selective agonist PPT (1,3,5-tris(4-hydroxyphenyl)-4-propyl-1H-pyrazole), ovariectomized mice are not able to acquire socially transmitted food preference – the alterations of this specific learning being neither due to the quality of interactions, nor to the food (Clipperton et al. 2008). In contrast, ovariectomized mice treated with the ER beta selective agonist WAY-200070 (7-Bromo-2-(4-hydroxyphenyl)-1,3-benzoxazol-5-ol) presented a massive increase of the duration of food preference (maybe partially through effects on submissive behavior), with the higher doses being able to trigger preferences similar to those observed in intact female mice during the proestrus and diestrus phases (Clipperton et al. 2008). This suggests the possibility of a balance between the activation of estrogen receptors – with ER beta activation countering ER alpha effects – in the modulation of taste-dependent

social learning. Further investigations may contribute to a better understanding of fine mechanisms of sexual regulation of taste-dependent withdrawal in human.

78.7 Perception of Hedonic Valence

Among the alterations of taste perception observed in humans suffering from eating disorders, those touching hedonism are highly interesting. In anorexic patients, hedonic self-rated perception of tastes are shifted toward a marked preference for sweetness, while high-fat solutions become aversive (Sunday and Halmi 1990). These alterations of hedonic valence do not seem however to stem from global disturbances of taste perception, since other dimensions of taste perception, such as taste intensity, are generally intact in anorexic patients (Klein and Walsh 2004). The mechanisms underlying these alterations in hedonism are still unknown. Some electrophysiological studies suggested that the brain processing of gustatory stimuli could be altered in anorexic patients (Tóth et al. 2004). Aversion to some particular kind of food (such as high-fat foods) might well reflect a form of conditioned aversion to "perceived" calories. Clearly, the "negative status" of some food is likely to relate at least to some extend to a learned association between the consumption of this food and subsequent disinhibition of eating behavior. Interestingly, the alterations of hedonism perception seem to somehow persist in anorexic patients, even following treatment (Sunday and Halmi 1990). Such, these shifts in hedonic perception could witness predisposing traits, rather than effects of the periods of self-imposed starvation.

Anorexic patients may present alterations of the reward value of food (Klein and Walsh 2004). However, food still represents a relevant stimulus for these patients, since food-related cues were demonstrated in neuropsychological experiments to be able to act as distractors (Sackville et al. 1998). Similarly, experiments realized with bulimic patients confirm this view, with cue reactivity demonstrated for taste, but also smell and sight, of typical binge foods (Staiger et al. 2000).

Such a role of hedonism seems to be also pertinent for animal models of food disorders. Actually, a recent work even suggests the possibility of a direct behavioral measure of hedonism in rats in the context of food disorders (Guitton et al. 2008). Indeed, once the conditioning has been performed using anxiety as unconditioned stimulus, consumption of beverage with the conditioned taste strongly correlates with the time of social interactions spent by the animal, following a linear regression with a different slope for each taste (Guitton et al. 2008). It has been suggested that the variation of the slope – which reflects at the individual level the relationship between active taste consumption and social behavior – could be a direct indicator of the hedonic valence of the considered taste (Guitton et al. 2008). In rats, food deprivation enhances the hedonic value of nonfood rewards, such as psychostimulants (Cabeza de Vaca and Carr 1998) and intracranial self-stimulation (Carr 2002). This suggests that starvation may have a "reward-potentiating effect," which may strongly reinforce abnormal behaviors in the case of human eating disorders. Further research is still needed to fully understand this phenomenon, but understanding the mechanisms underlying this process of reward-potentiation may further our knowledge on ontogeny of food disorders.

78.8 Conclusion

Either after a direct or indirect association between taste and on-line noxious state, or off-line retrieval of association between taste and negative emotional state, taste presentation can trigger social withdrawal in mammals. Even if clear demonstration of this phenomenon has been obtain on rats, these

properties of association between taste and social behavior have tremendous interest in the under-standing of eating disorders in humans (Table 78.1).

Modeling the cognitive aspects of eating disorders in animal clearly represents a highly challeng-ing issue – as it is the case for any psychiatric disorder. However, the use of adapted animal models unveils considerable promise as a mean to gain further insight into the molecular and biological mechanisms sustaining these abnormal eating behaviors. Further investigations will of course be needed, but the kind of behavioral approach described in this text on animal models may well con-tribute to the identification of new molecular targets, and to the development of innovative pharma-cological strategies to treat human patients suffering from food disorders.

Molecular regulation of the biological systems underlying this phenomenon is still far to be fully understood. However, understanding the fine regulation of the behaviorally observed forms of taste-dependent social withdrawal may well be one of the keys to understand the ontogeny of human food disorders.

78.9 Applications to Other Areas of Health and Disease

The main applications of research on taste-dependent sociophobia in animals are obviously the understanding of food and eating disorders, particularly anorexia nervosa and bulimia nervosa. However, applications to other areas of health, as well as to other specific diseases should not be neglected. In particular, working on this topic may help to understand some of the mechanisms modulating metabolic disorders such as diabetes.

By exploring complex conditioned responses different than the one classically analyzed in CTA, the interactions between taste detection, social behavior, and the association between these two com-ponents could help to further the analogies that several researchers have suggested between CTA and post-traumatic stress disorder (PTSD). Given the significance in terms of public health of PTSD, as well as the present lack of pharmacological agents to treat this pathology, the contribution of research performed on sociophobia induced following taste presentation may be crucial in the middle to long term.

Rats – like humans – are social animals and display a rich repertoire of social behaviors. In this view, testing social interactions in rats offers a possibility to test high-level behaviors, in addition to the simple aversive behavior classically observed with paradigms such as CTA. Such, investigation of social interactions in rodents (rats or mice) may represent an interesting tool to help further our understanding of pathologies strongly affecting behavior, and particularly psychiatric disorders. Finally, understanding how taste perception can influence social behavior and the maintenance of dynamic social ranking may account for a significant contribution in the research field of multimodal interactions in perception and cognition.

Summary Points

- Taste perception may have repercussions on social behaviors.
- Ingestion of poisonous or toxic food induces social withdrawal.
- Social withdrawal provoked by presentation of a taste is an active phenomenon.
- Food-related taste information can be transmitted from one animal to another conspecific.
- The social transmission of taste information between two animals can lead to a subsequent prefer-ence for the related taste in the animal which was not initially confronted to it.

- The association of a new taste and visceral pain results in a strong avoidance of the conditioned taste; however, if the animal detects this taste again, its perception will not induce modification of social behavior.
- In contrast, the association of a new taste and delayed anxiety-like state is more diffuse: the animal may have only a slight avoidance for the taste, but perceiving this taste anew will trigger massive alterations of social behavior, characterized by social withdrawal.
- The effects of this last form of association are rather specific to the conditioned taste and are not generalized.

Definitions of Key Terms

Anxiety-like state: Negative emotional state isomorphic to what is referred as anxiety in humans, the emotional state triggered by the perception of a potential danger (real or inferred).

Conditioned taste aversion: A particular form of associative learning between a new taste and an aversive delayed stimulus (usually visceral pain), which leads to a marked subsequent aversion for this taste and tolerates a very long interstimulus interval compared to other forms of associative learning.

Estrogen receptors: Endogenous receptors specifically activated by the binding with estrogenic hormones.

Neophobia: A form of novelty avoidance which occurs when an animal is confronted to an unknown taste, which reflects the inference of a putative toxicity of the food.

Poisonous or toxic food: Food which provokes deleterious effects when ingested by an animal; these effects can be either lethal or nonlethal (commonly provoking in this case transient malaise).

Socially transmitted food preference: Food preference acquired through social interactions with a conspecific which already tried this food without experiencing poisoning and display the taste on its whiskers. Socially transmitted food preference represents in rodents a socially acquired knowledge based on taste information.

Social withdrawal: Active (not a merely passive phenomenon) adaptation of behavior in order to decrease the occurrence and/or the duration of social interactions with conspecifics.

Chapter 79
Why Do We Dislike So Many Foods? Understanding Food Aversions

Christina L. Scott and Ronald G. Downey

Abbreviations

CR	Conditioned response
CS	Conditioned stimulus
UCS	Unconditioned stimulus
UCR	Unconditioned response

79.1 Introduction

Like breathing and drinking, eating is critical to our long-term survival. Given this fact, why do we avoid so many edible foods? This chapter will explore the major psychological factors that drive our eating behaviors (see Table 79.1). While there are clear physiological constraints to what we can eat (e.g., allergic reaction to peanuts or eating foods that contain large amounts of salmonella), this chapter will focus on why we avoid foods that we could eat with little danger to our health or survival. We will first focus on four major ways that these aversive behaviors develop (Passer and Smith 2007). These are:

- Classical conditioning
- Operant conditioning
- Observational learning
- Conscious choice

After briefly describing each of the four major ways that aversions to foods can develop, we will:

- Provide relevant examples of how aversive behaviors develop and are sustained over long period of time in our daily life, in spite of many efforts to change the behaviors
- Explain how our basic senses (e.g., vision, etc.) often drive learning
- Discuss how a variety of conscious choices impact out eating behaviors and
- Review the current methods that are used to try and change disruptive aversion behaviors

Table 79.1 Key features of food aversion

1. Food aversions develop quickly through the pairing of food with very negative events; e.g., foods that are too hot or foods that taste "bad."
2. Over time, we learn to seek out certain foods when we are reinforced by the positive nature of the food and we avoid those foods that produce a negative response.
3. We model our food preferences by observing other people; e.g., family, friends, etc.
4. Our senses of the smell, sight, feel (texture), and/or taste of food are all driving forces for eating or avoiding food.
5. We often consciously decide to avoid foods to obtain certain goals or avoid bad outcomes; e.g., a healthier lifestyle or manage health conditions.
6. Changing food aversions (or attractions) is enormously difficult.

This table lists the key facts of food aversion, including how they develop, interact with our basic senses, and affect our eating behaviors

79.2 Four Models of Food Aversion

79.2.1 Classical Conditioning

Classical conditioning is the most basic process of learning (Pavlov 1928). As is shown in Fig. 79.1, all living organisms have an innate response (e.g., approach or avoidance) when they encounter certain stimuli (e.g., heat, light, movement, taste), When babies are fed food that is too hot, they spit it out and cry. Thus, the association between the heat (unconditioned stimulus, UCS) and pain (unconditioned response, UCR) is established by the baby. Problems can occur when the baby pairs heat (UCS) and other properties of the food together (conditioned stimulus, CS) with the pain producing a conditioned response (CR). For example, if the food was strained carrots, the taste (or color, or texture, etc.) of carrots is now associated with heat/pain. When the baby eats carrots (hot or cold) in the future, the conditioned response is to spit them out.

79.2.2 Operant Conditioning

Operant conditioning is a more complex leaning process where the stimuli and responses are more complex, develop over a much more extended time, and involve reinforcement (positive or negative). Figure 79.2 outlines the basic process. Through operant conditioning we learn to effectively operate within a complex and ever changing environment through reinforcement (Skinner 1938). Simply put, when we are reinforced for a behavior, we are more likely to repeat the action, but when we are punished, we are less likely to repeat the behavior in the future. When offered a candy bar, a child is immediately reinforced with the sweet taste of milk chocolate and seeks to repeat the experience; however a bitter taste (a negative experience) of dark chocolate may serve as a disincentive and thus discourages the child from trying that food again.

79.2.3 Observational Learning

Observational learning occurs when we perceive and mirror the behaviors of others. No *immediate* reinforcement of the new behavior is required, but the perception exists that the modeled behavior will be rewarded in the future, either through social acceptance or direct reinforcement (Bandura 1969). A child who observes his father pushing away his plate with uneaten broccoli is more likely

Before Conditioning

Carrots   No fear, no anxiety

During Conditioning

Burns tongue.   Fear, anxiety,
                                                   and avoidance

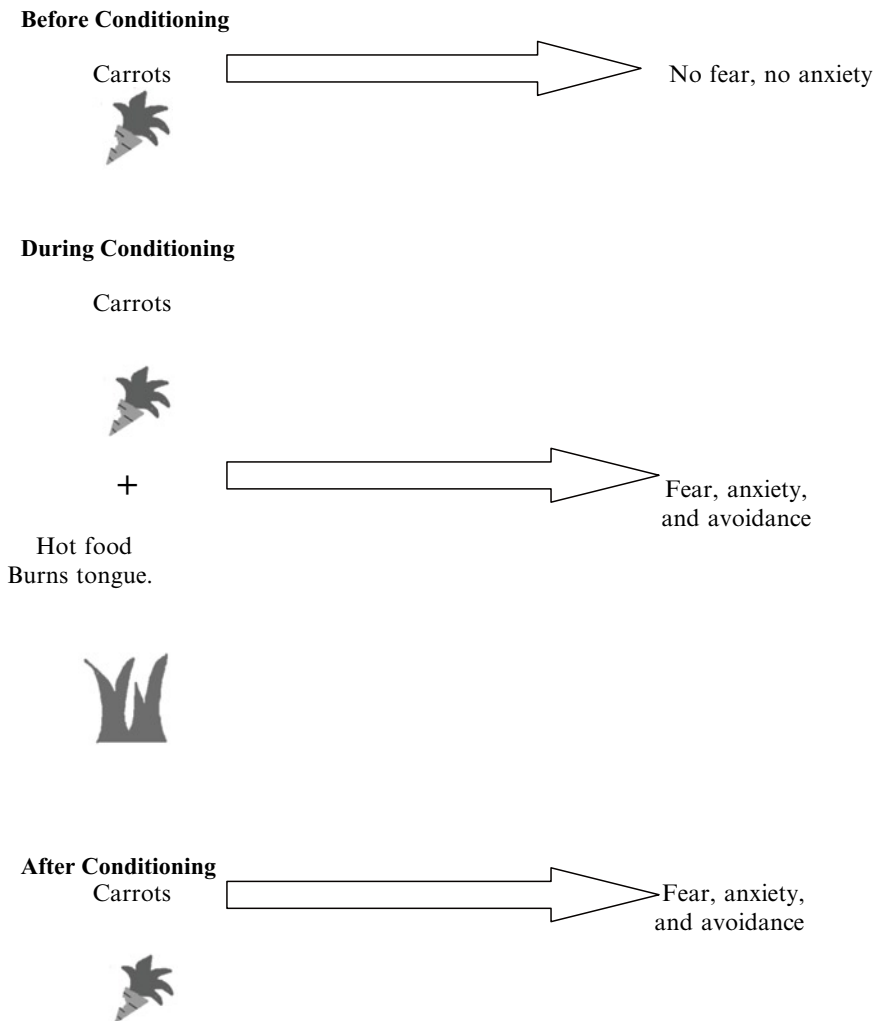
After Conditioning
Carrots   Fear, anxiety,
                                                   and avoidance


Fig. 79.1 Classical conditioning of food aversion. This figure illustrates how food aversions can develop by associating a negative event with a specific food

to emulate his father's behavior and push aside his/her own vegetables (see Fig. 79.3). This aversion to broccoli has not developed as a dislike for any specific properties of broccoli, but rather a desire to model the behavior of the father. Social learning plays a very powerful role in our eating behaviors, whether it is a toddler avoiding vegetables, or a teenager trying diet soda to "fit in" with the crowd. Social learning transcends a wide variety of situations and foods.

79.2.4 Conscious Choice

Finally, our eating behaviors can be directly influenced by our own judgments and decisions. Conscious choice influences us when we decide to avoid a food based on our own reasoning and when coupled with our past experience, and the outcomes we have witnessed in others (see Fig. 79.4). Suppose a teenage girl has a date planned for the following weekend and decides she wants to lose weight. Past

aversion. This figure
illustrates how reinforcement
creates a food preference and
punishment leads to a food
aversion.

REINFORCEMENT			
PROCESS	BEHAVIOR	CONSEQUENCE	RESULT
Positive	Response occurs ⟹ (milk chocolate is consumed)	Stimulus is presented ⟹ (sweet taste of milk Chocolate is enjoyed)	Response increases ⟹ (more milk chocolate is eaten)
PUNISHMENT			
Punishment	Response occurs ⟹ (dark chocolate is consumed)	Aversive stimulus is presented ⟹ (bitter taste is delivered)	Response increases ⟹ (dark chocolate is avoided)

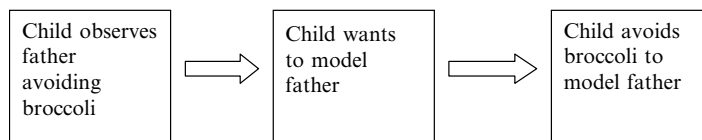
Child observes father avoiding broccoli	⟹	Child wants to model father	⟹	Child avoids broccoli to model father


Fig. 79.3 Observational learning of food aversion. This figure illustrates how we avoid specific foods by observing other people

Wants to lose weight for upcoming date.	⟹	Recognizes that fatty foods will cause weight gain.	⟹	Makes conscious choice to avoid fatty foods.
Fig. 79.4 Conscious choice model of food aversion. This figure illustrates how we consciously process information about our food choices

experience suggests that certain foods (e.g., fatty foods) may cause weight gain. Thus, the teenager makes a conscious choice to avoid fatty foods and opts for a garden salad. When choosing between foods we like, many of our food choices are determined by conscious decisions to select one food over another; sometimes even if we do not "like" the food we have chosen.

79.2.5 Summary of Learning Models

Thus, our responses to food are complex and determined by a variety of past events. Some of the responses (see Table 79.2) are very basic and almost instinctive (classical leaning). Others are acquired over a long time and require repeated experiences (operant learning). Equally complex

Table 79.2 Four models of food aversion. This figure outlines the four basic learning models associated with the development of food aversion

	Classical conditioning	Operant conditioning	Observational learning	Conscious choice
What behavior is required?	Accidently eat hot food (UCS) and pair it with the specific taste of carrots (CS).	Eat a piece of chocolate.	Based on watching other people, the same behaviors are replicated.	A decision is made to avoid a specific food.
How does learning occur?	Pairing of the UCS and CS leading to a conditioned response.	Reinforcement encourages future behavior and punishment discourages future behavior.	Observe behavior and motivated to replicate it.	Conscious motivation to avoid specific foods.
What is the sequence of events?	CS occurs before the CR.	Reward (punishment) occurs after the behavior.	Observation occurs before the behavior.	Conscious decision is made, behavior follows.
What is the outcome?	Strong negative reaction to specific foods due to unconscious pairing.	Strong positive or negative reaction to foods due to expected outcome.	Strong positive or negative response to specific foods based on prior observation.	Strong positive or negative response to specific foods based on a series of thought processes and decisions.

are the ways we learn from other individuals within our immediate environment (observational learning). Finally, as we grow and mature we make choices about what we do and do not want to eat and these choices may not be directly related to the sensory properties of the food. In the next sections we will discuss in detail how each of these processes can lead to potentially dysfunctional eating behaviors.

79.3 Sensory Processes and Eating

As will be outlined in the next sections, our sensory processes unconsciously determine many of our reactions. These include sight (appearance), smell, taste, and feel. While these will be discussed as separate senses, there is ample evidence (Martins and Pliner 2005) that they can be closely interconnected. For example, it is difficult for people to determine when taste and smell are different.

79.3.1 Smell

A food's aroma is one of the strongest signals we evaluate when facing an unfamiliar dish (Halpern 2002). If the scent "reminds" us of a similar food that we like, such as chicken or steak, we are more likely to respond favorably to the new dish. However, if the scent is strong and

unrecognizable, such as sauerkraut or fish, we tend to reject the new food without trying it. One of the strongest components of food aversion is the overlap between the way a food smells and its taste. If you've ever tried eating your favorite foods with a head cold, you quickly realized that the flavor of the food is diminished (Beauchamp and Bartohshuk 1997). Children, who are instructed to finish their vegetables, often plug their noses, to reduce the smell and, they assume, flavor of the offending vegetable. Memories of unpleasant smells in childhood are likely to follow us into adulthood and smells that remind us of disliked foods (such as Brussels sprouts) will be immediately rejected.

79.3.2 Sight (Appearance)

Go to a five star restaurant and you will be dazzled by the presentation of the food you are served, because "presentation is everything." Imagine two chicken dishes are placed before you; one features a plump, juicy, white chicken breast surrounded by colorful vegetables and a mound of mashed potatoes with a dollop of butter balanced on top; while the second dish features a dry, thin, graying chicken breast, next to a pile of green beans, and a baked potato wrapped in foil. The classical conditioning model suggests that we are immediately drawn to the more attractive meal because we associate good taste with attractive presentation that leads to satisfaction in our food choice. However, it is important to realize that our appreciation for the appearance of food is not innate. One look at the contents of baby food will remind us that as infants, our food preferences were mostly based on taste (and temperature) and not esthetics. However, as we grow older, we learn to value the appearance of our food. Toddlers find the round shape of Cheerios easy to grasp, which is reinforcing as they learn to manage finger foods, and in time, they will prefer whole crackers and cookies over broken pieces, even if the taste is identical.

79.3.3 Taste

From the time we are babies, we respond to food positively or negatively based on taste (Halpern 2002). The human tongue has approximately 9,000 taste buds that are devoted to recognizing the five elements of taste perception: sweet, sour, bitter, salty, and savory (Halpern 2002). Sweet tastes such as sugar are immediately reinforcing, while strong or bitter flavored foods such as cabbage and grapefruit are initially disliked. College students learn to consume large amounts of coffee by masking the bitter taste with sugar. Eventually many college students will desensitize to the bitter taste and they may require less sugar because the actual or perceived positive cognitive effect of the caffeine has become a stronger reinforcement.

79.3.4 Feel (Texture and Temperature)

As we demonstrated (Scott and Downey 2007) texture is strongly associated with food aversions and choice. On a hot summer's day nothing is more appealing that the cool creamy consistency of ice cream as it cools a burning throat. Although the flavor of the ice cream is important, the texture and

temperature are equally essential in our enjoyment. Melting ice cream loses its texture and although the taste remains the same, we may reject it. Foods that are not served at their ideal temperature are immediately judged as being less appealing. Cold coffee and warm white wine are immediately rejected as being unfit for human consumption. Tepid vegetables often remained untouched on a plate, as compared with the same vegetables served steaming hot. Anyone who has indulged in McDonald's French fries will attest to the fact that "fresh French fries" far outweigh the taste of lukewarm ones!

Foods with smooth even textures signal us at an unconscious level that what we are consuming is pure and consistent. Imagine eating a cup of yogurt or enjoying a fruit smoothie. Lumps or chunks produce an aversive response and we evaluate them as evidence that our food hasn't been blended properly. From our earliest experiences with food, we were served well-blended baby food, which featured a smooth and even consistency. We come to expect a certain texture from our food, such as creamy mashed potatoes and if we are served something outside of our expectations, we may find it aversive. A classic example would be the texture of soggy bread. As children we learn the ideal texture for bread by watching our parents. If it becomes too firm (stale) or too soggy (wet) we respond negatively and leave the bread untouched. Slimy and/or slippery foods such as oysters, mussels, and internal organs (e.g., liver) feature an unfamiliar and initially unappealing texture that results in most people avoiding these foods without trying them.

