On the other hand, Jackson, Djafarian, Stewart and Speakman (2009) found an association between increased hours of TV viewing and elevated body fatness among preschool children, but this association was not mediated by reduced physical activity. A weak but statistically significant association was found between hours of TV viewing and reduced physical activity among 3–4-year-old children (DuRant et al. 1994), while another study showed no relationship between physical activity and TV viewing among Mexican children living in Mexico City (Hernandez et al. 1999). Thus, there is a lack of consistency in findings from one study to another. In a follow-up study in adolescence of the potential adverse developmental outcomes of TV viewing in early childhood in two cohorts of children in Massachusetts and Kansas, USA, Anderson, Huston, Schmitt, Linebarger and Wright (2001) found no relationship between frequent TV viewing in early childhood and the development of obesity in adolescence. In fact, the single weak but statistically significant relationship was found between

Table 167.4 Key features of energy displacement hypothesis

- Increased time spent in early childhood in sedentary leisure activity of watching TV
- Increased time watching TV occurs at expense of other physical activity
- Children with increased sedentary behavior require lower energy consumption (food), but food intake remains same
- Food intake exceeds daily requirements for decreased physical activity
- Overweight and obesity result from energy intake exceeding energy expenditure

This table outlines one explanation of underlying mechanism by which children develop overweight and obesity in early childhood. Increased hours spent watching TV reduces time available for more physical activities, yet food consumption remains constant, leading to surplus energy intake to energy requirements, in turn resulting in development of overweight and obesity

amount of sedentary behavior (hours spent TV viewing) during adolescence for girls but not boys. The authors interpreted these results as further evidence of findings from multiple studies that females become more sedentary than males during adolescence. Consequently, time that could potentially be taken up with more active leisure pursuits becomes displaced with TV watching for adolescent girls (Anderson et al. 2001).

These equivocal results are not surprising, given the problem that, in large-scale epidemiological studies of factors that contribute to children's and adolescents' growth, it has been difficult to establish a link between physical inactivity and overweight and obesity (see: for example: Krassas et al. 2001, Hernanadez et al. 1999). What is overlooked in these studies is that TV viewing in early childhood does not always displace all forms of physical activity, and young children have been shown to maintain relatively stable levels of physical activity in addition to watching quite a few hours of TV during their usual leisure times (Rey-Lopez et al. 2008). Absence of a clear relationship between time spent watching TV and overweight and obesity among children in these different studies is likely to be linked to methods adopted commonly for data collection of the amount and type of participants' leisure activities. Many of the studies required children or their parents to keep a diary of their daily activities [e.g. Anderson et al. (2001) (early childhood phase of study); Wake and Hesketh 2003], while other samples of children's activity levels are derived from a short-term and an ultimately limited sample of children's regular activity (e.g. ABS 2004). Retrospective diary methods of information gathering have the potential problem of social desirability bias. That is, children and parents report what they should be doing rather than what they are actually doing, and often diaries are completed retrospectively, sometimes several days after a reported activity took place. Further, many studies that investigate links between amount of TV viewing and overweight and obesity in children and youth rely on measurements of TV viewing time that do not report the psychometric properties of the measure used, how the measure was administered, and how data were coded and tabulated. Such methodological problems inevitably compromise the reliability and validity of results that report statistically significant associations between TV viewing and activity levels (Bryant et al. 2007). Perhaps data collection daily at home or school, completed by children themselves, their parents, or their teachers, in the presence of researchers, might overcome problems with diaries completed retrospectively after too much time has elapsed. Such methods are, however, potentially intrusive into family or school life, are very labor-intensive, and dictate large research budgets. Other potential methodological problems include differences in the way children's activity levels are characterized in the different studies. The diverse behaviors of which children's physical activity is comprised has led researchers to recommend that activities be stratified as high activity (e.g. running; jumping, team sports), medium activity (e.g. walking round school playground during recess), and low activity (e.g. occasional movements during play activity) (Goran et al. 1997). Other researchers note that the intensity of the activity may also affect the amount of energy expended during an activity (Strauss et al. 2001).

Contradictory findings should also be considered in light of evidence that the same young children who report that their usual play activity is watching TV when at home alone or in the company of siblings and friends also report that they engage in vigorous outdoor-active play, such as riding bicycles, playing sports, and other physically active games, such as chasey or rough-and-tumble play (Jenvey 2003). It should be noted that children reported less time spent in more vigorous physical activity but also reported that their physical activity was more intense (Jenvey 2003). Moreover, the results of a large-scale survey of Australian children's leisure activities (ABS 2004) support Jenvey's (2003) findings. In the ABS survey, although young children (5–8 year-olds) spent a lot of leisure time in sedentary activities, mainly watching TV, playing computer games, and accessing the Internet, more than 60% of that age group also participated in organized sports and cultural activities, that included learning and practicing folk dancing (ABS 2004).

Larson (2001) notes that even young contemporary children from both developed and developing countries have far more leisure time than children of previous generations, whose time was taken up with household chores and contributing to income-generating activities. Increased technological assistance reduced repetitive manual labor associated with feeding, transportation, and providing a suitable home for children. When many children in developing countries were no longer needed to contribute to such activities, they had more free time available for all forms of leisure activity. Subsequently, children in developing countries also began to spend more of their leisure time watching TV (Larson 2001).

Additional research evidence indicates that certain inherited propensities to develop high leptin levels and fat-mass are implicated in the development of obesity in early childhood (Comuzzie et al. 2003). This latter finding indicates that some children will be more susceptible to early-onset obesity, and low levels of physical activity will have differential developmental outcomes for children according to their inherited predispositions.

Thus, a direct relationship between inactivity resulting from frequent TV viewing in early childhood and the development of obesity is not clearly established. Other factors, such as amount and type of all leisure activities each child engages in, and the level and intensity of the physical activity, together with inherited propensities that differentially predispose some children to the development of obesity in early childhood need also to be taken into account when attempting to ascertain the reasons for increasing levels of obesity among young children worldwide. As well as the amount of time children spend watching TV, it is also important to consider the content of the TV that young children watch.

167.6 Food Advertisements During Designated Children's Television Time and Amount and Type of Food Consumed by Young Children

Before considering the processes by which young children are influenced by advertisements on TV, it is important to consider just how many food advertisements are placed during times when young children are most likely to be watching. As much as 30% of non-program content during children's designated TV time in both Australia (Wilson et al. 1999) and New Zealand (Hill et al. 2006) contains advertisements for food, and the types of products advertised are of poor nutritional quality. That is, food types that are commonly referred to as "snack foods" that can be purchased in attractive packaging at supermarkets and "fast foods" made and sold at fast food outlets are frequently advertised during designated children's TV times. The types of foods advertised to Australian and New Zealand children on TV are similar to products advertised during peak periods of children's viewing in USA (see, for example, Kuribyashi et al. 2001; Harrison and Marske 2005) and for advertisement content on British TV during times of peak viewing by young children (for example, Pine and Nash

Table 167.5 Estimates of proportion of children's television (TV) programs that contain food advertisements

Proportion of food advertisements/children's TV programs[a]	Population and source
Approx. 30% of programs	New Zealand children (Wilson et al. 1999)
Approx. 30% of programs	Australian children (Hill et al. 2006).
Approx. 35% of programs	US children (Kuribyashi et al. 2001)
>25% of programs	British children (Pine and Nash 2003)

This table summarizes research estimates (as percentage of total TV program time), the proportion of designated children's TV programs that contain advertisements for *snack* and *junk* foods and which are broadcast in four different English-speaking populations. Proportional estimates show consistently high proportion of programme content in four different developed countries

[a]In all estimates, majority of food products advertised were most likely to contain levels of salt, saturated fats, and sugars that exceeded recommended daily allowances for children in target age ranges

2003). Table 167.5 summarizes estimates of the level of exposure of children to televised food advertisements across different child populations.

The foods advertised during children's TV programs were more likely to contain levels of salt, saturated fats, and sugars that exceeded recommended daily allowances for children of the ages in the target audiences (Harrison and Marske 2005). They also advertised highly processed foods that were low in dietary fiber (Kuribyashi et al. 2001). The latter compared the contents of food advertisements placed in Saturday morning children's programs with contents of food advertisements placed in Saturday evening adult programs across four free-to-air US TV stations. When the food types advertised during periods of peak viewing by children were compared with types of food products advertised during periods of peak viewing by adults, it was found that there were more food commercials shown during the peak (early morning) children's program hours; they were more repetitious and took up a higher proportion of the overall program time than food advertisements screened in the evenings during prime-time adult programming. Overall, food products advertised during Saturday morning programs, a period of peak viewing by young children, contained significantly higher levels of sugar and saturated fat than products advertised during Saturday evening programs, when the majority of the audience was adult (Kuribyashi et al. 2001).

While it is important to establish the frequency of exposure of young children to certain food types while they watch TV, it is equally important to consider how such advertising might affect children's food preferences, eating patterns, and general nutrition. Evidence from research in different countries indicates that both amount and type of food provided to young children by their parents, grandparents, and even older siblings are the most significant influence on the development of food preferences and eating patterns in early childhood (Cullen et al. 2000). Thus, if parents usually purchase and consume *snack foods* and *junk foods*, then such foods will be readily available to children in their homes. Messages contained in advertising content might reinforce young children's preference to consume foods available already in their home. Even when young children respond to the persuasive intent of the advertisements, it is not clear how young children might then influence their parents to purchase foods advertised on TV, if such foods are not usually provided by their parents or other family members in their homes. Taras, Sallis, Patterson, Nader and Nelson (1989) did show a more direct link between young children's exposure to certain food advertisements on TV and the types of foods they consumed. Mothers of 3–8 year-olds completed a questionnaire on children's TV viewing patterns and the nature of their requests for certain food products commonly advertised on TV (Taras et al. 1989). The more often children saw programs containing advertisements for certain food types, the more frequently they requested that their parents purchase the products. Different relationships were found for exposure to sporting goods advertisements and children's requests for sporting goods. The more time children spent watching TV generally, the less frequently they requested that their parents purchase sporting goods promoted in advertisements

they viewed on TV. The design of this study did not control for other potential confounds in the data. For example, children who watch a lot of TV are also exposed to advertisements for all sorts of products, but the type of food advertised (mostly snack, and processed packaged food) is relatively cheap, when compared with toys, sporting goods, and other products also advertised frequently during children's TV programs. Perhaps the more snack food that was requested by children, purchased subsequently by parents, and thus consumed by children occurred because of its cheapness relative to other advertised products (e.g. toys and sporting goods).

Additionally, there was no mention of how frequently parents succumbed to their children's demands to purchase products they saw advertised on TV. This is often referred to as the "pester factor", and is apparently one of the intentions of advertising that targets young children. Nevertheless, while advertisers identify its existence, and it is asserted that children's demands play a role in parents' response to their children's requests for certain products, there is little evidence to support this view-point (Jenvey and Jenvey 2003). It is likely that parents who monitor what their young children watch on TV would be far more vigilant about responding to their children's requests for the types of foods advertised (Jenvey and Jenvey 2003). Yet, few studies have surveyed parents of young children about this issue. A second omission from Tallis et al.'s (1999) study was information about the availability of those foods in children's households. Results of other studies show that types of foods available in young children's households, together with their parents' own consumption of food of poor nutritional quality, have a significant role in shaping the food preferences and diet of their young children (Guidetti and Cavazza 2008).

It is proposed that the psychological processes that underlie children being influenced by the media about food, attitudes to food, diet, and exercise involve the dual processes of imitation and modeling (Bandura 1986). At first, children tend to imitate the behaviors of influential adults in their environment. Reinforcement of behaviors of influential others occurs vicariously. Children are rewarded by watching others being rewarded, and are likely to use these people as models upon whom they can base their own behavior, in the expectation that they themselves will be rewarded directly for similar behavior. This process explains why children might show a preference for food advertised on TV, especially if the food is endorsed by popular TV characters, or high profile media, or sporting personalities. This process is understood well by corporate marketers, and is one of the reasons why popular actors, sporting and other media personalities are used for both questionable advertising campaigns (e.g. junk foods advertisements targeted at young children), as well as more prosocial campaigns that contain community service messages (e.g. support programs for child cancer sufferers and road safety campaigns).

Imitation and modeling also explain why parents, and mothers especially, act as important role models in the development of children's food preferences and eating habits. There is evidence to support the influence of parent's modeling both healthy and unhealthy eating habits and food preferences (Guidetta and Cavazzo 2008). Among young 3–8 year-old children, parents or immediate family members are the most significant role models for children's behaviors (Black et al. 2001; Cullen et al. 2000), and this understanding of the importance of parents and even grandparents modeling appropriate nutrition and exercise habits for their offspring has been incorporated into successful intervention programs to improve infant and young children's nutrition and physical activity, as well as to prevent or reverse the early onset of overweight and obesity (Black et al. 2001). Furthermore, in an epidemiological study of factors that contribute to fruit and vegetable consumption by 6–12-year-olds, the most significant predictors of fruit and vegetable consumption by children were, in order, the provision of fruits and vegetables in children's homes, parents' intake of fruit and vegetables, and parents' knowledge of childhood nutrition and dietary recommendations (Blanchette and Brug 2005). In this study, children's TV viewing, including exposure to televised food advertisements and the availability of

convenience food at children's schools were less significant predictors of the amount of fruits and vegetables children consumed (Blanchette and Brug 2005).

Thus, these latter factors were far less predictive of poor nutrition than parental factors, and they formed a complex of other factors related to both availability of snack foods in places other than children's homes and, less significantly, to passive TV consumption and exposure to food advertisements, the content of which are not fully described in the study.

Thus, the extent to which young children are influenced by this mode of advertising is still dependent upon: (a) whether parents provide such food for their children, (b) whether parents also model those poor dietary preferences, and (c) how well young children are able to persuade their parents to purchase the snack foods and junk foods frequently advertised on TV which are not usually present in children's households.

A consideration of other cognitive processes of young children may also explain why young, preschool, and early school-aged children may be more susceptible to the persuasive intent of TV advertisements for certain types of food products. It is often the case that advertisements are embedded in thematically related children's TV programs, and that their persuasive intent is not obvious to young children (Kunkel and McIlrath 2003). It has been demonstrated that young children (< 4–5 years) have difficulty distinguishing advertising content from program content on TV, and that they do not understand the persuasive intent of the advertisements (Kunkel and McIlrath 2003). Characteristics of young children's cognition are shown in Table 167.6.

As children mature cognitively, however, they begin to understand the persuasive intent of advertisements (Oates et al. 2002). Nevertheless, these authors noted that, in their study, a sizeable proportion (approximately 25%) of 10-year-olds were unaware of the persuasive intent of advertisements (Oates et al. 2002). What is important to understand is what differentiated the 25% of 4–5 year-olds, who understood the persuasive intent of advertisements from the 75% who did not. Similarly, it is important to find out why 25% of 10-year-olds still did not yet understand the persuasive intent of advertisements, when compared with the majority of their age group, who readily understood the persuasive intent of advertisements. To determine the validity of these findings, it is important to consider whether the minority of 10-year-olds who remain susceptible to the persuasive intent of TV commercials had other cognitive delays, for example, in perspective taking or global cognitive functioning. Additionally, there is no report of whether the group of 10-year-olds watched TV alone or in the company of adults or other children, who might have afforded them opportunities to discuss the content and function of advertisements they watched so that they could develop a more critical response to what they watch on TV.

It is a much-replicated finding that TV advertising, the intent of which is to influence young children to persuade their parents to purchase and consume products such as *snack* or *junk* foods, is placed frequently during programs that attract large numbers of child viewers (Kunkel and McIlrath 2003). There is also evidence that very young children are often unaware that the intent of advertisements is to

Table 167.6 Key features of cognitive immaturity of 3–6-year-olds

- Children's thinking characterized by primitive, pre-logical thinking
- Self-centered perspective that makes them unable to see events from another's viewpoint
- Have literal interpretation of what they see and hear
- What they view on TV is taken at face value
- Respond to content in advertisements and are unable to determine that the persuasive message only represents viewpoint of person or character in advertisement

This table outlines how young children, because of their stage of cognitive development, are unable to detect the intention of food advertisements to influence young children to purchase and consume products advertised

persuade children to themselves purchase and consume their products or to demand that their parents purchase such products. It has yet to be established, however, that there is a direct link between types of products advertised to children during children's TV programs, and parents' purchase and children's consumption of such food products to explain the development of overweight and obesity in many young children. It appears more likely that young children begin to consume nutritionally poor food in certain households where such foods are already available and where parents do not monitor what their young children watch on TV. Additionally, evidence is still needed to show that parents, older siblings, or grandparents are more responsive to young children's requests to buy junk foods, and those foods then are consumed by children instead of more nutritious foods. It is also critical to find out whether young children, who develop poor eating habits and food preferences from being exposed to excessive advertising of *junk* food when they watch TV, are also less likely to engage in physically active leisure pursuits that, in turn, leads to the development of early onset of obesity. Time displaced by watching TV may lead to reduced engagement in physical activity together with increased exposure to junk food advertisements and increases in parents' purchase of such foods *may* result in children eating more nutritionally poor food at the expense of more nutritionally appropriate food. This explanation suggests a multidimensional process rather than a one-dimensional process that leads to early and sustained development of overweight and obesity in early childhood.

Despite the plausibility of the different explanations reviewed, results from research investigating an association between TV and other passive media consumption and early onset of overweight and obesity in young children have been equivocal. Researchers have yet to delineate clearly the underlying mechanisms that link TV viewing with the development of overweight and obesity in early childhood. Methodological shortfalls in existing research include an over-reliance on BMI to characterize children's growth. Other studies lack adequate data on all leisure activities of children, the level and intensity of children's physical activities and reliable and valid documentation of children's TV viewing time. Within the family context there is a lack of information about the amount and type of food parents provided to their young children, including snacks; existing nutritional practices within families; parents' own eating habits and food preferences; and parents' level of physical activity. Table 167.7 summarizes recurrent methodological and conceptual shortfalls in existing research.

How increased TV viewing may be linked to the development of overweight and obesity and thereby the diseases that result from the onset of overweight and obesity in early childhood has yet

Table 167.7 Conceptual and methodological shortfalls of each explanation

Explanation	Conceptual problems	Methodological problems
Energy displacement	Characterizing and measuring typical activity in children	Need measures of all activities and their intensity
	Valid and reliable measure of time spent watching television (TV)	Need reliable and valid method of data collection for amount of time spent watching TV
Exposure to saturation amounts of TV advertisements for foods of poor nutritional quality	Establishing a link between children's awareness of products advertised and their requests to parents to buy same products	Find out whether products already purchased by parents and available in home
		Distinguish between knowledge of product and frequency of purchase
Energy Displacement + Cognitive Immaturity of Young Children	How reduced physical activity co-occurs with susceptibility to persuasive intent of advertisements	Measuring activity levels and children's cognition appropriately

Fig. 167.1 There are several potential biological, behavioral and social factors, in addition to excessive TV watching, that impact on children's growth and development, resulting in overweight and obesity

to be delineated. In Fig. 167.1, a multidimensional model is proposed to explain potential factors that best explain the underlying processes that make some young children more vulnerable to the development of overweight and obesity in early childhood.

Factors identified in Fig. 167.1 should be investigated within one study of a representative sample of young children, and the use of longitudinal research design would also overcome some of the underlying conceptual and methodological shortfalls in research to date. Using a multidimensional model as the basis for future investigations of processes by which young children become overweight and obese would then permit researchers to investigate interactions among variables and identify pathways that lead to the onset of overweight and obesity in early childhood.

Existing research tends to focus on a limited number of variables to investigate relationships between TV watching in early childhood and the development of overweight and obesity. Children do not develop in isolation, and their growth and development is not only affected by inherited propensities and individual behavioral differences but also their family and other social contexts in which growth and development take place.

167.7 Applications to Other Areas of Children's Health and Disease

There is conflicting evidence of an association between time young children spend watching TV and contemporaneous or later-onset development of overweight and obesity. Additionally, existing physiological and cognitive models are not yet able to characterize the processes through which TV viewing contributes to overweight and obesity in early and later stages of development. Thus, any suggested applications of research findings reviewed in this chapter to other areas of young children's health and disease remain tentative. Potential applications of research to other areas of children's health and disease are shown in Table 167.8.

It should be noted, however, that there is almost as much evidence showing no association between TV viewing and overweight and obesity during early childhood. If advertising agencies can produce advertisements that actually do influence young children to buy and consume food products of poor nutritional quality and to develop preferences for such food products, then similar advertising strategies could be implemented to promote more healthy food preferences for young children. For example, advertisements could be developed to persuade children, for example, to eat more healthy foods

Table 167.8 Potential applications to other areas of health and disease in young children

Behaviors associated with television (TV) viewing	Health and well-being	Disease
Increased sedentariness and reduced physical activity	May lead to overweight and obesity	May be related to early symptoms of cardiovascular disease
		Joint and muscular-skeletal problems
		Onset of diabetes
Energy consumption disproportionate to energy requirement	May lead to overweight and obesity	May be related to early symptoms of cardiovascular disease
		Joint and muscular-skeletal problems
		Onset of diabetes
Body image and self-esteem difficulties	May lead to adverse psychological effects related to overweight and obesity	Potential future mental health problems
Over-exposure to TV advertisements for *junk* and *snack* foods	May lead to poor diet, if types of food then consumed by children	Dietary imbalances
		Poor nutrition and later-life health problems
Susceptibility to persuasive intent of advertisement for food of poor nutritional quality	May lead to poor diet, if types of food then consumed by children	Dietary imbalances
		Poor nutrition and later- life health problems
Young children's susceptibility to persuasive intent of advertisements for food of poor nutritional quality	Cognitive strategies used in advertisements to persuade children about nutritionally poor products could be harnessed by health authorities to promote the attractiveness of appropriate foods to young children	Promotion of healthy eating at a young age
		Reduction of overweight and obesity in early childhood
		Potential reduction of future diseases linked to overweight and obesity

This table outlines some of the potential applications to other areas of children's health of research in which an association between amount of TV viewing in early childhood and the onset of overweight and obesity. Caution is recommended, because of the contradictory findings in existing research. Potential applications of findings to the promotion of healthy eating and preventative programs are listed

or to promote knowledge about good nutrition, adequate levels of physical activity, and alternative activities to occupy leisure hours that might otherwise be spent by young children watching TV.

167.8 Conclusion

The ubiquity, frequency, and sedentary nature of TV viewing that occupies a sizeable proportion of young children's leisure time in both developed and developing countries is considered by many researchers to be implicated in the increasing percentage of young children worldwide who are overweight and obese. Three commonly proposed explanations of the underlying processes that link TV viewing to the development of obesity in young children were evaluated. There were inconclusive findings to support the proposal that TV viewing displaces time available for more vigorous activity, reduced energy expenditure relative to energy intake, and the development of early-onset overweight or obesity. Additionally, there was inconclusive evidence to support the proposition that all young children are susceptible to persuasive intent of advertisements for food products of poor nutritional quality that appear frequently during children's TV, and that, arguably, contribute to unhealthy food preferences and eating patterns which predispose young children to the early onset of obesity. An interaction of energy displacement and susceptibility to develop preferences for unhealthy foods advertised when young children are most likely to be watching TV was identified as a more plausible explanation of the proposed link between TV watching and obesity in young children, but more

evidence is needed to support an interactive explanation. It was recommended that future research address both conceptual and methodological shortfalls in existing studies and a proposed multidimensional model to investigate all potential factors that contribute to the development of overweight and obesity in early childhood. Potential applications to other areas of children's health and disease were also discussed.

Summary Points

- Apparent increase in obesity at all stages of development. Increasing proportion of young (3–6 year-old) children overweight and obese. Trends in overweight and obesity found in diverse populations of children worldwide. Trend evident in developed and developing countries.
- Ubiquity of TV viewing as leisure activity among younger age group, documented in both developed and developing countries. This finding represents one of the main reasons for investigating any association between amount of time young children spend watching TV and the development of overweight and obesity in early childhood.
- Three main explanations proposed for linking amount of TV viewing with overweight and obesity in early childhood. These are: (1) Energy displacement explanation; (2) Cognitive immaturity of young children explanation; and (3) Combination of energy displacement and cognitive immaturity of young children.
- *Energy displacement* explanation: Time spent watching TV supplants time spent in other more physically active leisure, especially vigorous physical activities that require greater energy expenditure. Energy consumed (by food) exceeds energy required (for less physical activity and increased sedentariness), which in turn leads to early onset of overweight and obesity.
- *Cognitive immaturity* of young children (< 6 years) makes them more susceptible than older children to the persuasive intent of advertisements for *snack* and *junk* foods that are frequently broadcast during TV programs designed for and watched by very young children. Snack and junk foods are highly processed and contain proportions of saturated fats and sugar that far exceed recommended daily allowances in young children's diets. Marketers develop food products and packaging designed to influence children's food preferences and to encourage young children to pester parents to purchase such foods. Buying these products and regularly including them in daily food intake can lead to dietary imbalance, resulting in overweight and obesity when young children consume *snack* and *junk* foods at expense of other food groups. It is argued that younger children are more susceptible to such advertisements because they have difficulty in discriminating between TV content and advertising content, and thus remain unable to detect the persuasive pitch in advertisements because of self-centered cognition.
- *Energy displacement and cognitive immaturity of young children, in concert*, lead to preferences for and consumption of more processed, fat and sugar-laden foods of the types commonly advertised during designated children's TV programs. Increased sedentariness compounds adverse outcomes of poor food choices, leading to more rapid development of overweight and obesity.
- *Persuasive Intent of Advertisements*: Content of the advertisements often contain subtle and covert messages, designed to take advantage of young children's cognitive immaturity, especially in their inability to grasp the intentions or viewpoint of another, including intentions or viewpoints of real or fictitious characters who appear in food products marketed to children during children's TV programs. This leaves young children unable to determine that they are being persuaded, for example, to eat a certain type of food.
- While each of three explanations has some plausibility, evidence in support of all three is equivocal. Some studies report a significant association between TV viewing and development of

overweight and obesity in early childhood. However, several recent studies report no significant association between times spent watching TV or frequency of exposure to advertisements for *snack* and *junk* foods. Contradictory findings can be attributed to both conceptual and methodological shortfalls in many existing studies.

- One of the main methodological problems is the widespread use of BMI, measured at different periods during children's early development to characterize overweight and obesity of children across developmental periods. Besides measuring children's weight relative to their height compared with children of same age and sex, international expert committees recommend measuring children's skin fold thickness (to characterize fat stores) and upper arm and calf circumferences (to assess children's muscle mass). In addition, differences in growth rates on all parameters vary according to children's ethnicity and inherited predispositions, which are often omitted from studies.

- Other methodological shortfalls relate to how the potential range of all children's activities are measured, and whether intensity of physical activity is accounted for. The way in which TV viewing is measured often is not reported, and daily food intakes often are recorded retrospectively via parents' completing a questionnaire.

- There is a dearth of information that directly assesses associations between the actual types of foods advertised on TV and children's requests to parents to purchase those foods. Additionally, there is a lack of information about whether snack and junk foods are readily available in households, whether they are provided usually by parents for children to eat, or whether parents themselves eat such foods in the presence of their young children. There is also a near-absence in studies to investigate parents' and other family members' food preferences and eating habits and how much TV other family members watch.

- A multidimensional model is proposed to investigate more comprehensively the myriad of potential interacting factors that contribute to the development of overweight and obesity in young children. Within such a research model, factors that need to be considered are: (a) the inherited propensities of children that might contribute to increased fat stores; (b) differences in rate and dimensions of growth among different ethnic groups between and within populations; (c) the amount and types of foods provided in children's homes by their parents, together with parents own food preferences, eating habits, and exercise regimens; and (d) the use of valid and reliable measures to quantify children's TV viewing and food consumption.

- Only when methodological and conceptual shortfalls in existing studies are addressed in future research can there be an adequate understanding of the processes that lead to overweight and obesity in early childhood. Once process is delineated, then there will be potential applications of such findings to develop intervention and prevention programs to reduce adverse health outcomes associated with the development of overweight and obesity in young children. Such programs should adopt a multipronged approach to address all potential contributing factors.

- *Intervention and Prevention*: To improve general cardiovascular fitness and to increase bone density; reduce risk of later development of cardiovascular problems; Type II diabetes and kidney disease. To intervene or prevent certain psychological problems associated with overweight and obesity in childhood, including early onset of depression; problems with body image and self-esteem; and to prevent social isolation and withdrawal from activities with peers. In relation to advertising *snack* and *junk* foods during children's TV programs, public health programs could be implemented to reduce advertising hours and scrutinize content for advertisements shown during TV programs aimed at young children. Additionally, if advertisements were shown to be capable of promoting nutritious food preferences and sensible eating habits as well as to educate young children about appropriate nutrition.

Definitions and Explanations of Key Terms

Body mass index: Represents a shorthand way of characterizing children's growth. It is calculated after obtaining height and weight, and height is divided by weight squared to yield a BMI value that can be compared with normative values for child's age and sex. Is argued to be a problematic measure when used to characterize growth changes in children, especially during early childhood, as it does not take into account body types of different ethnic groups

Mid-upper arm circumference (MUAC): Recommended as indicative of children's growth. Measures muscle mass. Measured by finding median point between child's shoulder and elbow. Measured using flexible tape measure. Value is compared with normative data. Comparatively low measures, when compared with normative group can indicate protein malnourishment in young children.

Skin fold thickness: Considered reliable index of children's fat stores. Special calipers are used to measure (in cms/mms) children's fat mass from under their upper arm and just below their scapula. Subscapular skin fold argued to be the best indication of children's fat stores, and when compared with normative data can indicate under- or over-nourishment.

Imitation: Young children learn behaviors, which become stable over time, firstly by imitating models of those behaviors displayed by people deemed to be important in children's lives (role models), and parents are often the most powerful role models whom young children imitate. Additionally, influential or well-known figures also act as behavioral models for children to imitate. This explains why young children are likely to imitate behaviors, even opinions or beliefs expressed in advertisements featuring well-known personalities. If such models, for example, are seen by young children to eat certain food products or express a favorable opinion about a food product, then young children will tend to imitate that behavior (eat the product, if available or adopt the same opinion about a product that is expressed in the food advertisement. Reinforcement to repeat and stabilize such behaviors occurs through vicarious reinforcement (i.e. watching role models being reinforced for their behaviors).

Modeling: A more pervasive behavior than direct imitation. Young children begin to generalize behaviors initially imitated to other wider contexts. For example, preferences for, or opinions about, certain food products that are modeled by influential role models, in TV food advertisements, will be repeated by children, firstly in the context of the food advertisement but later in other contexts.

Cognitive immaturity of 3–6 year-olds: Young children are said to be cognitively immature, because their cognition is perception-dominated and egocentric.

Persuasive intent of advertisements: Content of the advertisements often contain subtle and covert messages designed to take advantage of young children's cognitive immaturity, especially in their inability to grasp the intentions or viewpoint of another, including, intentions or viewpoints of real or fictitious characters, who appear in food products marketed to children during children's TV programs. This leaves young children unable to determine that they are being persuaded, for example, to eat a certain type of food.

Key Points About Associations Between Television Viewing by Young Children and Development of Overweight and Obesity

- There is evidence of worldwide increase in proportion of young children (3–6 year old) who are overweight or obese compared with children of earlier generations.
- Trend exists in both developed and developing countries.

- Much replicated finding that most common free time activity of children worldwide, including younger children, is watching TV. Trend identified in both developed and developing countries. Thus, children's TV viewing patterns frequently targeted in research investigation as contributory factor in the development of overweight and obesity among young children.
- Apparent association between TV viewing and overweight and obesity explained in terms of three probable mechanisms: (1) Increased sedentariness, with attendant energy displacement. (2) Over-exposure to persuasive advertisements for food products of poor nutritional quality that are screened during designated children's TV programs. (3) Young children's cognitive immaturity renders them more susceptible to the persuasive intent contained in advertisements for snack and junk foods frequently broadcast when they watch TV. This exposure said to affect young children's food preferences and eating habits, leading to dietary imbalances associated with development of overweight and obesity.
- Studies yield mixed results when attempting to identify association between TV viewing-overweight and obesity.
- Reasons for conflicting findings attributable to conceptual and methodological problems in research studies to date.
- Conceptual problems include how best to characterize and measure children's growth parameters over time, especially during early childhood.
- BMI, most commonly used measure, has been criticized because it does not account for ethnic differences in growth patterns, and is not fully sensitive to subtle growth changes in early childhood.
- Methods for collecting TV viewing consistently lack adequate reliability and validity, thereby confounding studies' results.
- How best to characterize all activities, in addition to children's TV viewing during early childhood is still to be determined.
- Methods for collecting food consumption often are unreliable because they are collected retrospectively and are subject to social desirability bias.

Chapter 168
The Dopamine Transporter Gene (DAT1) in Obesity and Binge Eating Disorders

Karen Wight, Caroline Reid-Westoby, and Caroline Davis

Abbreviations

AD(H)D	Attention deficit/(hyperactivity) disorder
BED	Binge eating disorder
BMI	Body mass index
DAT	Dopamine transporter
DAT1	Dopamine transporter gene
DSM-IV-TR	Diagnostic Statistical Manual of Mental Disorders – Fourth Edition
RDS	Reward deficiency syndrome
UTR	Untranslated region
VNTR	Variable number tandem repeat

168.1 Introduction

Experts have often attributed escalating obesity rates to a clash between our genes – adapted to survive seasonal food shortages or possible famines in times past – and the current abundant food environment (Cummings and Schwartz 2003; Peters 2003). According to the *thrifty genotype hypothesis*, obesity can be viewed as a natural response to our modern surroundings with its excess of energy sources (Cummings and Schwartz 2003; Peters 2003). We have a biological drive to eat beyond caloric need when food is available and to store energy as fat, as this would have been beneficial years ago, leading to improved chances of survival when food was scarce. Nowadays, this inherent motivation is problematic, given that the availability, variety, and portion sizes of food have greatly increased (Jeffery and Utter 2003; Nestle 2003) – factors associated with higher caloric intakes and elevated obesity rates (Nestle 2003).

Despite drastic changes to our environment, some individuals are able to maintain a healthy weight. It is critical to determine what differentiates this fraction of the population from the large and escalating proportion who chronically overeat. The various forms of overeating are derived from one of two separate drives according to the *homeostatic–hedonic model* – motives based on needing food and

motives based on wanting food, respectively (Saper et al. 2002). The involvement of the hypothalamic pathways in the former has long been recognized; whereas, less is known about *hedonic* or *non-homeostatic eating*, which refers to eating for reasons other than caloric need, such as emotional states ("comfort eating") or environmental cues (e.g., seeing others eating, the sight and smell of food stimuli). Experts believe the action of the neurotransmitter *dopamine* on the brain's *common reward pathway* is primarily accountable for hedonic motivations for food intake, with the opioid system playing a more minor role. Individual variations in the tendency to overeat can be attributed – at least in part – to the genetically determined action and availability of dopamine. Among the dopamine-related genes studied, the gene encoding the dopamine transporter (DAT1) has received particular attention in relation to eating behavior. The purpose of this chapter is to review the literature on the role of the DAT1 in obesity and binge eating disorders.

168.2 Binge Eating

Reward-based motivations seem to overpower homeostatic drives in some individuals, given the frequent snacking, binge eating, and higher caloric intakes seen among many obese individuals despite their adequate energy stores. *Binge eating* represents an extreme phenotype of hedonic over-eating and is a significant risk factor for substantial weight gain over time (Fairburn et al. 2000). It is defined as the consumption of an abnormally large amount of food within a limited time span in the absence of physical hunger, and is associated with feelings of loss of control. Individuals typically engage in binge eating when alone because they often feel embarrassed and guilty about their behavior. Binge eating represents a defining behavioral symptom of both *binge eating disorder* (BED) and *bulimia nervosa.*

According to the Diagnostic Statistical Manual of Mental Disorders – Fourth Edition (DSM-IV-TR; see Table 168.1), BED is characterized by regular binge episodes (2–3/week) for a minimum of 6 months, without the use of compensatory behaviors such as purging, excessive exercise, diet pills, laxatives and/or diuretics for the purpose of weight loss, as often associated with bulimia nervosa (American Psychiatric Association 2000). Individuals with the disorder also tend to overeat through-out the day in addition to their binge episodes, and as a result, are usually obese – defined as having a

Table 168.1 Diagnostic criteria for binge eating disorder (Created from DSM-IV-TR criteria APA 2000)

A. Recurrent episodes of binge eating. An episode is characterized by:
- Eating, in a discrete period of time (e.g., 2 h), and amount of food that is definitely larger than most people would eat in a similar period of time under similar circumstances
- Feelings of loss of control over the amount or the type of food being consumed during the episode (e.g., feeling one cannot stop eating)

B. Binge eating episodes associated with at least three of the following:
- Eating alone because of feelings of embarrassment regarding eating
- Eating large quantities of food when not feeling physically hungry
- Eating until feeling uncomfortably full
- Eating much more rapidly than normal
- Feelings of disgust with oneself, depression, and/or guilt after a binge

C. Marked distress regarding binge eating

D. Binge eating occurs, on average, at least 2 days a week for 6 months

E. The binge eating is not associated with regular use of inappropriate compensatory behaviors, such as purging, fasting or excessive exercise, and does not occur exclusively during the course of bulimia nervosa or anorexia nervosa

Body Mass Index (BMI) over 30 kg/m^2. In a longitudinal study of BED, the proportion of obese individuals rose from 22% to 39% over 5 years – validating binge eating as a significant risk factor for substantial weight gain over time (Fairburn et al. 2000). At a weight loss clinic, as many as 30% of obese attendees met diagnostic criteria for BED (Striegel-Moore and Franko 2003; Yanovski 2003). Current opinion varies on how individuals with BED differ from obese adults who do not binge eat. A recent study found no difference between the groups on many personality variables, leading to the speculation that the distinction exists at the biobehavioral level (Davis et al. 2008).

Much of our understanding of BED stemmed from research on bulimia nervosa, as the former represents a relatively modern phenomenon. Bulimia nervosa is also characterized by recurrent episodes of binge eating; however, unlike BED sufferers, individuals with bulimia nervosa engage in extreme weight-control behaviors, such as self-induced vomiting, strict dieting, and the misuse of laxatives or diuretics (Fairburn et al. 2000). Bulimia nervosa patients are typically of normal body weight as a result of compensatory acts. Many of the underlying mechanisms for binge eating in bulimia nervosa resemble those contributing to BED.

Among both BED and bulimia nervosa sufferers, negative affect (e.g., anxiety, depression) has been acknowledged as a primary risk factor for binge eating (Stice et al. 2000). Largely accounting for the susceptibility to such depressive and anxious states associated with binge eating are genetically determined levels of brain neurotransmitters. Similarly, the brain neurotransmitters play a role in impulsivity and impulse control disorders – such as substance abuse, pathological gambling, conduct disorder, and attention deficit/(hyperactivity) disorder (AD[H]D) – which are often comorbid with binge eating disorders (Blum et al. 2000). A genetic contribution to binge eating is also suggested in twin studies testing for a familial transmission of the behavior (Bulik et al. 2003; Reichborn-Kjennerud et al. 2004). Moreover, candidate genes association studies support the role of certain genes in a predisposition to binge eating disorders. To date, the bulk of this research has focused on the genes contributing to the dopamine reward system.

168.3 Dopamine

The dopamine system is involved in several motor activities and cognitive functions. Dopamine neurons in the *mesolimbic* and *mesocortical* pathways – considered the brain's reward system – originate in the ventral tegmental area and, respectively, project to limbic structures including the nucleus accumbens and amygdala, and to the frontal cortex (Koob 1992; see Fig. 168.1). Along the mesolimbic pathway, dopamine is responsible for regulating our emotional capacity to feel pleasure and our desire and motivation to seek out rewarding experiences (Berridge 2003). The pleasure felt in response to these experiences reinforces certain behaviors and directs attention to relevant environmental cues by associating them with feelings of reward (Blum et al. 1996). Dopamine release in the nucleus accumbens (the "reward centre" of the brain) acts to promote an appetitive/approach response to reward cues that are contingent on carrying out a specific action (Nicola et al. 2005). For example, inactivation of the ventral tegmental area (the major dopaminergic input to the striatum) abolishes neuronal firing in the nucleus accumbens and reward-seeking responses to reinforcing stimuli such as food (Yun et al. 2004). These responses can also be reduced by administration of dopamine receptor antagonists (Nicola et al. 2005). On the other hand, a stimulant injection in the nucleus accumbens potentiates dopamine release and reward-related behavioral responding (Zangen et al. 2006).

Similar to the majority of bodily systems, dopamine response varies considerably across individuals (Davis and Fox 2008). In the case of the mesocorticolimbic pathways, those with inherently higher levels of dopamine availability are likely to have a larger hedonic capacity and a stronger
Fig. 168.1 Common reward pathway. All rewarding stimuli (e.g., food, sex) activate the same brain pathway: the mesolimbic pathway from the ventral tegmental area (*VTA*) to the nucleus accumbens, as well as the corticolimbic pathway from the nucleus accumbens up to the prefrontal cortex (Image adapted from National Institution on Drug Addiction (*NIDA*) at www.drugabuse.gov. NIDA cites this image as public domain and copyright permissions not required)

motivation to approach potentially pleasurable outcomes (Davis et al. 2004). In other words, they may experience greater pleasure from rewards, such as food, and therefore engage in more behaviors that will lead to its acquisition and consumption. Alternatively, a sluggish dopamine system is reflected in an anhedonic demeanor and a relative insensitivity to reward (Depue and Collins 1999).

Reduced dopamine availability is believed to place some individuals at increased risk of addictive behaviors according to the *reward deficiency syndrome* (RDS) (Blum et al. 2000). Basically, due to a breakdown in the brain "reward cascade," these individuals are said to require a "dopamine-fix" to feel good, and therefore, they are more likely to seek out stimuli that increase available dopamine such as illicit drugs (e.g., cocaine). The subcortical brain's response to reward does not appear to differentiate among being provoked by illicit drugs, natural reinforcers such as food or sex, or behavioral addictions such as gambling or shopping (Kelley et al. 2005). Nowadays, relative to drugs of abuse, highly caloric food represents an easily accessible, inexpensive, and reliable method to boost a sluggish dopamine system (Wang et al. 2004), and as a result, is one of the most common forms of self-medication (Davis et al. 2004).

The high comorbidity established clinically between substance-related and binge eating disorders supports the hypothesis of a shared biological basis. Moreover, chronic drug abuse and binge eating share many physiological and behavioral similarities, leading some experts to argue that non-homeostatic overeating is also appropriately modeled as an addictive behavior (Davis et al. 2004; Wang et al. 2004). Therefore, based on the RDS theory, researchers speculate dysfunctional dopamine availability due to variations in dopamine genes may predispose individuals to binge eating behaviors.

However, conflicting evidence suggests that an *elevated* dopamine signal also places individuals at risk for binge eating due to a stronger appetitive response to food cues. Consistent with these data, women who have high sensitivity to reward (and likely greater dopamine availability) were found to

report stronger food cravings (Franken and Muris 2005) and are more likely to overeat and binge eat (Davis and Fox 2008; Davis et al. 2004) compared with their less hedonic counterparts. Some experts propose that, similar to the response seen in substance abuse addicts, a downregulation may occur among obese individuals as their brain's way of compensating for chronically elevated dopamine levels produced by overeating, and this may account for the conflicting findings of low dopamine levels (Davis et al. 2004). Considering both theories, Davis and Fox (2008) suggest a dual vulnerability for overeating where low or high dopamine availability confers risk – albeit, in different individuals and perhaps with different levels of severity. Indisputably, several routes to obesity and binge eating exist, and are based on various biological vulnerability factors, including variations in the dopamine system.

168.4 Dopamine Transporter

Dopamine availability is highly polygenic, and primarily determined by the affinity and density of the dopamine transporters (DATs) and receptors, and the amount of dopamine synthesized and secreted into the synapse (Need et al. 2006). The DAT is a member of a family of sodium (Na$^+$) and chlorine (Cl$^-$) ion-dependent neurotransmitter transporters that is highly expressed in the human striatum and prefrontal cortex where it regulates the duration of dopamine activity (see Fig. 168.2; Cragg and Rice 2004). Specifically, as a membrane-spanning protein, the DAT functions by binding to dopamine to clear it from the synapse and transport it back into the neuron. Therefore, a greater density of DAT is believed to predict less dopamine reaching the postsynaptic cell (Table 168.2).

The human DAT1 gene (SLC6A3) that encodes for the DAT protein has been mapped to the short arm of chromosome 5 (5p15.3) and carries 15 exons (Giros et al. 1992; Vandenbergh et al. 1992).
Fig. 168.2 Dopamine transporter at synapse. As synaptic vesicles release dopamine into the synapse, some dopamine binds to the dopamine receptors on the postsynaptic neuron and some of the neurotransmitter is transferred back into the presynaptic neuron by the dopamine transporters (*DATs*). (Image adapted from National Institution on Drug Addiction (*NIDA*) at www.drugabuse.gov NIDA cites this image as public domain and copyright permissions not required)

Table 168.2 Key features of the dopamine transporter (DAT)

	Dopamine transporter (DAT)
Form:	Membrane-spanning protein and member of family of Na$^+$ and Cl$^-$ ion-dependent neurotransmitter transporters
Location:	Highly expressed in human striatum and prefrontal cortex
Function:	Regulates the duration and strength of the DA signal
Action:	Binds to DA to clear it from synapse and transport it back into the presynaptic neuron
Predicted effect on DA levels:	Greater density of DAT → ↑ DA reuptake → ↓ DA availability

DA dopamine, *Na$^+$* sodium, *Cl$^-$* chlorine

Table 168.3 Key features of the dopamine transporter gene (DAT1)

	Dopamine transporter gene (DAT1; SLC6A3)
Form:	Carries 15 exons; highly polymorphic
Location:	Short arm of chromosome 5 (5p15.3)
Function:	Encodes DAT protein
Key polymorphism:	Functional 40-base pair VNTR in 3′ UTR in exon 15
Predicted effect on DA levels:	10-repeat → ↑ DAT binding site density → ↓ DA availability (Relative to 9-repeat)

DA dopamine, *DAT* dopamine transporter

Of the polymorphisms identified, a 40-base pair *variable number of tandem repeat* (VNTR) in the 3′ untranslated region (3′ UTR) in exon 15 has been the most extensively studied (Fuke et al. 2001; Heinz et al. 2000; Mill et al. 2002). VNTR polymorphisms are series of altered fragment lengths that are related to each other by sequences of variable number of tandem repeated DNA segments in an interval between two restriction sites. For this VNTR, repeat numbers vary from 3 to 13, with the 9- and 10-repeat alleles occurring with the greatest frequency in the majority of human populations (Giros et al. 1992; Vandenbergh et al. 1992).

Although there have been some inconsistent findings concerning the functional effect of the DAT1 VNTR polymorphism, it is generally agreed upon that the 10-repeat variant is associated with particularly efficient DATs (Mill et al. 2002). According to the best available evidence, the 10-repeat variant yields an approximately 50–90% elevated DAT binding site density in comparison to the 9-repeat allele (VanNess et al. 2005). That is, the 10-repeat variant produces a greater amount of DAT protein, diminishing activity in the dopamine pathways due to heightened transportation of dopamine from the synapse back into the presynaptic neuron. For this reason, the 10-repeat variant has been considered the "high-risk" allele for certain psychiatric syndromes and conditions, and widely investigated due to its central role in the regulation of striatal dopamine availability – a crucial determinant of motivation (Table 168.3) (Yang et al. 2007).

Evidence supports a shared genetic causative mechanism between binge eating and substance dependence involving the dopaminergic system. As mentioned above, the DAT is the main mechanism for dopamine clearance from the synapse in dopaminergic neurons found in the midbrain. Researchers have established a relationship between the DAT1 genetic variants and individual differences in vulnerability to addictive behaviors including smoking (Jorm et al. 2000), alcohol dependence and withdrawal (Sander et al. 1997), and cocaine abuse (Crits-Christoph et al. 2008). The DAT1 has also recently been linked to compulsive overeating and obesity (Epstein et al. 2004).

168.5 DAT1, Obesity, and Binge Eating

Consuming a well-prepared dish is among the most enjoyable experiences in life, and because humans find food so rewarding, we are strongly motivated to acquire it. If feeding were exclusively regulated by homeostatic mechanisms, most people would likely be at their ideal body weight, and would view eating in similar ways to breathing, for example, as an essential but uninteresting part of life. However, many individuals consume more food than is required for survival and compelling evidence suggests that individual differences in food reinforcement play a role in overeating and subsequent obesity. The reinforcing value of food is associated with dopaminergic system activity (Epstein et al. 2007). In fact, consumption of food causes a rise in dopamine levels (Hernandez and Hoebel 1990).

Altering brain dopamine levels has been found to affect eating, where dopamine agonists generally diminish caloric intake (Leddy et al. 2004) and dopamine antagonists increase consumption and body weight (Wellman 2005); although, there is great individual variation in the population in response to these drugs (Davis et al. 2007). In line with this direction of evidence, some genetic studies report that genotypes and alleles associated with *lower* dopamine availability are overexpressed among obese individuals. For instance, in a sample of participants with an African American background, the likelihood of obesity was 5.16 times greater among individuals possessing the homozygous 10-repeat genotype of the DAT1 3′ UTR VNTR compared to that of the 9/9 or 9/10 genotypes; although, no association was found among non-Hispanic white participants (Epstein et al. 2002). Similarly, Epstein et al. (2004) found that participants who demonstrated high levels of food reinforcement (as assessed by a behavioral choice questionnaire) and possessed the 10/10 genotype had significantly greater caloric intakes in a food consumption task compared to subjects in the other groups. However, subjects in these studies were regular smokers and this limits the generalizability of the findings. Long-term tobacco exposure results in an upregulation of DAT activity (Li et al. 2004), which leaves less available dopamine and can increase sensitivity to food reinforcement. Therefore, these findings may not be replicable among participants without a history of smoking. To this effect, a study conducted recently among a larger sample of nonsmokers did not find any significant association between the DAT1 and energy intake, or between the DAT1 and food reinforcement (Epstein et al. 2007).

In contrast, some evidence suggests that obese individuals possess *higher* levels of dopamine availability. For example, using single position emission computational topography (SPECT) to measure striatal DAT availability among 50 healthy volunteers, Chen et al. (2008) found a significant negative association between age and BMI with striatal DAT availability, and BMI was the only significant predictor for DAT density. In other words, higher BMIs predicted lower DAT density, which in turn, is associated with greater dopamine levels. Elevated dopamine availability is believed to lead to greater hedonic capacity and a stronger motivation to approach food. In support of this theory, obese individuals have been reported to find food more rewarding compared to their leaner counterparts (Saelens and Epstein 1996). Specific to binge eating, a case-control study of Japanese women found an excess of short alleles (7- and 9-repeats) of the DAT 3′ UTR VNTR among patients with clinically significant binge eating behaviors (Shinohara et al. 2004). These results suggest that a strong dopamine signal, due to a decrease in the DAT protein, increased the reinforcing value of food, leading to a tendency to binge eat.

In order to test the appetitive response to elevated dopamine levels, many studies have used stimulant medications. The DAT is of specific interest in these studies as it represents the primary site of action of psychomotor stimulants such as cocaine, methylphenidate, and amphetamines, which bind to the transporters, thereby inhibiting the reuptake of dopamine into the cell and increasing its availability in the synapse. In particular, response to methylphenidate – better known by the brand name

Table 168.4 A proposed theory of associations among the dopamine transporter, the dopamine signal, and psychobehavioral response (Adapted from first printing in Davis et al. 2007)

10-repeat allele	↑ DAT Protein → ↓ synaptic DA	Increased risk for AD(H)D and therapeutic response to methylphenidate; increased response to exogenous stimulants
9-repeat allele	↓ DAT Protein → ↑ synaptic DA	Increased risk for binge eating
↓ DA signal	↓ Hedonic tone and ↓ sensitivity to reward	Increased risk for drug addiction
↑ DA signal	↑ Hedonic tone and ↑ sensitivity to reward	Increased risk for overeating

DA dopamine, *DAT* dopamine transporter

Ritalin and the most common treatment for AD(H)D – has often been studied and results generally indicate that ingestion of a small oral dose of the drug increased desire to eat in response to palatable food cues among human participants (Volkow et al. 2002). However, very high stimulation of dopamine pathways produced by chronic drug abuse typically curbs appetite (Cochrane et al. 1998). The same effect is seen in animal studies where drugs causing a substantial rise in dopamine induce anorexia (Bina and Cincotta 2000; Kuo 2002).

To further examine this relationship, Davis and colleagues (Davis et al. 2007) conducted the first study testing the suppression of appetite due to methylphenidate in relation to DAT1 genotype variation. Participants' "favorite snack" was provided as a food cue to judge appetite ratings. The results revealed that individuals with BED possessing at least one copy of the 9-repeat allele had a significant decrease in appetite ratings in response to the methylphenidate, in comparison to control participants with the 9-repeat variants or to BED and controls with the 10/10 genotype – all three of whom had negligible differences in appetite ratings between drug and placebo conditions. Results support the role of genetic factors influencing dopamine availability in regulating appetitive response to methylphenidate. A study by Leddy et al. (2004) also revealed a varied response to methylphenidate in a small sample of obese adults. Following a large dose of the drug, participants were fairly equally divided among showing a large decrease, a small or moderate decrease, or even an increase in caloric intake, and these effects did not correlate with initial body weight.

Some experts interpret the varied DAT relationship with obesity and binge eating to indicate that dopamine activation and subjective response have an inverted-U relationship (Volkow et al. 1999). That is, a moderate boost in dopamine levels is believed to foster appetitive motivation; whereas, the opposite may occur with greater augmentation to very high dopamine levels, causing a suppression effect in the case of eating (Davis et al. 2007). Davis et al. (2007) have proposed that such a nonlinear relationship would assist in understanding some of the apparent contradictions in the literature regarding the relationship between dopamine activation and eating behavior. Evident variations in dopamine availability and responses to dopamine-related medications have important implications for obesity and binge eating treatment. Further examination of the dopamine-eating behavior relationship will assist in allowing better targeting of interventions to individual susceptibility (Table 168.4).

168.6 Implications for Treatment of Binge Eating and Obesity

Behavioral neurogenetic research has begun, and will continue, to enhance our understanding of individual susceptibility to binge eating and obesity in order to develop effective treatment and prevention efforts. This chapter has reported evidence highlighting the heterogeneity of obesity in terms of its diverse risk pathways, despite a long history of researchers and clinicians regarding all obese individuals as one homogeneous group. For this reason, individualized treatment approaches are

required and should be determined by factors such as the causes and forms of overeating, biological contributors, and comorbid conditions. Individuals engaging in binge eating represent one subgroup requiring specialized interventions.

Treatment for binge eating in bulimia nervosa typically includes antidepressant medications to target the negative affect and comorbid mood disorders that often underlie and trigger binge behaviors. In terms of general obesity treatments, and of particular relevance, some of the weight loss medications endorsed by the US Food and Drug Administration stimulate norepinephrine and dopamine release in a manner similar to methylphenidate (Rucker et al. 2007). The studies discussed above indicate that the effectiveness and appropriate dosages of these pharmaceutical treatments are largely dependent on patients' baseline dopamine availability and genetic makeup. This chapter focuses on the role of the DAT; however, dopamine availability and drug response depends on variations in several related genes. In the future, with a greater understanding of the polygenic contributors to dopamine availability and treatment response, genetic testing may allow for better targeting of appropriate medications and dosages.

Large-scale clinical trials support the success of some of these drugs in reducing food intake and cravings, and fostering significant long-term weight loss (Rucker et al. 2007). Although, while these medications may be effective among some individuals in controlling eating behavior, the drawback is that they operate on the same systems which moderate mood. This is particularly concerning considering the high prevalence of depression and anxiety disorders found among patients with bulimia nervosa, BED and obesity. For this reason, some of these medications have recently been removed from the market.

In terms of implications for non-pharmacological interventions, other naturally rewarding but healthier activities should be encouraged. For instance, social activities, sex, and exercise are associated with a moderate increase in dopamine. Greater positive reinforcement should be given to individuals for engaging in healthy eating and physical activities. The recently increased attention in controlling food advertising is also promising as commercials often conceptualize high-fat or fast foods as treats or rewards, and therefore, likely enhance the motivation to eat them and the reinforcing value derived from their consumption. Moreover, the food consumed today has progressively moved toward high sugar and processed fare, some of which resembles drugs more closely than the natural whole foods our ancestors consumed. In fact, highly palatable, high-fat foods provoke a larger increase in dopamine relative to the consumption of healthier foods (Berridge 2003). Tackling our obesogenic environment is a necessary but particularly difficult route, and results will not likely be evident for several years. Currently, one of the most promising approaches appears to be first treating the comorbid disorders, such as depression and AD(H)D, which may contribute to, or exacerbate, binge eating.

168.7 Applications to Other Areas of Health and Disease: AD(H)D

The DAT1 has also been implicated in AD(H)D – a lifespan disorder characterized by developmentally age-inappropriate signs of impulsiveness, inattention, and/or hyperactivity (APA 2000). Relatively recently, it has been recognized that AD(H)D and obesity often coexist (Agranat-Meged et al. 2005). The occurrence of AD(H)D is especially high among individuals with Class III or morbid obesity (BMI > 40 kg/m^2), representing almost half of the sample in one study (42.6%) (Altfas 2002). Adding to the problem is the particular difficulty these individuals have adhering to weight loss programs – as evidenced by the greater clinic visits and longer treatment duration found among adults with AD(H)D attending a weight loss program relative to their non-AD(H)D counterparts (Altfas 2002). Among children with AD(H)D, the prevalence of overweight and obesity is also

significantly greater than the age-matched population. For instance, in a study of obese school-aged children, over half (57.7%) suffered from co-morbid AD(H)D (Agranat-Meged et al. 2005).

Recent reports indicate that overeating, and binge eating in particular, moderate the relationship between AD(H)D and obesity (Davis et al. 2006). Adults with AD(H)D were found to have a higher prevalence of BED compared to the general population (Mattos et al. 2004), and similarly, a sample of adolescents with AD(H)D was more likely to engage in binge eating than controls (Neumark-Sztainer et al. 1995). AD(H)D symptoms could plausibly predispose individuals specifically to binge eating.

The comorbidities suggest that symptoms or biological factors associated with the disorder increase the risk of weight gain and binge eating. Genetic and neuroimaging research generated the dopamine-dysfunction hypothesis for the etiology of AD(H)D, leading some researchers to propose the AD(H)D-obesity link partially results from sub-optimal dopamine levels (Davis et al. 2006). In support of this theory, several reports indicate that DAT density is approximately 70% greater in AD(H)D cases compared to healthy controls (Yang et al. 2007). In addition, numerous studies and meta-analyses have reported a significant association between the 10-repeat variant of the DAT1 VNTR in the 3′ UTR and the disorder (e.g., Yang et al. 2007), leading to its designation as the "high-risk allele" for AD(H)D; although, there has been some conflicting evidence.

Similar to the varied appetitive response to methylphenidate, the DAT1 appears to regulate treatment response to methylphenidate among AD(H)D patients. Studies indicate the poorest response occurs among individuals homozygous for the 9-repeat allele, whereas the best treatment response is associated with the 10/10 genotype (Bellgrove et al. 2005). As discussed above, the greater effectiveness of treatment in 10-repeat individuals is proposed to occur because it ameliorates a hypodopaminergic state mediated by DAT1. Results have direct implications for treatment approaches for AD(H)D, as well as for the binge eating behaviors found among many of these patients. Awareness of the association and the biological mechanisms will assist in obesity prevention among individuals diagnosed with AD(H)D, and obesity and binge eating treatment among individuals whose previous efforts have been hindered by AD(H)D symptoms.

168.8 Conclusion

The strong links with weight gain and the serious medical and psychiatric morbidities associated with binge eating and related disorders, indicate the behavior demands further exploration. Binge eating emerged in our society relatively recently, in part as a response to environmental factors, such as the altered food composition, decline of family meals, and increased depression rates. There is little doubt that the environment plays an important role in sustaining, if not increasing, current obesity and overeating rates. Nevertheless, not everyone in our obesogenic environment regularly overeats or has difficulty maintaining a healthy weight, suggesting that gene-environment interactions are likely to contribute to individual vulnerability.

The purpose of this chapter was to discuss the role of the DAT1 – encoding the protein responsible for regulating the strength and duration of the dopamine signal, and one of several genes that have been linked to food intake and body weight. Dopamine is an important and necessary neurotransmitter involved in eating behavior. Without it, we would have little motivation to eat because doing so would provide us little pleasure, as witnessed in rat gene knock-out studies. Hedonic motivations often appear to overpower homeostatic mechanisms regulating energy consumption, leading to consumption beyond caloric need. Based on this evidence, interventions aimed at regions within the reward system will likely be required to control eating behavior among individuals engaging in binge eating in order to achieve and maintain a healthy body weight. To date, a comprehensive strategy to address obesity and/or binge

eating disorders has yet to be established; although, recent and continuing advances in molecular genetics and neuroscience have greatly improved our understanding of the physiology of energy intake and have brought us closer to developing effective treatments. In the future, using a genetic approach to study eating behavior may enable us to identify susceptible individuals and allow for early intervention to prevent binge eating and weight gain, as well as their many comorbid disorders.

Summary Points

- Binge eating represents an extreme form of hedonic overeating and is defined as the consumption of an abnormally large amount of food in a limited time span in the absence of hunger. Binge eating is a central symptom of both bulimia nervosa and BED.
- Bulimia nervosa is characterized by recurrent episodes of binge eating and extreme weight-control behaviors such as purging, dieting, excessive exercise, and/or diet pill, laxative or diuretic use; whereas, individuals with BED engage in regular binge eating without the use of compensatory behaviors and are typically obese as a result.
- Evidence indicates a genetic contribution to predisposition to binge eating and associated disorders, with the majority of neurogenetic research focusing on the role of the brain neurotransmitter dopamine.
- Dopamine is responsible for regulating our motivation to seek out rewarding experiences and directing attention to relevant environmental cues by associating them with feelings of reward or pleasure.
- The action of dopamine on the brain's "Common Reward Pathway" is primary accountable for hedonic motivations for eating. Dopamine availability along these pathways varies considerably across individuals in the population, and this variation is believed to be partly attributable for individual differences in the tendency to binge eat.
- Two routes are evidenced to lead to bingeing. Based on the RDS model, individuals engage in compulsive overeating as a means to self-medicate low dopamine levels; whereas, a conflicting theory proposes that high dopamine levels are to blame as they cause a greater hedonic capacity and motivation to eat. Dopamine availability is highly polygenic and largely determined by factors including the affinity and density of dopamine transporters and receptors.
- The DAT is expressed in the striatum and prefrontal cortex, where it regulates the strength and duration of the dopamine signal by binding to synaptic dopamine and transporting it back into the neuron.
- The DAT1 gene that encodes the DAT protein contains a functional VNTR polymorphism in the 3′ UTR with the 10- and 9-repeat alleles occurring with the greatest frequency in the general population.
- The 10-repeat variant is associated with an elevated DAT binding site density (i.e., heightened dopamine reuptake and therefore, lower dopamine availability) compared to DATs encoded by the 9-repeat variant.
- In support of the RDS theory, some evidence indicates the 10-repeat allele – associated with lower dopamine availability – is overexpressed among obese individuals; although, more research is required as existing literature is likely confounded by the influence of comorbid smoking behaviors.
- In contrast, women engaging in binge eating behaviors were found to have a higher prevalence of the 9-repeat allele, which has also been associated with higher BMIs.
- An inverted-U relationship is hypothesized between dopamine availability and subjective response, based on studies using stimulant medications to boost dopamine in order to test the appetitive effect. That is, a moderate rise in dopamine levels is believed to increase appetite, whereas, very high dopamine augmentation likely suppresses eating.

Definitions of Key Terms

Binge eating: Binge eating is defined as the consumption of an amount of food that is unquestionably larger than most people would eat under normal circumstances within a discrete period of time (i.e., less than 2 h; APA 2000).

Binge eating disorder (BED): BED is characterized by recurrent episodes of binge eating (2–3 times per week for a minimum of 6 months) without the use of inappropriate compensatory behaviors, such as self-induced vomiting, misuse of laxatives or diet pills, fasting, or excessive exercising (APA 2000).

Bulimia nervosa: Bulimia nervosa is an eating disorder characterized by binge eating and inappropriate compensatory methods to prevent weight gain. In order to meet diagnostic criteria, a person must engage in binge eating and compensatory behaviors on average at least twice a week for the past 3 months (APA 2000).

Dopamine: Dopamine is a neurotransmitter that plays an important role in motivation and pleasure. Dopamine is characterized as a catecholamine (a molecule that acts as a neurotransmitter and/or hormone). It affects brain processes that control movement, emotional response, and ability to experience pleasure and pain.

Common reward pathway: Also referred to as the *mesocorticolimbic* pathway, the Common Reward Pathway is a circuitry in the brain that regulates and activates behaviors necessary for survival, such as feeding, sex, and maternal behavior. This pathway also underlies the development and maintenance of addictions.

Dopamine transporter (DAT): The DAT is a membrane-spanning protein that binds to synaptic dopamine. The DAT clears dopamine from the synapse, reuptaking it back into the presynaptic neuron, which ultimately leads to the termination of the dopamine signal.

DAT1 gene: The human DAT1 gene (SLC6A3) encodes for the DAT protein. It has been mapped to the short arm of chromosome 5 (5p15.3) and carries 15 exons. The gene is highly polymorphic, containing a functional VNTR in the 3′ UTR which is associated with DAT density.

Reward Deficiency Syndrome (RDS): According the RDS theory, deficient levels of dopamine in the reward pathways of the brain leave individuals susceptible to engaging in addictive behaviors as a means of increasing available dopamine.

Hedonic/non-homeostatic eating: As opposed to homeostatic eating, hedonic eating refers to food consumption driven by reasons other than survival, for example, to comfort emotional states (e.g., boredom, depressed mood) or for enjoyment in social situations.

Thrifty Gene hypothesis: The Thrifty Gene hypothesis postulates that genes predisposing individuals to overeating and obesity evolved because they were once beneficial. The ability to store excess energy as fat in times of food abundance was advantageous in order to increase one's chances of survival during times of famine.

Variable Number Tandem Repeat (VNTR): A VNTR is a gene polymorphism where a sequence of nucleotides is repeated a number of times in an interval between two restriction sites, causing different fragment lengths. The number of times the sequence is repeated varies within the population.

169.1 Introduction

Prader-Willi syndrome (PWS) is a complex multisystem genetic disorder that arises from the lack of expression of paternally inherited imprinted genes on chromosome 15q11-q13. The syndrome has characteristic phenotypes (Gunay-Aygun et al. 2001), including severe neonatal hypotonia, early onset of hyperphagia, and the development of morbid obesity, short stature, hypogonadism, learning disabilities, behavioral problems, and psychiatric disturbances with severe consequences that pose difficult management issues for patients, families, and caregivers. Recent epidemiological surveys have estimated the lower limit of birth incidence at about 1 in 30,000, and the population prevalence at about 1 in 50,000. Other recent studies have highlighted the high rates and varied causes of morbidity and mortality throughout the natural history of the disease, mainly due to obesity complications (Schrander-Stumpel et al. 2004; Tauber et al. 2008). Early diagnosis and an integrated multidisciplinary approach improve quality of life, prevent complications (particularly childhood obesity), and prolong life expectancy (Bachere et al. 2008).

169.2 Diagnosis of PWS

In the past few years, the diagnosis has been increasingly made during the first months of life. As clinical signs vary with age, the diagnostic criteria from Holm et al. (Holm et al. 1993) have been modified to improve the description of the signs that should lead to genetic testing (see Table 169.1) (Gunay-Aygun et al. 2001).

There are different methods for confirming the diagnosis and identifying the genetic subtype using peripheral blood lymphocytes. DNA methylation analysis is the only technique that can both confirm and reject the diagnosis of PWS and should therefore be the initial investigation of choice. Parental samples are not required for this analysis. If DNA methylation analysis shows only a maternal pattern, then PWS is confirmed. Further methods may then be performed to determine the genetic subtype and to guide genetic counseling, particularly with regard to the risk of recurrence. Fluorescence In Situ

Table 169.1 Indications for DNA testing (Copyright 2008, the Endocrine Society)

Age at assessment	Features sufficient to prompt DNA testing
Birth to 2 years	• Hypotonia with poor suck
2–6 years	• Hypotonia with a history of poor suck
	• Global developmental delay
	• Short stature and/or growth failure associated with accelerated weight gain[a]
6–12 years	• Hypotonia with a history of poor suck (hypotonia often persists)
	• Global developmental delay
	• Excessive eating (hyperphagia, obsession with food) with central obesity if uncontrolled
13 years through adulthood	• Cognitive impairment, usually mild mental retardation
	• Excessive eating (hyperphagia, obsession with food) with central obesity if uncontrolled
	• Hypothalamic hypogonadism and/or typical behavior problems (including temper tantrums and obsessive-compulsive features)

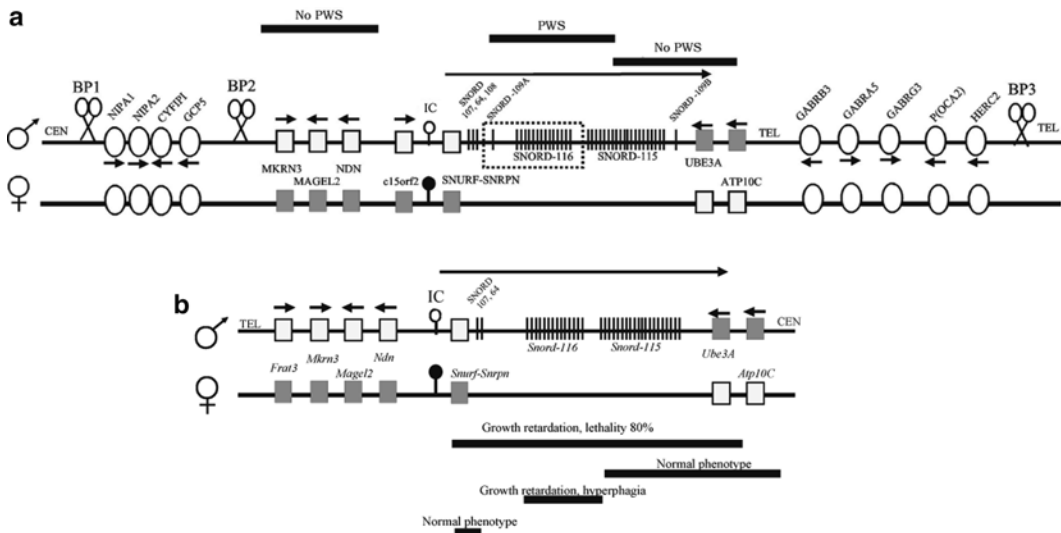
[a]This item was added by the authors (Goldstone et al. 2008)


Fig. 169.1 PWS chromosomal region on 15q11-q13 (not to scale) (**a**) and murine orthologous region (**b**). Imprinted genes are white boxes (paternal allele expressed) and grey boxes (maternal allele expressed) and nonimprinted genes are white ovals. Vertical bars indicate snoRNA C/D genes. BP1, BP2, and BP3 indicate common breakpoint (BP) regions for deletions: type I deletions are between BB1 and BP3, and type II deletions are between BP2 and BP3. Arrows indicate transcription direction and horizontal black bars represent some informative deletions. Empty and plain circles indicate, respectively, the hypo- and hypermethylated region overlapping imprinting center (IC). A frame indicates the minimal critical region likely to contain a gene of major interest for PWS (SNORD116 cluster)

Hybridization (FISH) and high-resolution chromosome analysis can detect chromosome 15q11-q13 deletions in PWS.

As a whole, 70% of patients present with a deletion, 25% with maternal uniparental disomy (UPD), 1–3% with imprinting defects, and the remaining few with translocation involving chromosome 15. Most cases are sporadic but a high recurrence risk is associated with imprinting defects.

Figure 169.1 shows the complexity of the chromosomal PWS region in man (A) and mouse (B).

169.3   Description of Nutritional Phases

The two classical phases: PWS has been classically described as having two phases: (1) poor feeding and frequent failure to thrive in infancy (FTT), and (2) onset of hyperphagia leading to obesity (Gunay-Aygun et al. 2001). Phase 1 occurs from birth to early infancy when infants with PWS have severe hypotonia and a poor ability to suck and often require tube feeding. FTT refers to the lack of weight gain despite normal calorie intake. Phase 2 is described as beginning between 1 and 6 years, usually between 2 and 4 years (Gunay-Aygun et al. 2001). Recent examination of the natural history suggests a more complex progression leading to four main nutritional phases with subphases in the first two (McCune H 2005).

169.3.1   Four Nutritional Phases

Not all PWS individuals go through all the phases and subphases, which may be further altered by the use of GH (see Sect. 169.7).

In the first phase, the infant is hypotonic and is not yet obese. Subphase 1a consists of feeding difficulties with or without FTT. In subphase 1b, the infant grows steadily along a growth curve, at a normal rate.

In the second phase, which occurs between 18 and 36 months of age, body weight and BMI start to increase very rapidly. In subphase 2a, the child's weight increases in such a way that it crosses one, two, or more weight percentiles without a significant increase in calorie intake. In subphase 2b, the child increases his or her daily calorie intake, becomes more autonomous and turns overweight or obese, and displays an abnormally increased interest in food. Still, the appetite is not insatiable and unrelenting as it is in phase 3.

Phase 3 starts as early as 3 years of age or as late as 15 years. This is the classical phase that most people typically associate with PWS, with aggressive food-seeking and markedly reduced satiety. Patients in phase 3 have delayed meal termination and require significantly greater calorie intake to experience loss of hunger compared with those without PWS.

In phase 4, an individual may still have an increased appetite, but it is not as aggressive and unrelenting as previously observed and seems to occur only in a subset of adults typically after 30 years of age.

169.4 Eating Behavior and Food Preferences

Children with PWS present a particular meal pattern with a slower initial eating rate but much longer meal duration and nondecelerating eating curves. They are also distinguished by an early return of hunger after the previous meal, with early meal initiation. These findings were demonstrated by Lindgren et al. (Lindgren et al. 2000) using an elegant protocol to study nine subjects with PWS (compared with obese and normal weight subjects). These subjects were served a copious lunch on a hidden scale built into a table and connected to a computer. The authors concluded that the eating behavior of patients with PWS might be due to decreased satiation rather than increased hunger.

Given free access to food, patients with PWS will consume approximately three times more than control subjects, according to Zipf and Bernston (Zipf and Berntson 1987). These authors examined food intake patterns in ten patients with PWS and nine age- and weight-matched obese children by making standard chicken-salad sandwich quarters continuously available for one hour. Moreover, this overeating occurs despite delayed gastric emptying, leading to extremely morbid obesity.

Exploring food preferences, Fieldstone et al. (Fieldstone et al. 1997) elaborated a taste test with three types of foods (high carbohydrate, high protein, and high fat) reduced to spread consistency. PWS subjects preferred high carbohydrate foods over high protein foods and high protein foods over high fat foods. Moreover, the preference for high carbohydrate foods was significantly higher in PWS subjects than in obese controls. In addition, PWS patients are more likely than controls with and without mental retardation to eat nonfood items (pica) and contaminated foods and to make inappropriate food combinations.

Overall, the drive for food remains a life-long source of stress for individuals with PWS and their families. Complications of obesity remain the major cause of deaths in adults with PWS in relation with cardiovascular or respiratory failures. These patients are also at risk of choking due to a swallowing defect combined with their abnormal voracity or gastric perforation after consuming high quantities of food, even in the absence of obesity (Stevenson et al. 2007).

169.5 Evaluation of Hyperphagia and Feeding Disorders in Patients with PWS

Measuring hyperphagia in PWS has long been a research challenge. The abnormal feeding behavior in PWS includes a morbid obsession with food, food stealing, money stealing to buy food, hoarding and foraging, pica behavior, reduced satiety, and early return of hunger after the last meal (Goldstone 2004).

As described above, the first studies on PWS eating behavior provided unlimited access to food to patients and measured the number of sandwich quarters consumed. This methodology was questioned, and specific questionnaires were subsequently developed. In 2003, Russell and Oliver (Russell and Oliver 2003) proposed a 16-item informant-based Food Related Problem Questionnaire with three subscales (preoccupation with food, impairment of satiety, and other food-related 'challenging' behavior) for people with PWS. More recently, Dykens et al. (Dykens et al. 2007) developed a 13-item Hyperphagia Questionnaire to be filled out by parents or caregivers. The development of this questionnaire sets a landmark for future research on the eating behavior of patients with PWS (see article by Dykens in chapter 2.1). It also provides insight into the connections between the various behavioral features of the syndrome, as well as the connections between behavioral and neuronal or biochemical features.

Further research should focus on the role of maladaptive behaviors or emotional problems in the manifestation of hyperphagia in PWS and the mechanisms associated with individual variability, including genetic subtypes, neurobiological factors, emotional functioning, development and aging, and therapeutic interventions.

169.6 Mechanisms Involved in Hyperphagia and Feeding Problems

169.6.1 Feeding and Satiety Signals

PWS has been described as a genetic hypothalamic syndrome, although the phenotype and pathophysiology of the so-called hypothalamic dysfunction have yet to be reported in detail. The necdin gene, which is located in the 4 Mbp PWS chromosomal region, has been clearly implicated in preventing apoptosis of hypothalamic gonadotrophin-releasing hormone (GnRH) neurons. The Magel 2 gene (another candidate gene close to necdin in the PWS region) seems to be involved in hypocretin regulation and sleep control, with an involvement of hypothalamic neurons. Nevertheless, paternal deletion of the three genes – necdin, MKRN-3, and Magel 2 – does not result in the PWS phenotype in humans (Kanber et al. 2009).

Recently, the major components of the distributed neural system controlling food intake and energy balance were extensively reviewed. Over the past 10 years, the limited view of a few mainly hypothalamic centers has gradually been modified by evidence of a much more complex and distributed system including various corticolimbic areas. It is now recognized that cognitive, hedonic, and emotional neural processes play important roles in energy intake and expenditure and in the resulting energy balance, and that hormones modulate many of these processes. This model fits very well with what is known about the integrated dysfunctions in PWS that encompass the hypothalamus and brain regions involved in cognitive, social, and affective processes.

169.6.2 Elevated Ghrelin Levels in PWS

The most striking and specific defect in the satiety signals in PWS is the high circulating level of the orexigenic stomach-derived hormone ghrelin. Ghrelin is a 28-amino acid acylated peptide, first isolated from stomach in 1999, with a strong orexigenic effect, and it is the most potent GH secretagogue through its hypothalamic actions. Ghrelin is now considered a pleiotropic hormone with various secreting organs (duodenum, pancreas, pituitary, hypothalamus, testis, ovary, bone, and cartilage) and a wide range of target tissues depending on its acylation status (hypothalamus, stomach and gut, pancreas, adipose and cardiovascular tissues, testis, ovaries, and muscle), acting through distinct receptors (Hosoda et al. 2006). A specific enzyme, Gastric O acyl transferase (GOAT), was recently reported to be involved in ghrelin acylation and may have an important regulatory role. In addition, the ghrelin antisense strand gene GHRLOS, a recently reported candidate non-coding RNA gene, may have a regulatory and functional role in the ghrelin axis.

There are two reservoirs of ghrelin: the gastrointestinal tract and the central nervous system (CNS). Most circulating ghrelin is released by the stomach into the general circulation and can cross the blood–brain barrier (BBB) in a highly regulated process (Banks et al. 2002). In the CNS, ghrelin is produced in the major site for feeding regulation, the arcuate nucleus (ARC), and by a group of neurons adjacent to the third ventricle between four hypothalamic nuclei: dorsomedial (DMH), ventromedial (VMH), paraventricular (PVN), and ARC. Interestingly, these neurons also express ghrelin receptor GHR1a, which specifically binds acylated ghrelin. Receptors have also been identified in other areas such as the dorsovagal complex which includes nucleus tractus solitary (NTS), area postrema (AP), and dorsal motor nucleus of the vagus. In these areas, the density of GHRs is higher in fasting rats than in fed ones. The vagal nerve obviously plays a crucial but not mandatory role in driving the central actions of ghrelin (Date et al. 2002).

Regarding its role at the level of the ARC, ghrelin demonstrated opposite effects to leptin, another hormone involved in the control of food intake and energy homeostasis that is secreted by adipocytes and acts on the same hypothalamic neurons (Schwartz and Morton 2002). Ghrelin increases NPY and AgRP release. Leptin also plays a role in neuronal plasticity and particularly in the implementation of neuronal pathways in early life; its levels appear to be normal in people with PWS.

Circulating ghrelin levels have been shown to be low in obesity, suggesting that conversely to leptin, there is no ghrelin resistance in obesity. Individuals with PWS, unlike those with other known causes of obesity, have hyperghrelinemia (Cummings et al. 2002; Haqq et al. 2003; Tauber et al. 2004), which could explain at least two major endocrine dysfunctions observed in these patients: obesity and GH deficiency (described in 40–100% of the patients and explaining the short stature). GH deficiency could be explained by ghrelin resistance, whereas obesity could result from a preserved action of ghrelin on appetite centers, possibly due to different receptors or modulators. Nevertheless, ghrelin levels were reported to be negatively correlated with visceral adiposity, fasting insulin, and the homeostasis model assessment insulin resistance index (Goldstone et al. 2005) in adults with PWS. Ghrelin levels decreased with age, in controls, and in patients with PWS (Cummings et al. 2002; Haqq et al. 2003). Most of the studies documented an inverse correlation between ghrelin levels and BMI in the individuals with PWS (Haqq et al. 2003; Tauber et al. 2004). Our group recently described the changes in plasma ghrelin over the course of life in PWS and controls and showed that ghrelin dysregulation in PWS occurs very early in life and precedes the onset of obesity (Feigerlova et al. 2008). Thus, plasma ghrelin levels were high from birth to adulthood in patients with PWS, regardless of age, but the physiological decrease with age was preserved.

Recent data suggest that ghrelin does more than regulate energy homeostasis and that it is involved in the gustatory pathways, locomotor activity, dopamine/serotonin reward networks, and neuronal plasticity.