79.3.5 Summary of Sensory Processes and Eating

Our five senses play a critical role in our food preferences and aversions. While a large number of food choices, including avoidance of certain foods or types of foods can be traced back to sensory types of processes, a large number are related to the human processes of choice and decision making. The underlying processes determining these choices and decisions are complex and multidetermined. The next section will explore some of the major ways we *decide* to avoid certain foods. However, it should be noted that these decisions may be unconsciously associated with some of the sensory properties of the foods.

79.4 Applications of Food Aversions to Other Areas of Health and Wellness

While many food aversions are unconscious reactions to something unappealing, unfamiliar, or unpleasant, a large portion of our food choices are made based on conscious choice (see Table 79.3). We may be operating based on previous negative experience or observing the behaviors of others, but the outcome is the same, we avoid certain foods for the following reasons:

• Questionable or unsafe foods
• Temperature
• Media warnings
• Dietary restrictions (health)
• Dieting and diet fads
• Going organic: organic foods, vegetarians, and vegans budget

Table 79.3 Applications of food aversions to other areas of health and wellness. This figure outlines how we make a decision to avoid specific foods in order to achieve a healthier lifestyle

	Questionable or unsafe foods	Temperature	Media warnings	Dietary restrictions (health)	Dieting & diet fats	Going organic	Budget
What is the thought process?	That food doesn't look/smell familiar!	That temperature isn't appealing.	It's unsafe or unhealthy to eat that!	Eating that food may put my health at risk.	That food is too fattening.	Artificially grown foods aren't as healthy as organic foods.	That specific food is too expensive.
Food example	Oysters	Warm Beer	Corn syrup	Glutens or sugar	Pizza	Produce	Lobster
What is the outcome?	Avoidance	Temporary avoidance	Temporary avoidance	Temporary avoidance	Temporary avoidance	Temporary avoidance	Temporary avoidance

79.4.1 Questionable or Unsafe Foods

At the most basic level, we may choose to avoid specific foods because they appear questionable or unsafe, even though we have enjoyed similar foods in the past. Most of us have sampled milk that has begun to spoil or been taken aback at the green fuzzy mold growing on our cheese. Although we enjoy these foods on a regular basis, we detect that the foods may be "spoiled" or "unsafe" to consume and we avoid them for that one instance. The same might hold true if we are served an undercooked steak (although some people ask for **rare** steak) or we are served raw fish (however, many people like Sushi). This tendency may be enhanced by our previous experiences with undercooked foods, such as a case of food poisoning, but we might be equally reluctant to eat an undercooked piece of chicken if we saw a recent news report cautioning the dangers of salmonella or E Coli contamination. The texture of a food may enhance this concern. If we faced with slippery or slimy foods such as runny eggs or raw oysters, we may be more reluctant to try them than firmer textures such as steak or chicken.

79.4.2 Temperature

Although certain foods seem to taste better when served hot, such as fajitas, French fries or filet mignon, other foods, such as ice cream and shrimp seem to taste better cold. Many of these preferences for temperature are based on culture and develop through social learning. In the United States, we prefer our milk and dairy products to be ice cold, while in Europe consuming milk and yogurt served at room temperature is commonplace and milk straight from the cow is desired in many cultures (Rappoport 2003). Imagine you are served a bowl of leek soup and it arrives cold. Although this recipe is both valid and delicious, we may find the cold soup aversive and turn it away, because we expect soup to be served hot. In the Hofbrauhaus in Germany, warm beer is served intentionally to enhance the flavor of the beverage; however many American tourists would be offended if their beer was not served chilled: a *conscious choice*.

79.4.3 Media Warnings

Although many food aversions develop through direct experience (classical or operant conditioning) or direct observation (social learning), many food aversions are a conscious choice based on media warnings. With recent warnings about transfat, MSG, and other additives/preservatives in food, the public is more health conscious than ever. In the 1980s a media campaign warning about the dangers of high cholesterol suggested that consumption of eggs could cause serious health risks. Consumers made a *conscious choice* to cut back on their egg consumption in order to be health conscious and new food avoidance behavior was created. In the late 1990s, consumers were surprised to see a series of new commercials with a very different message advertising "The incredible, edible eggs!" as an excellent source of protein. For many consumers, the decision to avoid or enjoy eggs became a combination of the conflicting messages they received and a *conscious choice* based their own personal preference for eggs.

In 2008, commercials speaking out against products containing corn syrup surfaced featuring concerned mothers protecting their children from foods made from corn syrup. No specific claims were made about the possible health risks of corn syrup, but the commercials clearly suggested that giving your child a Popsicle containing unnatural chemicals such as red dye and corn syrup was an irresponsible decision. These commercials were followed almost immediately by a rebuttal campaign, using the same social learning technique featuring a mother correcting another woman's misconceptions about corn syrup arguing that it is produced naturally from corn and in moderation is "the same as sugar." As consumers, we have to determine which foods contain high fructose corn syrup (read the label) and make a conscious choice whether we want to give them up based on the media warnings, or decide to just enjoy them.

79.4.4 Dietary Restrictions (Health)

For people diagnosed with Diabetes, Celiac Disorder, or Food Allergies, the conscious choice to avoid specific foods is a necessary decision to protect overall health and wellness. Diabetics may watch the high fructose corn syrup debate with interest, but ultimately realize that any form of sugar, for their well being, will need to be monitored carefully. They may actively seek out foods with less sugar or sugar substitutes, such as Splenda or Equal, while restricting their intake of foods high in carbohydrates or sugars. There may be instances when they make a conscious choice to **not** restrict their dietary selections, which could result in higher blood sugar levels, and possible medical complications.

Food allergies can range from mild to severe and most appear in early childhood. Children and adults with Celiac Disorder are allergic to Glutens and therefore need to adhere to a strict Gluten-Free diet, which means no foods made with wheat. This would systematically eliminate most breads, pastas, and pizza from their diet, unless they were made with special Gluten-free ingredients. Wanting to enjoy a piece of cake at a classmate's birthday party or a slice of pizza with friends afterschool becomes increasingly more frustrating for children with Celiac Disorder as they may associate specific foods with "fitting in" and social acceptance. The conscious choice to avoid specific foods can be a matter of life and death. Individuals with peanut or chocolate allergies can find themselves suffering from migraines to severe anaphylactic shock depending on the level of their exposure and the severity of their allergies.

79.4.5 Dieting & Diet Fads

While we may be drawn to "comfort foods" such as sweets or starchy foods (Conner et al. 1988), many of us make a conscious choice for a limited period of time to avoid specific foods in order to lose weight. Freshmen college students, who have packed on the "freshmen fifteen" over the course of their first semester of college, may suddenly restrict their fried food intake and late night pizza binges in order to wear swimsuits over spring break. Although most dieticians suggest that "lifelong changes" are necessary to lose weight and maintain the weight loss, most Americans "crash diet" (Crow et al. 2006),which means a drastic restriction in calorie intake, combined with a long list of foods that must be avoided for quick weight loss. The promise of quick weight loss has led to an ever-increasing number of "fad diets" such as the SouthBeach and Atkins diets, which suggest a low-carbohydrate and high-protein regimen. Although both programs promise immediate results, most people prefer carbohydrates and find it difficult to avoid them for a prolonged period of time. Although most of us recognize that sugary foods are higher in calories, we don't want to give up the sweet taste we enjoy, so we make compromises such as switching to diet sodas or using sugar substitute products (Appleton and Conner 2001). We want the benefits of a lower calorie lifestyle, but are unwilling to sacrifice our preference for sweet tastes. A recent trend in wellness has been a detoxifying procedure, where people will consume only fruit juice or green tea; some people make the conscious choice to avoid *all foods* for 3–10 days in order to clear the impurities from their system (Glittleman 2006).

79.4.6 Going Organic: Organic Foods, Vegetarians, and Vegans

With the recent warnings about food chemicals leading to cancer, many Americans are turning to organic products. The decision to avoid foods grown with pesticides, growth hormones, or preservatives is becoming increasingly more popular, especially with parents seeking to protect their children (Burke 2007). Specialized grocery stores such as Whole Foods and Trader Joe's offer a variety of organic options, including dairy products and produce and most large grocery chains now have organic food sections. The only known downside to organic products is their higher cost, which means the availability of organic foods is restricted to those who can afford higher grocery bills.

The decision to avoid meat (vegetarians) or the decision to avoid all foods that contain either meat or dairy products (vegans) can be made for a variety of reasons. Some people may wish to avoid chemicals and preservatives and opt for organic fruits and vegetables, while others may wish to make a statement about the treatment of animals raised for food. The recent bestseller, *The Omnivore's Dilemma* (Pollan 2006), highlights the overcrowding and mistreatment of cattle raised for consumption, and led thousands to swear off meat in support of animal rights. Many such individuals report that although they enjoy the taste of a good steak, they are making a conscious choice not to support an industry that mistreats animals.

79.4.7 Budget

Although we may enjoy the "surf and turf" option at a five star restaurant, our budgets may restrict the foods we choose to eat. As any college student can tell you, the conscious choice to eat Top

Ramen, is not one made for taste preference, but generally due to the low cost. Dollar menus have become increasingly more common at fast food restaurants, including McDonald's, Taco Bell, and Burger King. Recognizing the need for lower priced offerings, establishments such as Applebee's and Chili's have started offering $7 menu items, or combination dinner specials which feature a shared appetizer, two entrees, and a dessert for a lower price. Senior menus and children's menus are often coveted for not only their smaller portions, but specifically their lower prices. Limited budgets required conscious choices to find lower priced food.

79.4.8 Summary of Conscious Choice

A conscious choice to avoid a specific food is made after considering a wide range of evidence. We may already have a negative association/experience with a specific food or we may we evaluating the health risks associated with a food we have enjoyed for many years. Our choice may be permanent, such as making a lifestyle change to promote better health or it may be temporary because we watching our budget or restricting our calories. We are constantly evaluating new evidence regarding our food choices and making conscious choices about the foods we consume.

79.5 Changing Food Aversion Behaviors

As most of us can attest, change is not easy. The older we are, the more likely we are to be set in our ways, which is why changes in food aversions are best introduced in infancy or early childhood (Chatoor and Ganiban 2003). Such changes are therefore most commonly introduced by parents and not based on the child's desire to overcome a food aversion. The most common methods of changing food habits in children include food pairings (classical conditioning), rewards for eating specific foods (operant conditioning), and food blending (masking foods within liked foods) and can be seen in Table 79.4.

Havermans and Jansen (2006) suggested a classical conditioning approach for introducing vegetables to young children. Parents paired a positive flavor (sweet taste of sugar) with a neutral flavor (vegetables) in order to help children develop a positive response to vegetables. It is important to note that the children in the study saw the vegetables as a neutral stimulus and had not developed a strong aversion to any of the vegetables they were asked to consume. The stronger and more long-term someone's aversion to a specific food is, the more difficult it is to override the initial negative response, no matter how strong the pairing. Brunstrom and Fletcher (2008) sought to explore the effects of flavor–flavor pairings with young adults (18–25 years), but discovered that the pairings were only successful when the participants were hungry, and therefore more motivated to eat.

Another approach to changing food aversions is through rewards, which utilizes an operant conditioning model. Hendy et al. (2005) rewarded elementary school children for eating fruits and vegetables in the cafeteria, by giving them tokens for each food consumed. Children exchanged tokens for small prizes and 2 weeks after the study, food preferences for fruits and vegetables increased. However, the effect was not long-lasting and when children were sampled seven months after the study, their interest in fruits and vegetables had returned to the baseline. Parents can encourage their children to eat less appealing foods through reinforcement; however the change is generally only

Table 79.4 Changing food aversion behaviors. This figure reviews the structure, process, and limitations of the four primary methods for changing food aversion behaviors

	Classical conditioning	Operant conditioning	Masking	Lewin's change theory model
What behavior is required?	Positive pairing is required. Sweet taste (UCS) is paired with vegetables (CS).	Reinforcement of desired behaviors is required. Receive rewards for eating vegetables.	Small amounts of a new food are hidden within an enjoyed food. (e.g., putting sweet potatoes in pancake batter).	Repeated exposure, time and commitment to adapt to a new food behavior.
How does learning occur?	Pairing of the UCS and CS leading to a new conditioned response.	Reinforcement encourages future behavior and punishment discourages future behavior.	Remember behavior and have motivation to replicate it.	Combination of classical, operant and observational learning, but increased conscious motivation to avoid or approach specific foods.
What is the sequence of events?	CS occurs before the CR.	Reward occurs after the behavior.	Increased exposure to new food hidden in preferred food.	Three stage process: *Unfreezing*–override aversion *Change*–consume new food *Freezing*–adopt food into permanent lifestyle.
What is the outcome?	Limited positive outcome if initiated early in infancy or childhood.	No permanent change, behavior terminates without reward.	Limited positive outcome if initiated early in infancy or childhood.	High level of psychological distress involved with limited positive outcome. Tendency to revert back to original behavior.

temporary. When the reinforcement is withdrawn, it is likely that children return to their original eating behaviors and the new foods are abandoned.

Another suggested technique for parents to change children's choices involves masking less appealing foods with preferred foods (Mueller et al. 2004). Recipes such as sweet potato pancakes, allow parents to "sneak in" a serving of vegetables into an already accepted food. In order to promote healthier eating habits, parents may switch to wheat bread when serving peanut butter and jelly sandwiches, or incorporate whole grain tortillas when serving burritos. Occasionally these pairings are successful with adults, such as the acceptance of green beans, when they are buried deep within a casserole, consisting of a sauce of mushroom soup and fried onions. However, most adults are fully conscious that undesirable foods, such as vegetables are being blended into their food preferences. For both adults and children, if we "know" a specific food is "in there" we may be unable to convince ourselves to try the new food, especially when strong aversions are present.

As we discussed previously, we may decide to make a conscious choice to change our food behaviors, but change does not come quickly or easily. In 1947, Kurt Lewin introduced his

"change theory" which specifically identified three major stages necessary for a change in food habits to occur. The initial step involved changing a person's current mindset, and bypassing their defense mechanisms; a process he called "unfreezing." Suppose a person has a strong aversion for tofu, but has recently starting dating a vegetarian and is trying to make a change in his food habits. Suppose he has promised to give up red meat in exchange for tofu burgers. Unfreezing would involve trying to override the initial aversion to tofu, including the texture, taste, and smell. Lewin's second stage was the "change" where the individual would begin eating tofu, even if their initial response was negative. Lewin notes that this stage requires a substantial amount of time because the new food is still unfamiliar and the person may find himself tempted to return to old habits, such as eating red meat. The final stage is "freezing" in which the new mindset is locked in place and a person's comfort level is restored once the new food has been accepted. Lewin's model would argue that with time, tofu would become more familiar and a part of the individual's eating routine.

Lewin's model requires repeated exposure, time, and a commitment to changing a specific food habit before a new behavior is adopted and the process is not without emotional consequences. Lewin notes that anxiety and discomfort are hallmarks of the second stage "change" when we are learning to accept unfamiliar foods. Although we may make a conscious choice to change our eating patterns, all three stages are limited by the very fact that food aversions often exist at a *basic level*. We know vegetables are good for us and that tofu is a health alternative to red meat, but we "just *don't like* the taste, texture, and/or smell" and whether it is food blending, food pairing, or trying to adopt a new food habit altogether, our aversions persist. Most adults can't articulate why they avoid specific foods, but despite our best efforts to reverse them, the long-term changes are minimal.

79.5.1 Summary Changing Food Aversion Behaviors

The older we are the more resistant we become to changing our food aversions. Although we may believe that our eating behaviors are predominantly a conscious choice, there are many unconscious influences that make certain foods unpalatable to us (see Table 79.4). Masking the flavor of disliked foods, such as putting cheese and butter on Brussel sprouts is only effective if we have a mild aversion. Unlike young children, it may not matter to us as adults how the food is masked or rewarded; we are still unlikely to eat it.

Overall Summary

It is almost always impossible to pinpoint the exact moment when food aversions develop for individuals. As we have discussed they can develop through a variety of learning and conscious choices. These include: classical conditioning, operant conditioning, and observational learning. Many aversions are driven by our sensory processes of smell, sight, taste, and texture. We can also make decisions to avoid specific foods whether they are for health, diet, or cost. Once we have developed these avoidance (or approach) behaviors, changing them is enormously challenging. Attempts to modify our food choices typically have not resulted in long-term changes in our eating behaviors. In essence, we are "what we eat" because our food preferences have become an ingrained and long-term part of who we are as unique individuals.

Definitions

Celiac disorder: A chronic nutritional disturbance, usually of young children, caused by the inability to metabolize gluten. The disorder can be controlled by a special diet that emphasizes the elimination of all foods containing gluten.

Classical conditioning: A neutral stimulus (the *conditioned stimulus*) is repeatedly presented in association with a neutral stimulus (the *unconditioned stimulus*) that elicits a natural response (the *unconditioned response*) until the neutral stimulus alone elicits the same response (now called the *conditioned response*).

Glutens: The tough, viscid, nitrogenous substance remaining when the flour of wheat or other grain is washed to remove the starch.

Diabetes: A medical condition in which the body is unable to control the level of sugar in the blood.

E. coli: A dangerous form of Escherichia coli, a bacterium that normally lives in the human colon.

Observational learning: Behavior occurs as a function of observing, retaining, and replicating behavior observed in others.

Omnivore: An organism that eats both plants and animals

Operant conditioning: A behavior is either reinforced or punished, which directly affects the likelihood of the behavior being repeated again.

Organic: Raised or conducted without the use of drugs, hormones, or synthetic chemicals.

Vegan: A person who does not eat meat, fish, or any animal products such as cheese, butter, etc.

Vegetarian: A person who does not eat meat or fish.

80.1 Introduction

Accurate portion estimation is the key to controlling the amount of food ingested, a key element in the treatment of obesity and eating disorders (Dohm and Striegel-Moore et al. 2002), but it is a common clinical experience to find under-reporting of food intake among obese subjects and over-reporting among patients affected by anorexia nervosa (AN). Blundell (2000) provocatively affirmed that asking nutritionists to report information regarding their extramarital sexual encounters there would probably be a significant under-reporting, while asking on their donations to charity there would probably be an over-reporting.

Certainly, social acceptability contributes to food reporting but many other factors influence food amount estimation. Current levels of hunger/satiety (Beasley et al. 2004) and food palatability play a role in the evaluation as do the subjects' gender (Yuhas et al. 1989; Mac Diarmid and Blundell 1998), age (Frobisher and Maxwell 2003), and Body Mass Index (BMI) (Klesges et al. 1995). Children are less able to evaluate than adults; and women and overweight/obese subjects under-report their food intake more than men and normal-weight patients do.

Table 80.1 Factors influencing food amount evaluation among general population and subjects affected by eating disorders

- Cognitive biases
- Social acceptability
- Perceptive deficits
- Hunger and satiety
- Emotional states
- Reward sensibility
- Food palatability
- Eating disorders
- Subjects' age

Many factors influence food amount evaluation; among them cognitive biases and emotional states play a pre-eminent role in subjects affected by eating disorders. Moreover, perceptive biases affect the evaluation of subjects not affected by any eating disorder

In this chapter we will discuss how perceptive, cognitive, emotional, and social factors influence the evaluation of the amount of food consumed by patients affected by eating disorders. Moreover, the efficacy of proposed tools to improve the subjects' ability to evaluate their own food intake will be evaluated (Table 80.1).

80.2 Food Is Always Too Much. Food Amount Evaluation of AN Patients

Frequently, patients affected by AN claim to be unable to evaluate the amount of food served, engaging the therapists in endless Socratic debates regarding their real food intake, but the hypothesis that they really misperceive a food amount has been poorly studied.

More than 20 years ago, Yellowlees et al. (1988) surprisingly noted that in the many studies on AN only a minimal part was focused on food perception and little attempt was made to explain why they eat in such an unusual manner. So, they performed the first study regarding food perception in a sample of twenty patients affected by AN. Five items of food and four neutral objects of a similar size were video recorded. In the first experiment the objects were alternately placed in the middle of a dummy television screen, near a real TV screen. Each subject could compare the size of the real object with its image on the screen. The subjects were asked to manipulate the size of the object on the video screen until each image was, in their opinion, as close as possible to the size of the real object. No significant difference was found between AN patients and the control group in their ability to measure size. Both groups did, however, noticeably exaggerate the size of food, but patients with anorexia nervosa perceived it as 12% bigger overall than the control group members. The results did not change when the objects were placed in the dummy television screen for 10 s and then removed. The subjects were subsequently asked to adjust the video image from what they remembered.

To our knowledge no further research regarding food amount evaluation in patients affected by AN has been done in the subsequent 20 years. All of the studies on the perceptive abilities of these patients focused on their own body shape and weight estimation (Epstein et al. 2001). Their body size misperception seems to be more based on cognitive factors than by a perceptive bias (Skrzypek et al. 2001). Given that there is a tendency to a top-down process when judging food (Urdapilleta et al. 2005) and Stroop interference for food-related words (Overduin et al. 1995), cognitive factors could probably also influence their food amount evaluation. To test their ability in estimating food amount, thus avoiding these interferences, our research group (Vinai et al. 2007) carried out

a study in an experimental situation without any relation to food intake. Patients were informed that there was no effect on the therapy induced by their answer and particular attention was paid to avoid emotional and social influences on evaluation. We showed them subsequently a dish containing 27 high caloric and tasty yellow candies (A stimulus) and 27 plastic yellow LEGO® bricks of the same size and shape as the candies (B stimulus), placed in the same position on the plate to minimize the influence of shape, size, and disposition of the objects on number perception. Moreover, to avoid misperception through hunger on the evaluation, all the subjects had breakfast before being tested. No significant difference between AN patients and the control group in evaluating the number of the two stimuli has been found (both significantly underestimated the number of presented stimuli): 78% of AN patients and 78.6% of control subjects underestimated the number of candies, while 18.7% of the AN group and 21.4% of the control group overestimated them. Two AN patients (3.4%) and no control subjects guessed the correct number of candies. We found no correlation between the evaluation of number and the age of onset, or the duration of the illness, or the current or minimum BMI of the patients. The plastic bricks were evaluated in the same way as the candies (Fig. 80.1).

These results are apparently in contrast with the common clinical finding of overestimation of food intake among AN patients and with those of the study of Yellowlees et al. (1988), but the discrepancy can be explained by the differences between the experimental settings. In real life, as in the Yellowlees' experiment, the evaluation is not only the result of a flow of sensory information from periphery to brain, but also involves a *top-down* processing of a selection of inputs considered relevant by the subjects. In our study these processes have been minimized.

Summarizing, AN patients do not seem to be affected by a real perceptive deficit; they share the tendency of the general population to underestimate food amount. Top-down processes in
Fig. 80.1 Estimation of a number of tasty candies among patients affected by Anorexia Nervosa (AN) and control subjects. Seventy-eight percent of AN patients underestimate the number of tasty candies presented to them: 18.7% overestimated them and 3.4% correctly guessed the number. Patients affected by AN share the tendency to underestimate the amount of food with the general population. There are no significant differences between AN patients and control subjects in this evaluation. There is a general tendency among the normal weight population to underestimate the amount of food presented

judging food amounts seem to play a dominant role among them; e.g., when asked to categorize aliments, they cluster food on the basis of the consequences of ingestion (in terms of health, digestion, and weight gain), rather than on visual characteristics, as normal weight subjects do (Urdapilleta et al. 2005).

80.3 Surely I Have Eaten Too Much! Evaluation of Food in Patients Affected by Bulimia Nervosa

While there is a multitude of research about the eating behavior of patients affected by bulimia nervosa (BN), few studies focus on bulimics' perceptions of their peculiar eating behavior. Several findings led to the hypothesis that a distortion of what is a normal meal may represent a central cognitive mechanism of the disorder. Bulimic patients overrate the amount of food presented to them. This effect increases as caloric intake or actual amount increases at a greater rate than control subjects do (Gleaves et al. 1993). Overestimation of food amount could induce a more restrictive diet – the major risk factor for the onset of bulimic behavior. Moreover, the evaluation of caloric content of a food is subject to bias among these patients, worsening their tendency to reduce food intake. Their rating of the amount eaten is predicted by the estimate of the actual amount eaten, by the kind of food, and by mood level before eating (Keel et al. 2001). In a study including 165 females, those with bulimic behaviors and restrained eating were more likely to overestimate caloric content of the food presented (Stanton and Tips 1990).

Bulimic patients (Williamson et al. 1991) report overeating at a higher rate than control subjects, as they are affected by a bias distorting their perception of the amount of food eaten. Such cognitive biases could be the effect of an excessive concern about eating and dieting. As excessive weight is a threatening situation for these patients, they have interpretational biases toward foods that could induce weight gain (Williamson et al. 1991; Gleaves et al. 1993).

Caloric intake during binging episodes vary widely (Telch et al. 1990) and patients base their perceptions of having binged more on the type of food consumed than on the amount of food eaten (Rosen et al. 1985).

Bulimic individuals make cognitive attributions about different foods on a continuum from *safe* to *forbidden*, i.e., those high in calories and fat. The evaluation of an eaten food as forbidden, despite its caloric value, can trigger a binge episode in these patients and consumption of even small amounts of it may lead subjects to perceive their consumption as overeating (Herman and Polivy 1984; Rosen et al. 1985; Kales 1991). It has been reported (Kales 1990) that 69% of the episodes they evaluate as a binge contained *forbidden foods*, i.e., having a higher caloric density, whereas only 15% of the episodes defined as *nonbinge* contained them (Table 80.2).

Knight and Boland (1989) asked a group of women to consume either cottage cheese (nonforbidden food) or a chocolate milkshake (forbidden food) preload before tasting ice cream, informing participants that both foods contained the same number of calories. Highly restrained participants subsequently ate more ice cream when having first eaten the *forbidden* milkshake than they did after eating the cottage cheese. (Guertin and Conger 1999). Furthermore, these patients have perceptual distortions of their own body image in response to eating *forbidden* foods (Rosen et al. 1985) (Fig. 80.2).

Summarizing, subjective perceptions of overeating and binging are core factors in the onset of bulimic behavior; the perception of having overeaten and the self-reporting of having binged, rather than actual overeating, lead to disinhibition and binging (Polivy and Herman 1985). Given the lack of studies on the possibility of improving the ability of patients affected by BN to evaluate their food intake, further researches on this topic are needed.

Table 80.2 Key features of cognitive distortion regarding food intake among bulimic patients

- It is perceived as overeating, despite its caloric value.
- It can trigger a binge episode despite its caloric value.
- Most episodes they evaluate as binge eating contain *forbidden foods*.
- When they eat *forbidden foods* they have perceptual distortions of their own body image.

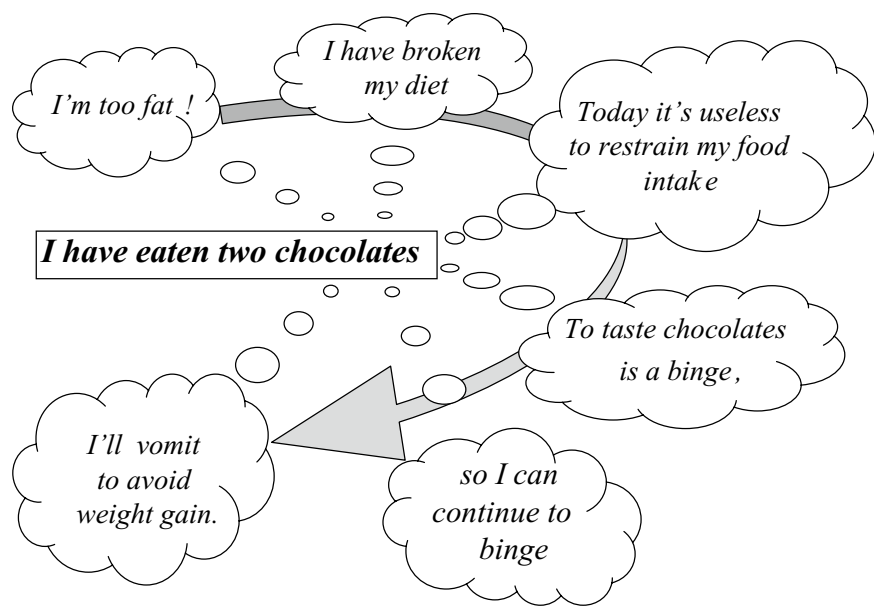
This table shows the effect of eating a *forbidden food* on patients affected by Bulimia Nervosa and its relationship with their eating behavior


Fig. 80.2 Cognitive and behavioral consequences of the intake of a *forbidden food*. The picture shows the worry induced by *forbidden food* intake in a patient affected by Bulimia Nervosa. Cognitive biases regarding their own body image, the amount of eaten food, and the consequences of its intake frequently induce the patients to overeat and to vomit

80.4 Probably I Didn't Eat So Much. Visual Evaluation of Food in Patients Affected by Binge Eating Disorder

Patients affected by Binge Eating Disorder (BED) frequently fail in evaluating the quantity of food when introducing large quantities of food in a short time, but it is not yet clear whether this is due to either a perceptive or a cognitive bias. Greeno et al. (1999) tested whether BED patients have an altered perception of food. They asked obese women either affected or not by BED to report their *typical* and *largest-ever* portions of foods. Moreover, they had to report the minimum amount of each of eight foods they considered a binge. Neither evidence of cognitive distortions among BED patients, nor significant differences between the groups have been found. However, binge eaters reported that their *typical* and *largest-ever* portions of foods were larger in a very significant way, confirming the need for focus on the global eating behaviors of these patients even in the absence of perceptual distortions.

80.5 Eyes Are Bigger Than Stomach. Perceptive and Social Factors Influencing Evaluation of Food Amount in the General Population

The difficulty in evaluating the amount of a presented food is not a peculiar characteristic of eating disordered patients. Normal-weight subjects' ability to describe an amount of food they have just chosen, without the aid of measuring devices, is poor (Guthrie 1984) and both overweight and normal-weight subjects fail in estimating food portions (Blake et al. 1989). Many perceptive biases explain these results. It has been highlighted by Ginsburg in studies on general population since 1978 that the arrangement of the stimuli influences the evaluation of their amount. Using circular lighting dots he found that regularly arranged stimuli are overestimated while those randomly disposed are underestimated; these results have been confirmed using stimuli of different shapes (Ginsburg 1980). Usually food is randomly disposed into the dish so it gets underestimated. The area collectively occupied by dots also provides a basis for judging their numerousness: the larger the occupancy pattern, the higher the number estimated (Allik and Tuulmets 1991). Moreover, item size influences the evaluation: there is an inverse relation between item dimension and estimation of numerousness (Ginsburg and Nicholls 1988). In addition, form and energy density of food may affect its assessment; people have more difficulties in estimating the correct serving size for amorphous foods (e.g., apple sauce) compared to solid foods (Yuhas et al. 1989; Ayala 2006) (Table 80.3).

In a recent study our research group (Vinai et al. 2008) investigated the influence of socioeconomic factors and food palatability on food amount evaluation among children. We tested 94 ten- to fifteen-year old children living in Mali in western Africa, and 124 subjects comparable in age and gender in northern Italy. They were asked to evaluate an amount of palatable candies. Both Italian and Malian children significantly underestimated them. This characteristic could represent a protective factor against food shortage, but in regions with food abundance it could play a role in the onset and maintenance of an obesity epidemic (Fig. 80.3).

Subsequently we asked the same subjects to evaluate an amount of altered food (toffees dyed with ink and ammonia so as not to be palatable), and found a significant difference between the groups. African children do not underestimate the number of toffees presented to them while Italian children continued to underestimate them as palatable ones.

Food amount evaluation seems to be asymmetrically regulated. Food shortage influences the evaluation of nonedible food but current food abundance has no effect on the evaluation of palatable food. There is no downregulation caused by food abundance in evaluating the amount of tasty food. We can hypothesize that the few generations in which there has been food abundance in Italy are not enough to modify the tendency to underestimate a palatable food; a characteristic developed over centuries of shortage, while they are enough to reduce the emotional impact of seeing wasted food (Fig. 80.4).

Table 80.3 Factors inducing perceptive biases in food amount evaluation among general population

- Disposition (randomly/regularly)
- Dimensions
- Area occupied
- Form (solid/amorphous)
- Energy density
- Food disposability

When food is randomly disposed it is frequently underestimated, such as when it is cut in small pieces, or when occupies a small area. Subjects fail more frequently in evaluation of the amount of amorphous food and of aliments with a high energy density

Fig. 80.3 Evaluation of the number of tasty candies in different cultural contexts. Children living in different cultural contexts (Mali in Africa/Italy in Europe) with different food availability share a tendency to underestimate the number of tasty candies presented
Fig. 80.4 Evaluation of the number of not edible candies in different cultural contexts. There are significant differences in evaluating an amount of altered, so no longer edible, candies between children living in different cultural contexts with different food availability. The 90% of the children living in Italy underestimate the number of candies. Only the 47% of the children living in Mali in Western Africa underestimate them
Summarizing cognitive and perceptive biases influence food amount evaluation among the general population inducing underestimation of food amount. In a context of food abundance they can represent a risk factor for overeating.

80.6 Applications to Other Areas of Health and Disease, Improving Food Amount Evaluation to Deal with an Obesity Epidemic

It is a common experience among people living in Europe to be surprised by the size of the portions as they enter a restaurant in the USA. The repeated exposure to extra-large portion sizes could have fostered the normalization of a high-energy intake. What was seen as an enormous portion 25 years ago may have down-sized to an 'average-sized' portion in the eyes of today's consumers (Dohm et al. 2005).

Table 80.4 Factors influencing food amount estimation among obese subjects

- Sensitivity to reward
- Large portions size
- Body Mass Index
- Preference for fatty foods
- Underestimation of portion size

Among factors influencing the food amount evaluation of obese subjects, the tendency to consider enormous amounts of food as normal, and the high caloric concentration of food seem to play a pre-eminent role

Mistakes in evaluating food intake have been reported by the Special Supplemental Food Program for Women, Infants, and Children (Webb and Yuhas 1988) and by several research programs focusing on obese subjects affected by type II diabetes (Rapp et al. 1986) or currently dieting (Howat et al. 1994). Obese persons generally under-report food intake and fail in estimating food quantity and calories more than normal-weight subjects do (Bandini et al. 1990); such mistakes are a barrier to the control of food intake (Davis et al. 2007). The largest miscalculation in reported caloric intake seems to be due to errors in portion-size estimation (Beasley et al. 2005), but it is still an open question whether obese patients actually have a perceptive bias needing specific training to accurately self-report their food intake during a weight loss program (Lansky and Brownell 1982), or intentionally under-report their food intake for social desirability reasons (Muhlheim et al. 1998). Moreover, they make great mistakes in converting food quantity to actual caloric values; indeed foods with the highest caloric density had the highest error level (Lansky and Brownell 1982).

Among obese women (Davis et al. 2007) an interesting interaction between obesity and *sensitivity to reward* on food amount ratings was found: high reward sensitivity was associated with the underestimation of food amounts. The authors hypothesize that a subject highly attuned to the rewarding properties of food will tend to have a biased perception of food amounts. In other words, larger portion sizes may be judged more *normal* by those who are easily rewarded in comparison to subjects with a more nonhedonic reaction to food. They also found that women with a strong preference for high-fat foods were more likely to underestimate the size of portions.

Reward sensitivity is positively associated with BMI and predisposes individuals to overeating (Loxton and Dawe 2001; Davis et al. 2004). Subjects' BMI seems to be a strong predictor of larger than recommended amounts of food. Individuals with a higher BMI may view a larger portion as *typical* and thus eat significantly larger portions of food (Burger et al. 2007). A strong preference for high-fat foods predisposes subjects to choose fast-food restaurants where portion sizes are typically larger than meals cooked at home (Briefel and Johnson 2004). Moreover, larger portion sizes tend to be underestimated more than smaller ones (Harnack et al. 2004) (Table 80.4).

The knowledge regarding food amount evaluation can be used in assessments of meal size and caloric intake of obese subjects and to develop psycho-educational programs to heighten awareness about correct portion sizes and to teach strategies for improving abilities to estimate food amounts (Davis et al. 2007) (Fig. 80.5).

80.7 Instruments to Improve Ability in Food Amount Evaluation Among Adults

Food diaries are widely used for dietary survey. One of the main problems of their use is to establish the size of consumed portions and the caloric value of food. Since 1984, Marilyn and Zegman found that 68% of a sample of 43 obese female subjects failed in evaluating calories using the *Handbook 456*, a
Fig. 80.5 Perceptive and cognitive biases in the evaluation of food amount. The graph reports the number of studies regarding food amount evaluation found in *Medline*® and their results. In the graph, the studies evaluating perceptive and cognitive biases are reported among patients affected by eating disorders, obesity, and normal-weight subjects. Several studies found perceptive deficits in the general population. Very few studies focus on food amount evaluation in BED and AN patients. Cognitive biases seem to play a primary role among patients affected by BN

small text showing caloric value of commonly used aliments. In the same year Guthrie (1984) suggested the use of tools to help patients in assessment of portion sizes. Given the importance of food amount evaluation in the assessment and therapy of ED and overweight patients, an objective measure that presents standard stimuli to assess an individual's judgment of food amounts is needed (Table 80.5).

Many instruments have been developed to improve subjects' ability in evaluating their own food intake. *Portion Size Measurement Aids* (PSMA) include two dimensional models: drawings of real foods, abstract shapes, household measures, food photographs, computer graphics, and package labels; and three-dimensional tools such as household measures, real samples, and models of food. Kircaldy et al. (1989) did not find any significant difference by comparing the accuracy of portion size estimates obtained with four different PSMA: color pictures of foods, abstract shapes, black and white drawings, preweighted amount of food. Their results were subsequently confirmed (Posner et al. 1992) comparing the effect of two-dimensional and three-dimensional models on evaluation. PSMA have been used separately and together but the validity of this tool is not yet clear (Cypei et al. 1997; Matheson et al. 2002).

The most common dietary assessment tool used in large epidemiologic studies of diet and health are the *Food Frequency Questionnaires* (FFQ); self-administered booklets asking participants to report the frequency of consumption and portion size of many foods over a period of time (Willet 2002). They contain sets of pictures of different portion sizes of foods. Each line item is defined by a series of foods or beverages (Table 80.6).

Table 80.5 Instruments to improve ability in food amount evaluation among adults

- Portion Size Measurement Aids (PSMA)
- Food Frequency Questionnaires (FFQ)
- Adjustable Wedge
- Food Portion Photograph Book (FPPB)
- Food Amount Rating Scale (FARS)
- Interactive Portion Size Assessment System (IPSAS)

Several instruments have been developed to improve subjects' ability in evaluating their food intake; among them photographs of food and a food amount rating scale seem to be the most effective. Among children, IPSAS and food photograph books adapted for children seem to be more effective than the instruments used for adults

Table 80.6 Key features of Food Frequency Questionnaires (FFQ)

FFQs ask participants to report the frequency of consumption and portion size of a series of foods and beverages (usually 100–150 items) over a defined period of time, e.g., the last month. Several questions on food preparation methods enable the researchers to further refine nutrient calculations. Food composition tables listing the average nutrient content of listed foods have been developed to estimate nutrient intake from SFFQ.

Food Frequency Questionnaires (FFQ) are self-administered booklets, commonly used in epidemiologic studies, developed with the purpose of obtaining a measure of usual diet

Kuehneman (1994) found no difference in the accuracy of food amount evaluation between subjects using PSMA and FFQ.

An *Adjustable Wedge* (AW) was proposed to assess wedge-shaped foods (e.g, pie, cake, and pizza) and tested by Godwin in 2006, among 320 subjects of both sexes, ranging from 18 to 65 years, using multiple sizes and types of wedge-shaped foods. The evaluation made with the AW was more accurate ($P < 0.05$) than the ruler in approximately one third of comparisons, but regardless of the aid used, some people have difficulty in estimating portions of wedge-shaped foods.

Photographs of food are useful instruments which are also widely used among people of different cultures, but despite the apparent simplicity of these tools, three skills are involved in their use: perception, memory, and cognitive functions. The subject has to be able to perceive the amount of eaten food, to remember it, to make a mental construction of an amount which is not currently present, and to relate it to the photograph. Any impairment in each of these skills can reduce the efficacy of the instruments. Regarding their efficacy, Nelson et al. (1994) found that photographs of small portions of food are overestimated while large ones are underestimated.

To assess individuals' estimation of food amounts Dohm and Striegel-Moore (2002) developed the *Food Amount Rating Scale* (FARS). It asks the subjects to rate 24 different portions of food described in the questionnaire (e.g., 1 bowl spaghetti, ½ cup tomato sauce, 1 bowl tossed green salad, 1/8 cup salad dressing, 2 pieces garlic bread) by checking via five definitions: *small amount, moderate amount, large amount, enormous amount, beyond enormous*, the definition which best describes each portion.

80.8 Food Amount Evaluation Among Children

Children also fail in estimating food amount and portion size and several research programmes tested the efficacy of the above described tools to improve their food amount evaluation. Matheson et al. (2002) evaluated errors associated with children's portion size estimates by means of 2 food portion measurement aids: the standard 2-dimensional food portion visuals and manipulative props.

Errors in quantitative estimates of gram weight of foods and energy intakes were large with both methods. Frobisher and Maxwell (2003) compared the ability of adults and children in evaluating portion size using food photographs and descriptions of portions. Forty-seven adults and 37 children were asked to describe a portion of nine food items using the terms small, medium, and large and to choose the photo in a photographic food atlas which best represented the portion size they had just served themselves. All subjects were asked to recall their food intake 3–4 days after the meal. There were very few differences in the estimation of portion sizes between the two testing periods but among children there was greater error than among adults. Children overestimate portions probably because they usually have smaller portion sizes than those depicted in the smallest portion size photograph in the food atlas. The findings suggested that for young subjects it was necessary to modify the tools for estimating portion sizes. Lillegaard et al. (2005) researching whether age influences the ability to estimate food portion sizes by viewing photographs of food did not find any age-related difference, but portion size was estimated more accurately when the actual served portion of food had exactly the same appearance as the foods on the photograph booklet. Foster et al. (2006) found that children's estimates of portion sizes were significantly more accurate (an underestimate of 1% on average) using age-appropriate food photographs than photographs designed for use with adults (an overestimate of 45% on average). Accuracy of children's estimates of portion size using age-appropriate tools was similar to that of adults; children overestimated a food weight by 18% on average and adults underestimated by 5%. In conclusion, providing children with food photographs depicting age-appropriate portion sizes greatly increases the accuracy of portion size estimates compared with estimates using photographs designed for use with adults.

New technologies have recently been used to help children's evaluation of the quantity of food. The *Interactive Portion Size Assessment System* (IPSAS) is a computer-based system to allow the child or interviewer to scroll through images of food depicting increasing portion size. These images are photographs of real foods that are used to indicate the portion served and any food left over. The system automatically records the portion size selected and stores this and related data, including the subjects' details. This data can easily be exported to a database or statistical software. Foster et al. (2008, 2009) assessed the accuracy of children's estimates of portion size using food photographs, food models, and the IPSAS. Significant differences were found between the accuracy of estimates using the three tools. Children of all ages performed better using the IPSAS and food photographs than when using food models. The authors suggest that IPSAS has potential for the assessment of dietary intake with children. Before its practical application it needs to be expanded to cover a wider range of foods and to be validated in a "real-life" situation. In conclusion, color food photography and the atlas seem to be useful tools for quantifying food portion size but new instruments are needed to improve food amount evaluation among children.

80.9   Transcultural Studies

Several studies assessed the utility of PSMA in different cultural contexts. Venter et al. (2000) developed the *Food Portion Photograph Book* (FPPB) in Southern Africa. Commonly eaten foods, preparation methods, recipes, and portion sizes were collected in a pilot study; then color photographs taken of foods prepared by the researchers and measured into three or four portion sizes were put together in the FPPB. One hundred and sixty-nine adult African volunteers were tested by presenting them with a portion of real food and asking them to estimate its size by matching it with one of the photographs. Of 2,959 portions tested, 68% were accurately estimated. The estimation was not affected by gender, age, or education of the participants.

In Italy, Turconi et al. (2005) developed a *color photographs food atlas* by weighing and taking digital photographs of three portion sizes of 434 foods and beverages typical of the Italian diet. They tested 448 volunteers ranging from 6 to 60 years old from a wide variety of social backgrounds, assessing 9,075 food portions eaten at lunch and dinner in relation to a set of color food photographs during 8 weeks of investigation. The results show that weights of portion sizes chosen from the set of photographs are significantly associated to weights of eaten portions and are regardless of age, gender, and BMI.

Huybregts et al. (2008) assessed the utility of photography in food recall after 24 h among women of Burkina Faso. Each photo album contains four photos for each item. Subjects were shown two previously weighed foods every morning, and another in the afternoon. The day after, the subjects were shown the pictures and had to choose the representative food of the day before. The use of images was effective for the estimation of food.