Ghrelin acts on hippocampal neurons to induce the formation of new synapses in the CA1 region correlated with enhanced spatial learning. Ghrelin-deficient mice exhibited impaired spatial learning that was corrected by ghrelin administration (Diano et al. 2006). These findings are consistent with the idea that ghrelin is involved in the appetitive phase of ingestive behavior, when it is important to find food in the environment. It is plausible that the ghrelin-induced changes in hippocampal function facilitate the recall of stored representations of prior experience with food. This is indicated by human subjects reporting a vivid, plastic image of their preferred meal upon intravenous ghrelin infusion. In addition, ghrelin activates dopamine neurons in the ventral tegmental area (VTA), increases dopamine turnover in the nucleus accumbens, and directly stimulates food intake when locally administered to the VTA. As local ghrelin receptor blockade in the VTA blunted rebound feeding following fasting, these observations suggest that enhancement of reward processing in the mesolimbic dopamine system is an integrated part of endogenous ghrelin orexigenic action (Olszewski et al. 2007).

While the well-known preprandial rise and postprandial fall in plasma ghrelin levels initially supported the hypothesis of a physiological role for ghrelin in meal initiation in humans, these more recent data favor a role of ghrelin in meal anticipation as shown in Fig. 169.2 (Frecka and Mattes 2008).

In humans, ghrelin bursts occur after the peak of hunger, and are related to habitual meal patterns (Frecka and Mattes 2008) and contents. Ghrelin levels may rise in anticipation of eating rather than eliciting feeding. These findings support the implementation of regular schedules for meal times and meal contents to control the eating behavior of patients with PWS. Ghrelin has been shown to be involved in food searching, food storage, foraging, and hoarding in hamsters.

Ghrelin also interacts with other important neuro-hormones possibly involved in PWS: lateral hypothalamic orexin neurons appear to mediate the orexigenic effects of ghrelin, and intra cerebro ventricular ghrelin activates magnocellular ocytocin neurons (Olszewski et al. 2007). Ghrelin may also support feeding driven by energy needs rather than reward (Bomberg et al. 2007).

Although somatostatin acutely suppresses plasma ghrelin concentrations in PWS patients, appetite is not reduced. A recent study found no benefit on weight or appetite in PWS from chronic administration of a long-acting somatostatin analogue (De Waele et al. 2008). This may suggest that early high
Fig. 169.2 Evolution of ghrelin, CCK, insulin, amylin, PYY, GLP-1, and OXM in humans before, during, and after mealtime

ghrelin levels set up an abnormal tuning for food seeking and anticipation of meals in patients with PWS, which cannot then be turned off. An alternative explanation could be that hyperghrelinemia is secondary to a primary defect that is not corrected by somatostatin. Recent evidence in human subjects suggests that both peptide YY (PYY) and oxyntomodulin (OXM, a product of differential processing of proglucagon in brain and gut) suppress circulating concentrations of ghrelin when given peripherally, whereas pancreatic polypeptide (PP) has no effect (Batterham et al. 2003a) Table 169.4.

169.6.3 Decreased Levels of Pancreatic Polypeptide

Levels of the anorexigenic gut hormone PP are reduced in PWS (Goldstone 2004). PP was discovered in 1975 and isolated from chicken pancreatic extracts. It is a 36-amino-acid peptide and a member of the PP-fold peptide family (also including NPY and PYY). The PP-fold family binds to receptors Y1–Y6, but PP binds with greatest affinity to the Y4 and Y5 receptors. It is produced in the endocrine type F cells, which are located in the peripheries of the pancreatic islets. Pancreatic polypeptide cannot cross the BBB and thus its central effects may be mediated in regions where the BBB is incomplete, such as the hypothalamus, AP, and adjacent brainstem areas (Katsuura et al. 2002). The release of PP appears to require an intact vagal cholinergic reflex. Peptide YY inhibits fluid and electrolyte secretion in the small bowel and delays intestinal meal transport. It may act as an "ileal brake," slowing gastric emptying and intestinal transit, so that nutrients can be absorbed in the small bowel. In humans, intravenous infusion of PP reduced food intake by 21.8% at a free-choice buffet, but did not affect gastric emptying (Batterham et al. 2003b).

Basal PP levels are elevated in anorexia nervosa, and in patients with advanced malignant disease. People with PWS had a blunted PP response to meals and short-term infusions of peripheral PP given to these subjects were shown to reduce subsequent food intake by 12% (Berntson et al. 1993). More recently, further evidence of PP's role in weight regulation came from a prospective study in Pima Indians. PP meal profiles were measured at baseline, and at a 5-year follow-up, and then correlated with change in weight. An increase in postprandial PP levels was associated with decreased weight gain, but surprisingly high fasting PP levels were associated with increased weight gain (Koska et al. 2004). These results suggest that different receptors may be activated. The precise role of PP in appetite regulation is not yet resolved. PP may be involved in the pathophysiology of obesity and dysregulation of body weight via effects on the parasympathetic nervous system.

Interestingly, the two main abnormal signals, one orexigenic (ghrelin) and the second involved in satiety control (PP), may explain the major feeding disturbances described in people with PWS. Part of their action requires an intact vagal nerve reflex and they both regulate gastric emptying. Both hormones are elevated in anorexia nervosa. A decreased parasympathetic tone has long been described in PWS together with a defect in gastric emptying and other gut dysfunctions possibly related to these hormone dysfunctions.

Besides a permanent state of hunger, people with PWS have disturbances in the anticipation of hunger and the representation of meal content, combined with satiety signal abnormalities involving the hypothalamus, corticolimbic networks, and the vagal system.

Table 169.2 summarizes the findings of studies on hypothalamic neuropeptides and their signaling inputs in PWS. It seems likely that in addition to these hormonal abnormalities in PWS, there are overriding brain defects, including hypothalamic, which lead to resistance to peripheral satiety signals (Goldstone 2004). The possibility of therapeutic avenues for reducing hyperphagia in PWS may depend on the existence of relative rather than absolute resistance to peripheral satiety signals.

Table 169.2 Summarized findings of studies on hypothalamic neuropeptides and their signalling inputs in PWS (Adapted from *Trends in Endocrinology and Metabolism*, Vol 15, Prader-Willi syndrome: advances in genetics, pathophysiology and treatment, pages 12–20. Copyright (2004) with permission from Elsevier)

• Normal leptin secretion	• Normal distribution and colocalization of neuropeptide Y (NPY) and agouti-related protein (AgRP) in infundibular nucleus (INF).
• Long isoform leptin receptor mRNA expressed in lymphocytes	
• Increased fasting plasma ghrelin	• Normal increase in NPY, measured by either immunocytochemical (ICC) staining or mRNA expression, or AGRP (ICC staining) in INF during illness.
• Reduced postprandial secretion of pancreatic polypeptide (PP)	
• Reduced fasting and postprandial insulin secretion	
• Normal cholecystokinin (CCK) secretion	• Reduced NPY (ICC or mRNA expression) in INF, compared with control, but not non-PWS obese adults, corrected for the duration of premorbid illness.
• Normal distribution of oxytocin and vasopressin neurons in the paraventricular nucleus (PVN).	
• Reduced number of total (38%) and oxytocin (42%)-containing neurons in the PVN.	• Normal AGRP (ICC staining) in INF, compared to control and non-PWS obese adults, corrected for the duration of premorbid illness.
• Normal number of neurons containing cocaine and amphetamine-regulated transcript (CART) in the INF, PVN, and lateral hypothalamic area (LHA).	• Deficiency of POMC-containing neurons in INF, CART-neurons in INF, PVN, and LHA is not complete.

169.6.4 Dysregulation of Serotonin Receptors

Sno RNAs located in the chromosomal region of PWS (Fig. 169.1) are candidate genes for the disease. It has been hypothesized that the Sno RNA HB-52 negatively regulates editing of the 5HT-2C receptor pre-RNA. Indeed, this post transcriptional regulation of this serotonin receptor involved in cognition and cessation of feeding changes its activity. The lack of editing in PWS through the increasing intrinsic activity of the receptor may explain some of the features of this disease. A recent study performed in a mouse model (PWS IC +/−) seems to confirm this hypothesis, although the link with the lack of Sno RNA HB 52 was not established in the publication (see below the chapter on animal models).

169.6.5 Abnormalities in Hypothalamus Histology

Quantitative neuroanatomical studies of postmortem human hypothalamic tissue from patients with PWS in the Netherlands Brain Bank have yet to find any pathological abnormalities in orexigenic neuropeptide Y or agouti-related protein, anorexigenic POMC neurons or GH-releasing hormone neurons in the infundibular nucleus, or orexin/hypocretin neurons in the lateral hypothalamus. Nevertheless, interpretation may be complicated by small numbers and the effects of premortem illness (Goldstone et al. 2003). However, appropriate changes in neuropeptide Y, agouti-related protein, and GH-releasing hormone were found in PWS subjects in cases of illness, obesity, and exogenous GH therapy. This suggests normal neuronal function in their response to alterations in peripheral signals. Cerebrospinal fluid orexin concentrations have nevertheless been reported to be low in cases of PWS with hypersomnia (Nevsimalova et al. 2005). Reduced immunostaining of processed vasopressin, its processing enzyme, prohormone convertase 2, and its molecular chaperone polypeptide 7B2 has also been found in the PVN and supraoptic nucleus of hypothalami from subjects with PWS, though diabetes insipidus is not a recognized clinical problem (Gabreels et al. 1998).

The total and oxytocin cell number is reduced in the hypothalamic PVN of adults with PWS, which may play a primary causative role in hyperphagia. Oxytocin and the PVN have anorexigenic roles in rodents. A 29% reduction in PVN oxytocin neurons was also seen in necdin knockout mice, though these mice are not obese (Muscatelli et al. 2000). Interestingly, oxytocin is an anorexigenic hormone with other newly described actions, particularly regarding social skills, trust, and pair bonding. Peripheral levels are normal although there was discordant data on oxytocin in CSF levels (Fig. 169.3).

169.6.6 Recent Neuroimaging Data

Several morphological neuroimaging abnormalities have been described in PWS: according to Miller et al. (Miller et al. 2007a), ventriculomegaly (100% of 20 patients with PWS aged 3 months to 39 years), decreased volume of brain tissue in the parietal-occipital lobe (50%), sylvian fissure

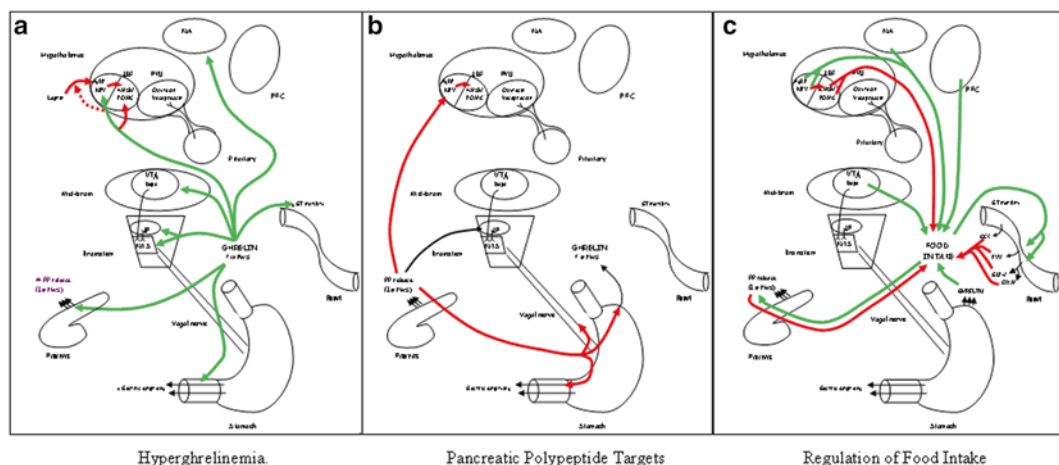
Hyperghrelinemia.   Pancreatic Polypeptide Targets   Regulation of Food Intake


Fig. 169.3 Features of feeding and satiety regulation. *Green arrows* stand for stimulation. *Red arrows* stand for inhibition. Sets of three black arrows stand for secretion. The *nucleus accumbens* (NA) is a collection of neurons within the forebrain that is thought to be involved in the reward circuit, and by which neuronal activity is modulated by dopaminergic input from the ventral tegmental area (VTA). The *prefrontal cortex* (PFC) is the anterior part of the frontal lobes of the brain. (**a**) Hyperghrelinemia. Ghrelin is secreted mainly by the stomach, but also by duodenum, pancreas, hypothalamus, testis, ovary, bone, and cartilage. Patients with PWS have greatly increased circulating levels of ghrelin. The effects of ghrelin on eating behavior are mediated via the arcuate nucleus (ARC) and the solitary tract nucleus (NTS) to merge in the hypothalamus. There, ghrelin opposes the actions of leptin through disinhibition of second line neuropeptides such as neuropeptide Y (NPY) and agouti gene-related peptide (AgRP). Ghrelin activates dopamine neurons in the ventral tegmental area (VTA) and increases dopamine turnover in the nucleus accumbens. Ghrelin also partly exerts its effect through vagal afferent loops. It increases fasting gastro-intestinal motility and the rate of gastric emptying. In PWS, it is hypothesized that a peripheral resistance to ghrelin opposes its stimulating actions (represented by # in the figure), which fits with clinical observations (patients with PWS have decreased GI motility, delayed gastric emptying and decreased PP release). (**b**) Pancreatic Polypeptide Targets. The inhibitory effect of PP on food intake might be indirect and regulated via vagal input to the stomach, pancreas, and other gastrointestinal organs. PP could also enter the brain to bind to AP and influence the adjacent nuclei, such as NTS and Dorso-Medial Nucleus to inhibit gastric emptying, which in turn suppresses food intake. Patients with PWS have reduced PP release both basally and postprandially. PP infusion in subjects with PWS reduced the levels of ghrelin. (**c**) Food Intake Regulation. Peripheral injection of PP inhibits food intake in both humans and mice. In Prader-Willi subjects, intravenous (i.v.) infusion of PP was reported to increase serum PP levels and significantly reduce food intake. GLP-1 is secreted within the circulation by the L-cells of the intestine, together with PYY and OXM; this secretion is stimulated by food intake. CCK is released by the I-cells of the intestine. These peptides all regulate negatively food intake. The ARC appears to be necessary for the stimulatory action of ghrelin on food intake

polymicrogyria (60%), and incomplete insular closure (65%) were found on 3D MRI scans, compared with 21 normal weight sibling controls and 16 individuals with early-onset morbid obesity of unknown etiology. On volumetric MRI, the same author (Miller et al. 2009) found that patients with PWS had smaller cerebellar volumes than a control group of 15 siblings. In several other studies, subjects with PWS had a higher prevalence of pituitary morphological abnormalities than did control subjects, without correlation with hormonal deficiencies (Tauber et al. 2000).

These abnormalities may play a role not only in cognitive, behavioral and neuroendocrine defects in PWS, but in hyperphagia as well. Indeed, recent functional neuroimaging techniques such as positron emission tomography and functional MRI (fMRI) in PWS have revealed abnormal brain activation patterns in corticolimbic structures, such as the amygdala and the prefrontal, orbitofrontal (OFC), and insular cortex, in response to food stimuli after ingestion of oral glucose or a meal (Shapira et al. 2005; Holsen et al. 2006; Miller et al. 2007b). These patterns suggest abnormal reward and motivational responses to food that may underlie the hyperphagia in individuals with PWS.

Hypothalamus dysfunction seems to be central in hyperphagia and underlies other abnormal functioning in PWS (temperature dysregulation, sleep–wake cycle abnormalities, and metabolic and endocrine disorders (Dimitropoulos and Schultz 2008)). Dimitropoulos et al. performed fMRIs on nine individuals with PWS (8–38 years old) IQ- and BMI-matched to ten controls, all in a hunger state, while they performed perceptual discrimination tasks on pictures of pairs of objects and high- or low-calorie foods. The authors showed that patients with PWS displayed a greater activation in the bilateral hypothalamus and right amygdala than controls for high-calorie foods. The OFC was more activated by high-calorie than low-calorie foods in the PWS subjects. The authors thus concluded to a hyper-activation of neural circuitry involving motivation, reward, taste, and food-seeking behaviors (hypothalamus, amygdala, OFC).

The lack of satiety in patients with PWS has also been investigated through fMRI (Shapira et al. 2005) by examining the regions related to satiation (insula, ventromedial prefrontal cortex, and nucleus accumbens). The activation of these regions was delayed after a glucose oral load in PWS patients compared with obese and lean controls. Hyperphagia thus appears to be linked to at least two mechanisms, since patients with PWS (vs. healthy weight controls) who were presented with visual food stimuli after eating a meal showed hyperfunction in limbic and paralimbic regions that drive eating behavior (e.g., the amygdala) and in regions that regulate food intake (e.g., the medial prefrontal cortex (mPFC)) (Holsen et al. 2006) (see article by Ogura in chapter 2.5).

In conclusion, although it has been clearly established that reward and motivation neural pathways and satiety dysfunction are involved in PWS hyperphagia, evidence has gradually emerged that the eating behavior of the patients with PWS arises from a complex mechanism combining insufficient neural development, hormonal dysfunctions, and an overall behavioral disorder involving psychiatric manifestations of the syndrome. In addition to the universal presence of the propensity to overeating and compulsive and ritualistic behaviors, people with PWS show pronounced emotional liability, and a striking inability to control their emotions, which predisposes them to temper outbursts. The frequent anger is often in response to frustration and to the feeling of not being understood, and it may be due to disturbances in understanding others, which in turn could be related to theory of mind and empathy.

169.6.7 Data from Animal Models

Most of the models that reproduce the genetic defects of PWS result in severe growth defect, feeding difficulties, and high lethality within the first days of life. However, surviving mice do not become obese.

Ding et al. (Ding et al. 2008) recently reported a new mouse model with great homologies with the PWS phenotype, but without the occurrence of obesity. This Snord116del mouse model seems to reproduce the abnormal feeding behavior and endocrine disorders described in humans with PWS. The hyperphagia of these mice is associated with prolonged meal times, pointing to a delay in meal termination that is most likely due to an inability to sense satiety. Interestingly, they also have elevated ghrelin, high insulin sensitivity, and low IGF-1, with growth delay that develops soon after birth. They may also have abnormal GH release though this has not been proved.

The authors concluded that the primary mechanism for hyperphagia in PWS is not a defect in energy homeostasis control, but in sensing satiety. They further concluded that the higher cognitive regions of the brain, such as the mPFC, which is involved in interpreting the incentive values of food, and those involved in planning complicated schemes to obtain food, may be changed secondary to the prolonged perception of hunger/lack of satiety. This is in line with the hypothesis developed by Holland (Holland et al. 2003) and with our own hypothesis on the impact of early hypergrhelinemia in the development and implementation of satiety circuits (Feigerlova et al. 2008).

Another interesting finding was reported by Doe et al. (Doe et al. 2009) using the imprinted centre deletion model. The authors studied abnormal editing of the 5HT2C receptor and alterations in its effect. Indeed, mice show impulsive responding, increased locomotor activity, and reactivity to palatable foodstuffs. Use of drugs confirmed the role of this serotonin receptor in these alterations.

The link between the lack of snoRNA genes and abnormal editing has yet to be proven. Although two patients have been described with the PWS phenotype and deletion of snoRNA HB85 (Sahoo et al. 2008; de Smith et al. 2009), an effect of snoRNA HB52 cannot be completely eliminated.

169.7 Management of Hyperphagia and Obesity

Obesity management in people with PWS involves strict and permanent environmental control, with early institution of a low-calorie, well-balanced diet, with regular exercise, rigorous supervision, restriction of access to food and money (after consideration of the legal and ethical obligations), and appropriate psychological and behavioral counseling for the patient and family. Early discussion with parents about the inevitability of hyperphagia, even during infancy, is essential to prepare them for the need to prevent obesity by setting firm limits and strictly controlling the food environment and the daily schedule (hour and contents of the meals). As an example of how important these steps can be, a young institutionalized adult declared that her anxiety and insomnia were improved the day she learned that the kitchen would be locked at night instead of simply being watched by a guardian who could possibly be away from his post for a short time. This aspect of management should thus be reemphasized at every visit, for our opinion is that total autonomy with regards to food is impossible and unrelated to the IQ of the patients.

Anecdotally, pharmacological treatment, including the available anorexigenic agents, has not been of benefit in treating hyperphagia, though there are few published placebo-controlled studies. Studies of the potential benefits of newer agents such as endo-cannabinoid antagonists were awaited in PWS, but recent concerns about psychiatric side effects led to withdrawal of these drugs. Restrictive bariatric surgery, such as gastric banding or bypass, has not been shown to reduce hyperphagia or achieve long-term weight reduction and is associated with unacceptable morbidity and mortality (Scheimann et al. 2008). While some of the studies of biliopancreatic diversion have reported successful weight loss, complications from the resulting intestinal malabsorption were frequent. Intragastric balloons are a risk for these patients and deaths have been reported (Grugni et al. 2008).

Physical activity in PWS is significantly reduced and is related to obesity, hypersomnolence, and persistent reduced lean mass and poor muscle tone. The resting metabolic rate is reduced relative to body size and this is related to the abnormal body composition, which further contributes to a reduction in 24-h energy expenditure (van Mil et al. 2000). Increased physical activity and exercise programs are beneficial in improving body composition in PWS.

169.8   GH Effects on Obesity and Body Composition

Body composition studies have shown both increased body fat and reduced muscle in PWS from infancy to adulthood (Carrel et al. 2004) with a selective relative reduction in visceral adiposity in PWS adults of both sexes (Goldstone et al. 2001). This may explain the relative hypoinsulinemia and normal triglyceride levels, with preservation of insulin sensitivity and protective elevation in adiponectin levels in these patients given their overall obesity.

GH treatment is routinely used for short stature in children with PWS in the USA, and since 2000 for treatment of short stature or abnormal body composition in Europe. As the age at diagnosis has markedly decreased in the past few years and is currently 3 months, the age for starting GH treatment has also decreased. Only a few publications have reported the possible benefits of early treatment on motility scores, cognitive function, and increased head circumference (Festen et al. 2008). The main effects of GH are the improvement in height, velocity, and adult height; the maintenance of lean body mass; and better control of BMI with a decrease in fat mass. It may also delay the occurrence of nutritional phase 3. By modifying the body shape of these children and increasing their motility, GH improves their socialization and, in some of them, lowers depressions scores (Whitman et al. 2002). Part of the GH effects may be related to the decrease in ghrelin under GH treatment (Hauffa and Petersenn 2008). Figure 169.4 shows the effect of GH in a boy who started treatment at 7 years with secondary normalization of BMI and body shape.

The benefits of GH cannot be obtained without integrated multidisciplinary care (Table 169.3).

[a]Indicates those particularly involved in transition

Figure 169.5 shows the effects of GH in a boy with PWS with morbid and uncontrolled obesity at 2 years due to poor family compliance with the diet. GH treatment was started in order to try to control the BMI, which nevertheless continued to increase with the aggravation of obstructive sleep apneas. This prompted us to stop the GH treatment and focus on parental guidance. Thanks to the strong collaborative work of all the caregivers, particularly the psychiatrist, family compliance was obtained. The child lost weight, normalized his BMI, and corrected his sleep respiratory disorder, and therefore resumed GH treatment.

Interruption of GH treatment at growth completion is required in most countries, though it may have a deleterious effect on BMI and body composition. Continuing GH in the adult is based on the potential benefits to bone mineralization, body composition, and maintenance of lean mass and muscular function. The effect on quality of life is difficult to prove, however, given the lack of an appropriate evaluation tool.

169.9 Transition from Childhood to Adolescence and Adulthood

The transition phase from childhood to adolescence and adulthood is of great importance in these patients. During the transition appointment, medical issues and psychosocial aspects concerning the patient are discussed. In the case of young adults, the emphasis is put on issues related to the processes of adolescence such as puberty, choice of profession, daily activities, relationships, and sexuality.

The prevalence of obesity in adults with PWS who received GH treatment in childhood is significantly reduced compared with those who did not receive it (personal data).

In conclusion, studies are needed to improve our knowledge of the natural history of hyperphagia and feeding disturbance in patients with PWS. Ongoing research on feeding and satiety signals such as ghrelin, PP, and ocytocin will help to unravel the mechanisms of the feeding behavior in these patients.

Fig. 169.5 Evolution of BMI in a young boy: effects of reinforced multidisciplinary care in a context of compliance difficulties
Table 169.4 Key facts of ghrelin

Circulating gut peptide

Orexigenic

Stimulate growth hormone secretion

Acylated in the Serine 3 amino acid

Circulating ghrelin increases before meals and decreases after

Low levels in obese people vs. controls

Elevated levels in PWS and anorexia

Balance between leptin and ghrelin at the level of arcuate nucleus neurons in the hypothalamus

Table 169.5 Key facts of growth hormone

GH is a peptide secreted by the anterior pituitary under hypothalamic control (GHRH, ghrelin, and somatostatin)

Induces somatic growth before cartilage fusion

Acts on different tissues: adipose tissue, muscles, bone

Has metabolic effects (lipid, glucose metabolisms), anabolic effect

GH secretion is decreased in some children having short stature. Treatment increases height and normalizes adult height

GH treatment is based on daily subcutaneous injections

Functional neuroimaging may open new perspectives on pathophysiology and treatment. Last, the effects of early diagnosis, the outcomes of GH treatment, and multidisciplinary care need to be analyzed properly in order to determine the best possible care for patients with PWS (Tables 169.4 and 169.5).

169.10 Applications to Other Areas of Health and Disease

Acquiring knowledge in hormones and signals controlling food and satiety signals in PWS may open new perspectives on pathophysiologics and therapeutical issues for persons with nonsyndromic obesity.

Summary Points

- *Two main features* characterize hyperphagia in PWS: a reduced satiety and an early return of excessive hunger.
- *Two main hormonal dysfunctions* might explain hyperphagia: hyperghrelinemia and decreased pancreatic polypeptide.
- *Oxytocin deficit* may be involved in hyperphagia.
- *Two neuronal networks* may be involved in the eating behavior of PWS: the cortico-limbic structures implied in reward mechanisms and the paralimbic regions that drive food behavior.
- *Better characterization of eating behavior* will help understanding hyperphagia pathophysiology and defining treatment goals.
- *Data on animal models* are insufficient to explain human clinical and biological findings.
- It is likely that the implementation of *early diagnosis, multidisciplinary care, and GH treatment* altogether will optimize patients' quality of life.

Definitions and Explanations of Key Terms

Hyperphagia: Eating disorder in which an individual eats abnormally large amounts of food in little time.

Orexigenic: Hormones that trigger a desire to eat. Ghrelin is the only real orexigenic peptide, since AgRP and NPY release is related to ghrelin activity.

Satiety: Time during which an individual does not feel the desire to eat. Satiety is related to the sensation of fullness without being tantamount to it. PP, CCK, GLP-1 and OXM are peptides which release triggers a satiety feeling.

Hypothalamic syndrome: Although there is no consensus definition of the hypothalamic syndrome, it is usually described as the collection of appetite disorders, hyperphagia and obesity, or anorexia, thirst abnormalities, tiredness, temperature dysregulation, sleep disorders, and behavioral difficulties. In the course of evolution, endocrine abnormalities usually develop, characterized by hyperprolactinemia and pituitary deficits (gonadotrophic, somatotropic, corticotropic, and thyrotropic). Central precocious puberty can also occur. Several causes can be involved: tumors, genetic syndromes such as Prader-Willi, infectious or inflammatory diseases, and idiopathic.

Reward networks: Collection of brain structures which attempts to regulate and control behavior by inducing pleasurable effects. It principally involves the mesolimbic (which goes from the ventral tegmental area via the medial forebrain bundle to nucleus accumbens, where mainly dopamine is released) and the mesocortical pathway (which connects the ventral tegmentum to the cerebral cortex).

DSM-III-R	Diagnostic and Statistical Manual of Mental Disorders, Revised Third Edition
BN	Bulimia nervosa
ED-NOS	Eating disorder not otherwise specified
DSM-IV	Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition
ICB	Inappropriate compensatory behavior in order to prevent weight gain
BED	Binge-eating disorder
DKA	Diabetic ketoacidosis
NIDDM	Non-insulin-dependent diabetes

170.1 Introduction

Type 1 diabetes is a disease characterized by a total absence of insulin production because the pancreatic β cells have been destroyed by an autoimmune mechanism. Problems associated with the regulation of blood sugar and the long-term complications are well known. An eating disorder is a disease in which a person has an abnormal eating behavior associated with an excessive fixation on body weight. Because type 1 diabetes patients who develop an eating disorder have great difficulty maintaining a therapeutic dietary regimen and often place priority on weight control over metabolic control, they face severe obstacles to proper diabetes control. As with eating disorders in the general population, an eating disorder concurrent with type 1 diabetes is most commonly seen in young women.

The research on the concurrence of an eating disorder and type 1 diabetes has been done since about 1980, mostly in Europe and North America. Empirical studies in this field have focused on the prevalence of eating disorders, poor metabolic control, the high risk of diabetic long-term complications, and nonadherence to the diabetes treatment regimen through behaviors such as insulin omission.

M. Takii (✉)

Table 170.1 Key features of type 1 diabetes

1. Type 1 diabetes results from extremely decreased insulin production by the pancreas because the beta cells (insulin secretion cells) are destroyed by an autoimmune mechanism.
2. The main treatment for type 1 diabetes is to supply extrinsic insulin. Persons with type 1 diabetes must take supplementary insulin by injections for the rest of their lives.
3. The onset age of type 1 diabetes is usually young, most often in childhood or the adolescent period, and the onset is fairly rapid.
4. Various self-care efforts are necessary for patients to maintain good glycemic control and to prevent diabetes-related complications.
5. Because the burden of having this severe disease and the requirements of managing it are often too heavy for young patients, they tend to have psychological and behavioral problems.
6. These problems lead to a deterioration of the metabolic control of the diabetes and to early onset of long-term diabetic complications that severely affect the quality of life of the patients.

This table lists the key facts of type 1 diabetes including the etiology by an autoimmune mechanism, the necessity of insulin supplementation for treatment, the young onset age of the disease, the difficulty of controlling it, and the risk for psychological/behavioral and medical problems

This report focuses on current findings and theories related to the epidemiology, clinical condition, mechanism of the onset of the eating disorder, and the treatment approach for patients with clinical eating disorders concurrent with type 1 diabetes. In addition, studies of eating disorders complicated with type 2 diabetes will be introduced.

The Department of Psychosomatic Medicine at Kyushu University specializes in the treatment of both eating disorders and diabetes. Diabetes patients who have psychological problems are referred from all over Japan. Over the past 15 years, we have treated more than 150 type 1 diabetes patients with a concurrent clinical eating disorder. Studies done in our department concerning the clinical condition and treatment of these patients are described in this chapter.

Also discussed are self-destructive behaviors associated with insulin omission and poor insulin manipulation, which are often deeply related to eating disorders and are among the most severe problematic behaviors of diabetes patients (Table 170.1).

170.2 Epidemiology/Clinical Condition

170.2.1 Early Review

Marcus and Wing (1990) did a literature review of the clinical condition of 57 patients with an eating disorder concurrent with insulin-dependent diabetes (IDDM). A summary is as follows:

1. Co-occurrence of these disorders is common.
2. The diagnosis of IDDM occurs before that of an eating disorder in the preponderance (90%) of the cases.
3. Ninety-five percent of the cases of eating disorders among IDDM patients have occurred in women.
4. Sixty-two percent of eating-disordered IDDM patients reported deliberate manipulation of insulin to promote weight loss. Regular elimination of insulin doses would be predicted to have negative consequences for glycemic control.
5. Poor glycemic control was reported in 75% of patients with eating disorders, and major diabetic complications may be prevalent as well.
6. The relationship between diabetes and anorexia nervosa (AN)/bulimia shows a kind of synergism in which one disorder worsens the other and where successful therapeutic interventions may consequently prove exceedingly difficult.

170.2.2 Prevalence of the Eating Disorders of Type 1 Diabetes Patients

A relatively large number of studies investigating the prevalence of the eating disorders of patients with type 1 diabetes have been published since late 1980s (Steel et al. 1987; Rodin et al. 1991; Fairburn et al. 1991; Peveler et al. 1992; Jones et al. 2000). Whether or not eating disorder frequency was higher in female patients of type 1 diabetes than nondiabetic peers was controversial.

Relatively more studies suggested that eating disorder frequency is higher in women with type 1 diabetes than in women in general (Steel et al. 1987; Rodin et al. 1991). For example, Rodin et al. (1991) reported a diagnosis of an eating disorder for 13- to 18-year-old women with type 1 diabetes in 13% of their sample (103 cases), based on DSM-III criteria (AN 1% and bulimia 12%) and in 5% of the sample based on the more severe DSM-III-R criteria (American Psychiatric Association 1987) (all bulimia nervosa (BN)).

Other studies have found that the eating disorder frequency does not differ from that of women in general (Fairburn et al. 1991; Peveler et al. 1992). Fairburn et al. (1991) diagnosed eating disorders in 11% of 54 women with IDDM aged 17–25 years (BN 5.5% and "eating disorder not otherwise specified (ED-NOS)" 5.5%) and in 7.5% of nondiabetic, control women (BN 3% and ED-NOS 4.5%) based on DSM-III-R criteria. No significant difference was found between the groups. ED-NOSs were defined as eating disorders other than AN or BN.

The differences in prevalences may have been because of differences in the method of diagnosis, the eating disorder diagnostic criteria, and/or the sample. The DSM-IV diagnostic criteria (American Psychiatric Association 1994) for the first time accepted insulin omission as an "inappropriate compensatory behavior in order to prevent weight gain" (ICB), which is necessary for a diagnosis of BN. The use of the earlier criteria may have led to underestimation of the prevalence of the eating disorders of type 1 diabetes patients (Affenito and Adams 2001).

Jones et al. (2000) conducted a large, multisite case-controlled study of 356 girls aged 12–19 years with type 1 diabetes and 1,098 case-matched controls. They used a two-stage design with both self-report questionnaires and structured diagnostic interviews of eating disorders and found that eating disorders that met the DSM-IV diagnostic criteria were 2.4 times more common in girls with diabetes (5 BN cases and 31 ED-NOS cases) than in their nondiabetic peers (10% vs 4%).

170.2.3 Classification of the Eating Disorders Associated with Type 1 Diabetes

Research indicates that eating disorders associated with binge eating, such as BN and binge-eating disorder (BED), are the most common types of eating disorders among girls with diabetes and that restricting eating disorders are much less common conditions (Jones et al. 2000; Affenito et al. 1997). BED is classified as an ED-NOS. Although BN and BED have frequent binge eating in common, the primary difference between BN and BED is the regular use of an ICB by BN patients, such as insulin omission, self-induced vomiting, misuse of laxatives, fasting, or excessive exercise (American Psychiatric Association 1994).

In a meta-analysis, Nielsen (2002) reported that although AN was not increased in females with type 1 diabetes compared with their nondiabetic peers, BN (OR = 2.9), ED-NOS (OR = 1.8), and subthreshold eating disorders (OR = 1.9) were increased.

Since 1994, we have treated 158 type 1 diabetes patients with clinical eating disorders: 151 female and 7 male. The classification of the eating disorders of female patients, based on DSM-IV, were

Table 170.2 Demographic and clinical features of female type 1 diabetes patients with bulimia nervosa (BN), with binge-eating disorder (BED), and without an eating disorder (CONTROL) (Adapted from Takii et al. 1999)

	BN (N = 22)	BED (N = 11)	CONTROL (N = 32)	P
Age (years)	23.2 ± 4.4	24.8 ± 7.5	23.9 ± 3.8	NS
Onset of DM (years)	14.5 ± 5.4	20.1 ± 8.2	15.9 ± 5.9	NS
Duration of DM (years)	8.7 ± 5.7	4.7 ± 1.8	7.9 ± 5.5	NS
Onset of BE (years)	18.2 ± 4.2	22.4 ± 7.0	(-)	<0.05
Duration of BE (years)	5.0 ± 3.9	2.5 ± 1.6	(-)	<0.05
BMI (kg/m^2)	21.6 ± 2.5	23.6 ± 2.7	20.7 ± 2.2	<0.05[a]
HbA1c (%)	12.3 ± 2.6	9.7 ± 2.1	6.2 ± 0.8	<0.0001[b]
Retinopathy (%)	40.9	0.0	6.3	<0.001
Neuropathy (%)	45.4	9.0	6.3	<0.005
EDI	93.5 ± 26.9	57.4 ± 25.0	36.2 ± 15.3	<0.0001[b]
SDS	53.3 ± 7.2	42.8 ± 7.2	37.1 ± 6.8	<0.0001[b]
Trait-Anxiety scale in STAI	58.9 ± 7.1	47.9 ± 9.0	42.2 ± 8.3	<0.0001[c]
Any co-occurring mental disorder	18 (81.8%)	5 (45.5%)	ND	<0.05
GAF	45.7 ± 7.7	56.5 ± 8.8	ND	<0.001

Female type 1 diabetes patients with bulimia nervosa (BN) have the most severe medical consequences of diabetes, psychopathology related to eating disorders, and general psychological disturbances; those without eating disorders (CONTROL) have the least; and those with binge-eating disorder (BED) are between BN and CONTROL

DM type 1 diabetes, *BE* binge eating, *EDI* eating disorder inventory, *SDS* self-rating depression scale, *STAI* state-trait anxiety inventory, *GAF* global assessment of functioning, *ND* not determined

Data are means ± SD. NS, $p > 0.05$

Differences were determined by one-way ANOVA followed by Bonferroni's adjusted t-test or by chi-square test

[a] BED > BN and CONTROL

[b] BN > BED > CONTROL

[c] BN > BED and CONTROL

100 cases of BN (66.2%), 35 cases of BED (23.2%), 11 cases of AN (7.3%), and five cases of ED-NOS other than BED (3.3%). Of the 11 cases of AN, only 1 was the restricting type, with the remaining 10 the binge-eating/purging type. For males, one case of BN (14.3%) and six cases of BED (85.7%) were found. Although the high proportion of binge-eating-associated eating disorders was similar to previous studies, the preponderance of BN patients may reflect sample bias because of the urgent necessity to give specialized treatment for the patient's severe medical condition: BN patients with type 1 diabetes have been shown to have the most severe medical problems in comparison with patients with other eating disorders such as BED, as will be presented in the following sections (Takii et al. 1999) (Table 170.2).

170.2.4 Psychopathological Aspects

170.2.4.1 Psychopathology Associated with the Eating Disorder

For young women with type 1 diabetes, some studies have shown that the psychopathology related to the eating disorder is more pronounced than for persons without diabetes (Rosmark et al. 1986; Fairburn et al. 1991).

Our research has shown that type 1 diabetes patients with a clinical eating disorder manifest significantly more severe eating disorder psychopathology than patients with an episode of binge eating but without a clinical eating disorder (abnormal eating habits), and that patients with abnormal

eating habits manifest significantly more severe eating disorder psychopathology than patients with normal eating habits (Tsukahara et al. 2009).

We also reported that female type 1 diabetes patients with BN had a significantly more severe eating disorder psychopathology than patients with BED and that patients with BED had a significantly more severe eating disorder psychopathology than patients without eating disorders (Takii et al. 1999) (Table 170.2).

170.2.4.2 General Psychopathology

Mood disorders have been reported to be common in patients with an eating disorder (Kennedy et al. 1994). They are also common in patients with diabetes (Talbot and Nouwen 2000). Vila et al. (1995) found that almost half of the 52 teenaged girls with type 1 diabetes and an eating disorder also reported significant depressive symptoms.

Our research has shown that type 1 diabetes patients with a clinical eating disorder had significantly more severe depression, anxiety, and diabetes-related distrust than patients with abnormal eating habits and that patients with abnormal eating habits had significantly more severe psychopathology than patients with normal eating habits (Tsukahara et al. 2009).

We also reported that female type 1 diabetes patients with BN manifested significantly more severe depression, anxiety, a higher rate of co-occurring mental disorders, and poorer psychosocial functioning than patients with BED and that patients with BED were significantly more depressive than patients without eating disorders (Takii et al. 1999) (Table 170.2).

170.2.5 Behavioral Problems

170.2.5.1 Noncompliance

Rodin et al. (1991) reported that patients with an eating disorder reported significantly more noncompliance with almost all aspects of their diabetes treatment, such as testing of blood and urine, taking insulin on schedule, following a dietary plan, maintaining blood sugar, fitting exercise into the treatment plan, and remembering to do everything specified for controlling IDDM.

170.2.5.2 Insulin Omission

Insulin omission is a problematic behavior in which diabetes patients deliberately omit or reduce their insulin dosage. Many studies have focused on the rates of insulin omission of female diabetes patients, the extreme disturbance of insulin omission to metabolic control, and the relationship between insulin omission and eating disorders (Rodin et al. 1991; Polonsky et al. 1994; Biggs et al. 1994; Affenito et al. 1997; Takii et al. 1999, 2002a, 2008; Goebel-Fabbri et al. 2008).

Polonsky et al. (1994) reported that 31% of women with IDDM reported intentional insulin omission and that approximately half of them reported omitting insulin for weight-management purposes (weight-related omitters). Weight-related omitters evidenced significantly greater psychological distress, poorer regimen adherence (including more frequent omission), poorer glycemic control, and higher rates of long-term diabetic complications than did non-weight-related omitters or nonomitters. Non-weight-related omitters tended to fall between weight-related omitters and nonomitters on most measures of psychological functioning, adherence, and glycemic control.

In a meta-analysis, Nielsen (2002) reported that insulin omission is increased when eating disorders coexist with type 1 diabetes (OR = 12.6).

As mentioned above, the DSM-IV diagnostic criteria (American Psychiatric Association 1994) have for the first time accepted insulin omission as an ICB, which is necessary for the diagnosis of BN. According to the criteria, insulin omission or reduction at least twice a week could be considered an ICB by BN patients. However, we found that, when type 1 diabetic females with BN omit insulin, they nearly always do it more frequently and in a more extreme way: omission of at least one-quarter of the prescribed insulin (Takii et al. 2002a, 2008). We define this degree of insulin omission as "severe insulin omission."

170.2.5.3 ICBs (Purging Behaviors) of Type 1 Diabetes Patients with an Eating Disorder

Rodin et al. (1991) reported the methods of inducing weight loss used by adolescent females with IDDM with and without an eating disorder. Of 13 patients with an eating disorder by DSM-III criteria, 7 (54%) omitted insulin, 9 (69%) dieted, 4 (31%) self-induced vomiting, 3 (23%) did extreme exercise to lose weight, and 1 (8%) abused laxatives. Of the 90 patients without an eating disorder, 5 (6%) omitted insulin, 30 (33%) dieted, 4 (4%) did self-induced vomiting, 17 (19%) did extreme exercise to lose weight, and 1 (1%) abused laxatives.

In a study of 55 female patients with BN, we reported that 44 (80.0%) did severe insulin omission, (omission of at least one-quarter of the prescribed insulin) 27 (49.1%) did self-induced vomiting, and 11 (20.0%) abused laxative (Takii et al. 2002a). In classifying the patients by type of ICB, we found that 22 patients did only severe insulin omission, 22 did both severe insulin omission and another ICB, and 11 did not engage in severe insulin omission but had another ICB. Table 170.3 shows a comparison of the clinical characteristics of these three groups and a group of female BED patients. We found that type 1 diabetic females with BN are not a homogenous group and that they can be classified into three distinctive subgroups by type of ICB. Individuals with severe insulin omission and another ICB (BN-IP) had the most severe medical problems, such as the poorest metabolic control and the highest rate of diabetic complications, and had severe psychological/behavioral pathology. Individuals without severe insulin omission and with another ICB (BN-NI) manifested the highest psychological distress. Individuals with only severe insulin omission (BN-I) had comparatively mild distress despite having the poorest metabolic control. The apparent comparative lack of distress of patients with only severe insulin omission as an ICB may largely result from taking the easy way of reducing their body weight, insulin omission, as an avoidance mechanism.

170.2.6 Medical Problems

170.2.6.1 Poor Glycemic Control

Many studies have shown that HbA1c levels are significantly higher in type 1 diabetes patients with an eating disorder than in patients without (Marcus and Wing 1990; Affenito et al. 1997; Rydall et al. 1997; Takii et al. 1999; Jones et al. 2000; Rodin et al. 2002; Goebel-Fabbri et al. 2002). For example, among 356 adolescent females with type 1 diabetes, Jones et al. (2000) reported that the HbA1c of 36 who had eating disorders (9.4 ± 1.8%) was significantly higher than that of the other patients (8.6 ± 1.6%). We reported that the HbA1c of 22 type 1 diabetic females with BN (12.3 ± 2.6%) was significantly higher than that of 11 female patients with BED (9.7 ± 2.1%), and that the HbA1c of

[f]BN-NI > BED, BN-I, BN-IP

patients with BED was significantly higher than that of patients without an eating disorder (6.2 ± 0.8%) (Takii et al. 1999) (Table 170.2).

170.2.6.2 Factors Related to the Exacerbation of Glycemic Control

We examined the psychological/behavioral predictors of elevated HbA1c of females with type 1 diabetes and BN or BED by multiple regression analysis (Takii et al. 1999). "Severe insulin omission" was found to be the factor most predictive of a higher HbA1c level, with a large amount eaten (2,000+ calories) in one binge-eating session the next most predictive.

170.2.6.3 Short- and Medium-term Complications

Unstable and poor metabolic control (so-called brittle diabetes), recurrent diabetic ketoacidosis (DKA), and severe hypoglycemic attacks easily occur in diabetes patients with a concurrent eating disorder (Rodin and Daneman 1992) and are likely to be associated with the need for more frequent

hospitalization (Glasgow et al. 1991). Because most eating disorders are accompanied by binge eating and insulin omission, it is natural that these patients have extreme hyperglycemia. Female type 1 diabetes patients who have frequently repeated DKA can be strongly suspected of severe insulin omission associated with a severe eating disorder. An irregular diet or the irregular use of insulin injections (based on excessive attachment to body weight) often lead to unstable metabolic control, which can in turn lead to severe hypoglycemic attacks. However, in our experience, severe hypoglycemia attacks are not often seen in type 1 diabetes patients with a clinical eating disorder.

170.2.6.4 Long-term Complications

A considerable number of studies have indicated that a concurrent eating disorder or disordered eating can lead to an increased risk of the long-term complications of diabetes (Steel et al. 1987; Affenito et al. 1997; Rydall et al. 1997; Takii et al. 1999; Goebel-Fabbri et al. 2002).

In a meta-analysis, Nielsen (2000) reported that a coexisting eating disorder with type 1 diabetes increases the overall common odds ratio for retinopathy to 4.8. Of the various problematic behavioral factors related to eating disorders, we found the duration of severe insulin omission (omission of at least one-quarter of the prescribed insulin) to be the factor most closely associated with the retinopathy and nephropathy of type 1 diabetic females with clinical eating disorders (Takii et al. 2008). As mentioned above, severe insulin omission is the factor most predictive of the HbA1c of patients with concurrent type 1 diabetes and an eating disorder (Takii et al. 1999). The duration of severe insulin omission was related to the duration of poorest glycemic control. This finding may help patients who deliberately omit insulin to become aware of the medical risks of insulin omission.

170.2.7 Longitudinal Course of an Eating Disorder in Diabetes

Reports related to the long-term course of eating disorders and disordered eating by patients with type 1 diabetes are rare. Rydall et al. (1997) reported the 4- to 5-year course of type 1 diabetic females who were 12–18 years old at study entry. Intentional omission or underdosing of insulin and dieting for weight loss increased in prevalence from baseline to follow-up. Binge eating, self-induced vomiting, and dieting for weight loss tended to persist at follow-up if they were present at base line. Herpertz et al. (2001) assessed a sample of 36 diabetic patients with an eating disorder (type 1 diabetes: $n = 13$, Type 2 diabetes: $n = 23$) over a period of about 2 years. They reported that the eating disorder tended to persist over time, with a considerable shift within the different types of eating disorders. Nielsen et al. (2002) combined information from earlier studies to estimate mortality and reported a standardized mortality rate of 4.06% for type 1 diabetes, 8.86% for AN, and 14.5% for concurrent cases.

170.2.8 Eating Disorders Complicated with Type 2 Diabetes

In comparison with studies of eating disorders concurrent with type 1 diabetes, such studies of type 2 diabetes patients are rare. Herpertz et al. (1998) reported that although there was no difference in the prevalence of all eating disorders between IDDM (36.3 ± 10.6 years of age) and non-insulin-dependent

diabetes (NIDDM) (54.2 ± 8.1 years of age) (point prevalence 5.5% vs 6.5%, lifetime prevalence 10.0% vs 9.9%), the prevalence of BN was higher in IDDM patients (point prevalence 1.5% vs 0.3%, lifetime prevalence 3.2% vs 1.9%) and BED was more frequent in NIDDM patients (point prevalence 1.8% vs 3.7%, lifetime prevalence 2.6% vs 5.9%). They also reported that type 2 diabetes patients with an eating disorder showed a greater psychopathology compared to patients without an eating disorder and that the diagnosis of an eating disorder did not seem to have a special influence on glycemic control (Herpertz et al. 2000). Papelbaum et al. (2005) reported that 20% of patients with type 2 diabetes (52.9 ± 6.8 years of age) displayed an eating disorder, that BED was the predominant eating disorder diagnosis (10%), and that the presence of an eating disorder was associated with a significant increase in the frequency of anxiety disorders.

170.3 The Mechanism of Eating Disorder Onset

170.3.1 Various Etiological Factors Peculiar to Type 1 Diabetes

Eating disorders are generally considered to have multiple etiologies including biological, psychological, familial, cultural, and social factors. Along with these general factors, many hypotheses have been proposed for the relationship between type 1 diabetes and the onset of an eating disorder. For example, "chronic dietary restraint" (Marcus and Wing 1990; Rodin and Daneman 1992; Polonsky 1996; Daneman et al. 1998; Goebel-Fabbri et al. 2002), "weight gain associated with appropriate diabetes self-care" (Marcus and Wing 1990; Rodin and Daneman 1992; Polonsky 1996; Daneman et al. 1998; Goebel-Fabbri et al. 2002), "uniquely effective forms of purging (insulin omission)" (Marcus and Wing 1990; Rodin and Daneman 1992; Polonsky 1996; Daneman et al. 1998; Goebel-Fabbri et al. 2002), "altered family dynamics" (Marcus and Wing 1990; Anderson 1990; Rodin and Daneman 1992; Maharaj et al. 1998), "greater prevalence of depressed and fluctuating moods" (Marcus and Wing 1990; Polonsky 1996; Goebel-Fabbri et al. 2002), "effects of type 1 diabetes on psychological development" (Marcus and Wing 1990), and "feeling out of control" (Schwartz et al. 2002). However, except for a few studies (Maharaj et al. 1998; Schwartz et al. 2002), empirical support is lacking.

The factors Marcus and Wing (1990) reported as the reasons that patients with type 1 diabetes would be vulnerable to eating disorders are as follows.

1. Factors related to the treatment of type 1 diabetes, such as being required to focus on diet and limit weight gain, weight gain by insulin therapy and good glycemic control, and the presence of a purging behavior peculiar to diabetes called insulin omission.
2. Type 1 diabetes may affect the psychological well-being of adolescents. Diabetes can interfere significantly with adolescent development by affecting body image, causing feelings of being different, and/or exacerbating dependence/independence conflict.
3. A family relationship such as a tendency among some parents to be overprotective or overinvolved with their youngster, rigidity, and a lack of conflict resolution.
4. Effects of chronic stress caused by chronic disease, which lead to lower self-esteem, affect body image, feelings of mastery or competence, necessitate changes in diet, and/or affect family environment.

Daneman et al. (1998) developed a model demonstrating how diabetic-related factors, such as weight gain after the initiation of insulin treatment or intensive diabetes management, dietary restriction for the nutritional management of diabetes, and insulin omission, interact to lead to

eating disorders. Furthermore, in an empirical study, Maharaj et al. (1998) found that the eating disturbances of adolescent girls with diabetes are associated with significantly more family dysfunction. Diabetic girls with eating disturbances reported less support, poorer communication, and less trust in their relationships with their parents than did diabetic girls without eating disturbances. Schwartz et al. (2002) reported that a lower sense of overall control and a lower sense of bodily control were both directly related to more severe eating-disordered symptoms.

170.3.2   The "Compulsive Self-care → Binge Eating" Hypothesis

We have proposed two etiology hypotheses. Figure 170.1 shows the "Compulsive self-care → binge eating" hypothesis. There is tremendous social pressure on diabetes patients to limit the amount of food they eat and to not become fat, which may lead them to feel cornered and cause them to endure serious distress. Such thoughts can be enhanced by well intentioned, but poorly considered diabetes education. If the patient is overly conscientious and the family is too strict, the patient may feel trapped and that they must engage in overly strict diabetes management. These patients often do compulsive self-care for a period of time after the onset of diabetes. During this time, they are often treated like "honor students" by the medical staff.

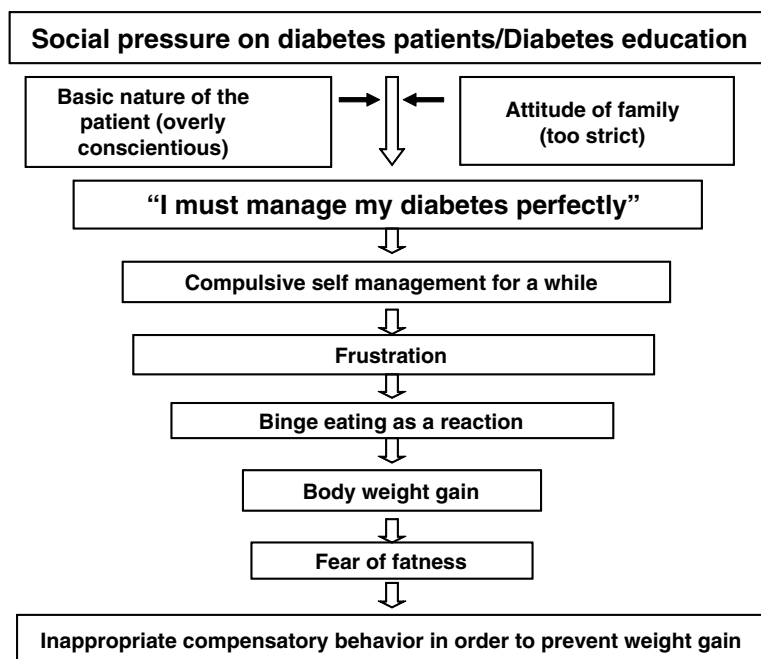
However, frustration gradually increases, and the patient becomes unable to tolerate the strict regimen. Binge eating often starts without a special trigger and escalates quickly. Furthermore, weight gain by the binge eating causes a fear of becoming fat, which often leads to inappropriate compensatory behaviors in order to prevent weight gain (ICB), such as insulin omission and self-induced vomiting.


Fig. 170.1 The "Compulsive self-care → binge eating" hypothesis. This figure shows the flow of how female patients with type 1 diabetes who initially engage in compulsive self-care begin to binge and develop an eating disorder

170.3.3 Trauma Hypothesis

We have also developed what we call our Trauma hypothesis. The age at which type 1 diabetes begins most frequently, from infancy to the adolescent years, is a time when the self is not yet well formed. The patients have not developed adult mechanisms to cope with stress in general. At this critical time, the patient is suddenly confronted by a serious disease and the need to face a strict self-care regimen, which often leaves the patient overwhelmed by the diabetes. Unless the patient is able to accept and control it, the diabetes may be experienced with remarkable pain. For these distressed young patients, key people surrounding them sometimes fail to give effective psychological support and, on the contrary, they may take an attitude lacking in understanding; scolding and blaming.

Because of a lack of understanding of type 1 diabetes, diabetes patients are often subject to prejudice, discrimination, and special handling, which can be quite hurtful to the patient. This can lead to feelings of ineffectualness, despair, and a sense of guilt for not being able to deal with the diabetes. Suffering from a sense of alienation and/or feeling of isolation with no outside assistance, diabetes patients may develop severe trauma.

The eating disorder may give the patient relief from this state of despair. It gives the patient a perverted psychological structure in which they no longer care about anything but body weight/shape. Moreover, because the patient thinks about nothing else while they eat binge, they are temporarily freed from stress.

170.4 Self-destructive Behaviors Associated with Insulin Self-administration

By the proper self-administration of insulin, the quality of life and the treatment outcome of patients with type 1 diabetes can be remarkably improved. However, while there are patients who are able to accept this powerful drug and to manage it for the betterment of their life, there are patients who do not use sufficient insulin (insulin omission) or who use insulin extremely inadequately, which can cause serious medical problems (self-destructive behaviors). The most miserable psychosocial problems of type 1 diabetes patients are self-destructive behaviors such as recurrent diabetic ketoacidosis (DKA), frequent severe hypoglycemia, and brittle diabetes (Rubin and Peyrot 1992; Schade et al. 1985). These behaviors are often deeply associated with insulin manipulation. Self-destructive behaviors seem to coincide with severe psychosocial disturbance; either individual psychopathology (Schade et al. 1985), family dysfunction (White et al. 1984), or both (Golden et al. 1985). Self-destructive behaviors and eating disorders probably overlap to a significant degree; both clinical conditions are deeply associated with insulin manipulation (Table 170.4).

170.4.1 Recurrent Diabetic Ketoacidosis

As mentioned above, a comparatively high percentage of female patients with type 1 diabetes omit or reduce insulin to control body weight. Furthermore, some patients with a concurrent clinical eating disorder inject much less insulin than prescribed by the doctor, and they often seem to be on the threshold of DKA. In such cases, DKA will develop from only a slight precipitant, such as an insulin

Table 170.4 Key features of self-destructive behaviors

1. Type 1 diabetes patients sometimes exhibit self-destructive behaviors that result in recurrent diabetic ketoacidosis, frequent severe hypoglycemic attacks, and brittle diabetes.
2. These behaviors are often done with insulin manipulation including insulin omission and overdosing.
3. These behaviors lead to extreme instability of glycemic control, life-threatening episodes, and frequent hospitalizations.
4. These behaviors seem to coincide with severe psychological disturbance of individual psychopathology, family dysfunction, or both.
5. The main reason for these behaviors seems to be an intention to escape from an environment with much stress and to gain the concern of others by creating a serious physical condition that requires hospitalization.
6. Self-destructive behaviors and eating disorders probably overlap to a significant degree; both clinical conditions are deeply associated with insulin manipulation.

This table lists the key factors involved in self-destructive behaviors including the types of these behaviors, the etiological role of insulin manipulation, medical outcomes, psychological disturbance of the patient and family, the patient's psychological intention to engage in these behaviors, and the overlap between eating disorders

resistance increase by a worsened physical situation (sick day), failure to inject the insulin at the proper time because of failure to bring an injection device or by loss of their precarious mental balance because of mental instability. Moreover, patients may repeat DKA in order to escape from severe psychosocial disturbances.

170.4.2 Frequent Severe Hypoglycemic Attacks

Frequent severe hypoglycemic attacks can be caused by the intentional injection of too large a quantity of insulin for the purpose of escaping from the stresses of life. When patients who are psychologically immature and susceptible to stress are continually exposed to a harsh and hopeless environment, it is natural in a sense to escape by taking advantage of their disease. Feeling that they have no place in the family, through hospital admission they can escape form the family and the vicious cycle of family problems. However, even in cases in which the environment is not so terrible, extremely psychologically immature patients often cause repeated, severe hypoglycemia in order to escape from the pressures of diabetes and their life in general by causing themselves to lose consciousness.

170.4.3 Brittle Diabetes

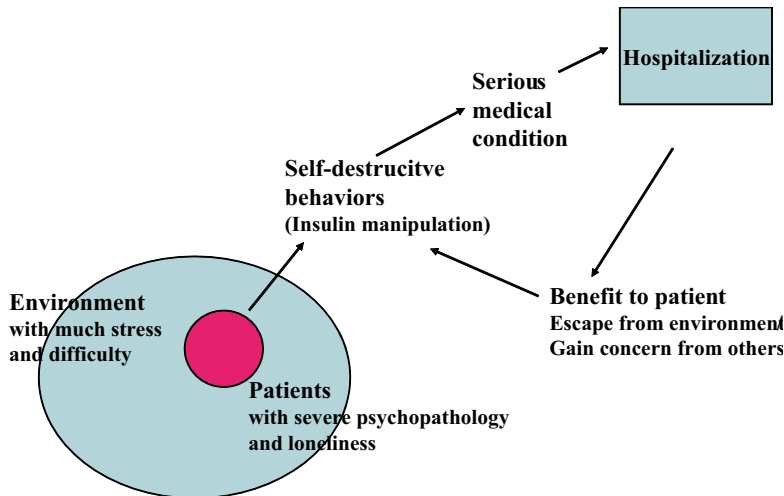
Brittle diabetes overlaps widely with recurrent DKA and frequent severe hypoglycemic attacks. It is defined as "unexplained large changes in blood glucose concentration" (Woodyatt 1934) or "unable to maintain a normal lifestyle because of frequent disruptions secondary to severe hyperglycemic and/or hypoglycemic episodes" (Schade et al. 1985). In their study of brittle diabetes and recurrent DKA, Schade et al. (1985) reported that most type 1 diabetic patients who were thought to have brittle diabetes or insulin resistance were afterward found to have omitted insulin or had poor insulin manipulation. They also reported that, of 30 patients, eight were diagnosed with factitious disease and eight malingering. The most common causes of these self-destructive behaviors seem to be (1) to escape from an environment with much stress and difficulty, (2) severe personality disorder, and (3) insulin omission because of anxiety to weight gain (Fig. 170.2).


Fig. 170.2 The mechanism of the self-destructive behaviors of diabetes patients. Self-destructive behaviors include recurrent diabetic ketoacidosis, frequent severe hypoglycemia, and brittle diabetes. An intention to escape from an environment with much stress and to gain concern from others by creating a serious physical condition that requires hospitalization seems to be the main reason for the self-destructive behaviors of diabetes patients

170.4.4 Management

Patients tend to hide their problematic behaviors because of an intensive sense of guilt or a fear of being criticized or deserted by people significant to them. Even when the medical staff suspect insulin misapplication, the patient may strongly deny it and the family may show strong resistance to admitting it. As a result, an unexplained inability to control blood glucose can often be attributed to insulin resistance. It is important that the medical staff recognize this psychological problem and recommend psychological treatment by a mental health specialist.

170.5 Treatment Approach for Type 1 Diabetes Patients with Eating Disorders

170.5.1 Treatment for the Clinical Eating Disorders of Patients with Type 1 Diabetes

Previous studies have indicated the difficulties of dealing with type 1 diabetes patients with eating disorders and the urgent necessity for developing effective treatments (Marcus and Wing 1990; Rubin and Peyrot 1992). However, interventions specifically for these patients have rarely been reported, and most have been case studies. Peveler and Fairburn (1992) provided a detailed description of management and outcome, in a report of the treatment of a series of six females with type 1 diabetes and BN in which they used modified cognitive–behavioral therapy for BN, mainly on an outpatient basis. Although the treatment usually resulted in improved eating habits and glycemic control, the success rate was lower than for nondiabetic BN patients. Moreover, the improved glycemic control of their patients seems to have been insufficient to prevent long-term complications.

170.5.2 Psychoeducation Program for Type 1 Diabetes Patients with Disturbed Eating

Several group psychoeducation programs for patients with disturbed eating attitudes, not clinical eating disorders, have also been reported. Olmsted et al. (2002) evaluated the effect of a six-session psychoeducation program for young women with type 1 diabetes and disordered eating attitudes and behaviors that included a "nondeprivational" approach and recommendations that all types of foods be eaten in normal amounts. Compared with a treatment-as-usual group, the psychoeducation group was associated with a reduction in eating disturbance, but not with improvement in the frequency of insulin omission or HbA1c levels. Alloway et al. (2001) reported that a six-session group psychoeducation program, which is based on a program for BN and subclinical bulimia that was modified slightly to adapt to type 1 diabetes, was no more effective than a wait-list control group for treating subclinical disordered eating by women with type 1 diabetes.

170.5.3 Treatment for Type 1 Diabetes Patients with Clinical Eating Disorders in the Department of Psychosomatic Medicine, Kyushu University

We have acquired much experience in the treatment of type 1 diabetes patients with clinical eating disorders, having treated more than 150 of such patients, referred from throughout Japan, from 1994 to 2009. The majority were engaged in recurrent binge eating, either BN or BED. We reported that patients with BN clearly showed more severe psychological and medical pathology than patients with BED (Takii et al. 1999). This finding of pathological difference may be useful for developing a comprehensive treatment system that allows intervention to be tailored to the pathological severity of the individual patient. We have developed two forms of intervention: "outpatient counseling at first visit" (Takii et al. 2002b) and "integrated inpatient therapy" (Takii et al. 2003).

170.5.3.1 Outpatient Counseling at First Visit

Each patient underwent "outpatient counseling at first visit". The main purpose of the counseling is to empathize with the patient's distress from living with diabetes and to reduce the stress associated with their self-care regimen. Table 170.5 presents a summary of the elements of "outpatient counseling at first visit".

   After the first visit, the patient returns to the referring physician for follow-up treatment. We reported that a great majority of the 10 BED patients significantly improved their eating pathology and glycemic control with a single session of our "outpatient counseling at first visit" as a turning point (Takii et al. 2002b) (Fig. 170.3). The reasons for this surprisingly good response are that these patients originally had mild psychopathology: Their binge eating was to a considerable extent due to the stress of the strict food regimen for the diabetes and their fixation on body weight/shape was comparatively mild. This counseling is performed for about 3 h by a doctor familiar with this area. The patients, for the first time since having developed type 1 diabetes, feel that they are understood deeply and accepted by significant others. They are given hope that they can live with diabetes through knowing how to more easily control it, in contrast with what they had previously thought. We tell them that type 1 diabetes is a disease in which there is no problem except that no insulin is produced and that they can gain good glycemic control only by proper insulin injection, without having to engage in a

Table 170.5 A summary of the elements of "outpatient counseling at first visit"

1. Bring out feelings about diabetes by listening for a sufficient amount of time that the patient gets a feeling of "validation" (to be deeply understood and accepted by the therapist).

2. Help the patient recover from the injured self-esteem. "It is very natural to be worried about diabetes and to long for eating when one's food is restricted".

3. Contradict too pessimistic an image of diabetes and present a hopeful and acceptable image of it. "Type 1 diabetes is no more than a deficiency of endogenous insulin. It is possible to have excellent glycemic control without special dietary/exercise therapy, if insulin is injected properly".

4. Teach the patient the importance of finding the easiest and most suitable diabetes self-care. "The patient cannot keep up excessive dieting or over exercising".

5. Encourage recovery/improvement of communication between the patient and family members, especially the mother.

6. Not demand that the patient attend our hospital as an outpatient or be hospitalized.

The main purpose of the counseling is to empathize with the patient's distress from living with diabetes and to reduce the stress associated with their self-care regimen
Fig. 170.3 HbA1c course of BN patients who had "Integrated inpatient therapy", BN patients who did not, and BED patients who did not. In BN patients who had the inpatient therapy (BN-inpatient:○), the HbA1c levels at discharge, 6, 12, 18, 24, 30, and 36 months after discharge were significantly lower than at first visit. In BED patients who did not have inpatient therapy (BED-outpatient: ▲), the HbA1c levels at 24, 30, and 36 months after first visit were significantly lower than at first visit. In BN patients who did not have the inpatient therapy (BN-outpatient:●), HbA1c level was not different between the first visit and any follow-up. All patients had "Outpatient counseling at first visit." Data are means ± S.E. *$p < 0.05$, †$p < 0.01$, ‡$p < 0,001$ (Adapted from Takii et al. 2002b. Copyright 2002 by Elsevier Science B.V.)

strict dietary regimen. Patients who are able to have such an experience through our counseling can relatively easily change their attitudes toward food/body weight and diabetes.

After a period of observation by the referring physician, patients without sufficient improvement are encouraged to undergo "integrated inpatient therapy" in our hospital. We reported that none of 19 patients with BN showed sufficient improvement at this stage, and nine agreed to undergo "integrated inpatient therapy" (Takii et al. 2003) (Fig. 170.3).

170.5.3.2 Integrated Inpatient Therapy

The main points of this inpatient therapy are (1) to rest the mind and body in a supportive and lenient but regulated ward environment, (2) revision of cognitions and behaviors such as fixed ideas about diet and body weight or poor eating behaviors (3) acceptance of diabetes based on the experience

that good glycemic control can be obtained without oppressive effort, and (4) the repair of family relationships based on insights by the patient. Table 170.6 presents a summary of the elements of our "Integrated Inpatient Therapy" (Takii et al. 2003).

On the day of admission, the patient is encouraged to decide the initial caloric intake, with the understanding that she should be able to and will be expected to eat the whole meal. In the conflict between the fear of becoming fat and the desire to eat, the patients waver considerably, but eventually most choose a comparatively small amount of food, such as 1,400 kcal a day. Similarly, the initial insulin injection dose is decided in consultation with the patient. In general, to eat all of the supplied meal is the easiest way for patients with an eating disorder to eat successfully.

However, in spite of the agreement, the majority of patients at first tend to leave part of the meal because of over-concern about body weight. The therapist calls the patient's attention to the fact that strict dieting is what has led to continued binge eating and instructs her not to leave any food uneaten. If the patient continues to resist eating all of her meal, the therapist does not advance to the next step of the treatment schedule: The patient's struggle to eliminate avoidance behaviors is the most important element of the inpatient treatment.

Even with this intervention, some patients regress from time to time when the meal is increased, either by leaving part of the meal or by secretly decreasing the insulin dose. The therapist must be aware of and stop this type of avoidance and again explain the rational behind eating the full portion

Table 170.6 A summary of the elements of "Integrated inpatient therapy" for type 1 diabetes patients with an eating disorder (Adapted from Takii et al. 2003. Copyright 2003 by Elsevier Inc.)

 I. Recovery period for the mind and body
   a. Recovery from mental and physical fatigue and depression
   b. Normalization of biorhythms
 II. Modification of behaviors and cognition
   a. Improvement of eating behavior
     Therapist control stage
       Decision, by the patient, of the initial calorie intake and insulin dose
       Completely and regularly eating meals
       Not eating snacks or confectioneries
       Incremental increases in the volume of the meal (200 kcal at a time) to a suitable-sized hospital meal (approximately 40 kcal/kg standard body weight each day)
     Patient control stage
       Free ingestion training
       Snack training
       Eating out training
       Staying at home training
   b. Promoting glycemic control competence
     Self-measurement of blood glucose
     Self-injection of insulin
     Practical coaching and training in adjustment of the insulin dose
   c. Modification of cognitive aspects
     Individual counseling
     Group therapy for eating disorders
III. Restoration of family relationships
   a. Spontaneous restoration process
   b. Family counseling
   c. Coaching family members: especially in how to understand and cope with the patient

In therapist control stage, patients are guarded from their eating disorder psychopathology by the therapeutic framework. In patient control stage, by phased removals of hospital staff control, the patient has to face by herself the stimuli that led her to eating disorder-related behaviors and she has to control her mind and behavior

and injecting the full dose of decided insulin. Through the process of making patients stick to their agreements on eating and insulin injection, they come to learn that they can control their body weight and diabetes with a normal food intake, that there is no need of food restriction, or to engage in a purging behavior, and that there will be good changes such as recovering a feeling of timely hunger and fullness, contrary to their expectations.

In therapist control stage, patients are guarded from their eating disorder psychopathology by the therapeutic framework, such as eating all of the food supplied, the prohibition of purging behaviors, not eating snacks, and the relatively restricted life in the hospital. In patient control stage, by phased removals of hospital staff control, the patient has to face by herself the stimuli that led her to eating disorder-related behaviors and she has to control her mind and behavior. These phased removals of control are as follows. (1) Free ingestion training: as the restriction that the patient must completely eat the meal is lifted, she must choose how much and what kind of food she eats; (2) Snack training: training in self-control in eating snack foods; (3) Eating out training: allowing the patient to eat in restaurants; and (4) Staying at home training: rehearsal for living in her own family/community circumstance. Although the patient often suffers setbacks, becoming unstable and/or having failures, including binge eating, these experiences are very good practical learning opportunities that help the patient face and overcome problems. The therapist does not allow the patient to escape from problems, but helps her attain a deep understanding and coaches her as to how to overcome them.

Along with a decreasing fixation on food and body weight, the patient often comes to reflect on herself, the relationship between significant people and herself, and her association with diabetes. The introspective environment of the ward and counseling twice a week facilitate the process. The patient comes to communicate with parents by letters and telephone calls (their place of residence is generally far from the hospital), which leads to a spontaneous restoration process for the family relationship. The therapist follows the process and holds family counseling to facilitate the process. The experience of being able to control diabetes without any special hardships tends to lead the patient to reconcile themselves to their diabetes.

After discharge from our hospital, the patients again return to the referring physician. We reported that the HbA1c levels of nine BN patients who underwent the inpatient therapy were significantly lower at discharge, 6, 12, 18, 24, 30, and 36 months after discharge than at first visit (Takii et al. 2003) (Fig. 170.3). Moreover, the patients had significantly lower psychological test scores related to eating disorder psychopathology, depressiveness, and anxiety; a reduced frequency and amount of binge eating; and fewer patients exhibited purging behaviors at 36 months after discharge than at first visit (Takii et al. 2003). Ten BN patients who did not undergo the inpatient therapy had no significant psychological/behavioral or medical improvement (Takii et al. 2003) (Fig. 170.3).

The effectiveness of the "integrated inpatient therapy" for type 1 diabetes patients with BN can be largely attributed to the therapeutic framework and intervention of the therapist, which block the avoidance behaviors against becoming fat. Because type 1 diabetes patients with BN have such an extreme fixation on body weight/shape, the therapeutic framework and intervention of a therapist, which block the avoidance behaviors, are essential in the treatment of type 1 diabetes patients with BN.

170.5.3.3   Long-term Psychotherapy and Adjustments of the Patient's Circumstances

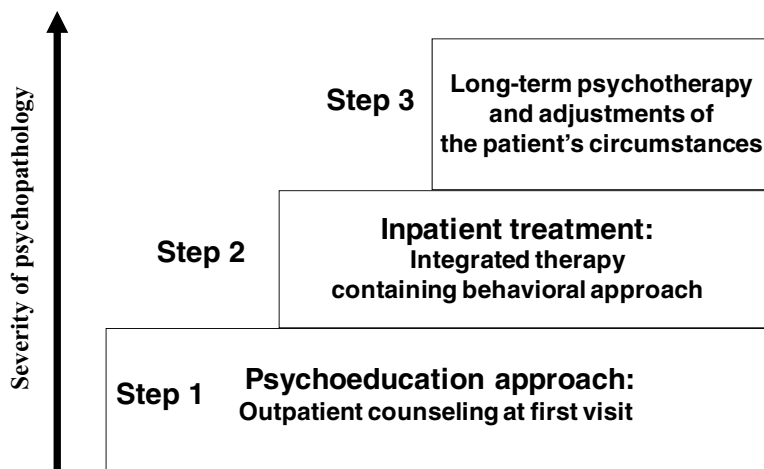
Although most type 1 diabetes patients with BN respond to the integrated inpatient therapy, some patients who have marked psychopathology tend to regress repeatedly, in spite of multiple episodes of inpatient therapy. The marked psychopathology includes severe personality disorder, trauma, and a marked delay of psychological/emotional development: For some patients, it seems as if their psychological development stopped after they developed type 1 diabetes. It is difficult for such


Fig. 170.4 Step-by-step treatment system for type 1 diabetes patients with a clinical eating disorder according to the severity of psychopathology. The number of steps necessary for successful treatment depends on the severity of the patient's psychopathology

patients to improve their eating disorders and control of diabetes without a reduction of their extreme psychopathology. It is important for the therapist to persevere in offering long-term psychotherapy and to strive to adjust the family circumstances to facilitate the patient's psychological growth.

Figure 170.4 shows the step-by-step treatment system of our department for type 1 diabetes patients with a clinical eating disorder, which is done according to the severity of patient's psychopathology.

170.6 Early Awareness and the Prevention of Eating Disorders by Type 1 Diabetes Patients

The treatment of diabetes patients with eating disorders has been reported to be extremely difficult. Moreover, even if the treatment is successful, huge expenditures of time and energy are required before the eating disorder and diabetic control become sufficiently improved. Prevention is much preferable to treatment.

Marcus and Wing (1990) suggested that emotional support and effective information in the context of a sound relationship may prevent problems as well as ameliorate mildly disturbed eating behavior. They emphasized that it is crucial to promote the development of a strong therapeutic relationship in which patients are encouraged to discuss their concerns about body shape and weight. They also indicated that diabetes patients need sound information about weight regulation and that adolescent IDDM patients need special help in learning to eat and drink in social situations, with a view to minimizing feelings of being different.

Rodin et al. (2002) suggested that current diabetes treatment approaches, which emphasize normalizing eating behavior and matching insulin administration to caloric intake, may lessen the experience of deprivation and reduce the risk of eating disturbances. From the suspicion that eating disorders are often not recognized in the diabetes clinic setting, they recommended that health-care professionals who treat young women with type 1 diabetes maintain a high index of suspicion for the presence of an eating disturbance, particularly among those who present with persistently poor metabolic control, repeated episodes of diabetic ketoacidosis, and/or weight and body shape concerns.

Rapaport et al. (1996) listed the following potential markers for the development of an eating disorder by a patient with diabetes: Frequent diabetic ketoacidosis, elevated HbA1c, anxiety about – or avoidance of – being weighed, frequent and severe hypoglycemia, nonadherence, brittle diabetes, delay in puberty or sexual maturation or failure to grow, bingeing with food or alcohol, and severe stress in the family. These markers are of special concern among young women.

We recently reported that the development of type 1 diabetes in preadolescence or adolescence seems to place girls at risk for the subsequent development of AN or BN (Takii et al. in print). Careful attention should be paid to these high-risk patients.

Chapter 171
Comparing Abnormal Eating Behavior in Type 1 and 2 Diabetic Patients

Patrick Ritz, Monelle Bertrand, and Hélène Hanaire

Abbreviation

ED-NOS   Eating disorder not otherwise specified

171.1 Introduction

Diabetes is classically divided into type 1 and type 2. Type 1 diabetes concerns less than 10% of diabetic people, who are typically young, thin, with an intense endocrine pancreatic failure. To closely regulate plasma glucose concentrations within narrow limits, the treatment is an obligatory complex schedule of multiple daily insulin injections and a mandatory monitoring of carbohydrate intake and of capillary blood glucose, to adjust insulin doses. Type 2 diabetes affects the vast majority of diabetic people, and is closely associated to overweight and obesity. The pathophysiology of type 2 diabetes is a combination of endocrine pancreatic failure (making insulin injections necessary during the course of the disease) and insulin-resistance, which is closely associated to fat intake, low physical activity, genetic background, and increased fat mass. The basis of the treatment of type 2 diabetes is the control of body weight through adaptation of the diet, and of physical activity, which remains necessary even when drugs are prescribed.

It is therefore obvious that patients suffering from diabetes have to change their predisease diet. Furthermore, diabetes affects patients who have "learned" to behave with food and eating, and an important question is to ask whether diabetes itself and/or diabetes care affects eating behavior. Indeed, diabetes management does place emphasis on strict dietary adherence, which could reinforce pre-existing "abnormal" eating behavior or indeed promote them in otherwise normal eating behavior patients (Goodwin et al. 2003). This review summarizes the knowledge about "abnormal" eating behavior in type 1 and type 2 diabetic patients. It is obvious from this literature search that the definitions used vary between authors. It sometimes crosses over with other concerns (such as body shape and image in adolescents) so that "insulin omission" is also considered in "eating behavior." It is also noticeable that most of the information come from a limited number of authors, studying mostly young females, with very little known about young males.

171.2 Definitions of "Abnormal" Eating Behavior

171.2.1 DSM Criteria

Strictly speaking, "abnormal" eating behavior can be approached as eating behavior disorders. Those are based on the diagnostic criteria proposed by the DSM panel of the American Psychiatric Association Tables 171.1 and 171.2 (APS 1994). Binge eating is one such disorder. It refers to the episodic consumption of an objectively large quantity of food that is accompanied by a loss of control during the consumption. When no such loss of control is felt, it is termed episodic overeating. It can be distinguished from bulimia nervosa by the absence of frequent inappropriate compensatory

Table 171.1 Diagnostic criteria of bulimia nervosa

- Recurrent episodes of binge eating characterized by both:
    1. Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances
    2. A sense of lack of control over eating during the episode, defined by a feeling that one cannot stop eating or control what or how much one is eating
- Recurrent inappropriate compensatory behavior to prevent weight gain
    1. Self-induced vomiting
    2. Misuse of laxatives, diuretics, enemas, or other medications
    3. Fasting
    4. Excessive exercise
- The binge eating and inappropriate compensatory behavior both occur, on average, at least twice a week for 3 months.
- Self evaluation is unduly influenced by body shape and weight.
- The disturbance does not occur exclusively during episodes of anorexia nervosa.

Type
- Purging type: During the current episode of bulimia nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.
- Nonpurging type: During the current episode of bulimia nervosa, the person has used inappropriate compensatory behavior but has not regularly engaged in self-induced vomiting or misused laxatives, diuretics, or enemas.

This table describes the clinical traits for the diagnosis pf bulimia nervosa according to DSM IV

Table 171.2 Diagnostic criteria of EDNOS (eating disorders not otherwise specified) (Adapted from APS, 2000)

Eating disorder not otherwise specified includes disorders of eating that do not meet the criteria for any specific eating disorder.
1. For female patients, all of the criteria for anorexia nervosa are met except that the patient has regular menses.
2. All of the criteria for anorexia nervosa are met except that, despite significant weight loss, the patient's current weight is in the normal range.
3. All of the criteria for bulimia nervosa are met except that the binge eating and inappropriate compensatory mechanisms occur less than twice a week or for less than 3 months.
4. The patient has normal body weight and regularly uses inappropriate compensatory behavior after eating small amounts of food (e.g., self-induced vomiting after consuming two cookies).
5. Repeatedly chewing and spitting out, but not swallowing, large amounts of food.