80.10 Conclusion

In conclusion, our findings suggest that assessment of what constitutes a binge or overeating, and judgment of food amounts in general, may be influenced by an individual's gender, ethnicity, dietary restraint status, level of depressive symptomatology, and current weight (Fig. 80.6).
Fig. 80.6 Errors in food amount evaluation. The graph reports the number of studies regarding food amount evaluation found in *Medline*® and their results. There is a tendency to underestimate food amounts among the general population, obese subjects, and patients affected by BED. The studies involving bulimic subjects found an overestimation of food amount and the few researches regarding AN patients had controversial results

Researchers studying issues related to dietary intake (e.g., obesity) or disordered eating (e.g., binge eating) need to account and check for the possible confounding effects of these characteristics on self-reports of food intake. Furthermore, using this information to educate study participants and treatment clients about how their perceptions may be biased could improve future food reporting (Dohm et al. 2005). Future investigations should include an income measure to account for the effects of socioeconomic status on portion-size estimation. In addition, we suggest that interventions for preventing weight gain in young adults should focus on the importance of portion sizes for all foods, regardless of macronutrient content, and on increasing the awareness of eating habits in response to media messages and product packaging (Burger et al. 2007). It is noteworthy that training improves ability in estimating food. Yuhas et al. (1989) tested two groups of students in a nutrition course, dividing them into two groups: only one group (76 subjects) received training on estimating food quantities. The training consisted of 10-min sessions in which subjects passed around and viewed food models labeled with their portion sizes while one of the researchers verbally indicated the quantities. There were two solid foods (meat loaf and fish), two liquids (milk and soup), and two amorphous items (spaghetti and apple sauce). Immediately after, subjects individually estimated portion sizes of one food on a display. The second group of subjects, who had received no training, also estimated the same foods on the same displays. Training improved estimations and women tended to estimate more accurately than men. These results suggest the importance of using specific training in order for ED and obese subjects to evaluate their food intake better.

Summary Points

- Perceptive and cognitive biases influence food amount evaluation in the general population and among patients with eating disorders.
- The general population tends to underestimate food amounts.
- Patients affected by Anorexia Nervosa are not affected by perceptive deficit – it is cognitive and emotional factors which influence their evaluation of food amount.
- distortion of what is a normal meal represents a central cognitive mechanism of Bulimia Nervosa.
- Bulimic patients over-rate the amount of food presented to them; this can induce a more restrictive diet, a risk factor for the onset of bulimic behavior.
- Consumption of small amounts of *forbidden food* may lead bulimic patients to perceive their consumption as a binge.
- The perception of having overeaten rather than actual overeating leads to binging in BN.
- No evidence of perceptive distortion among BED patients has been found.
- It is possible to improve the subjects' ability in evaluating food amount.
- Food photographs are useful tools to train subjects in estimating their food intake.

Key Terms

Anorexia nervosa: An eating disorder characterized by markedly reduced weight and aversion to food.

Binge eating disorder: An eating disorder characterized by episodes of over-eating with a sensation of loss of control, not followed by purging behaviors.

Body mass index (BMI): An index for relating a subject's body weight to his/her height. It represents the subject's weight in kilograms divided by his/her height in meters squared.

Bulimia nervosa: An eating disorder characterized by episodes of binge-eating followed by purging behaviors, such as self-induced vomiting, abuse of laxatives or diuretics, or excessive physical exercise.

Cognitive biases: The tendency to make errors in judgment based on the processing of information, applying knowledge and changing preferences; it includes errors in statistical judgment, social attribution, and memory.

Downregulation of food: The process by which a subject underestimates a food amount in response to an external variable such as food abundance.

Food amount rating scale (FARS): A multiple choice questionnaire which asks for a rating by checking as: small, moderate, large, enormous, and beyond enormous – the amount of 24 different portions of food described in it.

Food frequency questionnaires (FFQ): Booklets asking participants to report the frequency of consumption and portion size of many foods over a period of time.

Malian: People living in Mali in Western Africa.

Perceptive biases: Mistakes in evaluation due to a sensorial deficit.

Portion size measurement aids (PSMA): Tools useful for improving accuracy in food amount evaluation. They include household measures, drawings, abstract shapes, photographs, package labels, real samples, and models of food.

Stroop interference: When a word such as green, red, blue etc. is printed in a color differing from the color expressed by the word's semantic value (e.g. the word *green* printed in red ink), naming the color of the word takes longer and is more prone to errors than when the meaning of the word is congruent with its ink color. Patients affected by Anorexia Nervosa show interference on the Stroop color naming task for food.

Type II diabetes: An illness characterized by high blood glucose due to the inability of body cells to respond appropriately to insulin, a hormone produced by the pancreas to reduce blood glucose levels. It is distinguished from type I diabetes due to reduced production of insulin by the pancreas.

81.1 Introduction

The act of dieting involves the deliberate restriction of food intake in an attempt to achieve weight loss. Although moderate weight reduction in obese individuals can have clear health benefits, such as reduced risk of cardiovascular disease and increased aerobic and anaerobic aptitudes, the actual practice of weight-loss dieting is associated with a number of negative outcomes. For example, people who are on a diet often also exhibit mood swings, depression, lowered self-esteem and impaired cognition. Another unintended negative consequence of weight-loss dieting is the experience of unwanted food cravings. In fact, recurrent food cravings have the potential to disrupt and thwart dieting attempts. This highlights the need for effective techniques for reducing food cravings. However, contemporary intervention tools involving either suppression of craving-related thoughts or unreinforced exposure to food cues have shown only mixed success. This chapter describes a radically different approach to controlling food cravings based on converging evidence that mental imagery is a key component of the craving experience. Empirical data, which show that interfering with the cognitive processes that support craving-related mental images can suppress food cravings in dieters, are reviewed.

81.2 Food Cravings

The term "craving" refers to a motivational state whereby an individual feels compelled to seek and ingest a particular substance, usually cigarettes, alcohol or drugs (Baker et al. 1986). More recently, however, interest has fallen on *food* cravings. These have been described as an intense desire or urge to

e-mail: Eva.Kemps@flinders.edu.au

eat a specific food (Weingarten and Elston 1990). Food cravings are not to be equated with hunger, for they generally occur in the absence of hunger (Cornell et al. 1989). Hunger signals a physiological need to eat, which can be satisfied with any food. Cravings, however, are for a particular food, and can only be satisfied by eating that food. For example, one craves chocolate ice-cream, rather than something generically sweet. In particular, there is no substitute for chocolate when it is craved; other sweet foods, including white 'chocolate', cannot fully satisfy chocolate cravings (Michener and Rozin 1994).

Food cravings are a common and everyday experience (Lafay et al. 2001), with prevalence rates varying according to gender and age. Women tend to crave more than men (Weingarten and Elston 1991), and younger people crave more than older people (Pelchat 1997). Not surprisingly, there exist marked cross-cultural differences in the kind of foods craved (Hawks et al. 2003). For example, chocolate is the most commonly craved food in Western societies (Hetherington and Macdiarmid 1993), followed by chips, pizza, cake, and ice-cream. In Egypt, on the other hand, the most craved foods are vegetable dishes, some stuffed or cooked with meat (Parker et al. 2003).

The origin of food cravings has been attributed to a range of physiological and psychological factors. At a physiological level, food cravings have been linked to nutritional deficiencies (Wardle 1987), and in women to hormonal changes, such as menstrual-related changes (Dye et al. 1995) and pregnancy (Dickens and Trethowan 1971). At a psychological level, food cravings can be triggered by negative mood states, including feelings of boredom, loneliness, depression, anxiety, as well as stress (Hill et al. 1991). Food cravings can also by elicited by exposure to environmental cues, such as the sight or smell of tasty food (Fedoroff et al. 2003).

81.3 Food Cravings and Weight-Loss Dieting

Although food cravings are not invariably linked to dietary restraint, weight-loss dieting has been associated with an increased occurrence of cravings (Hetherington and Macdiarmid 1993; Pelchat 1997). Food cravings are thought to be part of the preoccupying cognitions concerning food, weight and body shape that accompany dieting behaviour (Green 2001). These dieting-related cravings can give rise to a range of negative consequences. In particular, food cravings have been implicated in the early dropout from weight-loss programs. For example, Sitton (1991) reported that attrition rates were almost three times higher for carbohydrate cravers than for non-cravers during the first month of a prescribed diet. Cravings for food can also lead to feelings of guilt and shame following consumption if dietary restriction fails (MacDiarmid and Hetherington 1995).

Importantly, dieting-related cravings are known to adversely affect cognitive processing. For example, dieters exhibit biased attentional processing of food and body shape words on the modified Stroop task (Green and Rogers 1993). Additionally, experimentally induced food cravings have been shown to slow responses on a simple reaction time task in highly restrained eaters and dieters (Green et al. 2000). This finding has important implications in that speeded responding to a visual probe (as in a reaction time task) is vital in vigilance tasks, such as inspecting items on an industrial production line, or manoeuvring through dense traffic. Slowed reaction times arising from food cravings could compromise performance of such everyday tasks, thereby reducing work efficiency or increasing accidents.

Finally, cravings triggered by chronic dietary restriction have been identified as a precursor to binge eating, particularly in the context of obesity (Schlundt et al. 1993) and eating disorders, such as bulimia nervosa (Mitchell et al. 1985). Obesity and eating disorders are themselves risk factors for the development of other serious medical and psychological problems, such as cardiovascular disease, Type 2 diabetes, depression and low self-esteem.

The incidence of such dieting-related food cravings is likely to be on the rise, fuelled by a continuing increase in obesity rates (Wadden et al. 2002) and body image concerns (Cash and Pruzinsky 2002). The advent of public health campaigns targeting the health risks associated with being overweight is intended to result in more people trying to lose weight. In parallel, the continual and pervasive presentation by the media of the thin ideal for women and the lean but muscular ideal for men can only serve to increase rates of body dissatisfaction, which many individuals attempt to resolve by dieting in an attempt to more closely approach the elusive societal ideal. As more people adopt food restriction (dieting) as the means for attempting weight loss in response to these messages, there will be a concomitant increase in accompanying levels of food craving. Thus the availability of a technique for curbing dieting-related food cravings is of considerable practical importance.

81.4 Reduction of Food Cravings

81.4.1 Thought Suppression and Cue Exposure Response Prevention

The techniques currently available for reducing food cravings involve either suppression of dieting-related thoughts or cue exposure response prevention. The rationale behind thought suppression is that people can avoid performing an unwanted behaviour by deliberately not thinking about it. Harnden et al. (1997) used this paradigm to investigate the effect of thought suppression on weight-related preoccupations in dieters. They instructed female dieters and non-dieters to either suppress or express thoughts about weighing themselves and to subsequently verbalise all thoughts that came to mind during a 5-min period. Although dieters mentioned more weight-related thoughts overall than did non-dieters, suppression reduced the frequency of such thoughts in both groups. The magnitude of suppression was, however, less for dieters than for non-dieters. Oliver and Huon (2001) further showed that women who reported high levels of disinhibited eating were more successful at suppressing thoughts about food and eating than were women low on disinhibition. However, high disinhibitors were more likely to use punishment and worry strategies to control their thoughts. These thought control strategies were themselves related to feelings of anxiety and distress (Table 81.1).

Table 81.1 Schematic representation of the craving reduction techniques of thought suppression and cue exposure response prevention

Thought suppression	Cue exposure response prevention
Period 1: Thought monitoring	Exposure *1* to craved food while resisting consumption, followed by a rating of food craving
Participants are instructed to think about anything they like, and to press a button if they think about the craved food	
Period 2: Thought suppression	Exposure *2* to craved food while resisting consumption, followed by a rating of food craving…
Participants are instructed to *not* think about the craved food, and to press a button if they do	
Period 3: Thought monitoring	Exposure *n* to craved food while resisting consumption, followed by a rating of food craving
Participants are again instructed to think about anything they like, and to press a button if they think about the craved food	

This table presents a step-by-step overview of the techniques of thought suppression and cue exposure response prevention as applied to the reduction of food cravings

Table 81.2 Mean pre- and post-imagery task food craving levels as a function of imagery task and dieting status (standard deviations in parentheses)

	Dieters		Non-dieters	
Imagery task	Pre	Post	Pre	Post
Visual	71.93 (24.11)	38.80 (26.32)	45.13 (29.95)	29.31 (25.02)
Auditory	49.40 (35.79)	35.96 (36.83)	28.93 (26.08)	21.11 (20.22)

This table shows that the visual imagery task reduced participants' level of food craving more than did the auditory imagery task, particularly for dieters. Craving was rated on a 100-point scale ranging from "no desire or urge to eat" to "extremely strong desire or urge to eat"

More generally, suppression of unwanted thoughts about food, eating or weight can paradoxically lead to an increase in such thoughts. For example, Johnston et al. (1999) showed that participants who had been instructed to suppress chocolate-related thoughts made fewer mentions of chocolate during a 5-min articulated thoughts task that involved planning a dessert menu for a dinner party than participants who had received no such instruction. However, those participants who engaged in thought suppression actually worked harder (performed better) on a subsequent task that yielded chocolate awards, indicating an *increase* in drive for chocolate. Although such a rebound effect is not necessarily always seen, ironic effects of thought suppression have been documented in a number of other areas, such as mood control, stereotyping and traumatic memories (Abramowitz et al. 2001). Furthermore, an increased occurrence of unwanted thoughts following attempts at suppression can itself lead to perceived loss of control over one's thoughts, and thereby give rise to feelings of failure and distress (Kelly and Khan 1994).

The second currently available technique, cue exposure response prevention, involves successive exposures to an appetitive target (food), with instructions to attempt to resist consumption. The elicited craving is expected to diminish across exposures because the appetitive cue is not reinforced by consumption. Tuomisto et al. (cited in Hetherington 2001) used this paradigm in an attempt to reduce food cravings in obese women. Following a baseline measurement of craving, the women were presented with warm pizza. They were asked to look at, smell and imagine eating the pizza, but not to eat it. Ratings of food craving were taken every 10 min. Although cravings decreased somewhat across exposures, they remained high compared to baseline. At a general level, cue exposure response prevention has been used with mixed success in the treatment of alcoholism (Conklin and Tiffany 2002), phobias and binge eating in patients with bulimia nervosa (Jansen 2001).

Thus, neither thought suppression nor cue exposure response prevention holds much promise as a technique for reliably reducing dieting-related food cravings. We reasoned that in order to develop a different (and potentially more successful) kind of craving-reduction technique, we first need to gain insight into the nature of the actual craving experience (Table 81.2).

81.4.2 The Nature of Food Cravings: A Role for Mental Imagery

There is accumulating evidence from a number of different sources pointing to a role for mental imagery in craving episodes. First, anecdotal accounts describe the experience of desire-related images in naturally occurring cravings (Salkovskis and Reynolds 1994). These accounts have now been corroborated by more formal surveys about everyday food cravings that show that respondents readily use imagery terms to describe their cravings. For example, Tiggemann and Kemps (2005) reported that 30% of their undergraduate student sample used phrases such as 'I could picture the pizza in my mind, picture eating it' when asked to write a short paragraph describing a previous food craving episode. In addition, when presented with a list of descriptive statements, respondents

strongly endorse imagery-based descriptors as characteristic of their cravings. Imagery descriptors in the visual modality (e.g. 'I am visualising it') in particular are rated highly; in contrast, auditory descriptors (e.g. 'I imagine the sound of myself having it') are not highly rated. Furthermore, when asked to assign specific percentages to each of the five sensory modalities involved in an imagined food craving experience, as shown in Fig. 81.1, the visual modality was the highest. These findings indicate that the imagery basis of food cravings is predominantly visual in nature (Table 81.3).

Second, instructing participants to imagine urge-related scenarios can induce cravings in the laboratory. For example, using a methodology derived from cigarette craving research, Green et al. (2000) reported a positive correlation between latency on a simple reaction time task following instructions to imagine a food scenario ('Imagine you are eating your favourite food') and self-reported desire to eat. Harvey et al. (2005) subsequently showed that craving levels increased following instructions to imagine a food scenario, but not a nonfood scenario. They also noted a positive correlation between participants' self-reported vividness of the image of the food scenario and their level of craving, indicating that stronger food cravings are associated with more vivid images.

Finally, a recent theoretical account of cravings, the elaborated intrusion theory of desire, proposes that sensory images are a central feature of any craving experience (Kavanagh et al. 2005).

Table 81.3 Key facts of food cravings

1. A food craving is an intense desire or urge to eat a *specific* food
2. The most commonly craved food in Western society is chocolate, followed by chips, pizza, cake and ice cream
3. Food cravings are a common, everyday experience, particularly in women and younger adults
4. Food cravings generally occur in the absence of hunger; they are instead triggered by hormonal changes, negative mood states and exposure to environmental food cues
5. Food cravings have been associated with a number of negative outcomes (particularly in weight-loss dieters), such as early dropout from weight-loss programs, feelings of guilt and shame, poor cognitive task performance and binge eating
6. Mental imagery is a key component of food cravings; specifically, when people crave they have vivid images of the craved food

This table lists the key characteristics of food cravings, including the various causes of food cravings, the potential consequences of food cravings, and the role of mental imagery in the experience of food cravings

Fig. 81.1 Mean percentages of sensory modalities involved in craving-related food images. This figure shows the relative involvement of each of the five sensory modalities in craving-related images of food. These are in order: visual (sight), gustatory (taste), olfactory (smell), tactile (touch) and auditory (hearing)
81.4.3 A Working Memory Approach to Reducing Food Cravings

In recent years, cognitive psychologists have adopted a working memory approach to conceptualise the phenomenological experience of mental imagery (Richardson 1999). A widely used and successful account of working memory is that originally proposed by Baddeley and Hitch (1974). The working memory model has undergone revision and elaboration over time but in its current version comprises an overarching central executive responsible for coordinating the activities of a number of modality-specific slave systems and an episodic buffer, a multimodal interface with long-term memory (Baddeley 2000).

The two initially proposed slave systems, which have attracted the most research attention, are the visuo-spatial sketch pad and the phonological loop. The visuo-spatial sketch pad maintains visual and spatial material and is involved in visual imagery. The phonological loop analogously maintains verbal material and is involved in auditory imagery. These slave systems are argued to have limited capacity. Thus a concurrent visual (or verbal) task will interfere with the content of the visuo-spatial sketch pad (phonological loop) by competing for the limited visual (verbal) storage capacity. In support, Baddeley and Andrade (2000) employed dual-task methodology to show that the vividness of visual imagery was reduced by tasks that selectively loaded the visuo-spatial sketch pad, whereas the vividness of auditory imagery was reduced by tasks that specifically utilised the phonological loop.

Inspired by recent developments in cigarette-craving research (Panabokke 2004), we (Harvey et al. 2005) applied this analysis to investigate whether interference from a competing task that requires the same working memory resources as those used to create and maintain craving-related images could suppress food cravings in dieters. As questionnaire data on the subjective experience of cravings have shown that craving-related food images involve visual rather than auditory content, we predicted that a competing visual task (loading the visuo-spatial sketch pad) would reduce food cravings relative to a comparable auditory task (loading the phonological loop). In our study, undergraduate women (self-identified dieters and non-dieters) underwent an imaginal food craving induction procedure and subsequently rated their level of craving. They were then cued to vividly imagine a series of nonfood items. A random half of each group formed visual images of common objects and scenes (e.g. a rainbow), whereas the other half formed auditory images of everyday sounds (e.g. a siren). Following the imagery task, all participants again rated their level of food craving. As predicted, the visual imagery task was superior to the auditory task in reducing the women's food cravings. Moreover, as can be seen in Table 18.2, dieters reported stronger cravings overall, and the magnitude of craving reduction was greater for them than for non-dieters. Thus visual imagery techniques offer potential scope for reducing dieting-related food cravings.

While forming a series of visual images and holding them in mind constitutes an excellent laboratory technique for investigating cravings, it is not only an elaborate, but also a cognitively effortful, procedure and therefore unlikely to be an effective craving reduction technique in a practical sense. Instead, we need to find a simple and relatively undemanding visual task. Fortunately, the working memory literature boasts several simple tasks known to load the visuo-spatial sketch pad. These include saccadic eye movements (visually tracking a rapidly moving stimulus; Idzikowski et al., cited in Baddeley 1986), dynamic visual noise (watching a flickering pattern of random black and white dots, similar to snow on an untuned television screen; Quinn and McConnell 1996) and spatial tapping (tapping four keys arranged in a square pattern; Farmer et al. 1986).

To investigate the craving reduction capacity of such simple repetitive tasks, we (Kemps et al. 2004) adopted a paradigm derived from experimental analogues of post-traumatic stress disorder (Table 81.4). These have shown that concurrent visual processing in the form of simple eye or arm movements, or watching a flickering pattern of random black and white dots, reduced the vividness and consequent emotional impact of distressing images (Andrade et al. 1997; Kavanagh et al. 2001). Accordingly, in view of the association between imagery vividness and food craving intensity,

Table 81.4 Key features of visual working memory based craving reduction

1. The visual component of working memory (i.e. visuo-spatial sketch pad) is involved in the generation and maintenance of visual images
2. Food cravings involve primarily images in the visual sensory modality
3. In working memory terms, food cravings engage the visuo-spatial sketch pad
4. The visuo-spatial sketch pad has limited storage capacity
5. Loading the visuo-spatial sketch pad with a concurrent task when experiencing a food craving reduces the intensity of the craving, because the task and the visual imagery associated with the craving compete for the same limited storage capacity
6. The intensity of a food craving is related to the vividness with which the craved food is imagined, such that stronger food cravings are associated with more vivid images of the craved food
7. Concurrent visual processing has its specific craving reducing effect by diminishing the vividness of craving-related food images

This table outlines the theoretical rationale behind the utility of visual working memory-based techniques for reducing food cravings, with emphasis on the visual imagery basis of food cravings, the mutual competition between food cravings and concurrent visual tasks for limited visuo-spatial sketch pad storage capacity, and the relationship between imagery vividness and craving intensity
Fig. 81.2 Mean imagery vividness and food craving levels (with standard errors) for dieters and non-dieters in each of the concurrent task conditions. This figure shows that the concurrent visual tasks of eye movements, dynamic visual noise and spatial tapping made food images less vivid and food cravings less intense for both dieters and non-dieters. Imagery vividness and craving were rated on a 100-point scale ranging from "no image at all" to "image perfectly clear and vivid", and from "no desire or urge to eat" to "extremely strong desire or urge to eat", respectively. *EM* eye movements, *DVN* dynamic visual noise, *ST* spatial tapping

we investigated whether engaging in relatively effortless visual activity could reduce food cravings in dieters (via the analogous mechanism of decreasing the vividness of the accompanying images).