Binge-eating disorder is recurrent episodes of binge eating in the absence if regular inappropriate compensatory behavior characteristic of bulimia nervosa. It is often, but not always, associated with obesity symptoms.

Night eating syndrome includes morning anorexia, increased appetite in the evening, and insomnia. Often obese, these patients can have complete or partial amnesia for eating during the night.

This table describes the clinical traits for the diagnosis of eating disorders not otherwise specified according to DSM IV

behaviors, whether purging (vomiting, excessive laxative and diuretic use) or nonpurging (excessive exercise, intentional fasting), both of which are characteristic of bulimia (Dingemans et al. 2002).

171.2.2 Other Definitions Arising from the Type 1 Diabetes Literature

Gary Rodin and coauthors (Colton et al. 2004) from the Department of Psychiatry, Toronto (Canada) have extensively studied behaviors in young type 1 females and have extended the definition to include fasting and dieting; self-induced vomiting; the abuse of laxatives, diet pills, diuretics, and other medications; and the use of intense, excessive exercise for weight control. The psychological traits and symptoms include preoccupation with body weight and shape, distortions of body image, and severely disturbed attitudes toward food, calories, and eating.

More specifically, they described eating disorder not otherwise specified (ED-NOS) and subthreshold eating disorders. A specific aspect of the definition of ED-NOS concerns diabetic patients (item 5), probably because weight concerns are very important in type 1 diabetic patients in whom body weight increases dramatically as a consequence of diabetes care (Colton et al. 2004).

ED-NOS is defined in the situations where there are:

1. All the criteria for anorexia nervosa except for amenorrhea; or
2. All the criteria for anorexia nervosa except the subject does not report a fear of weight gain or does not report a disturbance in the way in which their body weight and/or shape is experienced; or
3. All the criteria for bulimia nervosa except that the subject does not report self-evaluation being unduly influenced by shape and/or weight; or
4. All the criteria for bulimia nervosa except that the frequency of binge-eating and purging behavior occurred at least once per week for 3 months, or two times per week over the previous 4 weeks; or
5. An individual regularly engages in inappropriate compensatory behavior in the absence of binge eating (e.g., recurrent self-induced vomiting or insulin omission for shape and weight control at least one time per week for the past 3 months, or twice weekly over the previous 4 weeks); or
6. An individual engages in recurrent episodes of objective binge eating (at least one time per week for the past 3 months, or twice weekly over the previous 4 weeks).

Subthreshold eating disorders are defined in situations where:

1. An individual engages in occasional (three or more times) binge eating, and/or purging over the past 3 months; or
2. An individual whose self-evaluation is unduly influenced by shape or weight, and who regularly engages in extreme dietary restraint (<500 kcal/day); or
3. An individual whose self-evaluation is unduly influenced by shape or weight, and who regularly engages in intense, excessive exercise for the purpose of weight control (at least five times weekly) over the past 3 months.

171.2.3 Definitions from Obesity and Type 2 Literature

In the obesity literature, eating behavior has also been defined with tools assessing dietary restraint, disinhibition, hunger, and emotional and external eating patterns (Mela 1996).

Dietary restraint refers to the intention to restrict and control food intake to attain or maintain a desirable body weight. It can be assessed by questions such as "I often stop eating before being fully

satisfied in order to control the amount of food I eat". Disinhibition refers to overeating associated with a loss of control during eating and can be addressed by questions such as "Sometimes what I'm eating is so good I continue on eating even if I'm not hungry". Hunger represents perceived hunger sensations and can be assessed by questions such as "I cannot go on a diet for the simple reason that I get too hungry".

Emotional and external eating refers to the fact that compared with their lean counterparts, obese human subjects are argued to be more reactive to external cues (time, presence of food, situational effects, etc.) and less sensitive to internal hunger and satiety signals than their lean counterparts. According to this view, high external responsiveness would, given an environment of an easily accessible, abundant, and highly palatable food supply, encourage overeating and, hence, the development of obesity.

171.3 Description of "Abnormal" Eating Behavior and Type 1 Diabetes

Gary Rodin and coauthors have produced a large number of studies (Colton et al. 2004; Jones et al. 2000; Rodin et al. 2002; Colton et al. 2007a, b; Rydall et al. 1997; Olmsted et al. 2002) on eating behavior and type 1 diabetes. They mostly studied young type 1 diabetic females. An important concern in these women is that diabetes care leads to weight gain, as reflected by BMI being greater in diabetic women than in controls (22.7 vs. 20.6 kg/m²; Jones et al. 2000). According to Rodin and colleagues this raises preoccupations about body size and shape and leads to an adjustment of eating behaviors in order to deal with these concerns.

In the two largest reports from this group (on more than 350 individuals aged 12–19 years), DSM criteria are present with an odd-ratio of 2.4 as compared to control subjects (Jones et al. 2000; Rodin et al. 2002). There were no people suffering from anorexia nervosa and very few from bulimia (although with an odds ratio of 3 vs. controls). A total of 10% of the subjects (vs. 4% in the controls) are presenting DSM or ED-NOS criteria. The odds ratio of subthreshold eating disorders is 1.9 versus controls. Binge eating occurs in 3% of the patients (vs. 0.3% in controls; Colton et al. 2004), a figure also reported by Peveler et al. (5% in adult type 1 diabetic women, 2005).

In a smaller group of patients (n = 101) with similar BMIs as controls, the prevalence of ED-NOS is 8% and about eight times more frequent that in controls (Colton et al. 2004). If all eating behavior abnormalities are considered, about 20% of these young diabetic people are concerned (Colton et al. 2007a). Dieting in the month preceding the evaluation occurs in 15%, intense exercise in 10% (ten times more than in controls; Colton et al. 2004).

These data are summarized in Table 171.3.

It appears that diabetes care itself promotes "abnormal" eating behaviors since from this 20% figure, there are 10% more new cases after 1 year follow-up (Colton et al. 2007b) and the prevalence is close to 49% after 5 years of follow-up (Colton et al. 2007a). These follow-up data are summarized in Table 171.4.

Another cohort of 90 women (both adults and adolescents) was studied by Peveler et al. in England (Peveler et al. 2005). They found 8 out of 57 subjects presenting with either DSM or ED-NOS or subthreshold eating behavior disorders. It is noticeable that adult women omitted significantly more insulin injections to control weight (37%) than adolescents (15%). This figure was 1% in preteens, 11–14% in adolescents, and about 33% of the young adults studied by Rodin (2002). The 8–12 years follow-up of the British group told that insulin omission was stable in adults but doubled in adolescents (Peveler et al. 2005). Jones et al. showed that insulin omission was closely associated with "abnormal" eating behavior, since the prevalence was 42% in persons with disturbed eating patterns

Table 171.3 Prevalence of eating disorders in type 1 diabetes subjects

(Rodin et al. 2002). Similarly, self-induced vomiting doubled in adolescents (2–4 out of 33 subjects); while it was stable in adults (6 in 57 persons; Peveler et al. 2005).

"Abnormal" eating behaviors are also related to mood disorders that may be secondary to diabetes and/or its complications, which make it difficult to tell which is the chicken from the egg (Rodin et al. 2002). Although there may be a "genetic" component is these behaviors, Rodin et al. (2002) have shown that mothers of these adolescents bring them less support, and that the subjects show less trust in the relationship with their parents than patients without disturbed behaviors.

These "abnormal" behaviors are important to diagnose because they are associated with poorer metabolic control (9.4% glycated hemoglobin, vs. 8.6% in patients without "abnormal" eating behaviors), greater risk of ketoacidosis, and microvascular complications. In particular, diabetic

retinopathy is present in 84% of patients with an "abnormal" eating behavior, and 24% of patients without (Rodin et al. 2002; Rydall et al. 1997).

Treatment of "abnormal" eating behavior has been rarely studied. Rodin and colleagues show that a 6-session psychoeducation program improves signs of ED-NOS but not insulin omission or metabolic control (Olmsted et al. 2002).

Data in males are scarce. Ryan et al. (2008) report 43 type 1 diabetic subjects, with 27 males. No patient, male or female, met the full DSM criteria. However, over one-quarter (26%) of males presented with disordered eating behavior, either overeating or binge eating. It is noticeable that patients were older than in other cohorts. Of all patients exhibiting disordered behavior, 22% reported occasionally fasting or exercising excessively to lose weight; however, these episodes were infrequent and considered normal. Herpertz (1998) reported data from 143 German male subjects, with a lower prevalence of disturbed behaviors than in females (that was reported to be 10.8–16.9%; DSM plus ED-NOS criteria).

171.4 Comparison of "Abnormal" Eating Behavior in Type 2 and Type 1 Diabetes

Goodwin et al. (2003) in their assessment of 3,000 primary care patients observed that an eating disorder (based on DSM-IV criteria) was the only psychological condition associated with an increased diabetes risk. Goodwin et al. (2003) also found that diabetes was the only disease of the seven most common diseases evaluated that carried significantly increased odds of developing an eating disorder. Reports of "abnormal" eating behavior in type 2 diabetes suggest that binge eating has ranged between 5% and 21% and that the percentage of patients meeting full DSM criteria has ranged between 1.5% and 26% (Mannucci et al. 2002; Kenardy et al. 1994; Papelbaum et al. 2005; Crow et al. 2001). Observed overeating and binge-eating rates were 27% in French males and 11% in women mildly higher than those observed in other European diabetic populations (Ryan et al. 2008). This was higher than the prevalence in the French nondiabetic population, although caution should be taken with this information since the diabetic sample was rather small (n = 96). Mannucci et al. reported rates of full DSM criteria in 2.5% of type diabetes patients (similar to that in non diabetic or obese Italian patients), and binge eating in 7.5% females and 2.6% males (2002). Herpertz in Germany showed a 6.5–9% prevalence of DSM plus ED-NOS criteria (1998). Such rates may, however, be lower than rates observed in the United States (Kenardy et al. 1994; Papelbaum et al. 2005; Crow et al. 2001) but given the heterogeneity of measurements tools used across these studies it is difficult to compare results meaningfully (Table 171.5).

One-quarter of the Diabetes Prevention Program cohort of patients at risk for type 2 diabetes (n = 274) was studied by Delahanty et al. (2002) and showed a binge-eating rate of 19%.

Type 2 diabetic patients are significantly more dietary restrained than type 1 diabetic patients. Restraint was found to increase in line with BMI (Ryan et al. 2008; Herpetz et al. 1998). Dietary disinhibition score was generally low and similar between diabetic groups as it was for hunger (Ryan et al. 2008). It is noteworthy that both reported disinhibition and hunger were significantly higher in patients with "abnormal" eating behavior than in those without, while dietary restraint was similar. However, dietary restraint increases from the diagnosis to after 6 months in type 1 diabetic patients (Ritz 2008).

Although dietary restraint is not regarded as a DSM or ED-NOS criteria, the restraint theory proposes that increased restraint can facilitate the development of unusual eating habits as a result of stress incurred by the need to control body weight. In diabetic patients, any food intake may be considered to be a result of the "balance between their desire to eat and their wish to diet." A lapse in this self-control (a disinhibition effect) – for whatever reason – can result in overeating. In contrast to "normal" eaters,

Table 171.5 Prevalence of Binge eating in patients at risk or with type 2 diabetes

who are influenced by a sophisticated internal regulatory system that modulates external factors such as smell to initiate or end food intake, restrained eaters try to dominate all external factors. As a result, the food intake of restrained eaters becomes uncontrolled and unrelated to either their appetite or nutritional requirements. This situation, with its eventual subsequent disinhibition, could result in periods of significant overeating. Golay et al. (2001) emphasized the importance of using food diaries to reveal patients' eating habits as well as the need to help them to understand what a meal is and to reestablish a regular eating pattern.

171.5 Conclusion

"Abnormal" eating behaviors are prevalent in both type 1 and type 2 diabetic subjects. In type 1 subjects, classical criteria of DSM and ED-NOS are more prevalent than in the general population, and progress with the disease during adolescence to reach high rates in adults. Other less classical behaviors related to body size and shape concerns develop with the course of the disease, such as insulin omission or self-induced vomiting. Since these behaviors are associated with greater complication rates and poorer metabolic control, they should be searched systematically. Indeed, omitting the diagnosis leads to lack of treatment, although more research is needed about therapeutic approaches. The possibility of a gender effect warrants further exploration in larger patient cohorts. In type 2 patients, binge eating and overeating appear to be frequent and can be subject to specific approaches such as cognitive and behavioral therapy (Golay et al. 2001).

Dietary restraint, disinhibition, and hunger rates are high in both type 1 and type 2 patients. These parameters have been associated in a complex bidirectional relationship with body-weight management. Whether the systematic evaluation of those parameters should be performed remains a matter of debate.

All the studies reported have used somewhat different definitions of "abnormal" eating behaviors, and different tools to address prevalence. Future studies should pay attention to these aspects in order to compare data from different cohorts.

The authors display no conflict of interest between them and with industrial partners related to this work.

Summary Points

- Disordered eating behavior is frequent in type 1 diabetic patients.
- Disordered eating behavior is associated with a higher rate of microvascular complications in type 1 diabetic patients.
- Disordered eating behavior is related to dysregulation of body shape and image in type 1 diabetic patients.

- Disordered eating behavior is characterized by other traits in type 1 diabetic patients, such as intense exercise practice and self-induced vomiting to control body shape and image.
- Disordered eating behavior is probably underdiagnosed in type 1 diabetic patients
- Disordered eating behaviors are different in type 1 and type 2 diabetic patients
- Binge eating disorder is the most frequent disorder in type 2 diabetic patients
- Emotional eating, dietary restraint, and disinhibition are eating behaviors that are often observed in obese patients. Whether they are more frequent in diabetic obese patients remains to be established.

Definitions

Type 1 diabetes: A metabolic disorder characterized by an autoimmune aggression of the pancreatic cells producing insulin. Symptoms are those of hyperglycemia (polyuria, thirst) and those of insulin deficiency (weight loss, muscle mass loss). Patients require exogenous insulin as a treatment.

Microvascular complications: In all types of diabetes chronic hyperglycemia damage small vessels. Organs such as the eyes, the kidney, and nerves are damaged.

Self-induced vomiting: This is a symptom specific of type 1 diabetes. Some patients act so as to vomit in the wish that it will help controlling body weight.

Insulin omission: Voluntary omission of the treatment with insulin

The Diabetes Prevention Program: A trial design to prevent type 2 diabetes by lifestyle modifications (healthy diet, reduction of body weight, increase in physical activity).

172.1 Introduction

Type 2 diabetes, or non-insulin-dependent diabetes mellitus (NIDDM), is a chronic metabolic disorder that results from the body's inability to produce or effectively use insulin. While serious complications such as cardiovascular disease, retinopathy, neuropathy, and nephropathy can occur, successful management is possible through medication, healthy lifestyle choices, and weight loss when indicated. Because of the link between dietary choices and the development and management of diabetes, understanding disordered eating patterns in this patient population is clinically relevant. This chapter focuses on binge eating – one of the most common forms of disordered eating – and its relationship with type 2 diabetes.

172.2 Binge Eating: Definitions and Prevalence

Binge eating disorder (BED) is characterized by recurrent binge eating episodes during which an individual consumes a large amount of food in a relatively short period of time and feels a loss of control over eating (American Psychiatric Assocation (APA) 1994). Accompanying characteristics may include eating rapidly, eating until feeling uncomfortably full, eating large amounts of food when not physically hungry, eating alone because of embarrassment about how much food is being consumed, and feeling disgusted, depressed, or guilty after overeating. To meet diagnostic criteria as

A.A. Gorin (✉)

e-mail: amy.gorin@uconn.edu

defined by the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV) (APA 1994), binge eating episodes must occur on average two or more times per week for a period of 6 months or more and must occur in the absence of compensatory behaviors such as purging, fasting, or excessive exercise.

BED is present in approximately 1–5% of the general population (Hay 1998; de Zwaan 2001; Striegel-Moore and Franco 2003; Hudson et al. 2007) and is much more common in individuals who are overweight or obese than in normal-weight individuals (Fairburn et al. 1998; Dingemans et al. 2002). While the exact prevalence of BED in obese adults is unknown, a recent study with a community sample found that 16% of obese individuals screened positive for BED (Grucza et al. 2007) and there is some evidence that binge eating is more likely to be present as the degree of obesity increases (Telch et al. 1988; de Zwaan 2001; De Freitas et al. 2008). Some of the highest rates of BED have been found among overweight and obese individuals seeking weight-loss treatment, with rates between 20% and 30% often reported (de Zwaan 2001; Dingemans et al. 2002; Castellini et al. 2008).

Given that the vast majority of individuals with type 2 diabetes are overweight or obese, it is not surprising that binge eating rates in this population are also elevated (Wing et al. 1989; Herpertz et al. 1998; Crow et al. 2001; Kenardy et al. 2001; Mannucci et al. 2002; Meneghini et al. 2006; Allison et al. 2007; Gorin et al. 2008). In a sample of 215 women with type 2 diabetes, 21% reported binge eating at least once per week and 14% met diagnostic criteria for BED (Kenardy et al. 2001). More recent work examining the connection between binge eating and diabetes has come from Look AHEAD, an National Institutes of Health (NIH)-funded multisite, randomized, controlled trial examining the long-term effect of intentional weight loss on cardiovascular disease in overweight and obese individuals with type 2 diabetes. At study entry, 11.7% of the 5145 Look AHEAD participants self-reported having one or more binge eating episodes in the prior 6 months and 2.6% met diagnostic criteria for BED (Gorin et al. 2008). In a subsample of 845 participants who underwent more formal diagnostic interviews, 1.4% were found to meet the full BED criteria (Allison et al. 2007). These numbers illustrate some important points (Table 172.1). First, there is often a discrepancy in BED rates when comparing self-report assessments to standardized diagnostic interviews, with higher BED rates typically found with self-report questionnaires (Streigel-Moore and Franco 2003). Second, many

Table 172.1 Issues to consider in evaluating research on binge eating

Diagnosis via self-report vs. clinical interview	Inconsistencies in the prevalence of BED across studies often are due to differences in assessment methods. Self-report questionnaires, while often briefer and more cost-effective than other methods, may yield higher rates of binge eating than more stringent, structured, interview-based methods (Striegel-Moore and Franco 2003). Brief self-report measures, however, may be more practical in clinical settings and for repeated use when tracking individuals longitudinally.
Binge eating disorder vs. Binge eating behavior	The DSM-IV criteria for BED require an average of 2 binge episodes per week over a 6 month period. Many researchers have suggested that this frequency criterion is arbitrary and that subthreshold cases are equally important to study. Thus, some researchers have expanded their investigations to include as binge eaters any individuals who report binge eating behavior regardless of frequency.
Community vs. treatment-seeking samples	Much of the work on binge eating has been done on overweight and obese individuals presenting for weight-loss treatment, a population with much higher rates of binge eating than found in the general public. Studies on treatment-seeking samples may confound the psychological and physical risk of binge eating with the negative effects of excessive weight. More research on both community and clinical samples is needed to understand the unique impact of binge eating on health.

This table outlines issues that need to be considered when examining research on binge eating. Research findings will be influenced by whether a binge eating diagnosis is made via self-report or clinical interviews, whether the research focuses on binge eating disorder or binge eating behavior more broadly defined, and whether the study includes a community sample or treatment-seeking individuals.

individuals engage in binge eating at subthreshold levels, making binge eating one of the most common forms of disordered eating in overweight and obese individuals with and without type 2 diabetes. Finally, rates of binge eating may vary according to whether the investigation focuses on a clinical or community sample, with the highest rates typically observed in weight loss-seeking samples.

172.3 Demographic, Psychological, and Health Risk Factors Associated with Binge Eating

Overweight and obese individuals who binge eat tend to be younger and are more likely to be college educated than their non-binge eating peers (Wing et al. 1989; Sherwood et al. 1999; Kenardy et al. 2001; Meneghini et al. 2006; Gorin et al. 2008). In treatment-seeking samples, BED is also more likely to be diagnosed in women than in men (Hay 1998; Grucza et al. 2007); however, this gender difference is smaller than that observed in other eating disorders and in community samples in which equivalent rates are often found (Striegel-Moore and Franco 2003; Grucza et al. 2007). Binge eating is present across racial and ethnic groups (Taylor et al. 2007; Nicado et al. 2007), with some evidence that Caucasian and African-American individuals are more prone to binge eating than other ethnicities, a trend that has emerged in both diabetic and nondiabetic samples (Meneghini et al. 2006; Gorin et al. 2008; Allison et al. 2007, Striegel-Moore and Franco 2008).

In addition to demographic differences, the psychological profiles of binge eaters tend to differ from their non-binge eating peers. Binge eating is often accompanied by body image disparagement, interpersonal difficulties, and low levels of self-esteem (Kuehnel and Wadden 1994; Eldredge et al. 1998; Striegel-Moore et al. 1998), perhaps creating a vulnerability for the development of other psychological disorders. Indeed, there is a high degree of comorbidity between binge eating and depressive disorders. Telch and Stice (1999) found that women with BED were twice as likely as weight-matched non-BED women to have a lifetime prevalence of major depressive disorder (49% vs. 28%, respectively) and these findings have been replicated by others (e.g., Kolotkin et al. 1987; Mussell et al. 1995). Connections between binge eating and bipolar disorder, anxiety disorders, and substance abuse have also been reported (Swinbourne and Touyz 2007; Wildes et al. 2008). In addition to elevated risk of many Axis I disorders, individuals who binge eat appear more likely to have a lifetime prevalence of a personality disorder (Telch and Stice 1999).

On indicators of physical health, binge eating is associated with increased adiposity, which may result in a higher risk of developing weight-related health problems such as type 2 diabetes, increased blood pressure, high cholesterol, gallbladder disease, gastrointestinal issues, and so on for those who binge eat (e.g., Telch et al. 1988; Herpertz et al. 1998; Cremonini et al. 2009). While excessive weight is assumed to be the pathway linking binge eating with negative health outcomes, some initial studies suggest that binge eating and body weight exert independent negative effects on health (e.g., Kenardy et al. 2001; Cremonini et al. 2009). Specific to type 2 diabetes, Kenardy and colleagues (2001) found a relationship between binge eating severity and HbA_{1c} levels that remained significant even after controlling for body weight and exercise habits (see Table 172.2). A similar relationship was reported by Meneghini et al. (2006). In a sample of 140 obese diabetics, binge eaters had worse glycemic control and, among individuals who reported binge eating, there was a positive correlation between binge eating severity and HbA_{1c} levels. However, there are some conflicting reports regarding binge eating and its association with glycemic control. Ryan and colleagues (2008), for example, found that binge eating status was not associated with HbA_{1c} among 94 adults with diabetes. Similarly, in Look AHEAD, we found no difference between binge eaters and non-binge eaters in HbA_{1c} levels or on other diabetes-specific measures such as diabetes treatment regimens (Gorin et al. 2008). With

Table 172.2 Key features of HbA$_{1c}$: glycosylated hemoglobin

1. Glycosylated (or glycated) hemoglobin (HbA$_{1c}$) is produced in red blood cells when blood sugar attaches to hemoglobin
2. A HbA$_{1c}$ blood test identifies the average plasma glucose concentration over the prior 2–3 months, serving as a good indicator of diabetes management
3. Higher HbA$_{1c}$ values suggest higher levels of blood glucose. Levels between 4 and 6% are considered normal, however, among individuals with diabetes, levels at or below 7% are often considered ideal
4. Higher HbA$_{1c}$ levels, particularly over an extended period of time, indicate greater risk of developing diabetes complications
5. Individuals with type 2 diabetes should have their HbA$_{1c}$ tested at least two times a year

This table lists the key facts of HbA$_{1c}$ when used as a measure of diabetes control

Table 172.3 Key facts about binge eating in community and clinical samples

Prevalence	• Binge eating disorder is found in 1–5% of community samples
	• Unlike other eating disorders, nearly equal rates of binge eating are found in men and women
	• The highest rates of binge eating are typically found in overweight and obese individuals presenting for weight-loss treatment
	• Overweight and obese individuals who have type 2 diabetes have rates of binge eating that are on par to the general overweight and obese population
Related comorbidities	• Individuals who binge eat tend to have higher rates of depressive disorders, personality disorders, and more issues with self-esteem and body image
	• Binge eating is associated with weight gain over time and consequently with increased risk of weight-related comorbidities
	• In overweight and obese individuals with type 2 diabetes, binge eating is associated with worse reported physical health but is not consistently associated with glycemic control
Treatment options	• If an individual who binge eats is also overweight or obese and wants to lose weight, a lifestyle management program that promotes weight loss through behavioral strategies is likely to both reduce binge eating behaviors and produce modest weight loss
	• In individuals with type 2 diabetes, recent evidence suggests that binge eating is not associated with weight-loss outcomes unless the behavior begins or persists during treatment
	• In individuals with and without type 2 diabetes, binge eating should be monitored throughout weight-loss treatment and additional support should be provided if the behavior continues
	• Additional treatment options for binge eating are cognitive behavioral treatment, interpersonal therapy, dialectical behavior therapy, and some antidepressants

Key features of binge eating, including prevalence rates, commonly associated psychological and physical comorbidities, and treatment options are described in this table

over 5,000 participants, this is the largest and most representative study conducted to date examining the diabetes–binge eating connection. While the link between binge eating and glycemic control is questionable, several studies suggest that overweight and obese diabetes patients who binge eat self-report worse physical health than their non-binge eating counterparts (e.g., Kenardy et al. 2001; Gorin et al. 2008; Table 172.3).

172.4 Treating Overweight and Obese Patients Who Binge Eat

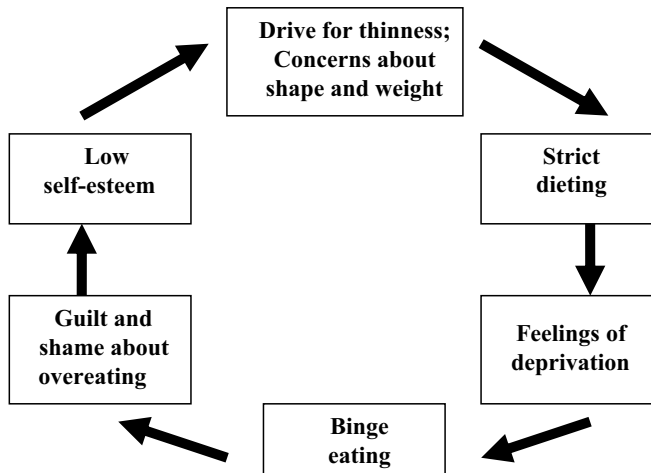
There is debate in the eating disorders and obesity literatures about how best to approach treatment in individuals who present with both binge eating and excessive weight. The primary question is whether binge eating needs to be addressed prior to initiating a weight-loss program (DeAngelis 2002). Those who advocate treating binge eating first often express concerns that the highly structured nature of


Fig. 172.1 Cognitive behavioral model of binge eating. This figure outlines the cognitive behavioral model of binge eating in which binge eating is believed to result from a cycle of concerns about weight and shape, strict dieting, and deprivation that leads to binge episodes followed by feelings of guilt and decreased self-esteem

behavioral weight-loss treatment will exacerbate binge eating in individuals with a predisposition for the behavior (e.g., Kenardy et al. 2001). This concern is consistent with the cognitive behavioral model of binge eating (Fig. 172.1), which conceptualizes binge eating as a result of a vicious cycle that begins with a thinness-obsessed culture that creates excessive concerns about weight and shape. In individuals predisposed to binge eating, these concerns lead to strict dieting and unrealistic food rules, which are impossible to maintain. Lack of adherence to these self-imposed rules leads to an abstinence violation effect, in which a small lapse in dieting gives way to a loss of control over eating and binge eating. Behavioral weight-loss treatment and its emphasis on caloric restriction, physical activity prescriptions, and increased attention to eating and weight through self-monitoring of food intake, physical activity, and frequent self-weighing may appear contraindicated for those patients engaging in binge eating.

There is some empirical evidence to suggest that binge eaters do not respond as well to weight-loss treatment and have poorer compliance than non-binge eaters. Pagoto and colleagues (2007) recently reported that binge eating was associated with poorer weight-loss outcomes among individuals participating in a hospital-based structured lifestyle program. Clinically significant weight losses were achieved by 37% of non-binge eaters compared to only 16% of individuals who reported binge eating at the start of treatment. Others have found that individuals who binge eat tend to report more extensive weight-loss histories, greater difficulties with weight control, and more unhealthy weight control practices than their non-binge eating peers, findings have emerged in both diabetic and nondiabetic samples (Venditti et al. 1996; Sherwood et al. 1999; Johnsen et al. 2003).

While findings such as these are concerning, most of the available evidence suggests that behavioral weight-loss treatment does not exacerbate or precipitate binge eating (Wadden et al. 2004; Butryn and Wadden 2005), that binge eating status is not associated with weight-loss outcomes (Sherwood et al. 1999; Teixeria et al. 2005; Delinsky et al. 2006), and that binge eating may in fact improve with weight-loss treatment (Wing et al. 1989; National Task Force 2000). For example, to examine whether behavioral weight-loss approaches precipitate binge eating, Wadden et al. (2004) randomly assigned 123 obese women reporting no binge eating at baseline to a 1,000 kcal diet using liquid meal replacement, a 1,200–1,500 kcal diet using conventional foods, or a nondieting program. Following treatment, there were no differences between the groups on binge eating behavior and

those in the active weight-loss programs lost more weight and reported less depression than those in the nondieting condition. Furthermore, in a study of participants in a self-help program for weight loss with a relatively high prevalence of self-reported binge eating (41% of participants), Delinsky and colleagues (2006) found no relationship between binge eating and weight-loss outcomes. Indeed there is evidence that participation in behavioral weight loss can improve binge eating behavior (e.g., Agras et al. 1994; Porzelius et al. 1995). Given that weight loss is a cornerstone of effective diabetes management, this is welcome news for binge eaters with type 2 diabetes.

The most recent evidence to suggest that behavioral weight-loss treatment is appropriate for individuals with type 2 diabetes has come out of the Look AHEAD study. In this trial, overweight and obese individuals with type 2 diabetes were randomly assigned to an intensive lifestyle intervention or to a diabetes support and education control condition. The goals of the lifestyle intervention (modeled after the Diabetes Prevention Program) were to produce a mean weight loss of ≥7% of initial weight through caloric restriction and increased physical activity (Wadden et al. 2006). Binge eating behavior was assessed prior to starting the program and 1 year later. We found that about 10% of participants reported binge eating in the 6 months prior to starting the program and that the majority of these individuals (67%) were no longer engaging in binge eating at the 1-year follow-up. We also found that very few individuals, less than 4%, started binge eating during the first year of treatment, suggesting as others have found that behavioral weight-loss treatment does not generally lead to initiation of binge eating behavior (National Task Force on Prevention and Treatment of Obesity 2000; Butryn and Wadden 2005). Finally, we found that binge eating interfered with weight loss only in the small minority of participants for whom binge eating started, or persisted during treatment (see Fig. 172.2). The attenuated weight losses in those who started or continued to binge eat during treatment likely reflect the smaller decreases in caloric intake achieved in these individuals (Fig. 172.3).

Taken together, the findings from Look AHEAD further confirm the current recommendations (National Task Force on Prevention and Treatment of Obesity 2000) that individuals who binge eat
Fig. 172.2 One-year weight loss by binge eating status in overweight and obese individuals with type 2 diabetes participating in the Look AHEAD trial. This figure shows the amount of weight loss (means and standard deviations) overweight and obese individuals with type 2 diabetes achieved in the Look AHEAD trial. Individuals who reported binge eating at baseline but not at year 1 lost just as much weight as individuals who were not binge eating at either time point and lost more weight than those who reported binge eating at only year 1 or who were binge eating at baseline and year 1. Yes/No = reported binge eating at baseline but not 1-year; No/No = did not report binge eating at either time point; Yes/Yes = reported binge eating at both time points; No/Yes = did not report binge eating at baseline but did at 1-year (Originally published in Gorin et al. (2008, 1450). Copyright 2008, American Medical Association. All rights reserved)
Fig. 172.3 One-year change in reported caloric intake by binge eating status in overweight and obese individuals with type 2 diabetes participating in the Look AHEAD trial. This figure shows changes in caloric intake (means and standard deviations) reported by overweight and obese individuals with type 2 diabetes in the Look AHEAD trial. Individuals who reported binge eating at baseline but not at year 1 decreased their daily intake just as much as individuals who were not binge eating at either time point and decreased their daily intake more than those who reported binge eating at only year 1 or who were binge eating at baseline and year 1. Yes/No = endorsed binge eating at baseline but not 1-year; No/No = did not endorse binge eating at either time point; Yes/Yes = endorsed binge eating at both time points; No/Yes = did not endorse binge eating at baseline but did at 1-year (Originally published in Gorin et al. (2008, 1451). Copyright 2008, American Medical Association. All rights reserved)

should not be discouraged from entering behavioral weight-loss programs. However, it is important to note that individuals who continued to binge eat and those who started to binge eat during treatment did not fare as well. Thus, it would appear useful to assess binge eating throughout treatment, not simply at entry into a program, and provide additional support as needed. Treatments for binge eating with proven effectiveness include several psychotherapies (cognitive behavioral, interpersonal, and dialectical behavior therapy) and antidepressants (Vocks et al. 2009), which may be considered as a supplement or alternative to behavioral weight-loss treatment.

172.5 Applications to Other Areas of Health and Disease

Binge eating is found in a large percentage of overweight and obese individuals with and without type 2 diabetes. If presenting for weight loss, these individuals are best served by a structured lifestyle modification program, with improvements likely to occur in both binge eating and weight status. Moreover, the modest weight losses of 5–10% of initial body weight typically produced by behaviorally based lifestyle modification programs will likely improve overall health parameters. Known benefits of weight losses of this size include a significant reduction in the likelihood of developing type 2 diabetes and hypertension and improvements in diabetes control, urinary incontinence, hyperlipidemia, and overall quality of life (e.g., Diabetes Prevention Program Research Group 2002; Subak et al. 2009). While psychotherapy and pharmacotherapy options have also been shown to be effective in treating binge eating (Vocks et al. 2009), these alternatives do not produce weight loss, which is an important component of successful diabetes management.

Summary Points

- Binge eating is one of the most common forms of eating pathology. Rates range from 1–5% in the general population to 20–30% in individuals entering weight-loss treatment. Binge eating rates in overweight and obese individuals with type 2 diabetes appear similar to the general overweight and obese population.
- Binge eating, by leading to excessive weight gain, may be associated with many obesity-related physical comorbidities such as hypertension and dyslipidemia. In overweight and obese individuals with type 2 diabetes, binge eating is associated with worse self-reported physical health but is not consistently associated with glycemic control.
- There is disagreement about how to treat overweight binge eaters. Some believe that the structured format of behavioral weight-loss treatment is inappropriate for this population. However, research suggests that most individuals who binge eat stop doing so during weight-loss treatment and have outcomes equivalent to non-binge eaters.
- Specific to type 2 diabetes, a recent study found that binge eating was only associated with poorer weight-loss outcomes if an individual started, or continued, to binge eat during a behavioral weight-loss program.

Definition of Key Terms

Binge eating disorder: Disorder recognized as a diagnosis of further study in the American Psychiatric Association's DSM-IV. Characterized by recurrent episodes of binge eating (eating a large amount of food in a discrete period of time while feeling a loss of control) and a lack of compensatory behaviors.

Behavioral weight-loss treatment: A structured lifestyle modification program, typically offered in academic clinics or university-based practices, which provides diet and physical activity prescriptions supported by training in key behavioral techniques such as self-monitoring, stimulus control, problem solving, and goal setting.

Diabetes Prevention Program: A landmark study published in 2002 demonstrating that a behaviorally based weight-loss program that produced modest weight losses (approximately 7% of initial body weight) and increased moderate intensity physical activity was more effective than metformin in reducing the risk of developing type 2 diabetes.

Look AHEAD trial: An ongoing randomized, controlled trial sponsored by NIH that is examining the long-term effects of intentional weight loss on cardiovascular outcomes in individuals with type 2 diabetes. Over 5,000 participants are enrolled in this 12-year, 16-center study (www.lookaheadtrial.org).

Nutrient Excess and Toxicity

Chapter 173
High Blood Glucose and Damage to Neuronal Tissue

Robert R. Miller Jr.

Abbreviations

AChE	Acetylcholine esterase
BDNF	Brain-derived neurotrophic factor
ChAT	Choline acetyltransferase
DHA	Docosahexaenoic acid
10-FTHF DH	10-formyltetrahydrofolate dehydrogenase
10-FTHF hydrolase	10-formyltetrahydrofolate hydrolase
GDNF	Glial cell line-derived neurotrophic factor
GFAP	Glial fibrillary acidic protein
GLUTS	Glucose transporters
HoCys	Homocysteine
5-Methyl THF	5-methyltetrahydrofolate
NTDs	Neural tube defects
NMDA	N-methyl-D-aspartate
SAH	S-adenosylhomocysteine
SAM	S-adenosylmethionine
STZ	Streptozocin
TBARS	Thiobarbituric acid reactive substances
T1D	Type-1 diabetes
T2D	Type-2 diabetes

173.1 Introduction

Type-1 diabetes (T1D; insulin-dependent), type-2 diabetes (T2D; non-insulin-dependent), and gestational diabetes can damage and impair the nervous system. Type-1 and type-2 diabetics have a 25-fold increase in the risk of retinopathy-associated blindness (Wolff 1993), a 4- to 12-fold increased risk of stroke and ischemia-induced cerebral damage (Scott et al. 1999; Bemur et al. 2007), and

R.R. Miller Jr. (✉)

e-mail: bob.miller@hillsdale.edu

approximately 50% of all type-1 and type-2 diabetics undergo some form of neuropathy (Negi et al. 2008). Among the various risk factors associated with stroke and ischemia, both mild and severe hyperglycemia within 24 h of the onset of cerebral ischemia exacerbates cerebral damage and increases mortality (Lanier 1999).

Hertz (2008) has recently reviewed how glucose is used as virtually the only metabolic fuel in adult neurons, astrocytes, and oligodendrites. Glucose-6-phosphate is anaerobically metabolized to pyruvate via glycolysis. Because neurons and oligodendrites lack pyruvate decarboxylase, astrocytes must convert pyruvate to acetyl coenzyme-A and then aerobically convert acetyl coenzyme-A to α-ketobutyrate. Under aerobic conditions, astrocytes supply neurons with α-ketobutyrate so neurons can complete aerobic respiration via the Kreb's cycle, or the astrocytes can convert α-ketobutyrate to glutamate and then decarboxylate glutamate to glutamine. Astrocytes then release glutamine to nearby neurons and neurons deaminate the incorporated glutamine to glutamate. Neurons can use glutamate as a neural transmitter, which when released, activates nearby N-methyl-D-aspartate (NMDA) receptors and opens Ca^{+2} channels.

During ischemia, astrocytes, oligodendrites, and neurons convert pyruvate to lactate (acidosis). Because of oxygen-debt, neurons are unable to oxidatively deaminate glutamate to α-ketobutyrate and release excessively high glutamate levels and overstimulate nearby neurons via NMDA receptors (Hertz 2008). Coupled with the overstimulation of NMDA receptors and increased cytoplasmic Ca^{+2} levels, changes in the nearby microvascular system are observed associated with local inflammatory responses that include neutrophil recruitment and the formation of reactive oxygen species (oxygen radicals, hydroxyl radicals, and peroxynitrite radicals). Reactive oxygen species can be generated by enhanced neutrophil NADPH oxidase and xanthine oxidase activities and by activation of neuronal nitrous oxide synthase. Any Fe^{+2}-containing enzyme, such as a cytochrome released from mitochondria into the cytoplasm of cells undergoing apoptosis, or any enzyme that produces H_2O_2 can potentially generate hydroxyl radicals (HO^-) at the expense of oxygen radicals (O^-). This is especially true if the newly produced H_2O_2 cannot be converted to H_2O and O_2 by either catalase or glutathione peroxidase. As H_2O_2 levels increase, H_2O_2 can decompose into HO^- via the Harber–Weiss reaction (Miller 2004).

$$H_2O_2 + Fe^{+2} \rightarrow OH^- + HO^- + Fe^{+3} \rightarrow \text{Fenton Reaction}$$

$$+Fe^{+3} + 2O^- \rightarrow Fe^{+2} + O_2 \rightarrow \text{Reduction of ferricion}$$

$$H_2O_2 + 2O^- \rightarrow OH^- + HO^- + Fe^{+3} \rightarrow \text{Harber-Weiss reaction}$$
All of these events initiate oxidative stress, oxidative damage via membrane lipid peroxidation, necrosis, apoptosis, mitochondrial involvement, and have recently been reviewed (Wolff 1993; Gonzalez-Zulueta et al. 1998; Vincent et al. 2005; Negi et al. 2008; Bemur et al. 2007; Norenberg and Rao 2007; Hertz 2008; Friedlander 2009). This article will review articles largely excluded from these reviews.

173.2 Type-1 Diabetes: Cognitive Impairment, Neuropathy, and Astrogliosis

Type-1 diabetic children, who suffer prolonged periods of hyperglycemia and momentary episodes of hypoglycemia, exhibit cognitive deficits (Northam et al. 2001; Hershey et al. 2005) and regional differences in brain anatomy as compared to nondiabetics (Sharma et al. 2003; Perantie et al. 2007).

Hershey et al. (2005) reported deficits in spatial memory as a function of hypoglycemia in type-1 diabetic children as compared to controls, and Malone et al. (2008) reported reduced neuron dendritic branching, reduced spine density within the parietal cortex, and hyperglycemia-induced spatial memory deficits in streptozocin (STZ)-treated rats. Exposure of rats to STZ, an agent that destroys pancreatic β-cells, caused reductions in hippocampus-dependent spatial learning, which was associated with hyperglycemia-induced increased brain sorbitol levels, increased brain inositol levels, and decreased brain taurine levels in male rats as compared to controls (Malone et al. 2008). Type-2 diabetics may also have abnormally low taurine levels in brain due to enhanced excretion of taurine (Sankarasubbaiyan et al. 2001). Beauguis et al. (2008) reported elevated expression of hypothalamic hormones, including oxytocin and vasopressin, and elevated plasma glucocorticosteroid levels, and astrogliosis within the hippocampus of STZ-injected female mice. Astrogliosis was measured by the induction of glial fibrillary acidic protein (GFAP) and is associated with neuropathy (Beauguis et al. 2008).

By the use of magnetic resonance imaging, Sharma et al. (2003) demonstrated reduced brain volume in adults (18–50 years old) who suffered T1D for a period exceeding 10 years as compared to controls. Also by use of magnetic resonance imaging, Perantie et al. (2007) reported smaller gray matter volume in the left temporal region in diabetic children (7–17 years old) who suffered from periods of severe hypoglycemia as compared to hypoglycemia-naive diabetic peers. Reduced gray matter within the left superior temporal and angular gyri has been reported in adults who suffered from T1D (Musen et al. 2006) and this same region of the human brain has been associated with episodic memory (Cabeza et al. 2004). Meanwhile, hyperglycemia in type-1 diabetic children was associated with reduced gray matter in the right cuneus and precuneus, reduced white matter in the right posterior parietal region, and increased gray matter volume in the right prefrontal lobes as compared to nondiabetic siblings (Perantie et al. 2007).

Neurons express GLUT-3 (glucose transporter-3), while astrocytes express GLUT-1 and GLUT-2. Consequently, nerves, retina, and kidneys will undergo an intense hyperglycemia-induced D-glucose influx in type-1 and type-2 diabetics because GLUT-1, GLUT-2, and GLUT-3 are insulin-insensitive as compared to GLUT-4 (Anderson et al. 2001). This D-glucose influx causes sorbitol synthesizes by the polyol pathway during neuropathy because hexokinase, which normally converts glucose to glucose-6-phosphate, becomes saturated and excess glucose is then converted to sorbitol via aldose reductase. The polyol pathway and subsequent formation of glycated proteins (advanced glycation end products; Wolff 1993) is active during diabetic retinopathy (Sun et al. 2006; Negi et al. 2008) and Sun et al. (2006) reported that the use of an aldose reductase inhibitor (ARI-809) ameliorated the severity of diabetic retinopathy.

173.3 Type-1 Diabetes: Peripheral Neuropathy and Glial Cell Line-Derived Neurotrophic Factor (GDNF)

Gastrointestinal dysfunction occurs in many diabetics and gastrointestinal tract motility changes involve losses of peripheral neurons (neuropathy). Increased apoptosis rates have been observed in neurons within dorsal root ganglion in STZ-treated rats (Guo et al. 2004) and the neuropathy has been associated with a reduction in neurotrophic factors (Leinninger et al. 2004). One such neurotrophic factor is GDNF. After being released by glial cells, GDNF binds to Ret tyrosine kinase receptors on neuron membranes and stimulates MAPK (Mitogen-Activated Protein Kinase) and P13K signaling pathways. Activation of the P13K pathway causes phosphorylation of Akt and inhibits the translocation of the forkhead box O3a (FOXO3a) transcription factor, which blocks apoptosis by inhibiting the transcription of the proapoptotic genes *Bim* and *Puma* (Srinivasan et al. 2005;

Anitha et al. 2006). Anitha et al. (2006) reported increased apoptosis rates in myenteric neurons, reduced Akt-phosphorylation in myenteric neurons, and delayed gastric emptying (increased intestinal transit time) in STZ-treated diabetic rats, and these hyperglycemia-related events were reversed with exogenous GDNF.

173.4 Type-1 Diabetes: Acetylcholine

The neural transmitter acetylcholine plays an essential role in learning and memory within the basalis magnocellularis and activates cholinergic innervation to the neocortex (Winkler et al. 1995). Thus, choline uptake, enzymes that modulate acetylcholine levels, and acetylcholine receptors are of interest. Mooradian (1987) reported that choline transport across the blood–brain barrier is reduced in STZ-induced diabetic rats. Type-1 and type-2 diabetic mothers have significantly lower plasma choline phosphoglyceride docosahexaenoic acid (DHA) levels in umbilical cords and in circulating red blood cells of pregnant women as compared to nondiabetic mothers (Min et al. 2005a, b). Improved spatial cognition with dietary DHA supplementation was associated with increased *Fos* expression within the CA1 nucleus within the hippocampus of nondiabetic rats (Tanabe et al. 2004), and a significant correlation coefficient between blood DHA levels and Peabody Picture Vocabulary Test scores (a test of listening comprehension and vocabulary acquisition) (r = 0.46; $p < 0.018$) was observed in healthy 4-year-old children (Ryan and Nelson 2008).

Once choline enters, neurons convert choline to acetylcholine via choline acetyltransferease. However, choline acetyltransferase (ChAT) activities were reduced in the hippocampus of STZ-treated rats as compared to controls (Blokland and Jolies 1993; Terwel et al. 1995). Terwel et al. (1995) observed decreased septum masses as hippocampal ChAT activities decreased in STZ-treated rats, and Blokland and Jolies (1993) reported impaired spatial discrimination performances as hippocampal ChAT activities decreased in STZ-treated rats. While Welsh and Wecker (1991) failed to report significant differences in choline or acetylcholine levels in either the striatum or hippocampus within brain slices obtained from STZ-injected rats, reduced release of acetylcholine in striatal slices of STZ-injected rats was reported.

Not only is the synthesis and release of acetylcholine reduced within the hippocampal region of STZ-treated rats, the degradation of acetylcholine to acetate and choline via acetylcholine esterase (AChE) is inhibited in STZ-treated (Ashokkumar et al. 2006) and alloxan-treated rats (Khandkar et al. 1995; Ghareeb and Hussen 2008). Like STZ, alloxan kills pancreatic β-cells and induces T1D. Ashokkumar et al. (2006) reported that brain AChE activities decreased as brain thiobarbituric acid reactive substances (TBARS) levels increased in STZ-treated rats. TBARS are a measure of oxidative stress and are lipid peroxidation intermediates. Ghareeb and Hussen (2008) reported that brain glutathione-S-transferase activities decreased as brain membrane-bound and soluble-AChE activities decreased in alloxan-treated rats. Oxidative stress is also supported by Ates et al. (2007) who reported increased lipid peroxidation levels, as measured by malondialdehyde, increased nitric oxide levels, and reduced glutathione levels in the hippocampus, cortex, cerebellum, brain stem, and spinal cord of STZ-treated rats as compared to controls. Administering the antioxidant, resveratrol, ameliorated hyperglycemia-induced oxidative stress in STZ-treated rats (Ates et al. 2007). Kamboj et al. (2008) reported that *N*-acetylcysteine attenuated hyperglycemia-induced decreased glutathione levels, decreased total thiol levels, and decreased AChE activities within the cerebral cortex, cerebellum, and brain stem of STZ-treated rats as compared to controls. *N*-acetylcysteine is a precursor of cysteine and exerts antioxidant effects by either reacting directly with electrophiles or by facilitating the generation of the antioxidant, glutathione (Song et al. 2004). Kamboj et al. (2008) also reported

cognitive deficits and reduced activities of several antioxidant enzymes including superoxide dimutase, catalase, and glutathione reductase within the cerebral cortex, cerebellum, and brain stem in STZ-treated rats as compared to controls. Thus, the loss of the "cholinergic phenotype" in the brains of type-1 diabetics correlates with the generation of reactive oxygen species and oxidative stress.

173.5 Type-2 Diabetes: Acetylcholine

Gautam et al. (2009) recently demonstrated that the failure of acetylcholine to stimulate brain neuronal M3 muscuranic acetylcholine receptors caused pronounced hypoplasia of the anterior pituitary gland. They produced brain-specific M3 muscuranic acetylcholine receptor knockout mice that exhibited a dwarf phenotype, abnormally small anterior pituitary glands, and reduced ability to synthesize and release serum growth hormone, prolactin, and gonadotropic hormone. Treatment of these M3 receptor-deficient knockout mice with CJC-1295, a synthetic gonadotropic hormone-releasing factor, restored normal pituitary size and serum gonadotropic hormone levels. Thus, acetylcholine and M3 muscuranic acetylcholine receptors within the hypothalamus play a role in the development of anterior pituitary.

While anterior pituitary development requires cholinergic neurons and the stimulation of M3 muscuranic acetylcholine receptors, overstimulation of M3 muscuranic acetylcholine receptors within the peripheral nervous system is associated with T2D. Most animals that model T2D, as reflected by obesity and hyperinsulinemia, have increased vagal cholinergic activities and are mediated by G-protein-coupled muscuranic receptor subtypes (M1–M5) within the parasympathetic nervous system (Caulfield and Birdsall 1998). Gautam et al. (2006) mimicked T2D by inducing obesity, glucose intolerance, and insulin resistance in male $M3R^{-/-}$ and $M3R^{-/-}ob^{-/-}$ mice by either feeding mice high-fat diets or by destroying glucose-receptive neurons in the ventromedial nucleus of the hypothalamus with gold thioglucose. The $M3R^{-/-}$ mice lacked G-protein coupled M3 muscuranic receptors and the $M3R^{-/-}ob^{-/-}$ mice lacked M3 muscuranic receptors and were also leptin deficient. In all experimental animals, the lack of M3 muscuranic receptors protected animals against overeating, hyperglycemia, hyperinsulinemia, and all mice lacking M3 muscuranic receptors had increased fatty acid β-oxidation rates. Thus, while fetal and neonatal animals may require M3 muscuranic receptor stimulation for anterior pituitary development, antagonists of peripheral M3 muscuranic receptors may help control T2D.

173.6 Type-2 Diabetes: Cognitive Impairment and Neuropathy

Individuals who suffer from T2D frequently exhibit insulin resistance, leptin resistance, hypertriglyceridemia, and obesity (Van Gaal et al. 1999; Ma et al. 2002; Margetic et al. 2002). Plasma leptin levels were correlated to plasma insulin levels, cholesterol levels, and triglyceride levels in 107 elderly women (67–78 years old) and the correlation coefficients (r) were 0.56 ($p \leq 0.001$), 0.23 ($p \leq$ 0.05), 0.25 ($p \leq 0.01$), respectively (Zamboni et al. 2004). Elevated circulating triglyceride levels among individuals suffering from T2D have been associated with poor cognitive performance (Perimuter et al. 1988). Insights into this complex and poorly understood set of relationships have come from studying lean and obese mice. Triolein (a triglyceride) injected directly into the brains of lean *CD-1* male mice impaired the NMDA receptor-mediated maintenance of hippocampal long-term synaptic potential as measured by three different measures of cognitive paradigms. The injection of free-palmitate into brains failed to induce cognitive deficits. Meanwhile, lowering blood triglyceride levels, through the administration of gemfibrozil, reversed cognitive impairments and improved

measures of oxidative stress in the brains of obese mice. Thus, hypertriglyceridemia somehow inhibits hippocampal long-term potentiation by blocking NMDA receptor activation and NMDA receptor-induced Ca^{+2} influxes into neurons (Farr et al. 2008).

173.7 Type-2 Diabetes: BDGF and VGF

Some individuals have a predisposition in developing T2D and this predisposition may involve brain-derived neurotrophic factor (BDNF). BDNF is a member of the neurotrophin family that includes nerve growth factor, neurotrophin-3, and neurotrophin-4/5 (Skup 1994; Barbacid 1995; Lewin and Barde 1996; Lindsay et al. 1994). BDNF promotes neurite outgrowth, provides tropic support for neurons in both the central and peripheral nervous system, and has been successfully used in the treatment of several neurological disorders (Sendtner et al. 1996; Yuen et al. 1996) and the injection of BDNF into obese mice ameliorated hyperglycemia (Ono et al. 1997; Tonra et al. 1999; Nakagawa et al. 2000). The recent creation of the transgenic mouse strain, *Timo⁻/⁻*, has resulted in reduced and disrupted hippocampal *Bdnf* expression and is associated with obesity and hyperglycemia (Sha et al. 2007). Recently, the injection of BDNF into predisposed obese and hyperglycemic mice (*db⁻/⁻*), which possess abnormal leptin receptors, blocked the onset of T2D (Yamanaka et al. 2008). Thus, reduced *Bdnf* expression appears associated with the onset of T2D.

VGF (nonacronymic protein) was originally identified as a neutrophin-regulated gene product in PC12 cells (Levi et al. 1985) and is robustly induced by BDNF and neurotrophin-3 and marginally induced by fibroblast growth factors and insulin (Levi et al. 1985, 2004; Salton et al. 2000). In the rat brain, VGF isoforms are distributed throughout the brain, spinal cord, and pancreas with very high abundance in the hypothalamus and hippocampus (Chakraborty et al. 2006). Interest in VGF grew markedly after VGF-deficient mice were created that are lean, hypermetabolic, and resistant to obesity (Hahm et al. 1999). Targeted deletion of the *Vgf* gene, through the creation of several strains of knock-out mice, promoted reduced circulating blood glucose and reduced circulating insulin levels in leptin-deficient *ob⁻/⁻* mice and in *MCR4⁻/⁻* mice, who fail to express hypothalamic melanocortin-4-receptors (Watson et al. 2005). Watson et al. (2005) hypothesized that VGF-ablation induced greater glucose use, greater insulin sensitivity, and obesity-resistance in mice predisposed to T2D.

Vgf gene expression produces *Vgf*-mRNA and a VGF precursor protein that is processed, cleaved, and secreted through a regulated pathway into a number of VGF peptides/isoforms (Chakraborty et al. 2006). Bartolomucci et al. (2006) isolated TLQP-21, which is a VGF-peptide, from rat brains. Surprisingly, chronic injection of TLQP-21 into the brains of rats fed high-fat diets, reduced circulating leptin levels and caused reduced body mass as compared to rats fed only high-fat diets (Bartolomucci et al. 2006). Thus, VGF-derived peptides may up- or downregulate appetite, metabolism, and leptin resistance through complex signaling pathways and are dependent on the presence of VGF isoform.

173.8 Gestational Diabetes

Neural tube defects (NTDs) are the most common abnormality seen within a fetus during gestational diabetes and a major source of neonatal mortality (Becerra et al. 1990; Ramos-Arroyo et al. 1992). Spina bifida, which is a failure of the neural tube to fuse in posterior regions, is the most common form of NTDs and is observed in infants of diabetic mothers (McLeod and Ray 2002). After neural tube fusion, the proliferation of neuroepithelial cells, the outward migration of cells, the differentiation of both neural tube cells and neural crest cells, and cell death via apoptosis of nonfunctional neurons follow.

Gao and Gao (2007) reported that STZ-induced gestational diabetes caused decreased cell prolifieration, as measured by bromodeoxyuridine incorporation into proliferating cells, and increased apoptosis rates in neuroepithelial cells within embryonic mouse spinal cords. Apoptosis was measured by terminal deoxynucleotidyl transferase-mediated dUTP nick end-labeled DNA fragments (TUNEL), and by monitoring activated caspase-3 levels via Western blots. Previously, Reece et al. (1985) observed decreased numbers of mitotic cells throughout the neuroepithelium but with a predominance at the site of failed neural tube closure in rat embryos cultured in male rat serum containing high D-glucose (7,500 mg/L) levels as compared to controls cultured with less glucose (1,250 mg/L).

A high incidence of congenital NTDs and reduced levels of *Pax-3* mRNA have been reported in mouse embryos collected from hyperglycemic dames whose diabetes was induced with either STZ or phlorizen treatments (Fine et al. 1999). *Pax-3* codes for a transcription factor necessary for neural tube development and reduced *Pax-3* expression was associated with apoptosis, as measured by TUNEL-labeled DNA fragments, within the neuroepithelium of mouse neural tubes (Fine et al. 1999). Jia et al. (2008) recently isolated and cultured neural progenitor cells from the cerebral cortex of mouse embryos (stage 12.2). When the neural progenitor cells were cultured in medium that contained high D-glucose levels (45 mM), increased reactive oxygen species levels, increased Annexin-V levels, and increased nuclear cAbl and p53 levels were observed as compared to control cells cultured in medium that contained less D-glucose (25 mM). Activated Annexin-V promotes membrane blebbing during apoptosis by carrying phosphatidylserine from the cytoplasmic side of the cell membrane to the external side of the cell membrane. Meanwhile, c-Abl is a Src-related nonreceptor tyrosine kinase that can move from the cytoplasm to the nucleus via actin cytoskeletal filaments. Nuclear c-Abl appears to contribute to p53-dependent apoptosis (Yuan et al. 1996).

173.9 Gestational Diabetes: Arachidonic Acid

Gestational diabetes is associated with abnormally low arachidonic acid levels and DHA levels in maternal red blood cells and umbilical cords (Min et al. 2005b). Because the n-3 isomer of arachidonic acid (20:4, n-3) can be elongated and desaturated to DHA (22:6, n-3) (Reitz 1992) and because the n-6 isomer of arachidonic acid (20:4, n-6) can be metabolized to a wide variety of potent signaling compounds, known as prostaglandins (Anggard and Samuelsson 1965), maternal deficiencies in arachidonic acid (both 20:4, n-3 and 20:4, n-6) may have profound effects on fetal development. In response to this hypothesis, subcutaneous injections of arachidonic acid into pregnant STZ-treated rats failed to alter maternal blood glucose levels, maternal weight gain, or embryonic weights. However, the incidence of NTDs was reduced from 11% to 3.8% ($p < 0.005$), the frequency of cleft palate was reduced from 11% to 4% ($p < 0.005$), and the incidence of micrognatha was reduced from 7% to 0.8% ($p < 0.001$) as compared to controls (Goldman et al. 1985). Unfortunately, it is unclear whether Goldman et al. (1985) injected the n-3 isomer of arachidonic acid, the n-6 isomer of arachidonic acid, or a mixture of both isomers (n-3 and n-6).

173.10 Gestational Diabetes: Increased Fetal Brain Insulin-Binding Sites

Insulin, insulin receptors, and glucose transporters (GLUTs) exist within the brain (Baskin et al. 1987; Schwartz et al. 1992). In order to test the effect of gestational diabetes on the density of insulin receptors, the density GLUTs, and the frequency of GLUTs within various regions of the embryonic rat brain, Leloup et al. (2004) implanted catheters into the jugular veins of pregnant mice and infused

the dames with either saline or 30% glucose solutions for a period of 48 h. Just before birth (21.5 days), the infusions were halted and rat fetuses were removed by cesarean sections. The major result was an increased density of insulin receptors in the ventromedial hypothalamus, the arcuate nucleus, the lateral hypothalamus, and in extrahypothalamic areas within the ventromedial hypothalamus in fetal brains obtained from hyperglycemic dames as compared to controls. Among the predominant neural GLUTs identified were GLUT-1 (endothelial and glial cells) and GLUT-3 (neuronal cells). GLUT-2 and GLUT-4 were also identified but at lower levels on astrocytes and neurons within the hypothalamus and spinal cord. The authors concluded that the effect of gestational diabetes was on the density of insulin receptors within the specific fetal brain areas and not on the GLUTs because no relationship could be found between GLUT densities and hyperinsulinism within specific areas of the fetal brain (Leloup et al. 2004).

173.11 Embryonic Diabetes: Apoptosis, Lipid Peroxidation, and Homocysteine

We have also been studying the effects of hyperglycemia in developing chick embryos (Miller et al. 2005; Coes et al. 2008; Miller et al. 2009). For some, this seems like an unlikely choice of animal to model a human condition. However, unlike the mammalian embryo, the avian embryo (cleidoic egg) is a closed system that offers the ability to solely observe embryonic responses to a teratogen as compared to combined maternal responses, fetal responses, and maternal-to-fetal transport systems. It has also been argued that adult birds may naturally reflect a hyperglycemic condition as compared to mammals (Hazelwood 1986). This last argument is partially based on the normally high, at least by mammalian standards, avian serum D-glucose levels (2,000–2,500 mg/L) (Hazelwood 2000).

We have made chick embryos hyperglycemic by injecting D-glucose, L-glucose, or pig anti-insulin antibodies into the air sac of fertile chicken eggs during the first 3 days of avian development. Controls were injected with avian saline (0.72% NaCl, v/v) (Miller et al. 2005; Coles et al. 2008; Miller et al. 2009). After incubation, we collected blood, brains, and livers from embryos at 11 days (theoretical stage 37; Hamburger and Hamilton 1951) and at 18 days of development (theoretical stage 44; Hamburger and Hamilton 1951). Chicks normally hatch in 21 days. Thus, 11 days of chick development is comparable to mid-second trimester and 18 days of development is comparable to mid-third trimester of human development. Our injection period of the first 3 days of chick development (E_{0-2}) is comparable to 0–38 days of human development (≤5.4 weeks). Early pregnancy factor can be detected in maternal serum 24–48 h after fertilization, while human chorionic gonadotropin levels within maternal urine cannot be detected until the second week of human pregnancy corresponding with implantation (Nahhas and Barnea 1990). Hence, our injection period in chick embryos corresponds to before and shortly after most women learn of their pregnancies.

The injection of either exogenous D-glucose or L-glucose, concentrations ranging from 9.29 to 18.58 μmol/kg egg, caused embryonic hyperglycemia, reduced embryo masses, and reductions in the % living chick embryos at 18 days of development (Miller et al. 2005). Also noted were increased serum alanine transaminase activities (a marker of liver trauma), increased hepatic caspase-3 activities (a marker of apoptosis), increased hepatic liver lipid hydroperoxides levels, and decreased arachidonic acid (20:4, n-6) levels within hepatic membrane phospholipids of all embryos injected with either exogenous D-glucose or L-glucose as compared to controls. Also noted was decreased DHA (22:6, n-3) levels within hepatic membrane phospholipids when eggs were injected with 18.58 μmol D-glucose/kg egg, 9.29 μmol L-glucose/kg egg, or 18.58 μmol L-glucose/kg egg as

compared to controls. The hyperglycemia-induced reductions in long-chain polyunsaturated membrane fatty acids, increased hepatic lipid hydroperoxide levels, and increased hepatic caspase-3 activities all indicate hyperglycemia-induced apoptosis and membrane lipid peroxidation within hepatic membranes.

Within chick brains at 18 days of development, decreased brain masses, increased brain caspase-3 activities (indicating apoptosis), and increased brain lipid hydroperoxides levels were all observed in exogenous D-glucose- or L-glucose-treated embryos as compared to controls. While the authors did not monitor the effects of hyperglycemia on brain membrane fatty acid composition, it appears likely that hyperglycemia-induced increased apoptosis rates and hyperglycemia-induced lipid peroxidation occurred in developing chick brains at 18 days of development (theoretical stage 44; Hamburger and Hamilton 1951) (Miller et al. 2005).

These observations were extended into an earlier developmental stage (11 days of development; theoretical stage 37; Hamburger and Hamilton 1951). L-glucose (9.29 μmol/kg egg) was injected into the air sac of fertile chicken eggs during the first 3 days of embryonic development (E_{0-2}), which promoted embryonic hyperglycemia, reduced embryo viability, increased membrane lipid peroxidation, increased brain homocysteine (HoCys) levels, and decreased S-adenosylmethionine (SAM)/S-adenosylhomocysteine (SAH) ratios at 11 days of development (Coles et al. 2008). Exogenous L-glucose, which inhibits GLUTs from binding endogenous D-glucose, caused a 1.7-fold increase in serum D-glucose levels ($p \leq 0.05$), a 1.4-fold decrease in percentage of living embryos ($p \leq 0.05$), a 1.1-fold decrease in embryo masses ($p \leq 0.05$), and a 1.4-fold decrease in embryonic brain masses ($p \leq 0.05$) as compared to controls. Exogenous L-glucose also caused a 3.8-fold increase in brain lipid hydroperoxide levels, a 1.9-fold ($p \leq 0.05$) decrease in Σ unsaturated/saturated brain membrane fatty acids ratios, and a 1.8-fold ($p \leq 0.05$) decrease in Σ long-chain/short-chain membrane fatty acids ratios as compared to controls. L-glucose-treated embryos had decreased levels of brain membrane arachidonic acid (20:4, n-6) and DHA (22–6, n-3) as compared to controls ($p \leq 0.05$). These observations are consistent with the hypothesis of hyperglycemia-induced brain membrane lipid peroxidation (Coles et al. 2008).

Exogenous L-glucose also caused a 12-fold increase in brain HoCys levels, a 2.5-fold decrease in SAM levels, and a twofold increase in SAH levels as compared to controls ($p \leq 0.05$) at 11 days of chick development. These hyperglycemia-induced alterations in HoCys, SAM, and SAH levels indicate methylation difficulties and were somewhat attenuated by exogenous folic acid (181.2 μmol/kg egg) (Coles et al. 2008). Hyperglycemia-induced hyperhomocysteinemia is also of great interest because HoCys is both an agonist and antagonist to the NMDA receptor (Lipton et al. 1997) and hyperhomocysteinemia has been observed in both type-1 (Khare et al. 2005) and type-2 diabetics (Onat et al. 2008).

Because hyperglycemia-induced membrane lipid peroxidation was observed in embryonic chick livers (Miller et al. 2005) and brains (Coles et al. 2008), it is tempting to test whether an exogenous antioxidant can ameliorate hyperglycemia-induced membrane lipid peroxidation. The antioxidant, resveratrol, ameliorated hyperglycemia-induced oxidative stress in STZ-treated rats (Ates et al. 2007). While other exogenous antioxidants may work, it is unlikely that exogenous resveratrol can ameliorate membrane lipid peroxidation and increased apoptosis rates within developing chick embryos. Hancock and Miller (2006) reported that while moderate (2.95 nmol/kg egg) to high levels of exogenous *trans*-resveratrol (29.50 nmol/kg egg) attenuated ethanol-induced decreased brain membrane arachidonic acid (20:4, n-6) and DHA (22-6, n-3) levels as compared to controls, these same dosages of *trans*-resveratrol failed to attenuate ethanol-induced increased brain lipid hydroperoxide levels and increased brain caspase-3 activities (Hancock and Miller 2006).

While *trans*-reveratrol is an antioxidant, *trans*-resveratrol also inhibits angiogenesis. *Trans*-resveratrol inhibited bovine endothelial cell growth by inhibiting fibroblast growth factor-2 induced phosphoryation of MAP kinases in a dose-dependent manner (Brakenhielm et al. 2001). In vivo studies using chick embryos, demonstrated that discs containing 1–100 mg per disc of *trans*-resveratrol produced avascular zones within chick chorio-allantoic membranes (Brakenhielm et al. 2001). The dosages of Brakenhielm et al. (2001) (1–100 µg of *trans*-resveratrol/disc) are similar to the dosages used by Hancock and Miller (2006). Interestingly, hyperglycemia-induced increased brain HoCys levels in developing chick brains (Coles et al. 2008) may also be a threat to the developing blood–brain barrier because HoCys is also known to inhibit endothelial cell proliferation and acts as an antiangiogenic molecule (Nagai et al. 2001; Rodriquez-Nieto et al. 2002).

173.12 Embryonic Diabetes: Homocysteine Metabolism and Oxidative Stress

The knowledge of hyperglycemia-induced increased brain and hepatic HoCys levels (Coles et al. 2008) was alarming to us because we have previously demonstrated that exogenous HoCys caused increased apoptosis rates (as measured by increased caspase-3 activities), increased brain membrane lipid peroxidation rates (as measured by increased levels of brain lipid hydroperoxides and decreased brain membrane long-chain polyunsaturated fatty acid levels), and decreased chick embryo viability at 11 days of development (Miller et al. 2003, 2006). We reported that exogenous HoCys-induced reductions in brain SAM/SAH ratios were partially attenuated by exogenous glycine (Miller et al. 2006). Elevated HoCys levels can cause oxidative stress because two HoCys molecules can undergo auto-oxidation and form a dimer (HoCys:oxidized disulfide) by liberating two hydrogen ions and two electrons. In doing so, hydrogen peroxide and hydroxyl radicals can be generated (Hayden and Tyagi 2004) and these reactive oxygen species can promote membrane lipid peroxidation and subsequent necrosis and apoptosis (Miller 2004).

HoCys is metabolized by the transsulfuration pathway and by the remethylation pathway (Fig. 173.1). In the remethylation pathway, methylcobalamine, which receives the methyl group from SAM, 5-methyltetrahydrofolate (5-methyl THF), or betaine (trimethyl glycine), methylates HoCys to methionine. Methionine is subsequently converted to SAM (Selhub 1999). Hence, folate deficiencies inhibit the remethylation of HoCys to methionine and cause hyperhomocysteinemia and have been associated with a variety of pathological problems (Carmel and Jacobson 2001), and folate deficiencies are well associated with increased incidence of NTDs (Boyles et al. 2006). Many methylases within a cell use SAM as the methyl donor. So as methylase activities continue during hyperhomocysteinemia, SAM levels decline while SAH levels increase (Selhub 1999). Consequently, NTDs may be caused by hyperhomocysteinemia and not by folate deficiencies.

Two enzymes in the remethylation pathway are 10-formyltetrahydrofolate dehydrogenase (10-FTHF DH) and 10-formyltetrahydrofolate hydrolase (10-FTHF hydrolase) (Fig. 173.2). Both enzymes catalyze the conversion of 10-formyltetrahydrofolate to CO_2 and tetrahydrofolate (THF). The difference between the two enzymes is that 10-FTHF DH requires NADPH while 10-FTHF hydrolase does not require NADPH. In the glycine cleavage system within the remethylation pathway, T-protein requires THF as a coenzyme and synthesizes N^5,N^{10}-methylenetetrahydrofolate, which is converted to the methyl donor, 5-methyl THF (Kikuchi 1973; van der Put et al. 2001). Low 5-methyl THF levels could not only inhibit the remethylation of HoCys to methionine, but also alter SAM/SAH levels because methionine is used to produce SAM, SAM is converted to SAH, and SAH is hydrolyzed to HoCys (Selhub 1999).

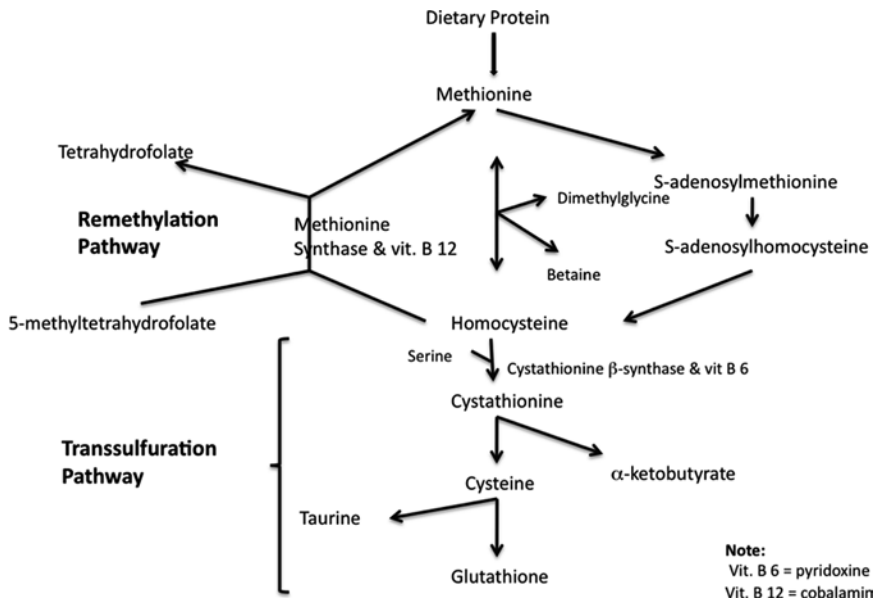
HoCys is also removed in the transsulfuration pathway (Fig. 173.1). The first and irreversible reaction is catalyzed by a pyridoxal-5'-phosphate (vitamin B_6) containing enzyme, cystathionine


Fig. 173.1 Homocysteine removal via remethylation and transsulfuration pathways. *Vit. B6* pyridoxine, *Vit. B12* cobalamin

β-synthase that condenses serine and HoCys to form crystathionine. Cystathionine is subsequently hydrolyzed by another pyridoxial-5'-phosphate containing enzyme, cystathionine γ-synthase, thus forming α-ketobutyrate and cysteine and excess cysteine is converted to taurine (Selhub 1999). Thus, as cystathionine β-synthase activity decreases and the rest of the transsulfuration pathway slows, increased HoCys levels and decreased taurine levels are observed.

We have recently studied whether embryonic hyperglycemia reduces the enzymatic activities of two enzymes in the remethylation pathway, 10-FTHF DH and 10-formyltethydrofolate hydrolase (10-FTHF hydrolase) (Fig. 173.2) and whether embryonic hyperglycemia slows the transsulfuration pathway, as measured by brain and hepatic taurine levels (Fig. 173.1). We injected white Leghorn chicken eggs with either 9.29 μmol L-glucose/kg egg (avian saline was the solvent) or avian saline (0.72% NaCl, w/v) during the first 3 days of avian development (E_{0-2}). At 11 days of development (theoretical stage 37; Hamburger and Hamilton 1951), blood from chorio-allantoic vessels was collected and serum isolated by centrifugation ($10,000\times$ g for 1 min). The mass of each chick embryo was measured followed by decapitation. Brains and livers were excised, tissue mass measured, and stored at $-80°C$ for subsequent biochemical analysis. Serum D-glucose levels were measured according to Coles et al. (2008) and brain and hepatic taurine levels were measured by high performance liquid chromatography as described by Barnett et al. (2009). The enzymatic activities of brain and hepatic 10-FTHF DH and 10 FTHF hydrolase activities were also measured according to Barnett et al. (2009).

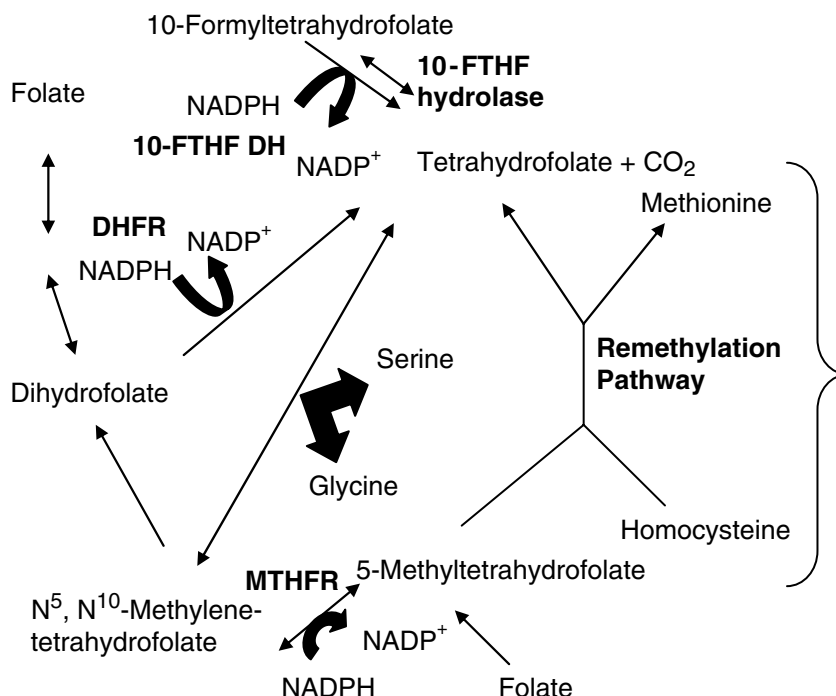
Exogenous L-glucose injected into early chick embryos (E_{0-2}) caused serum D-glucose levels to increase by approximately 2.6 fold ($p < 0.0001$) at 11 days of development (Table 173.1). Presumably, L-glucose inhibited the GLUTs from binding and transporting d-glucose from the developing circulatory system into cells. L-glucose-induced hyperglycemia was also associated with reduced embryo masses ($p \leq 0.0001$) and reduced brain masses ($p = 0.006$) as compared to controls. However, L-glucose-induced hyperglycemia was not associated with reduced hepatic mass or reduced % living embryos as compared to controls (Table 173.1) (Miller et al. 2009).


Fig. 173.2 The remethylation pathway and folate metabolism. *10-FTHF DH* 10-formyltetrahydrofolate dehydroge-nase, *10-FTHF hydrolase* 10-formyltetrahydrofolate hydrolase, *MTHFR* N^5,N^{10}-methylenetetrahydrofolate reductase, *DHFR* dihydrofolate reductase

Exogenous L-glucose-induced hyperglycemia caused approximately a 2.4-fold reduction in brain 10-FTHF DH activities ($p = 0.0035$) and a 2.5-fold reduction in hepatic 10-FTHF DH activities ($p = 0.0035$) as compared to controls (Table 173.2). Hyperglycemia failed to significantly affect either brain or liver 10-FTHF hydrolase activities. When serum D-glucose levels were correlated to brain 10-FTHF activities, the Pearson product moment (r) was -0.56 [F = (1, 13) 5.89; $p = 0.03$] (Fig. 173.3). When serum D-glucose levels were correlated to hepatic 10-FTHF activities, the Pearson product moment (r) was -0.55 [F = (1, 13) 5.63; $p = 0.04$] (Miller et al. 2009) (Fig. 173.4).

Exogenous L-glucose-induced hyperglycemia also caused approximately a 1.8-fold reduction in brain taurine levels ($p \leq 0.007$) and a 2.0-fold reduction in hepatic taurine ($p < 0.01$) as compared to controls (Table 173.2). When serum D-glucose levels were correlated to brain taurine levels, the Pearson product moment (r) was -0.60 [F = (1, 12) 6.68; $p = 0.02$] (Fig. 173.5). When serum d-glucose levels were correlated to hepatic taurine levels, the Pearson product moment (r) was -0.61 [F = (1, 9) 5.40; $p = 0.045$] (Fig. 173.6). Thus, exogenous l-glucose-induced hyperglycemia is inhibiting both the remethylation and the transsulfuration pathways in embryonic chick brains and livers at 11 days of development (Miller et al. 2009).

Table 173.1 The effect of exogenous L-glucose on chick embryo viability at 11 days of development

	Controls (avian saline)	Exogenous L-glucose (9.29 μmol/kg egg)	Statistical analyses
% living embryos	80.11 ± 6.95% $N = 4$ different sets of injections where 16–20 eggs were injected during each set	81.89 ± 10.85% $N = 4$ different sets of injections where 16–20 eggs were injected during each set	$t = 0.28$ df = 6 $p = 0.79$
Embryo mass (g)	3.367 ± 0.196 g $N = 12$	2.873 ± 0.291 g $N = 12$	$t = 4.62$ df = 22 $p \leq 0.0001$
Liver mass (mg)	54 ± 7 mg $N = 12$	52 ± 13 mg $N = 12$	$t = 0.33$ df = 22 $p = 0.74$
Brain mass (mg)	607 ± 71 mg $N = 12$	497 ± 92 mg $N = 12$	$t = 3.09$ df = 22 $p = 0.006$
Serum D-glucose levels	1112.65 ± 256.25 mg/L (6.18 ± 1.52 mM) $N = 12$	2915.12 ± 735.12 mg/L (16.18 ± 4.08 mM) $N = 12$	$t = 6.49$ df = 22 $p < 0.0001$

Fertile white Leghorn chicken eggs were injected with approximately 25 μL of either avian saline (0.72% NaCl) or 9.29 μmol L-glucose/kg egg in avian saline during the first 3 days of development (E_{0-2}) into the air sac of each egg. After sealing each injection sight with paraffin wax, all embryos were incubated in a forced air incubator at 37.5°C and turned every 4 h with the humidity ranging from 70% to 90%. At 11 days of development (theoretical stage 37, Hamburger and Hamilton 1951), blood was collected from chorio-allantoic blood vessels and serum isolated by centrifugation (10,000× g for 1 min). The mass of each chick embryo was determined followed by decapitation. Brains and livers were excised, tissue mass measured, and stored at –80°C for subsequent biochemical analysis. Serum D-glucose levels were measured according to Coles et al. (2008).

$r = -0.56$ [$F = (1, 13)$ 5.89; $p = 0.03$]

$y = 6.977 - 0.001$ (X); $R^2 = 0.312$

Fig. 173.4 The relationship
between hepatic 10-formyl
tetrahydrofolate dehydroge-
nase (10-FTHF DH) activities
and serum D-glucose levels in
embryonic chicks at 11 days
of development. $r = -0.55$
[$F = (1, 13)$ 5.63; $p = 0.04$],
$y = 6.395 - 0.0001$ (X);
$R^2 = 0.302$
$r = -0.55$ [$F = (1, 13)$ 5.63; $p = 0.04$]
$y = 6.395 - 0.0001$ (X); $R^2 = 0.302$

Hyperglycemia-induced inhibition of the remethylation and transsulfuration pathways explain increased brain and hepatic HoCys levels within embryonic chicks (Coles et al. 2008). This also raises questions as to whether exogenous 5-methyl THF or taurine ameliorates hyperglycemia-induced hyperhomocysteinemia, oxidative stress, and apoptosis in embryonic brains and livers.