In our investigations, dieting and non-dieting female undergraduate students formed and maintained images of commonly craved foods (e.g. chocolate, cake, ice-cream) elicited by pictures or verbal cues, while performing one of the three aforementioned visual tasks: saccadic eye movements, dynamic visual noise or spatial tapping. Participants rated the vividness of their images and the intensity of their food cravings. As predicted, all three tasks made participants' food images less vivid. Importantly, as can be seen in Fig. 81.2, this reduction in imagery vividness was accompanied by a reduction in participants' level of food craving. Dieters and non-dieters showed the same pattern of results. Thus simple, repetitive visual tasks hold promise as a practical technique for controlling food cravings in dieters.
Fig. 81.3 Mean imagery vividness and food craving levels (with standard errors) for dieters and non-dieters in each of the concurrent task conditions. This figure shows that dynamic visual noise was a more effective technique than thought suppression for reducing the vividness of food images and the intensity of food cravings in dieters; however, the techniques were equally effective for non-dieters. Imagery vividness and craving were rated on a 100-point scale ranging from "no image at all" to "image perfectly clear and vivid", and from "no desire or urge to eat" to "extremely strong desire or urge to eat", respectively. DVN = Dynamic visual noise; TS = Thought suppression

In a subsequent study, we (Kemps et al. 2008) examined whether these findings in dieting samples of normal weight university students extended to community samples of overweight people who are actively trying to lose weight. Overweight women following a prescribed weight-loss diet and non-dieting controls formed and maintained images of highly desired foods (e.g. chocolate, chips, pizza) while watching the dynamic visual noise display or suppressing thoughts about food. Both techniques successfully reduced food cravings for dieters as well as non-dieters. However, as shown in Fig. 81.3, their relative effectiveness differed markedly depending on the women's dieting status. While both techniques reduced cravings equally well for non-dieters, dynamic visual noise was clearly the more effective technique for dieters. Thus the utility of visually based tasks for curbing dieting-related food cravings clearly extends to overweight individuals who are trying to lose weight.

81.5 Conclusion

The working memory approach outlined here presents a radically different strategy for reducing dieting-related food cravings, one that is based on the visual imagery nature of food cravings. According to working memory theory, food cravings engage the visuo-spatial sketch pad, and can thus be reduced by loading this component with a concurrent task. Specifically, concurrent visual tasks have their craving reducing effect by diminishing the vividness of desire-related food images held in the limited capacity visuo-spatial sketch pad. Unlike thought suppression and cue exposure response prevention, concurrent visual processing does not focus directly on the craved food. As a result, it is likely to be found less aversive, making it not only an effective but also an attractive technique for reducing dieting-related food cravings.

81.6 Applications to Other Areas of Health and Disease

The next challenge is to see how well these techniques involving concurrent visual activity generalize outside the laboratory, how well they are able to control unwanted and problematic food cravings in clinically overweight and obese individuals, as well as in patients diagnosed with binge eating disorder and bulimia nervosa. These techniques may also have utility beyond the food domain, to cravings for other substances, such as nicotine, caffeine, alcohol and drugs. Deprivation of these substances, like food restriction, can lead to cravings. Such cravings are also imagery based, and involve, primarily, visual images (May et al. 2004; Kemps and Tiggemann 2009). In fact, emerging evidence shows that visual imagery tasks can similarly suppress cigarette cravings in smokers (Versland and Rosenberg 2007) and caffeine cravings in habitual coffee drinkers (Kemps and Tiggemann 2009). Future research could determine whether simple visual tasks, like dynamic visual noise, could also reduce these cravings, as well as cravings for alcohol and other drugs.

More generally, mental imagery has been shown to play a role in the development and maintenance of a variety of psychological disorders, including post-traumatic stress disorder, agoraphobia, body dysmorphic disorder and mood disorders. Imagery-based interventions have been used successfully in the treatment of these psychopathologies (Hackman and Holmes 2004). More recently, Lilley et al. (in press) showed that making simple eye movements while imagining a traumatic event reduced the vividness and emotional impact of distressing, intrusive images in a clinical sample with post-traumatic stress symptoms.

Summary Points

- Dieting to lose weight is associated with a number of negative outcomes, including the experience of unwanted food cravings.
- Although food cravings are a common everyday experience, dieting-related cravings can give rise to a range of negative consequences, such as binge eating, early dropout from weight-loss programs, feelings of guilt and shame and poor cognitive task performance.
- The prevalence of dieting-related cravings is likely to increase, because of increasing rates of obesity and body image concerns, highlighting the need for effective craving reduction techniques.
- The currently available techniques for reducing dieting-related food cravings involving either thought suppression or cue exposure response prevention have not proven very successful.
- Based on converging evidence pointing to mental imagery as a key component of the craving experience, recent findings show that interfering with the cognitive processes that support craving-related images reduces food cravings in weight-loss dieters.
- As food cravings involve images primarily in the visual sensory modality, engaging in a concurrent visual task is most effective in reducing dieting-related cravings.

Definitions and Explanations of Key Terms

Binge eating: The consumption of an excessively large amount of food in a single sitting, accompanied by feelings of lacking control over one's eating.

Cue exposure response prevention: A psychological intervention derived from conditioning models of psychopathology that involves successive exposures to an appetitive target, with instructions to attempt to resist consumption.

Food craving: A strong urge or desire to eat a specific food.

Mental imagery: The mental representation of stimuli that are not physically present.
Preoccupying cognitions: A chronic preoccupation with personally relevant or motivationally salient thoughts.
Thought suppression: A cognitive control strategy whereby an individual avoids thinking about a behaviour in order to prevent performing that behaviour.
Weight-loss dieting: The deliberate restriction of food intake in an attempt to lose weight.
Working memory: A system for the temporary storage of information in the face of ongoing processing.

Chapter 82
Abnormal Physiologic Responses to Touch in Feeding Difficulties

Donna Scarborough

Abbreviations

APIB   Assessment of Preterm Infants' Behavior
NBAS   Neonatal Behavioral Assessment Scale

82.1 Introduction

Development of early feeding skills in full-term infants is complex for a number of reasons:

- An infant undergoes a dramatic transformation during the first year of life in all aspects of development including: neurologic, anatomic, motor, sensory, physiologic, feeding/swallowing skills, communication, cognitive, social–emotional, and play. Each of these areas is interdependent, and, like the pieces of a jigsaw puzzle, can be viewed piece by piece or as a whole (Fig. 82.1).
- The transition of feeding behaviors from primarily physiologic responses to cognitively learned responses, or combinations of both.
- Infants and young children are dependent upon others during the feeding process and express themselves by indirect, nonverbal means. Thus, successful feeding interactions and development are dependent upon appropriate interpretations of behavior.

One aspect of feeding development that reflects this complexity is the ability of an infant to appropriately respond to touch input (Table 82.1). This section will examine early infant development, identify behaviors related to touch processing during the earliest stages of development, and examine long-term feeding complications and clinical applications related to an interruption of these early stages.

82.2 Early Developmental Levels

Since the 1950s, a number of researchers have described the childhood maturation process as proceeding in a sequential manner. Many of the early developmental theories proposed by Piaget (1952), Mahler et al. (1975), Greenspan and Lourie (1981), and Kopp (1982) have historically been important

Fig. 82.1 The complex puzzle of development. For a child to successfully develop each individual component must cohesively connect
Table 82.1 Key features of touch (Henricson et al. 2008; Pihko and Lauronen 2004; Jean 2001; Hendry et al. 1999)

- Touch or mechanoreception is only one component of the somatosensory system (Fig. 82.2)
- Touch includes perception of pressure, texture, form, and vibration
- Touch receptors are found at varying depths below the skin, and include Pacinian corpuscles, Ruffini corpuscles, Meissner corpuscles, and Merkel cells
- Each type of touch receptor responds differently to varying types of input
- Touch information from the body and limbs is carried to the dorsal root ganglia cells of the spinal cord, through the dorsal column–medial lemniscus pathway to the thalamus. From the thalamus, the information is then carried to the cortex.
- Touch from the face, oral cavity, and pharynx is carried from the trigeminal, glossopharyngeal, and vagus nerves to the thalamus. From the thalamus the information is then carried to the cortex.
- Touch is organized throughout each level with a clearly defined map of the body
- As early as the seventh month of pregnancy, touch pathways are intact enough to produce cortical responses
- The speed of processing and timing of processing improves as mylenation occurs
- Sleep stages impact processing of touch input in newborns
- The touch of firm pressure has a calming effect on the sympathetic nervous system

for classifying feeding behaviors. For the purpose of this section, a compilation and summary of these four theories targeting the first year of development is described utilizing the nomenclature of Greenspan and Lourie (1981) and Kopp (1982) (Fig. 82.3):

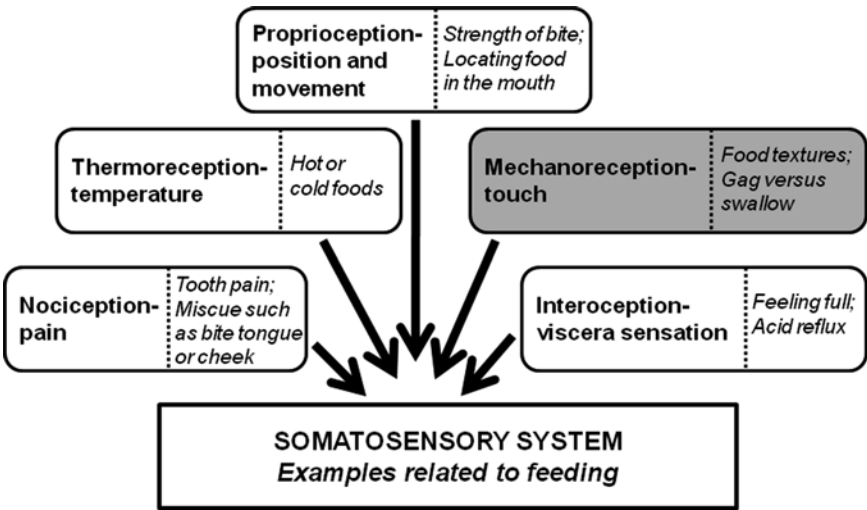
- The period of "homeostasis" or "neurophysiologic maturation," is a critical period from birth to 3 months of life when an infant's biological functions stabilize as a result of autonomic nervous system maturation. Examples of stabilizing biologic functions include temperature regulation, respiratory rhythms, sleep–wake cycles, and feeding and excretion patterns. Touch processing during the beginning of this stage involves generalized autonomic system responses, such as startling,


Fig. 82.2 Somatosensory system and feeding. The somatosensory system is very complex and critical for successful feeding. Touch or mechanoreception is only one component of this system and will be the focus of this section
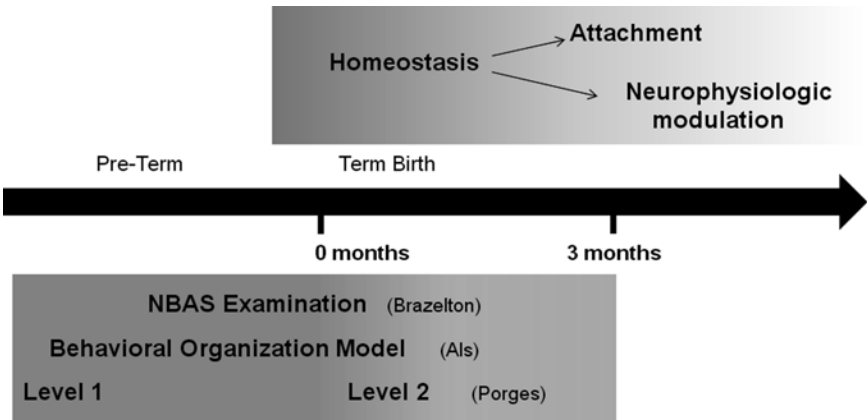

Fig. 82.3 Developmental levels for feeding. Homeostasis is the first developmental level for term infants. In typical development, this stage flows into the concurrent stages of attachment and neurophysiologic modulation. Preterm development is assessed through the NBAS (which highlights state behavior changes) and other models of preterm development

gagging, or state behavior changes. As the child progresses through this period of development touch responses become more appropriate such that an infant begins to differentiate between the soothing touch of being swaddled and the painful touch of a needle (Scarborough et al. 2006).

• The periods of "attachment" and "sensorimotor modulation" follow "homeostasis." During the period of *attachment* infants respond to the outside world, thus beginning the process of forming relationships and differentiating between caregivers. Concurrent with the period of attachment is the period of *sensorimotor modulation*. During this period of development the infant begins to utilize multiple sensory systems (i.e., touch, vision, balance) during interactions in order to modulate motor responses such that movements become voluntary rather than reflexive. An important component of this stage is that children will repeat behaviors or modulate movements without purposeful or conscious reflection. By the end of the first year of life, these periods of development should be complete.

82.3 Understanding Infant Behaviors During the Period of "Homeostasis"

Successful interpretation of infant behavior is one of the greatest challenges for developmental feeding specialists, particularly in very young infants. Although the period of "homeostasis" is considered the first stage of development for full-term infants, we know that development is on a continuum, thus later behaviors are dependent on successful achievement of previous neurologic maturation. Therefore, much of our understanding of behaviors of very young-term infants may be extrapolated from the healthy preterm infant population. In the 1970s, Brazelton published the Neonatal Behavioral Assessment Scale (NBAS) that classified infant behaviors while experiencing periods of stimulation or stress (Brazelton 1973) (Fig. 82.3). As part of this original research, it was postulated that the baby's state of consciousness or *state behavior* was the single most important element of the NBAS examination. State behaviors are seen as reflections of autonomic nervous system maturation, as well as reactions to incoming stimuli (Brazelton and Cramer 1990). Since that time, seven distinct states behaviors have emerged in infants older than 36 weeks gestational age (Brazelton 1984; Prechtl 1987). Furthermore, it is recognized that only in an alert, bright state does the newborn orient to external sources of input and takes in information (Brazelton 1990; Kaufmann-Hayoz 1987).

The "*behavioral organization" model* was proposed in the 1980s (Fig. 82.3). This model separates infant behavior according to distinct but interdependent neurologically based subsystems. Such subsystems included not only state behavior organization, but also autonomic, motor, attention, interaction, self-regulation, and balance systems (Als 1982, 1986; Als et al. 2005). The behavioral organization model also assumes that neurologic maturation will occur with increasing gestational age, which in turn, allows for improved interaction between systems. Although this model has primarily been applied to infants through 42 weeks gestation, we know that the modulation these subsystems continue through the period of homeostasis, which should be complete by 3 months of age (Chatoor et al. 1984; Porges 1996; Greenspan 1990). As a result of the behavioral organization model, an Assessment of Preterm Infants' Behavior (APIB) was developed, which allows clinicians to observe and score unique physiologic behaviors related to disorganization from each of the specific subsystems. Gagging, for example, is considered a sign of autonomic stress, whereas changes in posture and muscle tone are reflective of motoric stress (Als et al. 2005). Understanding which specific subsystems are disorganized allows clinicians and caregivers to provide the appropriate support to assist the infant in regulation.

82.4 Autonomic Homeostasis, Impact on Emotional and Behavioral Development

The *Polyvagal Theory* describes two distinct types of vagal responses that infants may present to stressors: the mammalian system and the reptilian vagal system (Porges et al. 1996). A mammalian response system is considered the optimal means for an infant to maintain physiologic homeostasis in response to stress by means of an increased arousal state. However, if this system is regularly challenged (i.e., medical interventions such as gavage feeding) then the heightened physiologic response pattern could become detrimental to the developing infant. The second type of vagal response has been deemed as the reptilian vagal system. Basically with this type of response pattern to stress, the autonomic nervous system shuts down. Clinical observations of infants who are utilizing reptilian strategies in response to stress can involve potentially lethal bradycardia (slow heart rate) and/or apnea. Therefore, depending upon the vagal system that an

Fig. 82.4 Infant stress responses. Basic representation of the Polyvagal theory, which indicates that two distinct types of vagal response patterns will evoke a heightened or reduced physiologic state

infant uses to respond to stress, either heightened or reduced physiologic states will be observed (Porges 1996, 2009) (Fig. 82.4).

Based on the Polyvagal Theory, a hierarchical model was developed that identified the importance of neural regulation of autonomic homeostasis as a precursor to emotional, cognitive, and behavioral regulation (Porges 1996). At the foundation of this model (Level 1), infants must be able to achieve internal physiologic homeostasis through autonomic regulation between the brainstem and peripheral organs, before attempting to cope with external factors. Once infants are able to successfully regulate single physiologic systems, the infants can then begin to coordinate multiple systems and respond to external challenges (Level II) (Fig. 82.3). Thus, the successful completion of a complex activity (such as feeding), which requires an infant to both negotiate internal homeostasis and with external demands, are dependent on regulation of autonomic system. Further, this model also has provided a means for studying long-term effects of abnormal autonomic nervous system functioning particularly related emotional dysregulation in preschool to adolescence (Beauchaine et al. 2007) Thus, the polyvagal theory has been ground-breaking for providing a means to identify autonomic nervous system regulation as an integral part of healthy cognitive, emotional, and behavioral development and for showing that difficulties with physiologic homeostasis can persist well beyond the first year of life.

82.5 Touch and Feeding and Interruption of the Period of "Homeostasis"

The behavioral response pattern of neonates and full-term infants younger than 3 months of age includes a variety of autonomic nervous system responses. For example, it is not uncommon to observe gagging and/or "state" behavior changes (such as uncontrolled crying, fussiness, drowsiness, or falling asleep) in young infants while processing touch input. Touch input refers both to touch to the body such as general physical handling and/or oral touch associated with feeding. Over time as the infant develops beyond the period of "homeostasis" (3 months of life) these autonomic nervous system
Fig. 82.5 Interrupting homeostasis. If normal development is interrupted at any point during the period of homeostasis (including the preterm period) then aberrant autonomic behaviors during feeding may persist well beyond the first year of life

responses become less generalized and more appropriate to environmental situations. For instance, gagging is a normal protective reflex when elicited by touch to the posterior oral regions; however, gagging to anterior oral touch or touch to more peripheral areas of the body is seen as a sign of immature physiological (autonomic) processing. Thus, in typical infants older than 3 months of age autonomic nervous system responses to touch are unusual (Scarborough et al. 2002, 2006).

Full-term infants and children who have had an interruption of oral feeding during at least 2 weeks during the period of "homeostasis" (first 3 months of life) have been found to respond to graded tactile input with signs of poor autonomic regulation (such as gagging and major state changes) (Fig. 82.5). In particular, these aberrant autonomic responses have been documented from touch to both nonoral body regions (i.e., shoulders) and to regions in the anterior portion of the mouth and are not evident in age matched healthy peers. Further, these aberrant autonomic behaviors have been observed in children as old as 18 months of age and tend to persist even with behavioral intervention (Scarborough et al. 2006).

82.6 Clinical Application

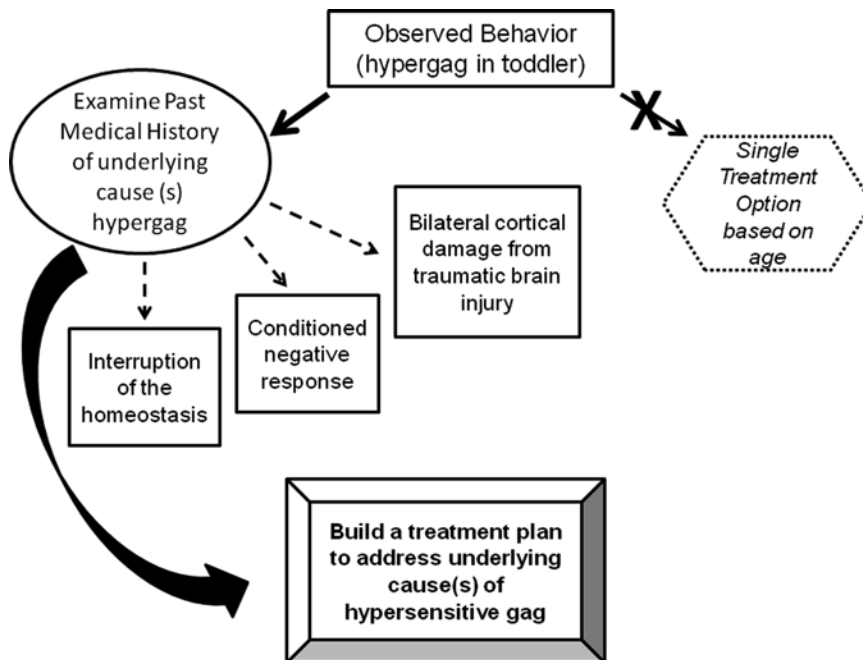
Like many areas of pediatrics, one of the challenges for the professional is making clinical judgments based on observed behaviors that could be the result of more than one etiology. As an example, a "hypersensitive" gag reflex is a regularly observed behavior within the pediatric feeding population (Fig. 82.6). A *hypersensitive gag reflex* will be defined for the purpose of this section as triggering a gag reflex from nonoral regions of the body or within the anterior 2/3 of the oral cavity regardless of the strength of the motor response (Scarborough et al. 2008). In the case of a hypersensitive gag reflex, obtaining the child's past medical history is a critical component to determining the cause of the behavior. For instance, a hypersensitive gag reflex observed in premature and full-term medically fragile infants who have a history of tube feedings during the period of homeostasis is likely the result of abnormal autonomic nervous system development (Scarborough and Isaacson 2006; Scarborough et al. 2006). In contrast, children who have a history of traumatic brain injury, specifically involving bilateral corticobulbar tracts demonstrate a "hypersensitive" gag reflex due to the loss of upper motor neuron inhibition (Schulze-Delrieu and Miller 1997). In other children, a hypersensitive gag reflex has been reported as a result of maladaptive parent–child interactions through conditioned negative responses (Byars et al. 2003). Therefore, when a hypersensitive gag reflex is observed during a feeding trial, it is critical that the clinician not assume an underlying cause of this behavior regardless of the age of the child without a complete medical history. Once the cause(s) of the hypersensitive gag reflex is found, then a targeted treatment plan can be developed


Fig. 82.6 Clinical decision flow chart. Clinical decisions for treatment need to look beyond age-related behaviors. This is to ensure that the underlying cause of a behavior is addressed

that appropriately remediates or offsets this negative feeding behavior. Further, if a single treatment technique is not effective for correcting the behavior, other treatments should be explored that target different levels of development.

Summary Points

The period of "homeostasis" is critical for modulation of touch responses through the autonomic nervous system.

- Normal early infant behaviors (under 3 months of age) related to general physical handling or oral touch during feeding may involve state behavior changes or gagging. These autonomic responses modulate to more appropriate behavioral patterns during the first 3 months of life in healthy infants.
- Developmental theories of preterm infants can provide valuable information regarding full-term infant behavior.
- Interruption of normal oral tactile input (i.e., tube feedings) in full-term infants during the period of homeostasis and earlier can lead to abnormal processing of touch and persistent behaviors such as gagging and extreme state behavior changes.
- Behaviors related to autonomic regulation can persist well past the first year of life.
- The same negative feeding behavior observed in older children may be the result of more than one cause acquired during early childhood. Therefore, assessment of feeding behaviors, such as the hypersensitive gag reflex, should include a comprehensive past medical history of the child.
- Treatment techniques should be geared to remediate the underlying cause(s) of an observed feeding behavior.

Explanation of Key Terms

Homeostasis: A critical developmental period of neurophysiologic modulation from birth to approximately 3 months of life when an infant's biological functions stabilize as a result of autonomic nervous system maturation.

Attachment: The developmental period following homeostasis when infants respond to the outside world, thus beginning the process of forming relationships and differentiating between caregivers.

Neurophysiologic modulation: The period of development that is concurrent with attachment when an infant begins to utilize multiple sensory systems to modulate motor responses such that movements become voluntary rather than reflexive without purposeful or conscious reflection.

Polyvagal theory: Proposes that successful adaptation of mammals is dependent on systematic and reliable withdrawal and reengagement of the vagus nerve as a mechanism to respond to environmental demands (Porges et al. 1996). This theory describes two distinct types of vagal responses that infants may present to stressors, the mammalian system and the reptilian vagal system. For a detailed review of this theory, see Porges 1996 and Porges et al. 1996.

Behavioral organization model: Separates infant behavior according to distinct but interdependent neurologically based subsystems. Such subsystems included not only state behavior organization, but also autonomic, motor, attention, interaction, self-regulation, and balance systems. The behavioral organization model also assumes that neurologic maturation will occur with increasing gestational age, which in turn, allows for improved interaction between systems. For a detailed review, see Als 1982, 1986; and Als et al. 2005.

State behaviors: Different levels of infant alertness that are considered as reflections of autonomic nervous system maturation, as well as reactions to incoming stimuli. For a detailed review of state behaviors, see Brazelton 1973, 1984.

Hypersensitive gag reflex: Triggering a gag reflex from nonoral regions of the body or within the anterior 2/3 of the oral cavity regardless of the strength of the motor response.

CCK   Cholecystokinin
PYY   Peptide YY
GLP-1 Glucagons-like peptide 1
IPPW   Isolated pyloric pressure wave
MMC   Migrating motor complex
IL   Interleukin

83.1 Introduction

Nutritional deprivation or malnutrition in critically ill patients have been shown to be associated with impairment of immunological function, prolongation of mechanical ventilation, increased length of intensive care unit (ICU) and hospital stay, increased infective complications, and ultimately higher mortality (Harrington 2004). Although the practice of nutritional support by either enteral or parenteral routes has now become standard treatment, for many years it was frequently either not provided routinely (Berger et al. 1997) or inadequately delivered to meet metabolic requirements (Heyland et al. 1995, 2003). Previously, the incidence of malnutrition amongst long-stay critically ill patients has been as high as 50% (Quirk 2000). Currently, enteral nutrition is the preferred mode of nutritional delivery in critically ill patients due to the ease of administration, reduced health-care costs, lower rate of sepsis, lack of requirement for central venous access, and enhancement of gastrointestinal barrier function with the potential reduction in bacterial translocation (Heyland et al. 1998, 2003).

Adequate delivery of enteral feeds to critically ill patients, however, is frequently hampered by a variety of factors; the most frequent is gastric dysmotility. A number of factors including mechanical ventilation, drugs (especially opiates and catecholamines), hyperglycemia, shock, circulating inflammatory cytokines, and the admission diagnosis have been implicated in the etiology of slow gastric emptying in critically ill patients. However, the majority of these factors were inferred from studies

e-mail: quoc.nguyen@health.sa.gov.au

performed in either animals (Dubois et al. 1975) or a non-critically ill population (Yuan et al. 1998). More recently, there is evidence to suggest that gastric dysmotility of critical illness may relate to disturbance of the complex interaction between enteral nutrition and gastrointestinal hormones that involved in the enterogastric feedback regulation. The aim of this chapter is to review the gastrointestinal motor and hormonal responses to enteral nutrition in critically ill patients, and how the complex interactions between these factors can potentially give insights into the pathogenesis of impaired gastric motor function in this population.

83.2 The Role of Enteral Nutrition in Critically Ill Patients

The impact of nutritional support on patients' outcomes has been examined extensively over last two decades. While many studies have documented that nutritional support changes metabolic outcomes, such as amino acid profile and nitrogen balance, the impact of this intervention on clinically important end points such as infection, length of stay, and mortality is less clear-cut. There are a number of methodological reasons that might explain the discrepancies among the reported studies. First, over 60% of trials that have examined this issue lacked sufficient statistical power (Heyland 1998; Heyland et al. 2003; Doig et al. 2005). This is further confounded by the heterogeneity of the critically ill population and differences in the mix of patients between the studies (Doig et al. 2005). In addition, the quality of many trials was suboptimal with a lack of randomization, controls, and blinding (Doig et al. 2005). Meta-analyses that have examined only high-quality randomized–controlled (level 2) trials suggest that, compared with patients who received standard care (i.e., IV fluid support only), nutritional support via either the enteral or parenteral route is associated with a 5–12% reduction in mortality (Heyland et al. 1995, 2003; Doig and Simpson 2005). In surgical and multitrauma patients, nutritional support improves wound healing, decreases the catabolic response to injury, and reduces infective complications (Kudsk et al. 1992; Heyland 1998; Heyland et al. 1998, 2003). Similar reductions in septic complications and a shorter length of stay in ICU and hospital have also been demonstrated in medical critically ill patients (Heyland et al. 1995, 2003; Doig and Simpson 2005).

The optimal time to start nutritional support in critical illness, however, is unknown. It is recognized that patients should not be deprived of nutrients for more than 5 days as earlier studies have demonstrated a higher mortality in surgical patients who had been deprived of nutrition for longer than this (Thomas and Robert 1979). In animals, nutrient deprivation for durations as short as 24 h may lead to intestinal mucosal atrophy and malabsorption (Alpers 2002). These abnormalities can be reversed or prevented by the early introduction of luminal nutrients (Alpers 2002). In a more recent randomized–controlled study, patients with nutrient deprivation for a mean duration of 4 days had a significant reduction in the villous height and crypt ratio and an increased gut permeability as assessed by the lactulose–mannitol test (Hernandez et al. 1999), compared those who received enteral feed within 24 h of admission.

Until recently, the concept of early aggressive feeding was not universally accepted by many critical care staff. Despite recognizing the importance of early feeding, a number of nutritional surveys in intensive care units have reported that less than 50% of eligible patients received enteral nutrition within 48 h of admission (McClave et al. 1999; Montejo 1999; Heyland et al. 2003), placing these patients at risk of intestinal mucosal atrophy, increase gut permeability, and malnutrition (Alpers 2002). As the integrity of the gastrointestinal tract is thought to be important for the prevention of bacterial translocation and subsequent infective complications (Alpers 2002), these findings suggest that delayed enteral nutrition may increase the risk of sepsis.

The impact of early enteral nutrition on outcomes in critically ill patients has been investigated in a number of randomized controlled trials (Minard et al. 2000; Artinian et al. 2006). These have produced conflicting results possibly due to a lack of adequate statistical power. A meta-analysis using

these data has also given an inconclusive answer with only a trend toward a reduction in infective complications and mortality, and no difference in length of stay (Heyland et al. 2003). Most recently, Artinian et al. (2006) conducted a large study that included 4,049 medical critically ill patients. This study showed that early enteral nutrition was associated with a 20% reduction in ICU mortality and a 25% reduction in hospital mortality. The benefit to mortality was most pronounced among patients with the highest Acute Physiology and Chronic Health Evaluation II (APACHE II) scores (Artinian et al. 2006), although a higher incidence of ventilated associated pneumonia was reported in patients who had received early feeding. The reason for this finding is unclear but may relate to the more prolonged exposure to nasogastric feeds, a known risk factor for gastroesophageal reflux and aspiration (Montejo 1999; Mentec et al. 2001). Based on current evidence, a number of international working committees have published guidelines for nutritional support in critically ill patients (Heyland et al. 2003; Doig and Simpson 2005). Of these, the Canadian Clinical Practice guideline is best known and has been most widely adopted (Heyland et al. 2003). Although there are minor variations among these guidelines, common themes include (Heyland et al. 2003):

- Nutritional support, either in the form of total parenteral nutrition or enteral nutrition, should be considered in all patients who are admitted to critical care.
- Enteral nutrition is the preferred modality of nutritional support in critically ill patients, particularly in those with intact gastrointestinal tract.
- In patients whom enteral nutrition is indicated, it should be commenced within 24–48 h of admission.

83.3 Regulation of Gastric Emptying and Enterogastric Feedback in Health

In order to appreciate the potential significances of gastric dysmotility and hormonal abnormalities in response to enteral nutrition in critically ill patients, an understanding of gastric emptying regulation in health, especially those related to "enterogastric" feedback mechanisms, is required. After ingestion of a meal, the rate of gastric emptying is tightly regulated by the presence of intraluminal nutrients in the duodenum and small intestine, a process known as the enterogastric reflex (Lin et al. 1989). This feedback response is important in preventing excessive dumping of gastric contents into the small intestine and allows nutrients to enter the small intestine at a rate of 2–3 kcal/min (Lin et al. 1989).

83.3.1 Gastric Motor Responses of Enterogastric Feedback

After ingestion of nutrients, the proximal stomach relaxes and acts as a reservoir. Subsequently, the fundus undergoes slow sustained contractions to distribute contents distally and is believed to have a major role in controlling emptying of liquids (Kelly 1980). In contrast, motor activity in the distal stomach is characterized by irregular contractions, which aid mixing and propagation of nutrient along the gastrointestinal tract. Mixing is due to intermittent isolated antral waves contracting against a closed pylorus. Gastric emptying of nutrient occurs predominantly in a pulsatile fashion when peristaltic wave activity continues through an open pylorus, aiding movement of contents into the duodenum (White et al. 1981). The peristaltic wave is dependent on the integration of motor activity in the proximal and distal stomach, as well as in the proximal small intestine (Horowitz et al. 1994). The rate of transpyloric flow is tightly regulated by the "enterogastric" feedback (Brener et al. 1983), whereby duodenal nutrient triggers a neurohumoral response that reduces antral waves, increases basal pyloric pressure and increases frequency of isolated pyloric pressure waves (IPPWs).

83.3.2 Humoral Response of Enterogastric Feedback

A large number of hormones, including cholecystokinin (CCK), peptide YY (PYY), motilin, GLP-1, and ghrelin, are involved in the "humoral" regulation of the enterogastric feedback responses (King et al. 1985; Horowitz et al. 1994). Of these, CCK and PYY are the best studied. The best-characterized CCK in humans is cholecystokinin-octapeptide (CCK-8) (Liddle et al. 1986). This peptide hormone is secreted by cells in the duodenum and upper jejunum in response to duodenal acid and nutrients, particularly lipids and proteins (Liddle et al. 1986). In humans, exogenous CCK-8 infusions that mimic plasma concentrations in the postprandial range induce significant fundic relaxation (Straathof et al. 1998), inhibit antral motility, increase basal pyloric pressure, and stimulate IPPWs (Fraser et al. 1993). These responses are abolished by coadministration of a CCK antagonist, loxiglumide (Mesquita et al. 1997). The effects of CCK on gastric emptying in humans are, however, conflicting. Although intravenous administration of both exogenous CCK-8 and CCK-3 at physiological concentrations is associated with a decrease in gastric emptying of both liquid and semisolid meals (Moran and McHugh 1982; Liddle et al. 1986), data on the impact of specific CCK antagonists on gastric emptying in humans remain controversial, which may be related to the different formulation of the CCK antagonists used among the studies. All studies that have used the intravenous form of the specific CCK antagonists, loxiglumide and lintitript, have reported an accelerated gastric emptying of both liquid and solid meal, as well as nutrient and nonnutrient meal (Fried et al. 1991; Kreiss et al. 1998). On the other hand, the two studies that used the orally administered CCK antagonists, such as MK-320 and loxiglumide, have failed to demonstrate a change in the gastric emptying rate of either solid or liquid meals, despite a positive effect on gallbladder motility (Liddle et al. 1989; Corazziari et al. 1990).

Peptide YY, also known as the "ileal-brake" hormone that regulates both gastric emptying and intestinal transit, is secreted by the endocrine L cells of the small and large bowel (Adrian et al. 1985). After an intraduodenal meal, plasma PYY increases even before nutrients reach the PYY-containing cells in the ileum, suggesting that PYY release is neurally mediated, probably via the vagus (Greeley et al. 1989). In humans, PYY 3-36 has been consistently reported to inhibit gastric emptying of liquids in a dose-dependent manner (Pironi et al. 1993). In contrast, there are limited data regarding the effects of PYY antagonists on gastric emptying in humans. Unlike CCK, the motor mechanisms underlying the slowing of gastric emptying of PYY 3-36 are less well studied. The impact of PYY on proximal gastric motor activity has not been examined. In humans, elevated fasting PYY concentrations are associated with less frequent phase 3 activity of the MMC arising from the antroduodenal region (Naslund et al. 1998), a reduction in the frequency of antroduodenal contractions (Ledeboer et al. 1999) and an increase in IPPW (MacIntosh et al. 1999). Currently, there are no studies that have examined the impact of PYY antibody on gastric motility in humans.

83.4 Upper Gastrointestinal Motility During Critical Illness

Disturbances in gastrointestinal motor activity occur in up to 70% of the critically ill patients who require mechanical ventilation (Heyland et al. 1996; Kao et al. 1998; Ritz et al. 2001; Nguyen et al. 2007b, d, 2008a, b). Delayed gastric emptying occurs in 40–80% of patients, and the prevalence depends on factors such as admission diagnosis as well as the techniques used to assess gastric emptying (Heyland et al. 1996; Kao et al. 1998; Ritz et al. 2001; Nguyen et al. 2007d, 2008a). Using gastric scintigraphy, up to 80% of critically ill patients admitted with head injury have slow gastric emptying (Kao et al. 1998; Nguyen et al. 2008a). In contrast, delayed gastric emptying occurs in only 40–60% of patients in unselected cohort, when assessed by either the paracetamol absorption test or ^{13}C-octanoic

Table 83.1 Gastric motor abnormalities reported during critical illness

Region of stomach	Gastric motor abnormalities
Proximal stomach	• Delayed and prolonged fundal relaxation
	• Reduced fundic volume waves
	• Greater proximal meal retention
Distal stomach	• Persistent MMC during feeding
	• Reduction in antral contractions and antral motility index
	• Increased isolated pyloric contractions and pyloric tone
	• Inverse correlation between pyloric motor activity and gastric emptying
Integration between gastric regions	• Lack of fundoantral motor association
	• Antral contractions frequently occur in close association with pyloric contractions
Duodenum	• Disorganized duodenal contractions
	• Increased number of retrograded duodenal contractions
Enterogastric feedback responses	• Increased fasting plasma CCK and PYY levels
	• Increased nutrient-stimulated plasma CCK and PYY levels
	• Plasma CCK and PPY inversely correlated with rate of gastric emptying

acid breath test (Heyland et al. 1996; Tarling et al. 1997; Ritz et al. 2001; Nguyen et al. 2007d, 2008b). Delayed gastric emptying of critical illness is associated with impaired motor function in all regions of the stomach during both fasting and fed state (Dive et al. 1994; Chapman et al. 2005; Nguyen et al. 2006a, 2007a, 2008c; Chapman et al. 2008) (Table 83.1). Clinical indicators of upper gut dysmotility include high gastric residual volumes (GRV), vomiting, reflux, and aspiration (Montejo 1999).

83.4.1 Fasted State

During fasting, the gastric phase of the migrating motor complex (MMC) in the antroduodenal region is significantly shorter in mechanically ventilated, critically ill patients than in controls (32 vs. 101 min) (Bosscha et al. 1998). In part, this appears to be related to a virtual absence of phase 2 of the MMC and a marked reduction in antral pressure waves (Dive et al. 1994; Bosscha et al. 1998; Chapman et al. 2005), whereas the lengths of phase 1 and 3 do not differ significantly from those of healthy volunteers (Bosscha et al. 1998). Although proximal gastric volume, pyloric tone, and the frequency of IPPWs are similar between critically ill patients and healthy subjects, the frequency of fundic volume waves is significantly lower in critically ill patients (Dive et al. 1994; Chapman et al. 2005; Nguyen et al. 2006a, 2007a).

83.4.2 Intragastric Nutrient Stimulation

During intragastric feeding, there is persistence of the gastric and small intestinal interdigestive pattern but less than 10% of the phase 3 activity fronts of MMC originate in the stomach (Bosscha et al. 1998). In a small observational study, a persistent fasting pattern was observed in one half of the patients and a mixed pattern of fasting and postprandial motility was seen in the other half (Bosscha et al. 1998). The number of antral pressure waves (Dive et al. 1994; Chapman et al. 2005) and the antral motility index (Bosscha et al. 1998) are also markedly reduced in critically ill patients during gastric meal, and there is a negative correlation between the antral motility index and gastric retention during gastric feeds (Bosscha et al. 1998).

83.4.3 Intraduodenal Nutrient Stimulation

More marked gastrointestinal motor abnormalities are observed during direct small intestinal feeding (Chapman et al. 2005). Relaxation of the proximal stomach is delayed although the magnitude of the relaxation is normal. Fundic slow wave activity is reduced and the recovery of proximal gastric volume to prestimulation levels is delayed. Antral motility is also reduced (Chapman et al. 2005) and is associated with an increase in isolated pyloric activity (Chapman et al. 2005). There is an inverse correlation between pyloric motor activity and gastric emptying (Chapman et al. 2005), suggesting that the increase in localized pyloric motor activity may contribute to the slowing of gastric emptying in critical illness. More importantly, these adverse motor changes are still observed in the critically ill patients even when the infusion rate is as low as 1 kcal/min, which does not alter distal gastric motor activity in healthy subjects (Chapman et al. 2005). These findings suggest that the gastrointestinal tract of critically ill patients responds to small intestinal nutrients differently from normal and the sensitivity of enterogastric feedback response to small intestinal nutrients in critical illness is enhanced.

83.4.4 Antrofundic Motor Integration

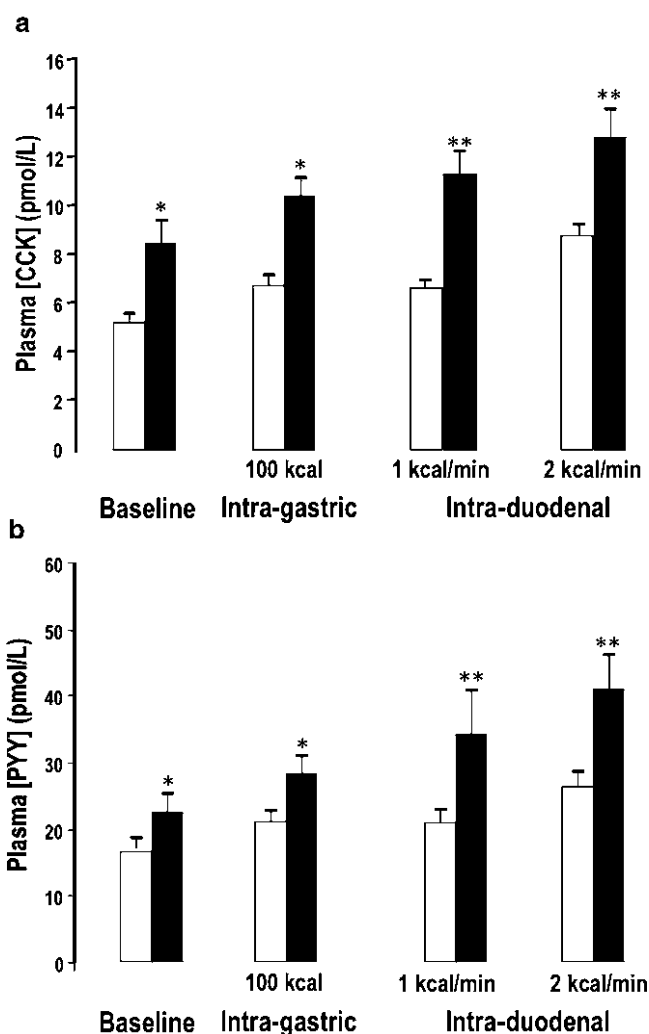
In addition to the generalized gastric dysmotilities, the association between the two gastric regions (i.e., antrofundic motor integration) has been shown recently to be disturbed. Antral contractions frequently occur in close association with pyloric contractions, particularly during infusion of a high nutrient load (2 kcal/min) (Nguyen et al. 2008c). Given the importance of this gastric regional association to the redistribution of proximal gastric content distally, the disruption to this antrofundic integration is likely to provide an explanation for the significantly greater meal retention in the proximal stomach in these patients (Nguyen et al. 2008a), especially in those with delayed gastric emptying.

83.4.5 Duodenal Motility

Although duodenal activity usually persists, the organization of the waves is abnormal with an increased proportion of retrograde contractions (Chapman et al. 2008). This has been reported to be associated with impaired transpyloric flow and slowing of gastric emptying (White et al. 1981). Disruption of the organization of duodenal contractions may also contribute to duodenogastric reflux and thereby, bile-induced esophagitis (Dive et al. 1999), which is common in these patients.

83.5 Hormonal Responses to Enteral Nutrition in Critically Ill Patients

Given the known abnormalities of gastric motor activity and enterogastric feedback responses in critically ill patients, it is not surprising that the gastrointestinal hormonal responses that regulate gastric motility through the enterogastric feedback mechanisms are also significantly disturbed (Nguyen et al. 2006b, 2007c, 2008b). Compared to healthy volunteers, both fasting and duodenal nutrient-stimulated plasma CCK and PYY concentrations are significantly elevated (Fig. 83.1) (Nguyen et al. 2006b, 2007c, 2008b). More importantly, plasma concentrations of CCK and PYY are greatest in patients with delayed gastric emptying (Fig. 83.2) and who do not tolerate enteral feeding (Fig. 83.3),

Fig. 83.1 Plasma CKK (**a**) and PYY (**b**) concentrations during fasting and 60 min after duodenal nutrient infusion at 1 and 2 kcal/min in healthy subjects (□) and critically ill patients (■). *$P < 0.05$, and **$P < 0.001$, vs. healthy subjects (Data adapted from Nguyen et al. 2006b, 2007c)


a clinical manifestation of slow gastric emptying (Nguyen et al. 2006b, 2007c, 2008b). As observed in healthy subjects (Nguyen et al. 2006b, 2008b), the elevation of plasma PYY concentration is observed within 20 min of nutrient stimulation in critically ill patients (Nguyen et al. 2006b), suggesting that the elevated PYY concentrations are most probably mediated by factors in the proximal small intestine rather than direct nutrient stimulation of the distal ileum (Adrian et al. 1985). CCK is likely to be an important "proximal" mediator given its known stimulatory effect on the release of PYY in the small intestine (Lin et al. 2000) and a positive correlation between the hormones have been demonstrated in these patients (Fig. 83.4) (Nguyen et al. 2006b, 2008b). More importantly, the elevated fasting plasma PYY concentrations in these patients during the first week of admission have been shown to normalize 3 weeks after discharge from the ICU (Nematy et al. 2005).