Fig. 173.5 The relationship between brain taurine levels and serum D-glucose levels in embryonic chicks at 11 days of development. $r = -0.60$ [$F = (1, 12)$ 6.68; $p = 0.02$], $y = 2.236 - (3.837 \times 10^{-4}) X$; $R^2 = 0.358$

r = –0.60 [F = (1, 12) 6.68; p = 0.02]

y = 2.236 –(3.837 X 10^{-4}) X; R^2 = 0.358

Fig. 173.6 The relationship between hepatic taurine levels and serum D-glucose levels in embryonic chicks at 11 days of development. $r = -0.61$ [$F = (1, 9)$ 5.40; $p = 0.045$], $y = 12.799 - (0.002) X$; $R^2 = 0.375$
r = –0.61 [F = (1, 9) 5.40; p = 0.045]

y = 12.799 –(0.002) X; R^2 = 0.375

Chen et al. (1998) reported that taurine is essential for proliferation and neurite extension when culturing human fetal neurons isolated from the cerebral hemispheres in glial-free media and the folate pathway is well associated with the prevention of NTDs (Boyles et al. 2006).

173.13 Applications to Other Areas of Health and Disease

Oxidative stress, enhanced rates of apoptosis, and elevated HoCys levels are also observed in the brains of alcoholics and the brains of fetuses exposed to alcohol. Hyperhomocysteinemia is also seen in a number of serious and debilitating diseases (Carmel and Jacobson 2001) and exogenous HoCys is teratogenic in at least embryonic chicks (Miller et al. 2003, 2006). Consequently, exploring the regulation of folate metabolism; the regulation of the transsulfuration pathway; the use of antioxidants; the use of exogenous folates and possibly taurine; and a better understanding of how neurotrophic factors regulate developing neurons may not only provide us with a better understanding of the physiology and development of the nervous system, but may provide important clinical insights into several serious and debilitating diseases.

Summary Points

- Type-1 and type-2 diabetics have increased risk of ischemia-induced vascular damage. During oxygen-deprivation (ischemia), neurons are unable to convert glutamate to α-ketobutyrate and release excessively high glutamate levels. This causes increased cytoplasmic Ca^{+2} levels, increased reactive oxygen species levels, increased oxidative-stress, increased membrane lipid peroxidation, and apoptosis.
- Type-1 diabetics (insulin-dependent) exhibit spatial and episodic memory deficits and are associated with neuropathy within the hippocampus, hypothalamus, and possess reduced gray matter within the temporal lobes.
- Peripheral neuropathy in STZ-treated rats causes reduced (GDNF) levels, reduced activation of Ret tyrosine kinase receptors, and increased apoptosis rates.
- Type-1 diabetics (insulin-dependent) have reduced choline acetyltransferease activities, reduced AChE activities, and reduced acetylcholine levels and are associated with oxidative stress within the hippocampus and cerebral cortex (Table 173.3).
- During fetal/neonatal development, acetylcholine must stimulate brain neuronal M3 muscuranic acetylcholine receptors in order to prevent an underdevelopment of the anterior pituitary gland. However, the lack of M3 muscuranic acetylcholine receptor activation protects against the onset of type-2 (non-insulin-dependent) diabetes.

Table 173.3 Key features of neuropathy in type-1 diabetics

1. Neuropathy can occur as a result of momentary oxygen deprivation during ischemia-induced vascular damage and type-1 and type-2 diabetics are prone to ischemia-induced vascular damage.
2. During oxygen deprivation, neurons cannot convert glutamate to α-ketobutyrate and overstimulate nearby neurons with excessively high levels of glutamate via the N-methyl-D-aspartate receptor.
3. During neuropathy, reactive oxygen species are produced causing oxidative-stress and are seen during necrosis and apoptosis.
4. Oxidative stress causes membrane lipid peroxidation and is observed during necrosis and apoptosis.
5. Reduced utilization of cholinergic neurons is seen during oxidative stress and is associated with cognitive deficits.
6. Reduced levels of a tropic factor, such as glial cell line derived-neurotrophic factor, has been observed in peripheral neuropathy in streptozocin (STZ)-treated rats.
7. Elevated levels of circulating homocysteine in type-1 diabetics and decreased brain taurine levels are seen in STZ-treated rats.

This table lists key facts associated with neuronal damage (neuropathy) in type-1 diabetics and animals used to model type-1 diabetes

- Type-2 diabetics (non-insulin-dependent) are frequently obese, insulin-resistant, leptin-resistant, have elevated circulating triglycerides levels, and exhibit poor cognitive performance. Recent injection of triglycerides into the brains of lean mice impaired the NMDA receptor-mediated maintenance of hippocampal long-term synaptic potential (Table 173.4).
- Reduced and disrupted expression of hippocampal *BDNF* is associated with the onset of T2D. While VGF (nonacronymic protein)-deficient mice tend to resist the onset of T2D, exogenous TLQP-21 (a VGF isoform) reduced circulating leptin levels and ameliorated obesity in mice.
- Gestational diabetes stimulates c-Abl- and p53-induced signaling, reduced *Pax-3* expression, and increases apoptosis rates within mouse neural tube neuroepithelial cells.
- Gestational diabetes is frequently associated with abnormally low maternal arachidonic acid (20:4, n-3 and 20:4, n-6) and DHA (22:6, n-3) levels. Meanwhile, exogenous arachidonic acid injected into STZ-treated pregnant rats ameliorated the frequency of gestational diabetes-induced NTDs (Table 173.5).
- Gestational diabetes in pregnant rats caused increased density of insulin receptors within the ventromedial hypothalamus and lateral hypothalamus of fetal rats brains. However, no relationship between the densities of various GLUTs to hyperinsulinemia within various regions of the fetal brain was observed.
- Hyperglycemia in embryonic chicks has been induced and is associated with increased membrane lipid peroxidation rates, increased apoptosis rates, decreased SAM/SAH, and elevated HoCys levels within embryonic brains and livers.

Table 173.4 Key features of neuropathy in type-2 diabetics

1. Neuropathy can occur as a result of momentary oxygen deprivation during ischemia-induced vascular damage and type-1 and type-2 diabetics (T2D)are prone to ischemia-induced vascular damage.
2. During oxygen deprivation, neurons cannot convert glutamate to α-ketobutyrate and overstimulate nearby neurons with excessively high levels of glutamate via the *N*-methyl-D-aspartate receptor.
3. During neuropathy, reactive oxygen species are produced causing oxidative-stress and are seen during necrosis and apoptosis.
4. Oxidative stress causes membrane lipid peroxidation and is observed during necrosis and apoptosis.
5. Overstimulation of M3 muscuranic acetylcholine receptors in the peripheral nervous system has been associated T2D.
6. Reduced levels of a tropic factor, such as brain-derived neurotrophic factor, have been observed in obese, hyperglycemic mice.
7. Elevated levels of circulating homocysteine and the overexcretion of taurine are seen in type-2 diabetics.

This table lists key facts associated with neuronal damage (neuropathy) in type-2 diabetics and animals used to model T2D

Table 173.5 Key features of neuropathy in gestational (embryonic) diabetics

1. Neuropathy can occur before the vascular system fully develops because neuralation begins prior to angiogenesis.
2. While embryonic-derived neurons can undergo in vitro glutamate toxicity, the exact role of glutamate and the *N*-methyl-D-aspartate receptor in gestational/embryonic diabetes is unclear.
3. During neuropathy, reactive oxygen species are produced causing oxidative stress and are seen during necrosis and apoptosis.
4. Oxidative stress causes membrane lipid peroxidation and is observed during necrosis and apoptosis.
5. The role of acetylcholine and acetylcholine receptors during gestational (embryonic) neuropathy is unclear.
6. While reduced levels of tropic factors are possible, exact roles in embryonic neuropathy are unclear.
7. Elevated homocysteine levels and decreased taurine levels are seen in brains and livers of hyperglycemic chick embryos.

This table lists key facts associated with neuronal damage (neuropathy) in animals used to model gestational (embryonic) diabetes

- Elevated embryonic HoCys levels are teratogenic, cause NTDs, stimulate oxidative stress, and stimulate apoptosis in developing chick brains. In chicks, hyperglycemia-induced brain HoCys levels correlate with a hyperglycemia-induced inhibition of the folate-mediated remethylation pathway and inhibited taurine synthesis via the transsulfuration pathway.
- Oxidative stress, enhanced apoptosis rates, and elevated HoCys levels are observed in the brains of alcoholics and in embryonic brains exposed to alcohol. Consequently, exploring the regulation of folate metabolism and the transsulfuration pathway may provide us with a better understanding of hyperglycemia-induced neuropathy and alcohol-induced neuropathy.

Definitions of Key Terms

Apoptosis: Apoptosis and necrosis are two different forms of cell death and can occur at the same time. Necrosis begins with increased membrane fluidity via membrane lipid peroxidation and can be initiated by reactive oxygen species. The ultimate loss of cell membrane integrity spreads to all eukaryotic membranes and results in a total failure of all organelles, inhibition of protein synthesis, and random DNA fragmentation. Apoptosis, sometimes referred as genetically programmed cell death, is dependent on protein synthesis and utilizes a number of proteins including Annexin-V, poly(ADP-ribose)polymerase (PARP), and a number of caspases. PARPs deplete the NAD^+ pool by adding a poly-A tail to DNA fragments and can be detected by deoxynucleotidyl transferease-mediated dUTP nick end-labeled DNA fragments (TUNEL). Apoptosis can be initiated from outside the cell (extrinsic pathway) or inside the cell (intrinsic pathway). While complex, the extrinsic pathway begins with a receptor-ligand interaction at the cell membrane level or a lack of a tropic factor leaving a vacant binding-site on a membrane receptor. This initiates a signal transduction cascade that activates a number of initiator caspases and transcription factors. Ultimately, the activation of Bcl-2 proapoptotic signals, reactive oxygen species, and increased cytoplasmic Ca^{+2} levels activate Bcl-2 family proteins on the outer mitochondrial membrane. Once Bcl-2 family proteins are activated, the intrinsic pathway begins where mitochondria release cytochrome-c and Ca^{+2} into the cytoplasm. This activates the cytoplasmic protein Apaf-1 that binds and activates procaspase-9 and procaspase-3. Procaspase-3 is activated to caspase-3.

Caspase-3: Caspase-3 is a "killer" caspase and a protease. It will bind and cleave any protein that has a DEVD (aspartate-glutamate-valine-aspartate) domain. Whether apoptosis is initiated by the extrinsic pathway, which spreads to the intrinsic pathway, or initiated by direct activation of the intrinsic pathway, caspase-3 is activated and it's enzymatic activity level and/or presence is a convenient measurement of apoptosis rates.

Homocysteine: HoCys is a non-protein-coding amino acid. It is teratogenic in chick embryos and causes both apoptosis and membrane lipid peroxidation. Elevated levels of HoCys are seen in a number of debilitating disorders and can be caused by folate deficiencies and/or inhibition of the transsulfuration pathway.

Ischemia: Type-1 and type-2 diabetics have a 4- to 12-fold increased risk of stroke and ischemia-induced cerebral damage. As the microvascular system becomes occluded, downstream oxygen and glucose levels are momentarily depleted prompting necrosis and energy depletion of downstream cells. Inflammation of the occluded microvascular system is partially due to neutrophil recruitment causing enhanced neutrophil NADPH oxidase and xanthine oxidase activities and the production of reactive oxygen species. Increased oxidative stress is thought to exacerbate ischemia-induced cerebral damage and can promote apoptosis in nearby cells (Bemur et al. 2007).

Lipid peroxidation: Reactive oxygen species can cleave polyunsaturated fatty acids into shorter-chain fatty acids and toxic aldehydes and affect membrane integrity (fluidity).

> **Oxidative stress:** Membrane lipid peroxidation and increased apoptosis rates can ultimately kill cells undergoing oxidative stress. Oxidative stress is exacerbated by decreased levels of antioxidants, such as glutathione, and reduced antioxidant enzyme activity levels. Antioxidant enzymes include superoxide dimutase, catalase, glutathione peroxidase, and glutathione-*S*-transferase.
>
> **Reactive oxygen species:** Reactive oxygen species include oxygen radicals, hydroxyl radicals, and peroxynitrite radicals. During ischemia, reactive oxygen species can be generated by enhanced neutrophil NADPH oxidase and xanthine oxidase activities and by activation of neuronal nitrous oxide synthase.

174.1 Introduction

For millennia, lead exposure has harmed human health. While lead is found naturally within the Earth's crust, anthropogenic activities have resulted in widespread contamination of the environment (air, water and soil). Since the late 1970s, public health agencies and associated governmental efforts have dramatically increased the awareness of the toxicity of this element and provided regulation for common sources of lead exposure in a majority of the world's population. The most widely recognized efforts in reduction are associated with elimination of lead additives from the production of paint and petroleum products (gasoline, petrol). However, diet remains a significant source of lead exposure for humans within the modern, industrialized urban centers to the remote Brazilian Amazon. We will review how dietary lead exposures can arise from the ingestion of water, food, vitamins, supplements, pharmaceuticals, and traditional remedies. Lead contamination can occur at any step upon transferring these items from source to the consumer including the contamination of raw materials and implements involved in the preparation, processing, handling, and transport of these items (Table 174.1).

Table 174.1 Dietary sources of lead

- Contaminated drinking water arises from lead contaminated municipal water systems and from leaded pipes and plumbing, often within older homes.
- Food and other ingested items have significant lead levels after grown in lead-contaminated soil or in regions near sources of airborne lead particle emissions such as smelters, incinerators or roads with automobiles using leaded gasoline.
- Contamination of food and other ingested items may occur during the processing, preparation, handling by the producers, and transport to the consumer.
- Contamination of food and beverages may occur after being prepared on leaded cookware, served on lead glazed pottery, ceramics, and crystal and stored in lead-contaminated containers.
- Traditional medicines, pharmaceuticals, supplements, and vitamins are prepared or contaminated with leaded source materials.
- Ingestion of nonfood items related to pica activity provides another source of dietary lead.

This table provides an overview of common sources of lead found in ingested items

Table 174.2 Health effects associated with lead exposure (Adapted from ATSDR 2007)

System	Effect	Vulnerable population
Cardiovascular	Increased risk for hypertension	Adult, General
Developmental	Decrease birth length, stature, head circumference; Delayed sexual maturation	Pediatric, General
Endocrinological	Elevated TSH	Adult, Occupational
Gastrointestinal	Colic	Pediatric, General
Hematological	Decreased ALAD activity	Mixed Age and Source
Immunological	Increased serum IgE	Pediatric, General
Musculoskeletal	Dental caries and bone loss	Mixed Age, General
Neurological	Impaired motor skills, cognition, IQ, attention, executive functioning, social behavioral skills	Pediatric, General
Renal	Decreased GFR	Adult, General
Reproductive	Decreased fertility	Male, Adult Occupational

Lead exposure affects numerous systems within the human body. The effects listed in the table vary in their reversibility. The general population, particularly children, is vulnerable due to multiple sources of lead within the environment.

A number of factors modulate how dietary sources of lead harm the body. Factors such as the form (organic versus inorganic) of lead, age of a person, nutritional status of the individual, and pregnancy influence lead absorption.

Neurological aspects have been examined in cellular and animal models. Complex mechanisms of neurotoxicity are known. For human studies, epidemiologic cohorts have been established and longitudinally monitored to explore cognitive and neurobehavioral aspects of low, moderate, and high lead exposure levels.

While the focus of this work is on the neurological aspects of dietary lead, it is important to recognize that once lead is in the bloodstream, the systemic effects are largely independent of the source whether ingested or inhaled, but rely on the bioavailability pertaining to dose. Lead exposure affects all the major systems within the human body (Table 174.2).

Finally, this review will summarize future directions of research and public policy. Increasing numbers of studies find that low-level lead exposure is associated with adverse cognitive effects. These effects warrant continued action toward identifying sources and reducing lead levels in the environment that potentially threaten human health via ingestion or inhalation.

174.2 Dietary Sources and Intake of Lead

Lead levels within food itself are quite variable due to heterogeneous distribution of lead deposited within the soil and water, the contamination during open shipping of raw items and during processing, the transfer of lead from contaminated storage containers and plastic food wrappers with painted decals, and the transfer from inadequately glazed or heavily worn cookware and ceramic serving dishes. Dietary intake also depends upon cultural practices and individual diet. National regulations regarding lead usage and the practices monitoring compliance can also influence the amount of lead available for dietary consumption. Food lead concentrations have decreased dramatically in most nations primarily due to the reduction of airborne lead emissions and the prohibition of lead solder in storage cans, especially in milk for infant formula. Yet, in 2009 approximately 19 countries continue to use leaded petroleum products. Examining blood lead exposure models at levels above and below the contemporary action level of 10 µg/dL remains relevant toward understanding lead toxicity

Table 174.3 National statistics for dietary intake of lead from food (Adapted from Moschandreas et al. 2002; Marti-Cid et al. 2008; ATSDR 2005; UNEP 2008; EU SCOOP 2004)

Nation State(s)	Average dietary intake in µg/kg of body weight per day	Population
Australia	0.06–0.39	Adult males 25–34 years
	0.02–0.35	Adult females 25–34 years
	0.02–0.43	Boys 12 years
	0.01–0.34	Girls 12 years
	0.03–0.93	Toddlers 2 years
	0.01–1.19	Infant 9 months
Burkina Faso	0.9	52 µg Pb per day for 60 kg average weight
European Union	0.6	42 µg Pb per day for 70 kg average weight
Finland	0.24	17 µg Pb per day for 70 kg average weight
Mexico	3.5	3 µg/kg lead in food
Poland	1.48	Males 103.5 µg Pb per day for 70 kg average weight; 88.5 µg Pb per day for 60 kg average weight
Spain	0.644–0.85	Adult male assuming 70 kg living in Catalonia
USA	0.918	Males over 55 years
	0.895	Males over 20 years
	0.890	Males 13–19 years
	0.946	Females over 55 years
	0.920	Females over 20 years
	0.824	Females 13–19 years
	1.164	Children 7–12 years
	1.952	Children 1–6 years
	3.117	Non-nursing infants
	1.009	US population

This table provides a composite of national statistics reporting contemporary levels of lead intake for individuals in select nations obtained from dietary sources

in all populations. As lead is not degradable and thus, land is the ultimate repository, lead contamination continues to threaten many populations.

The United Nations Environment Program estimated that in 1987 the global average daily intake of lead was about 80 µg/day from food and 40 µg/day from drinking water. More recently, the joint Food and Agriculture Organization of the United Nations (FAO) and World Health Organization Expert Committee on Food Additives established a provisional tolerable weekly intake (PTWI) of 25 µg/kg of body weight, which is the equivalent of 3.5 µg/kg of body weight per day (WHO 2000). Examples of contemporary national estimates of daily intake of lead via food are shown in Table 174.3.

174.2.1 Levels of Lead in Raw Foods

In the European Union, data from national surveys of the adult population find that the major sources of dietary intake include bakery wares, cereals, fruits, vegetables, and beverages (Table 174.4). Levels of dietary lead intake for children were 6–15% above that of adults (not shown).

National surveys tend to focus on adult populations. Children may have lower absolute values of dietary lead intake; however, given their lower body weights, they may have a larger lead burden as they drink more fluids, eat more food, and breathe more air per kg of body weight.

In edible plants, lead contamination may occur from surface deposition of particulate matter or from the soil via the root system using direct foliar uptake and translocation within the plant.

Table 174.4 Daily intake (μg/day) of lead by adults from EU National Surveys (Adapted from EU SCOOP 2004)

Food	UK	DE	NO	BE	DK	FI	FR	HE	IT	IR	PT	SE	Mean
Bakery and cereals	4.0	6.0	2.2		2.35	0.08	9.63	3.2	4.35		0.53	1.43	3.4
Beverage	14	9.7	10.1	18.7	8.61	0.48	13.7		4.2		12.2	1.17	8.9

Sum per Nation	27	47	21	38	18	7	57	25	34	1.1	133	5	**42**

This table provides the amount of lead determined in national surveys of products consumed by adults within the European Union. The data were collected during different periods in the 1990s and 2000s and vary due to study methodology, regional and cultural factors

The bioavailability of lead within the soil depends on pH, amount of organic matter present, amount of additives (i.e. limestone) within the soil, soil moisture levels, cation exchange capacity, and the forms of lead in the soil. For a majority of raw foods, lead is present at low concentration levels. However, contamination during production and processing is responsible for enhanced lead intake via dietary sources. While cocoa beans have the lowest reported values for a raw food, manufactured cocoa and chocolate products have among the highest values reported for all foods (Rankin et al. 2005). Atmospheric emissions of lead particulates contaminate shells, which protect the raw cocoa bean quite well from lead. However, as the beans are harvested, sun dried, and processed, contamination of the cocoa bean can occur upon mixing with the shells. Subsequent transport, distribution, and product formulations also allow for further lead contamination.

In a remote, riverside population within the Brazilian Amazon, with no known documented source of environmental or occupational lead, Barbosa and colleagues found 57% of participants had blood lead levels equal to or higher than 10 µg/dL (Barbosa et al. 2009). The mean blood lead levels were 13.1 ± 8.5 µg/dL (males 15.3 µg/dL vs females 7.9 µg/dL). Upon investigating, the villages with the highest exposures had two sources of lead: the production of farinha and hunting. The artisanal production of farinha (flour) from manioc requires roasting the pulp over fire on metal plates that contain leaded alloy. The young men spend several hours stirring the pulp, inhaling lead vapors, and ultimately consuming the farinha with produced food. Raw manioc had a mean lead concentration of 0.017 µg/g $\pm$ 0.016 (range 0.003–0.04 µg/g) while that for farinha was 0.19 µg/g $\pm$ 0.10 (range 0.09–0.38 µg/g). The lead exposure from hunting arises from contamination of the game from bullets with leaded alloys.

174.2.2 Transfer of Lead to Food from Children's Hands

For Western societies, there is at least a century of human industrialized activity, which produced pervasive contamination of air, soil, and water. Airborne lead particles from industrial sources continue to be deposited in soil and water, and thus, enter the food supply. Household lead contamination occurs in homes previously painted (interior and/or exterior) with leaded paint and/or situated near major highways as the deposition of lead particulates from decades of leaded petroleum product emissions contaminate the soil. In 2000, 1.2 million housing units in the United States with low-income families having children under 6 years of age were reported with deteriorated paint, dust, or bare soil contaminated with lead (Jacobs et al. 2002). Young children, especially toddlers, obtain leaded dust on their hands as they crawl, learn to walk, fall, and move about their residential environment. Freeman demonstrated that children with previously elevated lead levels transferred significant amounts of lead dust to their food (Freeman et al. 2001) by handling food items with their hands. The residential environment, the parents and children's hygiene habits influence the amounts of dietary lead exposure.

174.2.3 Pica Activity

Pica activity, the consumption of nonfood items, particularly in children and pregnant women, greatly increases the risk of lead intake. Pica activity is attributed to cultural and low socioeconomic factors as well as nutritional deficiencies. For children engaging in pica behavior, the soil ingestion rate may be as high as 5 g/day. Blood lead levels ≥ 10 µg/dL in children 6–71 months of age have been associated with yard soil containing lead concentrations exceeding 500 mg/kg (ATSDR 2007).

174.2.4 Lead Contamination of Water

Another dietary source of lead is water used for drinking and in the preparation of beverages, particularly coffee, tea, and infant formulas. Within the United States (US), the Environmental Protection Agency (EPA) monitors municipal water supplies. In 1991, the EPA set an action level for lead in tap water at 0.015 mg/L (15 ppb) with estimates that less than 1% of the public water systems have water entering the distribution system at levels above 5 µg/L (ATSDR 2007). Lead in US drinking water potentially contributes 10–20% of total lead exposure in young children. Lead found in US drinking water is usually derived from corrosion of lead pipes, lead-based solder, and brass, chrome, or bronze plumbing fixtures with older residences. Lead corrosion can occur with soft, acidic water (low pH) and by increasing the dissolved oxygen demand. The temperature and length of time that drinking water resides in a pipe alters the lead concentration within the water. Studies found that 57% of public school buildings in Philadelphia in 2000 and 2001, as well as 22% reported in Seattle during 2004, had lead water levels exceeding recommended levels (Bryant 2004; Sathyanarayana et al. 2006). Lanphear et al. found that children who lived in housing with a water lead concentration greater than 5 ppb had blood lead concentrations that were 20% (1 µg/dL) higher than children living in housing with water lead concentrations below 5 ppb (Lanphear et al. 2002). In Washington DC, increased levels of lead in drinking water were found when the municipal utility changed the disinfectant from free chlorine to chloroamine, which precipitated out lead from leaded plumbing. The incidence of blood lead levels exceeding 10 µg/dL for children less than 30 months increased more than four times (Edwards et al. 2009). Lead in drinking water may be a significant contributor to lead burdens, especially in persons with elevated blood lead levels where no paint or soil source of contamination is found (Levin et al. 2008).

174.2.5 Lead in Traditional Medicines

Traditional medicines, herbal remedies, and other supplements often contain significant amounts of lead either contaminated in processing or directly included in the formulation of the product. Karri et al. found 76 case reports of lead encephalopathy associated with traditional medicine published between 1966 and February 2007 (Karri et al. 2008). For 95% of the reports, the patients involved were infants and young children with outcomes that included death (11%) and residual neurological deficits (21%). Such products are listed in Table 174.5 along with their intended benefit and regional origin. The amounts of lead within the products are variable.

174.2.6 Standards for Lead Intake

The US Food and Drug Administration provisional total tolerable intake levels (PTTI) currently set for young children, for adults, and for pregnant and lactating women are 6, 62.5, and 25 µg/day, respectively. Mindak et al. determined the lead content of 324 multivitamin–mineral products and found that an overall median value for lead exposure was 0.576 µg/day (Mindak et al. 2008). The estimated median and maximum lead exposures varied for young children (less than or equal to 6 years) at 0.123 and 2.88 µg/day, older children (7 years and over) at 0.356 and 1.78 µg/day, adult women at 0.842 and 4.92 µg/day, and for pregnant and lactating women at 0.845 and 8.97 µg/day. In another study, the concentration of lead found in 95 major dietary supplements with an emphasis on botanical-based products, ranged from 20 to 48,600 µg/kg with a median concentration of 403 µg/kg. (Dolan et al. 2003) For 11 products, the lead levels would exceed the tolerable lead intakes for children

Table 174.5 Traditional medicines, herbal remedies and supplements with lead (Adapted from CT 2009 and NY 2009)

Traditional medicines and herbal products	Uses and conditions treated	Region of origin
Albayalde	Vomiting, colic, apathy, lethargy	Mexico, Central America
An Kung Niu Huan Wan (Peaceful Palace Ox Gallstone Pill	Vertigo, delirium, high fevers, measles, restlessness	China
Anzroot	Gastroenteritis	Middle East
Azarcon, also known as Alarcon, Maria Luisa, Coral, Rueda	Gastrointestinal symptoms	Mexico
Ba Bow Sen	Hyperactivity and nightmares in children	China
Bal Chamcha	Problems w/liver, digestion, teething, milk intolerance, irregular stools, colic, regurgitation, bloating, parasites, poor sleep, poor dentition, myalgia	India
Bal Jivan	Baby tonic	India
Bala Goli/Fita	Dissolved in "gripe water"; used for stomach ache	India
Bala Guti	Children's tonic	India
Bala Sogathi	Growth of children, teething, cough, cold, fever, and diarrhea	India
Balguti Kesaria	Tonic tablets for infants with sudha and gold rickets, coryza, cough griping, skin roughness, worms, and dental problems	India
Bao Ning Dan	Traditional remedy for acne, pain, and removing toxins	China
Bezoar Sedative Pills	High grade fever, encephalitis, inflammation, infection, infantile convulsions, and viral meningitis	China
Bint Al Zahab	Diarrhea, colic, constipation, general neonatal use	Middle East, Iran
Bokhoor	Fumes calm infants	Saudia Arabia
Cebagin	Teething powder	Middle East
Chuifong tokuwan	Joint pain, arthritis	Asia
Cordyceps	Hypertension, diabetes, bleeding	China
Deshi Dewa	Fertility	India
Emperor's Tea Pill	Maintain body's natural balance	China
Farouk	Teething powder	Saudi Arabia
Ghasard also known as Ghazard and Qhasard	Aid digestion	India
Greta	Digestive problems	Mexico, Central America
Hai Ge Fen	Gastrointestinal ailments	China
Hepatico Extract	Healthy liver and regularity	China
Jambrulin	Diabetes, sugar control	India
Jeu Wo Dan	Cast dressing	China
Kandu	Intestinal problems	Asian
Kohl also known as Kajal and Surma	Eye cosmetic; Infant eye treatment; skin infections, navel of newborns	Middle East, Africa, South Asia, India
Koo Sar, Koo Soo	Menstrual cramps	Hong Kong
Liga	Digestive and stomach problems	Mexico
Litargirio	Deodorant/antiperspirant	Dominican Republic
Lu Shen Wan	Mumps, fever, infections, sore throat	China
Maha Yograj Guggul	Musculo-skeletal disorders	India
Mahalakshmi Vilas Ras with gold	Cold related symptoms, blood deficiency, wound healing, asthma	India
Mahayogaraj Guggulu	Rheumatic pain	India

(continued)

Table 174.5 (continued)

Traditional medicines and herbal products	Uses and conditions treated	Region of origin
Mahayogaraj Guggulu with silver and Makardhwaj	Rheumatic pain, bile, pigmentation disorders, blood purification, eye problems, weakness	India
Molleja de Pollo Molida	Stomach ache	Mexico
Murrah, al-murrah	Colic, stomach aches, diarrhea	Saudi Arabia
Navratna Rasa	General debility, rickets, calcium deficiency	India
Pay-loo-ah	Rash and high fever	Southeast Asia
Po Ying Tan	Childhood complaints	China
Qing Fen	Cast dressing, pain	China
Rueda	Colic, calm children	China
Santrinj	Teething powder	Saudi Arabia
Sundari Kalp	Menstrual health	India
Saoot	Eye injury, teething, navel of newborns	Middle Eastern
Surma	Teething powder	India
Swarna Mahayograj Guggulu with gold	Rheumatism, gas, cerebrovascular accident, menstrual cycles, menopause, progesterone deficiency, mental disorders, fertility	India
Tibetan Herbal Medicine	Mental retardation	Tibet, India
White Peony Scar Repairing Pills	Scars	Hong Kong
Zhui Feng Tou Gu Wan/ Zhiufeng Tougu Wan	Bone ailments, joint pain, numbness	China

This table provides a reference of traditional medicines, herbal remedies, and supplements known to have significant lead concentrations, their intended usage, and region of origin

and women of child-bearing age. In a survey of lead concentrations in 45 pharmaceutical products by Kauffman, the average mass of lead ingested by the consumer was 0.22 µg/day (Kauffman et al. 2007). The highest lead containing product, a calcium antacid and supplement, was estimated to deliver a maximum daily lead mass of 2.7 µg/day. Lead contamination of calcium supplements has been reported in several studies with older studies tending to find greater lead levels (Bourgoin et al. 1993; Ross et al. 2000; Scelfo and Flegal 2000; Kim et al. 2003). However, overuse of supplements with "safe lead levels" can result in lead intake in excess of current tolerable limits, particularly in vulnerable populations such as children, pregnant, and lactating women.

174.3 Factors Influencing Lead Absorption Within the Body

Lead can be characterized as organic or inorganic depending upon the chemical form. Organic complexes such as tetraethyl lead (TEL) and tetramethyl lead (TML), added to petroleum products for usage as antiknock agents in automobile engines, decompose into trialkyl and dialkyl lead compounds such as lead halides and ammonium lead halides upon atmospheric release and exposure to sunlight. These compounds further react with the air, water, and soil in the environment to produce inorganic forms, which are likely to be ingested as inorganic lead alloys and lead salts. Nearly all forms of lead from anthropogenic sources that are released to soil are inorganic lead compounds. Inorganic lead compounds can be inhaled and swallowed depending on the particle size. In the human body, inorganic lead is metabolized upon forming ligand complexes with amino acids, non-protein thiols, and various proteins (ATSDR 2007). Inorganic lead can be measured in tissues, blood, serum, urine, sweat, saliva, breast milk, cerebrospinal fluid, bone, nails, teeth, and hair.

174.3.1 Nutritional Modifiers

Nutritional factors are often mentioned as important modifiers of the metabolism and toxicity of lead. Essential elements, such as calcium, iron, and zinc, interact with lead as demonstrated in studies of both animal models and humans. These interactions are complex and inter-related. Evidence in the literature (see review (Ros and Mwanri 2003)) supports the nutritional statements listed in Table 174.6; however, some concepts remain controversial.

A recent clinical trial found that for mild-to-moderately lead-poisoned children with sufficient dietary calcium, further supplementation aimed at providing 1,800 mg of calcium per day had no effect on the change in blood lead levels (Markowitz et al. 2004). Another trial evaluated the efficacy of iron and/or zinc supplementation on cognitive performance in school children living in a lead-contaminated city (Rico et al. 2006). For 6 months, children were given 30 mg of iron, 30 mg of zinc, both or placebo daily. At three time points (baseline, end of the trial, and 6 months after the supplementation trial ended) children were evaluated with cognitive tests of memory, attention, visual–spatial abilities, and learning. Among the groups, no consistent or persistent differences in cognitive performance were found. The existing evidence does not support the usage of dietary interventions as a key strategy for a reduction in childhood lead exposure (Ballew and Bowman 2001).

There is a large body of literature supporting the concept that children absorb more lead than adults. Specifically, water-soluble lead absorption appears to be higher in appropriately nourished children than adults, 40–50% versus 3–10%, respectively (ATSDR 2007). However, the fact that blood lead levels rise may be related to bone turnover associated with growth rather than increased absorption within the gastrointestinal tract.

174.3.2 Lead Mobilization from Bone

Without current exposure, women's blood lead levels may rise from the mobilization of lead from bone, which occurs during times of physiological stress such as pregnancy, and lactation in response to calcium demands of the developing fetus and nursing infant (Manton 1985; Gulson et al. 1998). Since lead readily crosses the placenta, fetal lead exposure can be significant and related to adverse postnatal outcomes (reduced birth weight and gestational age, postnatal mental retardation, and impaired neurobehavioral development) as fetal blood lead concentration is highly correlated with

Table 174.6 Nutritional features associated with ingested lead

- Lead ingested during fasting is absorbed at a much higher rate than lead ingested with a regular food intake.
- Retention of lead in children is important due to more rapid gastric emptying times.
- Calcium inhibits the absorption of lead in mammals by binding to and displacing lead from common mucosal carriers in the intestinal tract, though it is short-lived, as calcium must be present with lead.
- Calcium deficiency mobilizes lead from the bone and distributes it via the blood to soft tissues, thereby increasing the concentration of lead in critical organs, particularly the brain.
- For experimental animals, iron deficiency increases lead absorption from the intestinal tract. In humans, the relationship is uncertain.
- Lead and iron compete for critical binding sites; lead further aggravates the features of iron deficiency.
- Iron deficiency and lead toxicity both adversely affect cognitive development. Children with elevated blood lead levels should also be evaluated for iron deficiency, as those at risk for one are likely to be at risk for the other.
- Blood lead levels and activity of zinc-containing heme enzymes, such as ALAD, are inversely related indicating lead can replace zinc in these systems.

The table summarizes how calcium, iron, and zinc influence dietary lead absorption and concentration levels

maternal levels (Goyer 1990). Calcium supplementation at levels of 1200–1,500 mg/day is recommended for pregnant and nursing women. For postmenopausal women and those with osteoporosis, bone mineral resorption can cause lead stored in the bones to be released into the blood.

174.4 Neurological Impact of Lead Exposure

174.4.1 Mechanisms of Action

The neurological impact of lead exposure has been examined in humans, animals, and in vitro systems for several decades (see reviews by Lidsky and Schneider 2003; Toscano and Guilarte 2005; Garza et al. 2006). Significant advancements have been made to our understanding of how lead exerts neurotoxicity to humans and animals. Multiple toxic mechanisms of action for lead are present in the brain, which are often variable in presentation, overlapping in function and opposing in dose–effect relationships. These mechanisms are listed in Table 174.7 (Garza et al. 2006). A common factor among many of these mechanisms is the ability of lead to mimic calcium. In both the developing and adult brain, the ability of lead to substitute for calcium allows selective passage into the brain across the blood–brain barrier. As mentioned previously, intrinsic factors (age, sex, etc.), genetic mechanisms of metal transport, nutritional factors, and dosage factors (form, concentration, duration, and timing) can modulate the lead concentration that reaches the human brain. Lead exposure during distinct periods of neurodevelopment can produce different effects. Chronic "low-level" exposure may also produce different effects from acute "moderate to high-level" exposures. Such modulation of factors can influence human outcomes and contribute to contradictory findings in model systems. While many animal models employ a dietary ingestion method for lead dosing, the majority of human epidemiological studies assume the primary exposure source is inhalation. The neurological aspects of lead exposure are dependent on exposure source as bioavailability modulates dose.

Many contemporary studies have sought to unravel the molecular and biochemical underpinnings associated with the cognitive and behavioral deficits associated with lead exposure. In children, the cognitive and behavioral effects of early, developmental lead exposure are now regarded as irreversible. Animal models, rats, and nonhuman primates with blood lead concentrations on the order of 10–15 μg/dL demonstrate deficits in learning, which are similar to those observed in children associated with lead exposure (Rice 1996; Cory-Slechta 2003).

Table 174.7 Neurotoxic effects and mechanisms of action for lead in the brain

- Apoptosis
- Calcium competition and substitution
- Disruption of calcium homeostasis
- Lipid peroxidation
- Alterations in neurotransmitter synthesis, storage, and release
- Excitotoxicity
- Alterations in the expression and operation of receptors
- Interference with second messenger systems
- Interference with mitochondrial metabolism
- Damage to the oligodendroglia and astroglia
- Zinc substitution in zinc-mediated processes

This table details the mechanisms of action found associated with lead toxicity in model systems

174.4.2 Protein Kinase C

In models of acute exposure, lead directly stimulates Protein Kinase C (PKC) activity at picomolar levels, which are 4–5 orders of magnitude greater than the action of calcium (Markovac and Goldstein 1988). Tomsig and Suszkiw subsequently found that lead, depending on the concentration range, was capable of both activating and inhibiting the enzyme (Tomsig and Suszkiw 1995). PKC influences synaptic transmission via synthesis of neurotransmitters, ligand-receptor interactions, conductance of ion channels, and dendritic branching. Evidence suggests that lead targets the γ-isoform of PKC, a calcium-dependent, neuron-specific isozyme of PKC involved in long-term potentiation, memory function, and spatial learning.

174.4.3 Neurotransmitters: Cholinergic, Dopaminergic, and Glutamatergic

Neurotransmitter systems, particularly cholinergic, dopaminergic, and glutamatergic, have important roles in brain development and cognitive function. Lead exposure decreases neurotransmission. For chronically lead-exposed animals, upregulation of cholinergic, dopaminergic, and glutamatergic receptors are generally consistent with findings of diminished presynaptic function.

Within the central nervous system (CNS), activity within the cholinergic neurons projecting from the basal region of the forebrain to the hippocampus is key for memory and learning activities. Lead blocks the evoked release of acetylcholine and diminishes cholinergic system function. Bielarczyk and colleagues found depression of choline acetyltransferase activity in the cortex and hippocampus of young adult rats exposed to lead only during early development (Bielarczyk et al. 1996). The study also found decreased functional cholinergic innervation in the hippocampus. These reported denervation-like effects in the hippocampus could represent an important factor in long-term learning and cognitive impairments following developmental exposure to low levels of lead (Bielarczyk et al. 1996).

The dopaminergic and glutamatergic systems play a role in many aspects of cognitive functioning including attention, impulsivity, flexibility, learning, and memory. Based on studies of rodents and nonhuman primates, it has been known for some time that the dopamine system is particularly sensitive to lead (Cory-Slechta 1995). Lead may impair regulation of dopamine synthesis and release. The prefrontal cortex has the highest concentration of dopamine of all cortical areas and is the region primarily involved with cognitive and executive functions. For the glutamatergic system, chronic developmental lead exposure increases the threshold of long-term potentiation (LTP) induction with a biphasic dose–effect relationship, and decreased magnitude of LTP. Decreases in stimulated glutamate release are a significant factor contributing to lead-induced changes in LTP. Alterations in the N-methyl-D-aspartate (NMDA) subtype of glutamate receptor can produce deficits in synaptic plasticity that affect learning and memory (Toscano and Guilarte 2005). Developmental lead exposure is able to modify NMDA receptor subunit expression, subunit composition, and synaptic localization resulting in activity changes for calcium-sensitive signaling pathways.