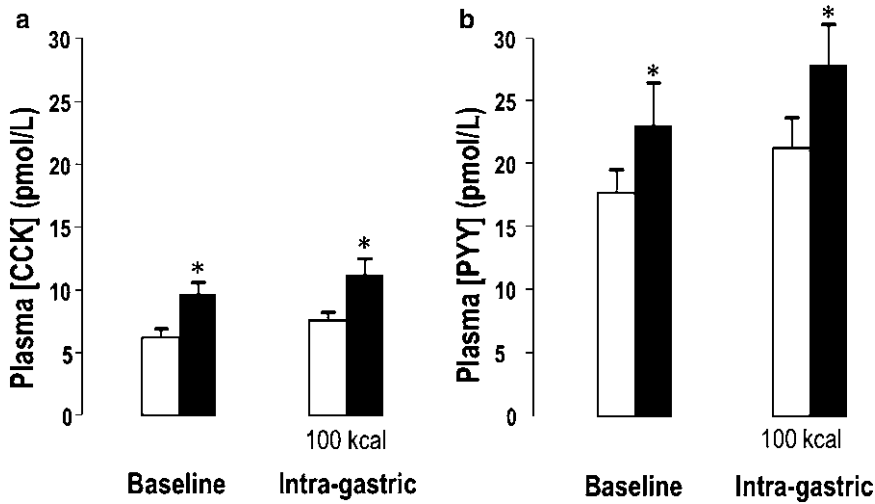
Preliminary data also suggest that plasma concentration of ghrelin, an enterogastrone that stimulates gastric motility and increases gastric emptying (Murray et al. 2005), is also disturbed in these patients with a reduced fasting level during critical illness and returned to normal level as the patient recovers from their illness (Nematy et al. 2005).


Fig. 83.2 Plasma concentrations of CCK (**a**) and PYY (**b**) during fasting and 120 min after an intragastric feed (100 kcal) in critically ill patients with normal (□) and delayed (■) gastric emptying (GE). *$P < 0.05$, vs. patients with normal GE (Data adapted from Nguyen 2008b)
Fig. 83.3 Plasma CCK (**a**) and PYY (**b**) concentrations 60 min after intraduodenal nutrient infusions, at rate of 1 and 2 kcal/min, in critically ill patients who tolerated (□) and did not tolerate (■) enteral feeding. *$P < 0.01$ vs. feed tolerance (Data adapted from Nguyen et al. 2006b, 2007c)

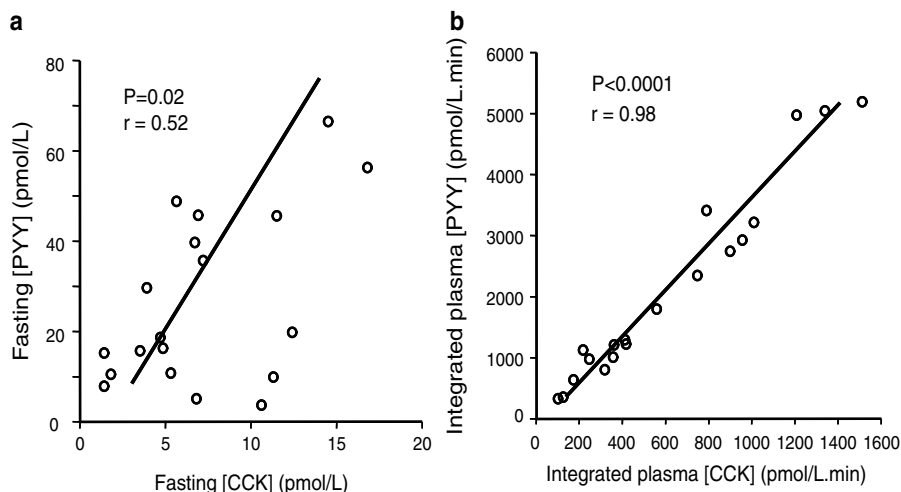
The mechanisms responsible for the abnormally high plasma CCK and PYY concentrations during fasting and in response to small intestinal nutrient infusion in critically ill patients remain unclear. Recent data suggest that the presence of inflammation may have a role in the regulation of entero-endocrine cells in the small intestine (McDermott et al. 2006). In a mouse model, upper gut inflammation has been reported to increase plasma CCK concentrations and reduce energy intake, via an


Fig. 83.4 Relationship between plasma PYY and CCK concentrations in critically ill patients during (**a**) fasting and (**b**) duodenal nutrient stimulation (expressed as integrated plasma levels (AUC $_{(0-180min)}$, pmol/L min)) (Data adapted from Nguyen et al. 2006b)

effect on CD_4 T-lymphocytes, and the related inflammatory cytokines (IL-3 and IL-4), can upregulate CCK-expressing cells (McDermott et al. 2006). Systemic inflammation with elevated inflammatory cytokines is common in critically ill patients (Souba 1994) and this could result in increased CCK responses to intestinal nutrients in these patients. Although nutritional deprivation has been shown to be associated with slow gastric emptying and elevated plasma CCK concentrations in non-critically ill subjects (Corvilain et al. 1995), these effects have not been observed in critically ill patients who had enteral nutritional delayed for the first 4 days of admission as compared to those who had been fed within 24 h of admission (Nguyen et al. 2008b).

Common factors in critical illness such as mechanical ventilation, and drugs like sedatives, and inotropic therapy may also contribute, at least in part, to the abnormal PYY and CCK responses. Apart from inducing splanchnic hypoperfusion, mechanical ventilation with high-end inspiratory pressure may also increase pulmonary and systemic cytokine release (Mutlu et al. 2001), with a secondary effect on small intestinal enteroendocrine cell function (McDermott et al. 2006). There is a trend for plasma PYY concentrations to be higher in patients who received inotropic therapy but it is unclear whether this elevation is a physiological response to shock, or a direct consequence of the inotropic drugs. In animals, PYY infusion causes intestinal vasoconstriction and a rise in systemic arterial blood pressure (Lundberg et al. 1982).

83.6 Relationship Between Gut Peptides and Gastric Emptying in Critical Illness

There are several findings that support a potential role for enhanced enterogastric feedback in the pathogenesis of slow gastric emptying in critical illness, and the underlying mechanism may relate to abnormal humoral factors such as gut hormones. First, the motor abnormalities in both proximal and distal regions of the stomach in response to small intestinal nutrient stimulation are consistent with enhanced enterogastric inhibitory effects (Chapman et al. 2005; Nguyen et al. 2008c). Second,

plasma levels of the two major gastrointestinal hormones that mediate this enterogastric feedback are significantly elevated in critically ill patients (Nguyen et al. 2006b, 2007c, 2008b). In a recent study (Nguyen et al. 2008b), although there were no differences in gastric emptying and gastrointestinal hormones between critically ill patients who were randomized to receive enteral feeds on either day 1 or day 4, both fasting and nutrient-stimulated plasma concentrations of CCK and PYY were higher in the subset of patients who had delayed gastric emptying compared to those with normal gastric emptying. Third, there is an inverse relationship between the rate of gastric emptying and both the plasma levels as well as the integrated changes in the plasma levels of CCK and PYY (Fig. 83.5) (Nguyen et al. 2008b).

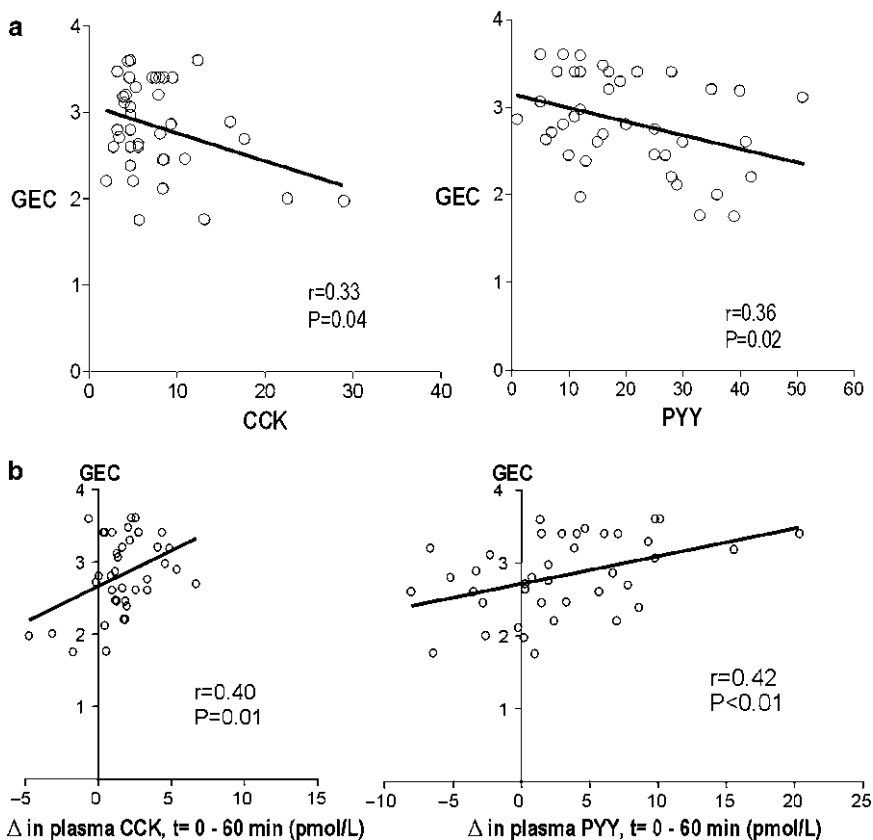
Together, these findings suggest that although only a small amount of nutrients is delivered into the duodenum in patients with delayed gastric emptying, the "increased sensitivity" of the duodenal receptors leads to a greater hormonal release for the same nutrient load, and that there is a complex interaction between gastric emptying, intestinal nutrients and hormonal release in critically ill patients. However, according to Grossman (1974), the physiological role of these hormones in critically ill patients can only be established if they suffice all three criteria: (i) there is a rise in plasma levels of the hormone in association with the stimulus; (ii) exogenous administration of the hormone at a "physiological" concentration produces a similar motor response; and (iii) the response is blocked by specific hormone antagonists (Grossman 1974). So far, there are no


Fig. 83.5 The relationship between plasma PYY and CCK concentrations during (**a**) fasting and (**b**) from baseline to 60 min, and the rate of gastric emptying assessed by gastric emptying coefficience (GEC) in critically ill patients (Data adapted from Nguyen et al. 2008a)

studies that have examined the role of CCK or PYY antagonists in critically ill patients, an area that warrants further evaluation.

83.7 Relationship Between Gut Peptides and Feeding Behavior During Critical Illness

An impaired conscious state, from either the underlying disease(s) or sedation for mechanical ventilation, is almost universal in critically ill patients. Oral intake is often not possible, and should be avoided due to the risk of aspiration, which make the assessment of appetite or feeding behavior difficult, if not impossible. Thus, it is not surprising that there are only very limited data in this area.

In non-critically ill, hospitalized patients, appetite and feeding behavior are significantly impaired, and are characterized by a premature feeling of fullness and loss of hunger (McWhirter and Pennington 1994; le Roux et al. 2005). More importantly, anorexia and the associated cachexia from cardiac failure in patients with severe pulmonary hypertension have been shown recently to be associated with an exaggerated and early PYY response to a test meal when compared to control subjects (le Roux et al. 2005). A marked reduction in appetite and oral intake was also noted recently in a small group of conscious, non-mechanically ventilated critically ill patients (Nematy et al. 2005), which resulted in poor nutritional status prior to and during ICU stay. In this study, appetite and food intake were positively associated with percentage increase in ghrelin and negatively with decrease in PYY. Although the appetite scores increased significantly after discharge from ICU, the mean daily energy intake remained lower than estimated energy requirements 4 weeks after discharge from hospital (Nematy et al. 2005). This prolonged suppression of appetite after critical illness may explain why malnutrition continues to be a persistent problem several months after ICU admission. There are no data on the relationship between CCK and appetite or feeding behavior in critically ill patients. Given the known effect of PYY and ghrelin on appetite and oral intake, however, these preliminary findings suggest a potential role for deranged plasma levels of gut peptides in the mediation of anorexia during critical illness.

83.8 Conclusions

Enteral nutrition undoubtedly improves the outcomes of critically ill patients, especially when it is delivered within the first 24 h of admission. In response to enteral nutrition, the humoral response of enterogastric feedback inhibition is abnormal, and both fasting and duodenal nutrient-stimulated plasma CCK and PYY concentrations are significantly elevated in critically ill patients. More importantly, plasma concentrations of CCK and PYY are greatest in patients with delayed gastric emptying or feed intolerance, a clinical manifestation of slow gastric emptying. Overall, an inverse relationship exists between the rate of gastric emptying and both fasting and postprandial plasma CCK and PYY concentrations after a gastric liquid meal. In view of the enhanced enterogastric inhibitory feedback on both proximal and distal gastric motility during critical illness, these findings strongly support the potential role of plasma CCK and PYY in the pathogenesis of gastric dysmotility in these patients. However, demonstration of a causal relationship requires the use of specific antagonists. As currently available prokinetic agents have major limitations, further evaluation of hormonal agents, especially CCK-A antagonists, may potentially provide alternative avenues for the treatment of feed intolerance in critically ill patients.

83.9 Applications to Other Areas of Health and Disease

Impaired gastric motility and appetite, leading to reduced oral intake and malnutrition, are common in many non-critically ill, hospitalized patients. The potential role of gut peptides, such as CCK and PYY, which mediate enterogastric feedback inhibition as well as appetite and oral intake should be explored in these patients. With the current availability of antagonists against CCK and PYY, the therapeutic implications of these agents for "*anorexia of the sick*" are potentially enormous if the role of gut peptides is to be proven.

Summary

- Adequate administration of enteral nutrition improves the outcomes of critically ill patients, but is frequently hampered by gastric dysmotility.
- Delayed gastric emptying of critical illness is associated with impaired motor function in all regions of the stomach during both fasting and fed state.
- In response to enteral nutrition, enterogastric feedback inhibition is abnormally heightened during critical illness.
- Both fasting and duodenal nutrient-stimulated plasma CCK and PYY concentrations are significantly elevated in critically ill patients, and are greatest in patients with delayed gastric emptying or feed intolerance.
- There is an inverse relationship between the rate of gastric emptying and both fasting and postprandial plasma CCK and PYY concentrations after a gastric liquid meal.
- There is an inverse relationship between fasting plasma concentrations of PYY and appetite and oral intake during critical illness.

Keywords and Definitions

Enteral nutrition: A method of giving nutritional support into the gastrointestinal tract via a feeding tube to subjects who cannot have oral intake.

Gastrointestinal hormones: A group of hormones or peptides secreted by cells of the gastrointestinal tract that regulates satiety, oral intake, and gastrointestinal motor function via their central and/or peripheral actions.

Critical illness: Medical condition(s) that lead to death rapidly if there is no provision of life support or organ support systems.

Gastric dysmotility: Disturbance of gastric motor activities that leads to impaired gastric function and delayed gastric emptying.

Enterogastric feedback inhibition: A physiological feedback process in which exposure of nutrients in the small intestine leads to slowing of gastric emptying, so that nutrition enters the small intestine at a controlled rate of 2–3 kcal/min.

Feed intolerance: The inability to tolerate nasogastric feeding due to impaired gastric emptying that leads to large gastric residual volume.

Chapter 84
The Brain and Leptin Resistance and Implications for Food-Related Disorders

Nina Eikelis and Gavin Lambert

Abbreviations

ob	The gene that encodes leptin protein
ob/ob	Obese mouse with a mutation in the leptin gene
db	The gene that encodes leptin receptor
db/db	Obese mouse with a recessive mutation in the leptin receptor gene
Ob-Rb	Splice variant of the leptin receptor gene
BBB	Blood–brain barrier
CSF	Cerebrospinal fluid
BMI	Body mass index
Jak	Janus Kinase, implicated in signaling by leptin
STAT	Signal transducer and activator of transcription protein
SOCS	Suppressor of cytokine signaling

84.1 Introduction

Obesity is a complex multifactorial disease involving environmental, genetic, behavioral, and psychological components. Despite its increasing prevalence and our improved understanding of the disease, only limited effective obesity management plans are in place. The discovery of leptin, an appetite-suppressing hormone principally produced in adipocytes, rejuvenated the field and initially generated great hopes for the treatment of obesity. Leptin was discovered through positional cloning in 1994 by Friedman's group at the New York's Rockefeller University (Zhang et al. 1994). Researchers soon demonstrated that administration of leptin to genetically obese mice (*ob/ob*) resulted in these animals losing weight dramatically. The weight loss was attributed to both suppression of appetite and increased metabolism. Leptin appeared to act via a negative feedback loop: when an animal overeats and is starting to gain weight, the increase in body weight leads to the increase in leptin expression and secretion, which stimulates energy expenditure and suppresses appetite, which in turn leads to the animal losing weight (Fig. 84.1). Unfortunately, the *ob/*ob mice did not turn out to be the model of

Fig. 84.1 Negative feedback of leptin regulation: as body weight increases so does leptin synthesis and secretion by adipocytes. Within the central nervous system (hypothalamus) leptin acts to decrease food intake and increase energy expenditure, thereby reducing body weight

common human obesity and the hopes for leptin to be an antiobesity drug soon dimmed after it was established that overweight and obese humans are not leptin deficient at all. In contrast, their circulating leptin levels are extremely high and are in proportion to the level of adipose tissue.

84.2 Regulation of Food Intake

There are many physiological and psychological mechanisms that are known to be involved in the regulation of food intake and body weight. For many years the brain, and in particularly the hypothalamus, was considered to be the center that integrates peripheral signals in the control of appetite and body weight. Early studies provided an anatomical basis to suggest that central mechanisms must operate to regulate food intake. The first evidence came from the experimental studies in rats where lesions of the lateral area of the hypothalamus led to animals losing weight, while lesions to the ventromedial hypothalamus resulted in animals overeating and becoming obese (Hennessy and Grossman 1976). Experimental evidence of this type led to the widely held view that food intake was controlled by two opposing hypothalamic nuclei (or centers): namely, one which initiates feeding and the second that brings about satiation.

More recently, a feedback system for the regulation of food intake and body weight has been proposed. This feedback is dependent upon not only the amount and the quality of the ingested food but also on the nutrient content. A number of investigations have provided evidence of a variety of hormonal systems and other mechanisms that can shape the central response to nutritional stimuli. For example, the gastrointestinal tract is known to be lined with a number of different sensory receptors responsible for "sensing" shape and texture of food. This information is sent to the brainstem via the vagus nerve (Sclafani et al. 2003), so that activation of the vagal nerve leads to satiation.

The concept that humoral factors generated in proportion to energy stores provide feedback to the central nervous system was first suggested by Kennedy in the 1950s (Kennedy 1953). Moreover, the gastrointestinal–brain axis has long been viewed important in meal termination, with gastrointestinal peptides such as cholecystokinin (CCK) and peptide YY (3–36) as examples. More recently, ghrelin (which is primarily produced by stomach) has challenged this notion. Ghrelin is a unique hormone that was found to stimulate food intake (Strader and Woods 2005). Injections of ghrelin, both centrally and intravenously, result in increased feeding and generation of adiposity (Hashimoto et al. 2007). Ghrelin levels peak in both humans and animals in anticipation of food intake.

Insulin is another key player that signals to the central nervous system about body adiposity. Insulin has been found in cerebrospinal fluid (CSF) where its concentration is increased following the infusion of glucose (Kontoyannia et al. 1974). Moreover, when insulin was infused into the lateral ventricle of baboons, a dose-dependent suppression of food intake and body weight was recorded (Porte and Woods 1981).

Another satiety factor which is the focus of this chapter is leptin. Leptin is synthesized primarily by adipocytes (fat cells) and is then secreted into the bloodstream. Leptin primarily acts in the hypothalamus on leptin receptors and initiates signals to stop eating and increase energy expenditure. Plasma levels of leptin follow body fat content closely: as body weight increases, so does the leptin concentration in blood. In addition, injections of leptin into obese animals with leptin gene mutations result in animals losing weight, both through reduction in food intake and increase in energy expenditure.

84.3 Obesity

Obesity is defined as excess in body weight that often results in significant impairment of health. It is a known factor for a number of chronic conditions including heart disease, hypertension, diabetes, kidney disease, and some forms of cancer. Obesity, including being moderately overweight, is also associated with a significant increase in odds of mood and anxiety disorders. An expert panel, convened by the National Institutes of Health in 1998, recommended that Body Mass Index (BMI), the ratio of weight to height (kg/m^2), be used to classify overweight and obesity. A person's BMI correlates significantly with risk of disease and death; for example, the risk of heart disease increases with increasing BMI in all population groups.

Maintaining a stable body weight requires that the food intake matches energy expenditure. Therefore obesity can only present when energy intake (food) exceeds energy expenditure (Fig. 84.2). Although at first sight it might seem that obesity is simply the result of changes to our diet and a reduction in physical activity, efforts to attribute obesity to a high level of energy intake (food intake) or to a low level of energy expenditure have been unsuccessful. Studies show that obesity is a multifactorial
Fig. 84.2 Energy balance is the difference between calorie intake (food) and energy expended through metabolism and daily activities. Finding the right balance of energy intake and expenditure allows one to achieve and maintain a healthy body weight

disease and is caused by more than one factor. One such factor that has come under examination over the past 15 years is the role of genetics, with a particular focus on the leptin gene and genes that are involved in leptin regulation.

84.4 Leptin Genetics

Earlier theories describing appetite and energy expenditure were suggestive of an adipose-derived circulating factor that sends signals to the central hunger and satiety centers in the brain to modulate food intake and body weight. However, the experimental techniques to validate such hypotheses were lacking at the time. Two strains of obese mutant mice, the *ob/ob* and *db/db*, proved invaluable in the study of food intake, energy expenditure, and body weight regulation.

84.4.1 The Leptin Gene

Leptin was discovered through positional cloning using the leptin-deficient mouse (Zhang et al. 1994). Leptin was initially found to be expressed in white adipose tissue (Zhang et al. 1994), however, further studies found leptin to be synthesized in a wider variety of tissues than originally thought, including placenta, stomach, mammary gland, heart, and brain (Bado et al. 1998; Eikelis et al. 2004; Morash et al. 1999). The *ob* gene encodes a 4.5 kilobase messenger RNA with a highly conserved 167 amino acid open reading frame. Leptin in humans has been localized to chromosome 7 and consists of three exons separated by two introns (Zhang et al. 1994). A nonsense mutation in codon 105 has been identified in the *ob/*ob mouse (Zhang et al. 1994). A C→T mutation results in a change of amino acid and a premature stop codon. Overexpression of the leptin gene has been found in both subcutaneous and visceral tissues of overweight and obese individuals (Lonnqvist et al. 1995).

In humans, the first research investigating mutations in the leptin gene failed to identify any individuals with a mutation in the coding region of the leptin gene (Considine et al. 1995; Maffei et al. 1996). A mutation in the leptin gene in humans was first reported in two children in 1997 (Montague et al. 1997). The mutation was a deletion of a single nucleotide in the codon 133 of the leptin gene. This deletion caused a frameshift mutation and a premature stop codon resulting in a nonfunctional protein (Montague et al. 1997). In a separate report, a mutation in codon 103 has been reported in three members of a Turkish family (Strobel et al. 1998), also resulting in the leptin protein to be generated with no biological activity. The phenotype of leptin-deficient individuals is similar to that seen in *ob/ob* and *db/db* mice and is characterized by early onset obesity, hyperphagia, and hypothalamic hypogonadism.

84.4.2 The Leptin Protein

Human leptin is synthesized as a 167-amino acid precursor protein that includes a 21 amino acid signal sequence that is cleaved upon secretion from the cell. Mature leptin is 146 amino acids in length, and under reducing conditions migrates as a band at approximately 16 kDa on sodium dodecyl sulfate–polyacrylamide gel electrophoresis**.** The sequence of amino acids is highly conserved between species. The largely hydrophilic amino acid sequence of leptin has no notable structure

motifs or membrane spanning domains other than an *N*-terminal signal sequence (Zhang et al. 1994). In addition, the leptin protein contains a disulfide chain that appears to be important for its biological function (Grasso et al. 1997). Human leptin is 84% homologous to mouse and 83% homologous to rat leptin. The extensive homology of the *ob* gene product among species suggests that its function is also highly conserved. Structural analysis indicates that it is similar to the cytokine family of proteins and as such consists of four alpha-helicies (Madej et al. 1995).

84.4.3 The Leptin Receptor

The leptin receptor is encoded by the *db* gene. Tartaglia et al. were the first to describe the leptin receptor in a mouse (Tartaglia et al. 1995). It belongs to the interleukin 6 receptor family of cytokine receptors. There are a number of leptin receptor isoforms that result from alternative messenger RNA splicing as well as proteolytic processing of the subsequent leptin products (Chua et al. 1997). In all species, leptin receptor isoforms can be divided into three classes: secreted, short, and long (Fig. 84.3). The secreted leptin receptor only contains the extracellular domain but it binds leptin with the same affinity as the membrane-bound receptor. The secreted leptin receptor perhaps modulates circulating leptin levels by delaying its clearance and determines the amount of free versus bound leptin. In obese individuals, a significantly larger proportion of leptin circulates in the free form compared to lean individuals (Sinha et al. 1996). In addition, the amount of free leptin increases in proportion to BMI, which perhaps suggests that leptin-binding protein (soluble leptin receptor) is saturated in obesity.

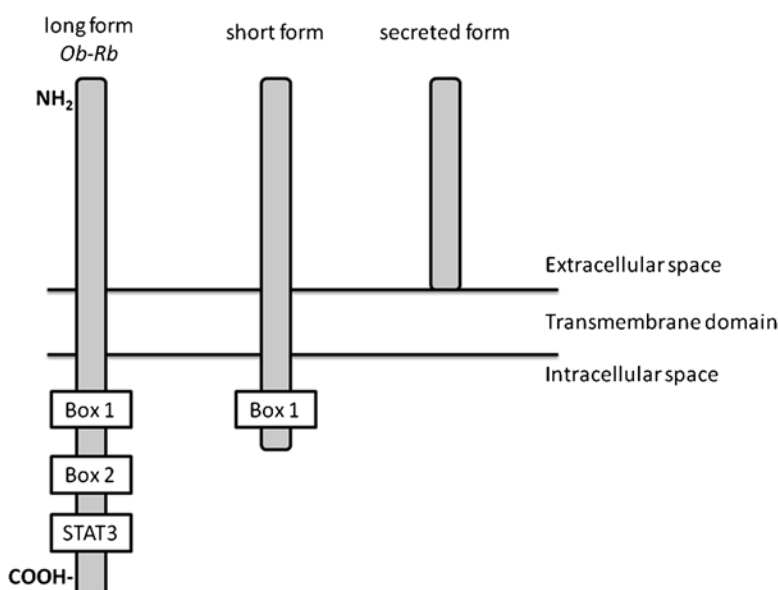
Short forms and a long form of the leptin receptor contain identical extracellular and transmembrane domains, but then differ in intracellular sequence because of alternative splicing. The long form of the leptin receptor, often referred to as *Ob-Rb*, is the only leptin receptor that contains all


Fig. 84.3 Schematic representation of leptin receptor isoforms. All leptin receptors share an identical extracellular domain (ligand-binding domain), but differ in their carboxy terminus. Only the long isoform, *Ob-Rb*, has all the intracellular motifs required for signal transduction via Jak-STAT3 pathway

intracellular motifs required for signal transduction (Tartaglia et al. 1995). Indeed, the originally described *db/db* mice lack only the long form of the leptin receptor, but have the same phenotype as mice lacking all leptin receptor isoforms as well as leptin-deficient mice (*ob/ob*) (Chua et al. 1997; Tartaglia et al. 1995). While the role of the short-form and secreted leptin receptors are less clear, they have been suggested to be involved in leptin transport across the blood–brain barrier (BBB; El-Haschimi et al. 2000).

Ob-Rb is highly expressed in the hypothalamus in both the human and rodent brain. Experimental studies identified the hypothalamic arcuate, dorsomedial, paraventricular, ventromedial, and lateral nuclei as the principal sites of leptin receptor expression in the central nervous system (Fei et al. 1997; Mercer et al. 1996). Interestingly, all of these nuclei have previously been implicated in the regulation of body weight. Indeed the ablation of these centers results in increased feeding and other neuroendocrine abnormalities that mimic the phenotypes of *db/db* and *ob/ob* mice, which indicates that these hypothalamic nuclei are crucial for leptin signaling (Elmquist et al. 1999). Outside the hypothalamus, the leptin receptor is also found in the thalamus and cerebellum (Guan et al. 1997; Mercer et al. 1998).

Similar to the *ob* gene, mutations in the *db* gene are extremely rare in humans. The first demonstration of a leptin receptor mutation in humans was reported by Clement (Clement et al. 1998). In these patients, a single G A substitution in exon 16 resulted in a nonfunctional leptin receptor lacking both transmembrane and intracellular domains. As a result of this mutation, the truncated leptin receptor is unable to activate the signal transduction pathway. Similar to the *ob* gene mutation in humans, a mutation in the leptin receptor gene causes hyperphagia and early onset obesity.

84.4.4 Leptin Signaling Pathway

Binding of leptin to *Ob-Rb* causes a rapid activation of receptor-associated Janus kinase-2 (Jak2), a tyrosine kinase, which in turn leads to leptin receptor phosphorylation (Bjorbaek et al. 1997). This initial activation of Jak2 is a crucial step in leptin signaling as the leptin receptor does not have enzymatic activity on its own. Activated Jak2 tyrosine phosphorylates itself as well as a number of tyrosine residues in the intracellular domain of *Ob-Rb*, and in particular Tyr_{985}, Tyr_{1077}, and Tyr_{1138} (for review see Villanueva and Myers 2008). Each of these tyrosine residues recruits a specific set of downstream signaling proteins when phosphorylated. For example, phosphorylated tyrosine at residue 1,138 binds and mediates activation of signal transducer and activator of transcription 3 (STAT3), which in turn activates transcription of suppressor of cytokine signaling 3 (SOCS3). Phosphorylated STAT3 is a second messenger for the long-form leptin receptor. Not surprisingly, mutations at Tyr_{1138} abolish STAT3 signaling by the leptin receptor (Baumann et al. 1996).

84.5 Leptin Resistance Phenomenon

As briefly mentioned in the Introduction, early results of clinical investigations clearly demonstrated that overweight and obese humans are not deficient in leptin. In fact, there are only a few reported cases of obesity caused by the mutation in the *ob* or *db* gene (Clement et al. 1998; Montague et al. 1997; Strobel et al. 1998). Therefore, despite promising results of leptin replacement therapy in obese leptin-deficient mice, endogenous leptin is ineffective in reducing appetite or increasing energy expenditure in overweight and obese humans. Consequently, it soon became apparent that neither

endogenous hyperleptinemia nor leptin replacement even at supraphysiological doses would be effective in the clinical setting. This failure of elevated leptin levels to suppress feeding and initiate weight loss was termed "leptin resistance."

A number of mechanisms have been proposed to contribute to the development of leptin resistance and consequently obesity. Animal models of obesity provided excellent systems to explore how leptin functions and to identify which central mechanisms or signaling pathways might be compromised. The delivery of leptin into the brain seems to represent the crucial step in the regulation of food intake and energy balance given that leptin exerts its effects in the hypothalamus.

Although leptin administration has been reported to reduce food intake and normalize body weight in leptin-deficient mice, the relevance of this genetic model to the treatment of obesity remains to be determined. On the contrary, the diet-induced model of obesity may more adequately reflect the physiology of the obese human than does the leptin-deficient *ob/ob* mouse. For example, diet-induced obese mice exhibit resistance to peripherally administrated leptin, while they retain sensitivity to leptin after intracerebroventricular infusion (Van Heek et al. 1997). These observations perhaps suggest that some overweight and obese humans, who appear to be unresponsive to elevated circulating endogenous leptin, may respond to a leptin analogue delivered directly into the central nervous system. To overcome the multitude of barriers that stand in the way of potential therapeutic agents reaching the central nervous system, numerous drug delivery strategies have been developed, which generally aim at either manipulating drugs or disrupting the BBB (for review see Misra et al. 2003).

In a study conducted by Wilsey and colleagues (Wilsey et al. 2003), leptin resistance in rats was caused by 100 days of high fat feeding. After the establishment of obesity, the animals received a single central injection of recombinant adeno-associated virus particle encoding leptin. Lean chow-fed control counterparts responded robustly to such treatment, as evident by significant weight loss. In contrast, rats fed a high-fat diet were completely unresponsive to central leptin overexpression (Wilsey et al. 2003). Furthermore, central leptin treatment caused a significant increase in the STAT3 signaling pathway in lean rats, but failed to do so in obese animals fed a high-fat diet. The authors concluded that central overexpression of leptin is not a potent strategy to reverse diet-induced obesity.

Although leptin was thought initially to be synthesized primarily by adipocytes, there are a number of studies demonstrating leptin production in sites other than adipose tissue (Bado et al. 1998; Eikelis et al. 2004; Esler et al. 1998). Previous observations from our laboratory of leptin overflow in the internal jugular vein were suggestive of leptin production in the brain itself (Eikelis et al. 2004; Esler et al. 1998; Wiesner et al. 1999). Simultaneous sampling of arterial and venous blood across a range of organs is a useful tool to identify which organ releases leptin (or other hormones, transmitters, etc.) to or removes it from plasma. The central venous catheter was used to sample blood from the internal jugular vein. Using this method, we investigated the capacity of the human brain to extract leptin from plasma to test whether this was reduced in obesity as might be predicted by the leptin resistance model. Our expectations were that measurable leptin uptake into the brain from plasma might be present in lean but not obese people. Surprisingly, our initial findings indicated a net efflux of leptin from the brain (Eikelis et al. 2004; Esler et al. 1998; Wiesner et al. 1999). Even more surprising was the observation that leptin release was greater in overweight compared to lean men. The leptin efflux from the brain may well have derived from brain production and/or uptake from plasma. The production of leptin in the brain has implications for the prevailing idea of leptin resistance in obesity, as it has been proposed that the primary flaw in obesity may be a reduction in leptin transport to the brain. Our demonstration of leptin production by the brain itself contradicts this idea.

To verify this observation, we have used human donor tissue to directly examine leptin gene expression in the human hypothalamus (Eikelis et al. 2007). The source of the obtained tissue included a mix of male and female donors, of different age and BMI. Leptin was detected in hypothalamic tissue of some donors. However, we found no relation of leptin gene expression in the

hypothalamus to the BMI or gender (Eikelis et al. 2007). Interestingly, in our studies leptin gene expression was only evident in donors who died suddenly and unexpectedly, as opposed to if deaths were from suicide or illicit drug use. Therefore, we can speculate that contrasting nutritional state, with possibly poor nutrition just prior to death with suicide or drug use, may have lead to different levels of leptin gene expression in the brain. Interestingly, in a separate study while arterial leptin concentration in patients with major depressive disorder and healthy volunteers was not different, leptin release from the brain into the jugular vein in patients with major depressive disorder was reduced (Eikelis et al. 2006). These two observations of reduced leptin release by the brain of depressed patients and the fact that leptin was only seen in the brains of the donors who died of natural causes (as opposed to death by suicide) suggest that leptin may play a role beyond appetite control. Indeed, leptin has also been linked to depression, in at least rats, and implicated as a neurotrophic factor. In an elegant study by Pinto et al. (2004), leptin was demonstrated to act as a neurotrophic factor in a mouse hypothalamus. Leptin-deficient mice were found to have reduced numbers of synapses in the arcuate nucleus of the hypothalamus, the defect which was rapidly normalized and detectable within several hours of treatment (Pinto et al. 2004).

As mentioned earlier, leptin resistance may arise as a result of the transport of leptin into the brain may become compromised, the end result being the inability of leptin to reach its target in the hypothalamus (Banks and Farrell 2003). The blood–brain barrier (BBB) plays an important role in the communication between the brain and the peripheral tissues, by controlling the entry of major hormones into the brain from blood. The blood–CSF barrier at the choroid plexus and BBB at the cerebral endothelium are two major controlling sites for entry of circulating proteins into the brain. It has been suggested that leptin receptors in the choroid plexus (Devos et al. 1996; Tartaglia et al. 1995) and at the BBB (Bjorbaek et al. 1998; Golden et al. 1997) may mediate leptin transport into the brain. Interestingly the short form of the leptin receptor has been found to be expressed in the choroid plexus and has been suggested to act merely as a leptin transporter (Tartaglia 1997).

The study by Zlokovic et al. (2000) used an in situ brain perfusion model to determine simultaneously the rates of leptin transport across the blood–CSF barrier, into the hypothalamus, and at the BBB in lean rats with the assumption that radiolabeled leptin behaves in a manner similar to unlabeled endogenous leptin. They reported a rapid and high-affinity transport system that mediated leptin entry into the hypothalamus and across the blood–CSF barrier. In contrast, low-affinity transport was found at the BBB outside the hypothalamus (Zlokovic et al. 2000). Leptin transport across the blood–CSF barrier appears to be saturated at higher plasma leptin levels, therefore suggesting that the choroid plexus may serve a rate-limiting function to avoid increases in CSF leptin concentrations. In obese individuals, increases in circulating leptin levels are not accompanied by increases in the CSF leptin concentration (Caro et al. 1996). Analysis of leptin concentration in the CSF of obese individuals was reported to be similar to those found in nonobese matched controls (Schwartz et al. 1996). These observations do suggest that impairment in the transport of leptin across the blood–CSF barrier may underlie leptin resistance, at least in part, in some obese individuals.

Another possible mechanism that may explain leptin resistance in some cases of obesity involves a defect in the leptin receptor itself. When we have examined the full-length leptin receptor expression in the human hypothalamus across a wide range of adiposites, we have found no relation between the level of *Ob-Rb* expression and BMI (Eikelis et al. 2007). These results do suggest that the leptin resistance phenomenon cannot be simply explained on the basis of leptin receptor down-regulation in obesity. In addition, as discussed earlier, while leptin receptor mutations have been reported in humans, they are very rare.

Since most cases of human obesity are not associated with leptin deficiency or mutations in the leptin receptor, a defect may lie in the signaling cascade. Whereas a large body of evidence suggests that central leptin resistance contributes to the development of diet-induced obesity, the molecular
Fig. 84.4 Representative photomicrographs of c-fos positive nuclei in the periventricular nucleus of the hypothalamus. Shown are the sections from a lean and obese rabbits given 100 μg leptin intracerebroventricular 90 min before the perfusion. In the lean rabbit (*left*), central leptin injection resulted in many c-fos positive cells being present in the periventricular nucleus. The central injection of leptin in an HFD animal (*right*) caused only few fos-immunoreactive cells in the corresponding nuclear cells

mechanisms behind this resistance are not clearly understood. Intracerebroventricular leptin administration to lean rabbits indicated that leptin activates specific nuclei in the hypothalamus, as indicated by c-fos immunoreactivity (Fig. 84.4, unpublished observations). However, rabbits fed a high-fat diet for 3 weeks were unresponsive to central leptin injections as evidenced by minimal c-fos activation (Fig. 84.4, unpublished observations).

This demonstration excludes the possibility that leptin resistance in the overweight rabbits induced by diet was due to impaired transport of leptin, as leptin was given intracerebroventricularly and therefore bypassed the BBB. Therefore, in this case, diet-induced obesity may have had an effect on the downstream signaling pathways. Given that signaling through STAT3 second messenger system appears critical in the leptin signaling cascade, a major focus has been on identifying whether STAT3 is in fact impaired in diet-induced obesity. Accordingly, a defect in STAT3 activation by leptin in the arcuate nucleus of the hypothalamus was reported in diet-induced obese mice (El-Haschimi et al. 2000).

84.6 Eating Disorders

There exist many theories and much data indicating that in obesity there exists a strong biological component underlying hunger and eating behavior. What about people with eating disorders? What are the mechanisms underlying hunger and eating for people with such disorders? While emotional, behavioral, and environmental factors play a significant role in the onset of eating disorders, a great deal of research also points to the possibility of a genetic component.

In general terms, there are mainly three kinds of eating disorders: binge eating, anorexia nervosa, and bulimia. Binge eating is characterized by one eating a very large amount of food until she or he feels uncomfortably full. This binge eating is done when one is not hungry. According to the DSM-VI, anorexia nervosa has two types; a restricting type and a binge-eating/purging type (American Psychiatric Association 1994). Anorexia nervosa restricting type is when one extremely restricts food intake, and it is not followed by binge-eating or purging behavior. On the other hand, anorexia nervosa binge-eating/purging type is described as a person who is engaged in purging and binge-eating regularly. A common symptom of

anorexia is one putting her or himself on self-starvation to avoid feeling fat or gaining weight. Although people with this disorder weigh far below normal, they still have the perception of being overweight. Eventually they are at risk of losing their lives due to malnutrition. To fulfill the diagnostic criteria for bulimia, the binge eating habits and compensatory behavior have to occur at least twice a week for 3 months. Despite their excessive concern about body weight, bulimics are usually of normal weight.

Research shows that eating disorders are characterized by abnormalities in central neurotransmitter levels. For example, it has been shown that eating disorders are associated with elevated concentrations of serotonin (Kaye et al. 1998). Numerous other hormones and neurotransmitters in the brain have been linked to eating disorders. Stress triggers the production and secretion of cortisol, and chronically elevated levels of this stress hormone have been observed in patients with anorexia and bulimia. The results of clinical studies show that pharmacological doses of glucocorticoids (such as cortisol) can increase circulating plasma leptin in the short term (Newcomer et al. 1998). Furthermore, these cortisol-induced increases in leptin concentration suggest a mechanism that may contribute to anorexia and weight loss associated with this condition.

Given that eating disorders are associated with abnormal eating behavior and dysregulation of the endocrine axis, extensive research has been carried out to understand the role of leptin in the pathophysiology of eating disorders. Anorexia and bulimia are both associated with altered eating patterns and purging behaviors, malnutrition, and/or denutrition with consequent metabolic changes that, in turn, are responsible for several organic alterations, including abnormalities in reproductive hormone activity and neuroendocrine functions.

It is known that when body fat mass and weight drop past a certain point, leptin levels also drop, which leads to the stimulation of appetite. While under normal conditions of unrestrained food intake leptin serves as a measure of the available energy stored in the adipose tissue, under conditions of acute changes in energy intake as seen in eating disorders, leptin secretion varies independent of the available fat stores and may be affected by a macronutrient content (Kolaczynski et al. 1996). Indeed, the study by Monteleone et al. also suggested that factors other than body weight changes may affect leptin synthesis and secretion (Monteleone et al. 2002). In this study, the assessment of leptin dynamics was done in untreated patients with bulimia and matched healthy volunteers during the acute fasting and refeeding. While patients with eating disorders did exhibit low leptin levels at baseline compared to healthy individuals, they did not respond to short-term fasting; however, leptin levels increased after refeeding (Monteleone et al. 2002). Therefore, while even at low plasma values, leptin still holds its function as a sensor of body weight mass, its function as an index of acute changes in energy balance is lost.

84.6.1 Leptin in Anorexia Nervosa

Anorexia nervosa is an illness characterized by a chronically low body weight and distorted body image with an extreme fear of gaining weight. Individuals diagnosed with anorexia nervosa control their body weight through starvation and, in some cases, increased exercise (Klein et al. 2007). The patients lose their weight by reducing their total food intake. Since anorexia nervosa is at the opposite end of the spectrum from obesity, an attempt has been made to determine whether a correlation exists between leptin concentration in anorectic patients and BMI, percent body weight, and duration of illness.

A study by Eckert et al. reported low leptin levels in patients with anorexia during starvation and subsequent increase in leptin concentration following refeeding (Eckert et al. 1998). While low leptin levels are strongly associated with the increase in energy intake, this physiological stimulus is perhaps overridden in patients with anorexia nervosa by a morbid fear of food. The fact that leptin levels increased upon nutritional rehabilitation in these patients does suggest that there is a normal physiological response of leptin to body weight increase in anorexia. In the same study, it

was demonstrated that while there was a strong correlation between body weight and leptin concentration in healthy female control subjects, that correlation was absent in anorectic women during starvation (Eckert et al. 1998). Interestingly, the linear correlation appeared in anorectic females during refeeding, suggesting perhaps that at very low BMI there is a threshold below which leptin cannot be lowered any further (Eckert et al. 1998). This concept is consistent with data indicating sources of leptin aside from adipose tissue.

The fact that leptin rose dramatically during refeeding raises the question as to whether weight-induced increase in leptin levels during rehabilitation limit further weight gain. Longitudinal studies have also demonstrated that in patients with anorexia nervosa undergoing recovery, circulating leptin levels rise progressively and reach values disproportionate to those measured in stable-weight healthy individuals (Hebebrand et al. 1997). This observation further suggests that hyperleptinemia in anorexia nervosa patients during refeeding may be one of the factors making it difficult for patients to reach and to maintain their weight. Furthermore, a too rapid gain in weight with concomitant high circulating leptin levels in these patients was found to be associated with poor prognosis (Remschmidt et al. 1990). In another study, leptin concentration was measured in CSF of patients with anorexia nervosa and control individuals. While the leptin concentration in the CSF of the anorectic patients was lower compared to healthy individuals, the ratio of CSF to plasma was significantly elevated (Mantzoros et al. 1997). Furthermore, leptin levels in these patients increased, or were comparable, to the control levels after treatment (refeeding) even though they had not reached their desired body weight. Altogether, these results do suggest that the rapid restoration of leptin levels before reaching the desired body weight could contribute to resistance of these patients to increase weight and recovery.

84.6.2 Leptin in Bulimia Nervosa