174.4.4 Neurological Symptoms Associated with Lead Encephalopathy

In humans with frank lead encephalopathy, blood lead levels typically exceed 70 μg/dL and manifest with initial symptoms that include headache, loss of memory, hallucinations, muscle tremors, ataxia, dullness, poor attention span, and irritability. At these blood lead levels and above, gastrointestinal

distress and other systemic features can also be present. As the condition worsens, seizures, paralysis, coma, and death can occur. In fatal cases, histopathological features include cerebral edema, perivascular glial proliferation, altered capillaries, and neuronal damage consistent with hypoxic–ischemic injury.

Exposures at blood lead levels exceeding 40 µg/dL, typically found in adults with occupational lead exposure, can produce symptoms including headache, malaise, altered mood state, fatigue, lethargy, forgetfulness, irritability, dizziness, and paresthesia. In addition to these features, a significant number of studies have reported neuropsychological effects such as disturbances in manual dexterity, reaction time, visual–motor performance, and cognitive performance.

174.4.5 Pediatric Epidemiological Studies

Human epidemiological studies in children assume that the majority of lead exposure arises from inhalation of automotive emissions and the ingestion of dust from paint residues. However, one study of children demonstrated convincing dose–response deficits in cognitive abilities of lead exposure arising from drinking water (Fulton et al. 1987).

174.4.6 Epidemiological Studies and Intelligence Quotient

Needleman and colleagues investigated pediatric low-level lead exposure in children from Chelsea and Somerville, Massachusetts. This study documented cumulative exposure to lead using a measurement of lead in deciduous teeth, assessed confounding factors, and employed multivariate statistical procedures. Needleman and colleagues reported a covariate-adjusted difference in child IQ of approximately 4.5 points between groups "high" and "low" in tooth lead (Needleman et al. 1979). Teacher ratings of children's behavior in the classroom indicated more behavioral problems and academic difficulties among children with higher concentrations of lead. Many cohort studies were developed to verify these findings and refine study design (i.e. employ blood lead measures). Subsequently, a number of meta-analyses have established that lead is robustly associated with dose-related declines in IQ (Needleman and Gatsonis 1990; Pocock et al. 1994; Schwartz 1994). Lanphear and colleagues conducted a pooled analysis of seven prospective studies that were started prior to 1995 (Lanphear et al. 2005). The analysis involved 1,333 children with complete data on confounding factors used in the multivariable analyses. A significant number ($N = 244$) of children with blood lead concentrations that never exceeded 10 µg/dL were included in the analysis. The participating sites included Boston, MA; Cincinnati, OH; Cleveland, OH; Kosovo, Yugoslavia; Mexico City, Mexico; Port Pirie, Australia; and Rochester, NY. The primary outcome measure was full-scale IQ assessed in school-age children with the Wechsler scales (mean age of testing was 7 years). The median lifetime average blood lead concentration was 12.4 µg/dL (5th–95th percentile 4.1–34.8 µg/dL). The mean IQ of all children was 93.2 (SD 19.2). Multivariable regression analysis resulted in a six-term model including the log of concurrent blood lead, study site, maternal IQ, a measure of caretaking quality (Home Observation for Measurement of the Environment (HOME)), birth weight, and maternal education. Using a log-linear model, the study's authors estimated a decrement of 1.9 points (95% CI 1.2, 2.6) in full-scale IQ for a doubling of concurrent blood lead. However, the IQ point decrements associated with an increase in blood lead from 1 to 10 µg/dL were 6.2 points (95% CI 3.8, 8.6) compared to 1.9 points (95% CI 1.2, 2.6) with an increase in blood lead from 10 to 20 µg/dL. The individual effect estimates indicated steeper slopes in cohorts with lower blood lead levels.

In the Rochester Lead Study analyses using only children with peak blood lead levels less than 10 µg/dL found for each 1 µg/dL increase in concurrent blood lead levels was associated with a statistically significant, covariate-adjusted 1.8 point decline in IQ at 5 years of age (Canfield et al. 2003a). Nonlinear semiparametric smoothing revealed a covariate-adjusted decline of more than 7 IQ points up to 10 µg/dL of childhood average blood lead, whereas a more gradual decline of 2.5 points was associated with an increase in blood lead from 10 to 20 µg/dL.

174.4.7 Neuropsychological Deficits in Pediatric Lead Cohorts

Cognitive abilities, such as attention and executive functions, language, memory and learning, and visuospatial processing have been explored in association with lead exposure. Two of these abilities, attention/executive functions and visual–spatial skills, have demonstrated convincing evidence of diminishment associated with lead exposure (Table 174.8).

174.4.8 Attention Skills

Bellinger and colleagues examined a subset of the Chelsea and Somerville cohorts at 19–20 years of age with a battery of attentional measures (Bellinger et al. 1994). Higher tooth lead concentrations were significantly associated with poorer scores on the Focus-Execute and Shift factors of the battery, supporting the notion that early lead exposure is associated with poorer executive/regulatory functions thought reliant on frontal or prefrontal regions of the brain. Canfield and colleagues evaluated executive functioning and learning in the Rochester Lead Study cohort using the Shape School Task with embedded protocols requiring inhibition and attention switching mental sets (Canfield et al. 2003b). The mean blood lead level at 48 months was 6.5 µg/dL (range 2–21) with 80% of the children below 10 µg/dL. Following covariate adjustment, blood lead concentration at 48 months was negatively associated with children's focused attention, naming efficiency, and inhibition of

Table 174.8 Lead-associated findings reported from pediatric epidemiological cohorts of low-to-moderate lead exposure

- Decreased measures of general intelligence
- Deficits in tests of visual–spatial skills
- Impaired performance on tests of spatial working memory
- Increased errors on test of visual–motor integration
- Impaired performance on tests of spatial memory span
- Increased time required for tests of manual dexterity
- Increased numbers of errors and false alarms on continuous performance test
- Impaired performance on tests of cognitive flexibility
- Deficits with short-term memory
- Impaired performance on test requiring inhibition of automatic responding
- Impaired performance on tests of attention and attention switching
- Decreased academic school performance
- Increased externalizing behaviors, aggressive behaviors, disruptive behaviors
- Increased teacher and parent rankings for hyperactive behavior
- Increased antisocial, delinquent behaviors

This table summarizes the neurobehavioral deficits found from published studies of childhood lead exposure

automatic responding. Children with higher blood lead levels also completed fewer phases of the task and knew fewer color and shape names. At 6 years of age, the Working Memory and Planning protocols from the Cambridge Automated Neuropsychological Test Battery (CANTAB) were administered to assess mnemonic and executive functions (Canfield et al. 2004). Following covariate adjustment, children with higher blood lead concentrations showed impaired performance on tests of spatial working memory, spatial memory span, cognitive flexibility, and planning as indexed by tests of intradimensional and extradimensional shifts and an analogue of the Tower of London task. At 16 years of age, a comprehensive neuropsychological battery was administered to Cincinnati Lead Study participants (Ris et al. 2004). Childhood blood lead levels in the Cincinnati cohort were high with 30% of the cohort having at least one blood lead concentration in excess of 25 µg/dL during the first 5 years of life. After covariate adjustment, the strongest association between lead exposure and cognitive performance was found for attention factor scores derived from a principal components analysis with the findings more prominent among male subjects.

In 1943, Byers and Lord reported problems with attention and aggression in their patients who recovered from acute lead encephalopathy (Byers and Lord 1943). Needleman reported that disturbances in behavior and social conduct are prototypical sequela among victims of lead poisoning (Needleman 2004). Parents frequently report that following recovery from an episode of acute poisoning their child's behavior changed dramatically, and became restless, aggressive, impulsive, and inattentive. In the Yugoslavian prospective study, concurrent blood lead levels were significantly associated with parent ratings on the Destructive Behaviors subscale of the Achenbach CBCL upon covariate adjustment (Wasserman et al. 1998).

Lead levels measured in blood and/or teeth have been associated with teacher ratings of hyperactive behavior, attentional and behavioral problems in many studies (Needleman et al. 1979; Fergusson et al. 1988; Silva et al. 1988; Thomson et al. 1989). Using data from the National Health and Nutrition Examination Survey (1999–2002), Braun and colleagues examined the available blood lead concentrations for 4,704 subjects 4–15 years of age, 4.2% of whom were reported to have ADHD and stimulant medication use (Braun et al. 2006). Following covariate adjustment, higher blood lead concentrations were significantly associated with ADHD. Subjects with blood lead levels > 2 µg/dL were four times more likely to have a diagnosis of ADHD and be on stimulant medication. Braun and colleagues determined that nationally lead exposure accounts for 290,000 excess cases of ADHD in US children.

174.4.9 Visual–Motor Integration Skills

Studies employing specific measures of visual–motor integration skills, such as the Developmental Test of Visual Motor Integration, the Bender Visual-Motor Gestalt Test, demonstrate strong evidence linking deficits with early lead exposure (Winneke et al. 1990; Dietrich et al. 1993; Baghurst et al. 1995; Wasserman et al. 2000). Ris and colleagues observed a significant association between prenatal maternal blood lead levels and deficits in visual–spatial and constructional skills as indexed by Visual-Constructional factor scores for Cincinnati Lead Study participants at 16 years (Ris et al. 2004).

174.4.10 Neuroimaging

Several case reports describe neuroimaging features associated with lead encephalopathy arising from the use of traditional medicines and occupational exposures (Mani et al. 1998; Atre et al. 2006; Karri et al. 2008). In general, blood lead levels within the encephalopathic range can produce focal

lesions with abnormal signal, calcified lesions, and edema. The distribution of the lesions is variable, but encompasses every brain lobe, including gray and white matter structures.

For children exposed to lead at low-to-moderate levels, "clinical" neuroimaging modalities (i.e. computerized tomography and magnetic resonance imaging (MRI)) provide very little insight into lead-associated injury responsible for cognitive deficits. Trope and colleagues performed MRI and MRS studies on a sample of 16 subjects with a history of elevated blood lead levels (23–65 µg/dL) prior to 5 years of age (Trope et al. 2001). The average time of evaluation was 8 years. Compared to age-matched controls composed of siblings or cousins without a history of undue lead exposure (i.e., ≤10 µg/dL), lead-exposed subjects exhibited a significant reduction in *N*-acetyl aspartate:creatine ratios within frontal cortical gray matter. *N*-acetyl aspartate is a metabolite shown to decrease in processes that involve decreased neuronal and axonal functioning and loss.

Using volumetric MRI, Cecil and colleagues also examined a subset of the Cincinnati Lead Study cohort (Cecil et al. 2008). In studies of 157 subjects between the ages of 19 and 24 years, analyses of whole-brain MRI revealed significant decreases in brain volume associated with childhood blood lead concentrations. Following adjustment for other significant covariates including age at time of imaging and birth weight, the most affected regions were within the frontal gray matter, specifically the anterior cingulate cortex and ventrolateral prefrontal cortex, which are areas associated with executive functions, including mood regulation, decision-making, and interpretation of sensory inputs. Areas of lead-associated gray matter volume loss were larger for males.

Using functional MRI, the influence of childhood lead exposure on language function was examined in a subset of 42 young adults from the Cincinnati Lead Study (Yuan et al. 2006). Subjects performed an integrated verb generation/finger-tapping paradigm. Higher childhood average blood lead levels were significantly associated with reduced activation in Broca's area, a recognized region of speech production in the frontal lobe of the left hemisphere. Higher blood lead levels were also associated with increased activation in the right temporal lobe, the homologue of Wernicke's area, which is associated with speech perception. These associations were statistically significant following adjustment for covariate including birth weight, and marijuana usage as assessed by a positive urine screen. Lead exposure during childhood reorganizes the brain circuitry responsible for language function in a striking, dose-dependent fashion.

174.5 Future Directions of Research and Policy

174.5.1 Research

The complex mechanisms of lead toxicity require further elucidation. Questions remain such as: (a) is there any "safe" level or threshold of exposure? (b) at what ages are humans, specifically children, most vulnerable to lead? (c) can dietary modifications and pharmaceutical interventions help to minimize the neurotoxic effects of lead? As we uncover more about the "normal" functioning of brain systems with emerging imaging technologies, we will also have the opportunity to study how lead perturbs cellular networks, as lead affects numerous neural systems.

Controlled trials of environmental interventions aimed at reducing an existing lead exposure source are necessary to offer options to exposed populations. Continued research understanding the low-level effects of lead exposure needs to be coupled with studies of concurrent exposures to other prevalent neurotoxicants. Examination of the current action level, 10 µg/dL, to possibly lower levels for children is important based upon emerging evidence of low-level lead exposure effects.

Table 174.9 Steps for reducing the harmful effects of lead exposure

- Remediate lead-contaminated soil, especially where children play and where food items are grown.
- Removal or abatement of leaded paint in homes.
- Removal of leaded dust from homes with frequent cleaning.
- Removal of cookware and storage containers containing lead.
- Replace water system lines to homes, plumbing, and pipes within homes.
- Provide nutritious diets with appropriate amounts of iron, zinc, and calcium.
- Provide appropriate monitoring of lead hazards in homes, schools, and other places where children play.
- Eliminate leaded additives in petroleum products, paint, jewelry, cosmetics, and other consumer items in all nations.
- Eliminate usage of traditional medicines, and supplements, which purposely include lead within the formulation.
- Minimize production of industrial materials containing lead.

This table summarizes actions that can be employed to minimize lead exposure

174.5.2 Policy Implications

Lead continues to threaten significant numbers of the world's population, as it remains present in several sources. The goal must be the prevention of lead exposure in all populations (Table 174.9). Elimination of lead additives to petroleum products and paint needs to be enacted in all nations. Primary prevention strategies to eliminate lead hazards in homes and workplaces must be implemented. Lead paint residues, particularly within dust and soil, are often found in the homes located in older, urbanized centers. Screening of high-risk, older housing units in urbanized centers for leaded paint and plumbing is needed to prevent exposure. Lead abatement, while costly, could provide greater savings in special education, medical, and crime-related costs. Lead added to paint continues to be found in toys and other consumer products. Support for regulations and resources for enforcements of existing standards must be strengthened.

Severe restrictions on industrial and all nonessential uses of lead will greatly minimize occupational exposures in addition to the general population. Uniform lead limits are also needed to insure the lowest achievable exposure to lead from pharmaceutical and dietary supplement products (Kauffman et al. 2007).

174.6 Applications to Environmental Neurotoxicants and Human Health

The decades of research in the field of lead neurotoxicity have demonstrated that exposure to lead is associated with neurological and neurobehavioral disorders in adults and children. Exposure to lead during infancy and childhood produces essentially irreversible deficits in cognition, attention, executive functions, intelligence, learning, memory, and increases in externalizing behavioral problems. The success in reducing environmental lead sources was difficult to achieve. Novel approaches with genetics, imaging, and epidemiological statistical modeling developed for investigating lead exposures offer tremendous potential to other toxicants. Confirmed and suspected ubiquitous toxicants such as mercury, traffic-related exhaust particles, tobacco smoke, polychlorinated biphenyls, pesticides, and some plastics may be responsible for human morbidities and disease in children and adults. Applying the lessons learned from lead to existing and emerging toxicants could improve the lives of significant numbers within the world's population.

174.7 Key Facts of Lead Toxicity

- Lead exposures have decreased dramatically due to the elimination of lead additives in petroleum products, paint, and lead solder in food cans.
- Lead remains a health threat as it remains present in our environment, in dust, land and water. Food grown in contaminated soil, handled by children living in home environments with lead dust from leaded paint residues and water obtained from leaded plumbing continue to serve as a source for potential lead exposure in children.
- Traditional medicines, herbal remedies, and supplements can contain significant amounts of lead.
- Factors such as age, sex, fasting status, nutritional deficiencies such as zinc and iron deficiency and pregnancy status for women modulate the amount of lead that enters the blood stream and ultimately, the brain.
- Human epidemiological studies find significant cognitive, neuropsychological, and motor deficits related to blood lead levels, even at levels below the currently set action level of 10 μg/dL.

Summary Points

- Despite efforts to reduce human exposure, lead contamination, particularly via dietary sources, remains a significant global health problem.
- Dietary lead exposures can arise from the ingestion of contaminated water, food, vitamins, supplements, pharmaceuticals, and traditional remedies.
- Lead contamination can occur at any step upon transferring these items from source to the consumer including the contamination of raw materials and implements involved in preparation, processing, handling, and transport of consumed items.
- Factors such as the form (organic versus inorganic) of lead, age of a person, nutritional status of the individual, and pregnancy influence lead absorption.
- Complex mechanisms of lead neurotoxicity are implicated from in vitro, animal, and human epidemiological studies.
- Meta-analyses of pediatric epidemiological cohorts have established that lead is robustly associated with dose-related declines in IQ.
- Recent advanced neuroimaging studies suggest gray matter neuronal volume loss and reorganization of function associated with low-to-moderate childhood lead exposure.

Definition and Explanations of Key Terms

Anthropogenic: Processes or materials are those derived from human activities
Cognitive: Process of thinking, comprehension, reasoning, learning, or understanding
Covariate: It is a variable that is possibly predictive of outcome under study
Epidemiological: Study of factors affecting the health of populations
Executive functions: Processes for planning, cognitive flexibility, abstract thinking, rule acquisition, initiating appropriate actions and inhibiting inappropriate actions, and selecting relevant sensory information
Hippocampus: A structure within the limbic system of the brain thought responsible for long-term memory and spatial navigation

> **Long-term potentiation:** Major cellular mechanism responsible for memory and learning as neurons simultaneously communicate.
>
> **Neuropsychological:** Refers to brain processes and behaviors relating to mental and behavioral functions
>
> **Neurotoxic:** An agent which adversely acts on nerve cells
>
> **Toxicant:** A chemical compound introduced into the environment by human activity that has an affect on organisms

175.1 Introduction

Mercury is a heavy metal emitted into the atmosphere from both natural (such as volcanoes) and human sources (power plants, mining, waste incineration etc.) (http://www.epa.gov/mercury).

Atmospheric mercury in rainwater enters lakes and oceans, where microbial activity converts inorganic mercury into organic methylmercury. Methylmercury is readily absorbed and actively transported into tissues. Thus, methylmercury bioaccumulates in aquatic food chains and concentrations are magnified through the food chain. Larger, longer-living predators (e.g. swordfish, shark) have higher tissue concentrations, while smaller or shorter-lived species (e.g. shellfish, salmon) have very low concentrations. (http://www.epa.gov/mercury/report.htm)

Our knowledge of the effects of methylmercury poisoning on a population is based on two well-known industrial accidents. Industrial pollution of Minamata Bay, Japan in the 1950s poisoned local fish stocks and when local people consumed these contaminated fish, they suffered extensive neurological damage including paraplegia, ataxia, paresthesias, confusion, and in some cases, death (Tsubaki and Takahashi 1986). Visual symptoms reported include sudden bilateral blindness, constricted visual fields, and poor night vision. Seed grain contaminated by mercury mistakenly made its way into the food chain in Iraq in the 1970s and caused similar acute and chronic effects (more than 6000 people hospitalized, 459 deaths, and extensive neurological defects). (Bakir et al. 1973)

175.2 Neurological Findings

In adult monkeys and humans, methylmercury exposure has been linked to constriction of the visual field and abnormal color vision (Korogi et al. 1994). Korogi et al performed MR imaging of the brains of patients with known Minamata disease. The visual cortex, the cerebellar vermis and hemispheres, and the postcentral cortex were significantly atrophic. MR also demonstrated lesions in the calcarine area, cerebellum, and postcentral gyri. Korogi et al later looked at the striate cortex in patients with known Minamata disease and visual field constriction. They found a correlation between the visual field defect and the extent of dilatation of the calcarine fissure. (Korogi et al. 1997).

Ventura et al (Ventura et al. 2004) have reported on electrophysiological findings in patients with a history of mercury intoxication. Full-field ERGs showed that scotopic, photopic, peripheral, and midperipheral retinal functions were affected, and the multifocal ERGs indicated that central retinal function was also significantly depressed.

Electrophysiological testing of workers exposed to mercury vapors found a significant reduction of Visual Evoked Potential (VEP) latency, especially for the N75. (Urban et al. 2003) Further work completed in 2003 identified greater color confusion, greater errors on color, testing and an increased frequency of type III dyschromatopsias (blue–yellow confusion axis) in comparison with the control group. Cavalleri et al (Cavalleri and Gobba 1998) studied a group of workers with high levels of urinary mercury and found a dose-related impairment of color discrimination. Following changes to their work practices, mercury levels 12 months later had fallen to one-tenth of the previous levels and their color vision had returned almost to normal.

Neurological recovery after removal of the source of mercury is variable. Color vision impairment as a result of occupational mercury exposure was noted to be irreversible in one large study (Feitosa-Santana et al. 2008). Mercury-exposed patients had significantly worse color discrimination ($p < 0.02$) than controls, as evaluated by the size of MacAdam's color discrimination ellipses and color discrimination thresholds along protan, deutan, and tritan confusion axes. These changes persisted and were unchanged three years later. Other symptoms such as peripheral neuropathies have been noted to persist with little improvement, even up to 30 years later, after prolonged occupational exposure to inorganic mercury(Letz et al. 2000)

175.3 Children and Mercury Exposure

Children with raised blood mercury concentrations have been studied for changes in visual function testing. Saint-amour et al (Saint-Amour et al. 2006), examining preschool Inuit children living in Nunavik Northern Quebec, reported similar reduced VEP latency to those found in mercury-exposed workers. Many seaside communities depend on fish as a major food source. A large study by Davidson et al. (1998) followed 711 mother and child pairs in the Seychelles over a 5-year period from pregnancy through childhood. Using 6 age-appropriate test of neurodevelopment, no adverse effect was found to be associated with a raised hair mercury level of 6.5 ppm (US average is quoted as 0.47–3.8 ppm).

175.4 Pregnancy and Mercury Exposure

Methylmercury crosses the placenta, and fetal exposure correlates with maternal exposure. Following the Minamata and Iranian disasters, marked neurodevelopmental abnormalities were found in children exposed in-utero to very high levels of mercury. 'Gochfeld 2003' Very high doses

of methylmercury have been associated with mental retardation, poor motor function, ataxia, and seizures (Harada 1995).

In the mid-1980s, 2 large cohort studies were initiated: one in the Republic of Seychelles called the Seychelles Child Development Study (SCDS) (Van Wijngaarden et al. 2006) and the other in the Faeroe Islands. (Myers and Davidson 1998) In the Seychelles study, of a total of 46 primary end points, only one end point showed a possible adverse association with prenatal methylmercury exposure. The Faeroes study reported adverse associations between prenatal methylmercury exposure and tests of memory, attention, language, and visual–spatial perception measured at 7 years of age.

Seafood species are also rich dietary sources of selenium. Selenium may reduce tissue accumulation of mercury in fish and humans. (Seppanen et al. 2000) The protective effect of selenium may partly account for conflicting results of studies of mercury exposure and neurodevelopmental indexes in children. (Raymond and Ralston 2004)

175.5 Chronic Diet-related Exposure

We recently published an unusual case of diet-related mercury poisoning resulting in visual loss in a 36-year-old man of Caribbean origin living in the UK. (Saldana et al. 2006) His unexplained neurological symptoms (peripheral neuropathies, reduced visual acuity, central scotomas) were eventually linked to his raised blood mercury levels at 13.9 µg/l. The Environmental Protection Agency (EPA) quotes the US average blood mercury to be 1.3 µg/l (http://www.epa.gov/waterscience/fishadvice/advice.html). He underwent electrophysiological testing and multifocal visual evoked potential showed almost abolition of the central responses in both eyes. Multifocal ERG also showed mild reduced amplitudes and delayed responses.

His liking for imported Caribbean fish known to be high in mercury levels (3 or 4 red snapper fish, every day) was identified as the likely source and his change in diet has to date produced little improvement.

A previously published case-report highlights a 53 year-old woman with similar dietary exposure. She had been eating fresh fish between 6 and 12 times per week for more than 10 years and ate swordfish at least twice a week. Her hair mercury levels measured 67.8 ppm (US average is quoted as 0.47–3.8 ppm). She initially presented to her doctor with skin erythema, and later developed stomatitis, headaches, and tinnitus. (Risher John 2004) No further details were provided as to her progress after reducing exposure to mercury.

175.6 Applications to Other Areas of Health and Disease

The EPA states the reference dose, (ie the allowable upper limit of daily intake) for methylmercury of 0.1 ug/kg per day, which is 50 µg/wk for a 70-kg woman. This was calculated from the lower 95% confidence limit at which gestational exposure to mercury may produce abnormal neurological test scores, multiplied by a 10-fold uncertainty factor. The EPA also has published a focused advisory for women of childbearing age, nursing mothers, and young children. (http://www.epa.gov/waterscience/fishadvice/advice.html)

The advisory specifically advises such individuals to avoid shark, swordfish, golden bass, and king mackerel (each containing >50 µg methylmercury per serving); to eat up to 12 oz/wk (two average meals) of a variety of fish and shellfish lower in mercury; and to consult local advisories for locally caught freshwater fish. However, a recent Lancet article showed mothers who consumed more than the US recommendations (340 g or three portions per week) had children who scored better on tests of fine motor, communication, and social skills. (Myers and Davidson 2007)

A large review published in JAMA highlighted the benefits of regular fish consumption (1–2 servings per week of oily fish) in adults (Mozaffarian and Rimm 2006). It identified the reduction in risk of coronary death by 36% and total mortality by 17%.

Summary

- Many studies have tried to identify whether the known benefits of a diet rich in seafood are outweighed by the dangers posed by methyl mercury.
- Large studies on childhood neurodevelopment in communities with a high rate of fish consumption show conflicting results depending on the type of neurological tests used.
- Overall, it is felt that any adverse effects of methylmercury are likely to be minimal alongside the known nutritional advantages of fish oils and omega-3 in a child's neurodevelopment.
- Fish consumption in adults has been shown to confer significant cardiovascular health benefits. Studies suggest people may be avoiding fish consumption due to the risks of methylmercury toxicity and may miss out on the known health benefits of fish consumption.
- Visual changes associated with mercury exposure depend on the duration and degree of exposure.
- Toxic effects on the brain and optic pathways are unfortunately likely to be irreversible.
- Diet-related visual loss is extremely rare and is not a risk to people who keep within the common-sense guidelines

---

Definitions

Inorganic mercury: A heavy metal found in the environment, which is nontoxic and cannot be absorbed in this form

Methylmercury: When mercury is converted into this organic form it can be absorbed and accumulated in tissues resulting in toxicity

Minamata disease: Called after the Minamata area in Japan where it was first described, it is a broad spectrum of neurological disorders caused by exposure to high doses of methylmercury.

Neurodevelopmental testing: A complex series of tests that compare many neurological functions (such as memory, language, motor function and spatial awareness) in subjects with expected age-matched levels in a control population.

Electrophysiological testing: Visual stimuli are introduced to the patient and the electrophysiological responses produced by the photoreceptors are measured by contact skin probes around the eyes. These findings are compared to expected average responses in a control population.

Key facts on mercury exposure and vision

1. Most significant cases of visual loss are as a result of industrial accidents, where there was exposure to very high levels of methylmercury.
2. Most people will only be exposed to methylmercury in any significant quantities if they consume seafood.
3. Certain fish (e.g. those higher up the food chain) will have considerably higher levels of methyl mercury than those short-lived species
4. Recommended guidelines suggest 1–2 servings of oily fish will provide most people with the beneficial effects without being at risk of methylmercury toxicity.

176.1 Introduction

Dementia is characterized by severe cognitive decline, which impacts on daily living (American Psychiatric Association 1994). Its most common form is Alzheimer's disease (AD). Dementia is on the increase with an increasing aging population, particularly in developing countries. The human and economic costs of dementia are high and it is therefore important that cheap and easily adaptable preventive measures are identified. Given its biological plausibility (see Sect. 176.8), eating soy could be a potential preventive measure against cognitive impairment. This chapter describes the effect that phytoestrogens have on the brain and cognitive function in the elderly. The incidence of AD is lower in East Asian countries than in Western populations (see Sect. 176.9). Furthermore, East Asian populations consume significantly more soy in their daily diets. It has thus been hypothesized that these observed differences in AD prevalence can be attributed, in part, to the isoflavone-rich diets in Japan and China compared to the USA and Europe and the potential positive effects that isoflavones can have on the brain. However, other healthy lifestyle choices (e.g., consumption of fruit and vegetables, less alcohol consumption, more exercise and a lower body mass index, etc.) could also attribute to lower AD risk in these countries. In this chapter, we review the biochemistry of phytoestrogen, the food it occurs in and its effect on the brain using data derived from animal and cell culture studies, as well as data from observational and treatment studies in humans.

176.2 Soy, Tofu and Phytoestrogens

The soybean is an important part of the diet in East Asian countries, with increasing popularity in Western countries (see Table 176.1). Soy is used in the production of a number of food products, with the most well known being tofu (see Table 176.2). Soy foods contain varying quantities of phytoestrogens.

Phytoestrogens are naturally occurring polyphenolic molecules found in plants. Phytoestrogens are found in abundance in the soybean (and soybean-based products such as tofu) as well as other fruits, vegetables, grains, legumes and clover (Kurzer and Xu 1997). Phytoestrogens, or plant hormones, are very similar to estrogens (E) in their physiochemical and physiological properties (Murkies et al. 1998; Setchell 1998; Kurzer and Xu 1997). The Food Standards Agency (FSA) defined phytoestrogens as 'any plant substance or metabolite that induces biological responses in

Table 176.1 Key facts of soy

1. The soybean is an oilseed that is an important source of protein and vegetable oil and contains omega-3 fatty acids, alpha-Linolenic acid, and is the richest source of isoflavones.
2. Oil (20%) and protein (40%) account for approximately 60% of the weight of the soybean, with the remainder consisting of carbohydrate (35%) and approximately 5% ash (Mohamed and Xu 2003).
3. The majority of the compounds in the soybean are heat-stable, which makes the soybean suitable for high-temperature cooking to produce tofu, soymilk and textured vegetable protein (Mohamed and Xu 2003).
4. Soy-based foods have been eaten in Asian societies for over 1,000 years and are an important part of everyday diet (Murkies et al. 1998).
5. Soy is used to make foods such as tofu, tempe miso, natto as well as other products such as soy milk and soy sauce (Murkies et al. 1998).
6. Soy consumption is substantially higher in Asian societies than in Western countries with populations in Japan, Taiwan and Korea consuming approximately 20–150 mg/day from a variety of soy-based foods, compared to a much lower (approximately 1–3 mg/day) intake in Western populations (Murkies et al. 1998)

This table shows the key facts about soy which includes its composition, origins and uses in diet

Table 176.2 Key facts of Tofu

1. Tofu is of Chinese origin, although the exact origins and discovery have not been confirmed.
2. Tofu is made by coagulating soy milk from the soy-bean curd and using salt or acid coagulants. This is then formed into blocks and processed in a variety of ways to form different types and textures.
3. Tofu is relatively bland in taste and therefore picks up flavours easily. Because of this, it is used in Asian cooking in a wide variety of ways including soups, stews, stir-fries, eaten raw or stuffed with other fillings.
4. Although it originated from China, the spread of Buddhism (which places high importance on proteins and has a strict vegetarian diet) meant that tofu was then introduced into the diet in Korea, Japan, and other parts of East Asia, such as Indonesia, in the late eighth century.
5. In Western countries, tofu was not well known until the middle of the twentieth century with increasing popularity and adoption of vegetarian diets. It is not eaten widely but is popular amongst vegetarians, and promoted as a 'healthy superfood'.
6. Tofu contains isoflavones (a type of phytoestrogen) primarily in the aglycone form which previous research has shown has effects on the human brain similar to that of estrogen (a natural sex hormone).
7. The effects of consuming tofu on brain function are not fully known with studies reporting both positive and negative effects.
8. The effects of tofu consumption on the brain have been attributed to the high quantities of isoflavones (a type of phytoestrogen which mimics the effects of natural estrogen) as well as possibly other chemicals (e.g., formaldehyde) added in the processing of tofu which may be toxic to the brain.
9. It is possible that age, gender, quantity consumed and habitual intake may influence if tofu consumption has a protective or negative effect on cognitive function.

This table lists the key facts about tofu explaining its origins, the differences between populations in its consumption and its effects on cognitive function

vertebrates and can mimic or modulate the actions of endogenous, usually by binding to estrogen receptors' (FSA 2002). Es are naturally occurring hormones that promote secondary female sex characteristics and fertility. However, their role in also maintaining cognition in older women and men is now disputed, despite basic sciences data supporting their potential protective effects on the brain (see book edited by Hogervorst et al., 2009). The role of phytoestrogens in protecting the brain is less well investigated and this chapter aims to review the existing evidence available.

176.3 Phytoestrogen Classification

Phytoestrogens can be classified into three main categories; lignans, coumestans, and isoflavones. The most potent estrogenic aglycone isoflavones, and those mostly discussed in the current chapter, are daidzein and genistein (Fig, 176.1).

Isoflavones resemble estrogens in their heterocyclic phenol structure. The location of the hydroxyl groups allows binding to the estrogen receptor (ER) protein, and the A and C rings of isoflavones are similar to the A and B rings of 17β-estradiol (E2), the most potent E (Ganora 2008).

176.4 Application to Other Areas of Health and Disease

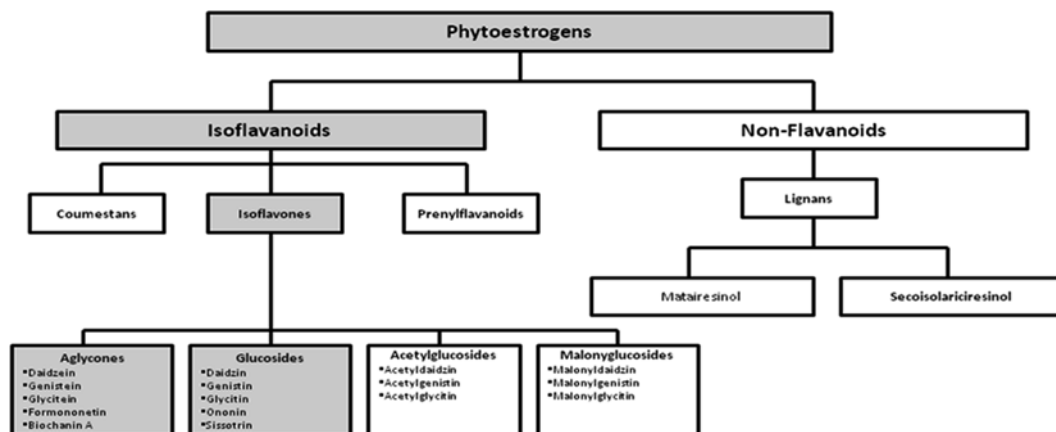
Before we discuss the possible effects of isoflavones on the brain and cognition, it may be important to highlight other more researched benefits (or potential increased risks) of phytoestrogen consumption. East Asians (who show high consumption of soy products) and Western populations show different prevalence rates for certain health conditions (Adlercreutz 1990), which could indirectly impact on cognitive health and risk of secondary dementias (APA 1994). Table 176.3 briefly describes some of these areas of research findings.


Fig. 176.1 Classification of phytoestrogens. This figure shows the classification of phytoestrogens. This chapter focuses on the isoflavones aglycones and glucosides
Fig. 176.2 Chemical similarities of aglycone isoflavones and oestradiol. Figure shows the structure of 17β-oestradiol, as well as the aglycone isoflavones genistein, daidzein, and glycitein. Aglycone isoflavone structures possess the phenolic (A) and hydroxyl (B) moieties also seen in estradiol, with a similar distance between the two groups (FSA 2002)

Table 176.3 Application to other areas of health and disease

- Asian population having a lower prevalence and incidence of some cancers, e.g., breast cancer (Wu et al. 2008) and prostate cancer (Dhom 1991).
- High soy intake has been associated with lower incidence of breast cancer (Wu et al. 2008) and prostate cancer (Coward et al. 1993).
- Concern has recently arisen from the reports of in vitro and animal studies finding an *increased* risk of breast cancer with soy isoflavones (Ju et al. 2006).
- Geographic differences in cardiovascular health have also been positively linked to soy intake (Azadbakht et al. 2007), as has a low prevalence of osteoporosis (Chiechi et al. 2002), and some menopausal symptoms (Maskarinec 2003).
- However, most research into the health effects of phytoestrogens has been on the basis of animal models and in vitro cell culture studies with only limited clinical assessments (see Knight and Eden 1996).

This table lists some other areas of health and disease which have shown cross-cultural variation and been linked to soy intake

176.5 Biological Mechanisms Explaining Neuroprotective Effects of Phytoestrogens

A number of studies have shown neuroprotective effects of isoflavones on various biological mechanisms. For full reviews see Murkies et al. (1998); Setchell (1998); and Adlercreutz and Mazur (1997). Isoflavones (and coumestans) thus have the ability to bind to the ERs in the mammalian body, but with less affinity than E2. They have shown greater binding to the ER-beta (ERβ) than the ER-alpha (ERα) receptor sites and can moderately interfere with the endogenous E-responsive signalling (Fitzpatrick 2003). On the other hand, genistein initiates greater gene transcription of ERα compared to ERβ, and also has the ability to bind to the progesterone (P) and androgen receptors (Fitzpatrick 2003) In postmenopausal women, who have very low levels of endogenous estrogens, phytoestrogens have greater potential to bind to ER than in premenopausal women, whose endogenous estrogens levels are much higher which renders greater competition for ER sites (Kuiper et al. 1998). Phytoestrogens can thus behave as estrogenic antagonists in environments with high levels of estrogens (e.g., during the ovulatory phase in premenopausal women), but can act as estrogenic agonists in low estrogenic environments (e.g., in postmenopausal women) (see Boettger-Tong et al. 1998; Murkies et al. 1998).

Although a great deal of attention has been paid to effects of phytoestrogens on peripheral systems, research is limited concerning the influence of phytoestrogens on the nervous system and cognitive function (Linford and Dorsa 2002; Halbreich and Kahn 2000) Phytoestrogens can directly protect the brain and act upon mechanisms thought to be implicated in Alzheimer's disease (AD, the most common form of dementia), such as the formation of tangles by tau protein phosphorylation and accumulation of the toxic amyloid-beta (Aβ) in plaques (Kim 2000). Phytoestrogens have been found to demonstrate a neuroprotective effect by attenuating tau protein phosphorylations (Kim et al. 2000), and by protecting cells against Aβ-induced apoptosis (self-programmed cell death) (Bang et al. 2004). The hippocampus is thought to be implicated in early AD (Reitz et al. 2009). Phytoestrogens have been found to regulate choline acetyltransferase, nerve growth factor, and brain-derived neurotrophic factor in the hippocampus, and also in the frontal cortex of female rats (Pan et al. 1999), which also is thought to play an important role in cognitive aging (see, e.g., Isingrini and Taconnat 2008).

Genistein and daidzein have also been found to protect hippocampal and cortical neurons against several forms of induced neurotoxicity (Occhiuto et al. 2008; Sonee et al. 2004). In an in vivo rat model study (Zeng et al. 2004), genistein reversed Abeta25–35-induced apoptosis and related cell pathology. Abeta25–35-induced apoptosis is associated with an increase in intracellular levels of

free Ca^{2+}, the accumulation of reactive oxygen species (ROS), and the activation of caspase-3 and is further characterized by loss of cell viability and neuronal DNA fragmentation. Trieu et al. (1999) reported that cerebral lesions in mice caused by singlet-oxygen-induced cerebral strokes were reduced by 44% with genistein treatment compared to controls, supporting the potential antioxidant effects of soy isoflavones. Genistein was also found to increase the activity of anti-oxidant enzymes (Lee et al. 2005) and has earlier also been shown to have antioxidant effects on neurons exposed to free radical damage (Lee et al. 2005).

We must note that although these studies distinctly show neuroprotective qualities of genistein, other studies have reported that genistein can also induce apoptosis and damage in neurons. The association between phytoestrogens and brain function may therefore not be linear (e.g., more is always better). For example, Choi and Lee (2004) reported that rats consuming a very large dose of genistein (20 mg/day) showed an increase in lactate dehydrogenase (LDH), a marker of neuronal damage, in brain tissue, which was not the case for rats on low genistein regimes (2 mg/day). DNA fragmentation was seen in both treatment groups. It must be noted that these amounts of genistein given to rats in these studies would far exceed the normal amount of isoflavones that are given to human participants in treatment trials or eaten in a normal daily diet. For example, assuming a rat weighed approximately 300 mg and the average human weighs approximately 60 kg, a rat being given a dose of 2 mg/day is then the equivalent of giving a human 1,200 g/day of genistein. As we have previously discussed, even in populations where isoflavone consumption is very high (e.g. 100 mg/day = 0.1 g/day), this toxic dosage would equate to over 12,000 times the quantity of normal daily consumption.

176.6 Different Soy Foods and their Composition

Many databases have been developed to list the isoflavone content of soy foods (Beecher et al. 2000; Horn-Ross et al. 2000). A summary is given in Table 176.4. Soy is the richest source of genistein, is abundant in daidzein, and is the only source of glycitein (Zhao and Brinton 2007). The estrogenic effect of soy has been attributed to genistein and daidzein, as well as the daidzein metabolite, equol. Equol has high estrogenic activity. However, there are individual (genetic) and cross-cultural differences in the ability (or lack of it) to produce equol in the intestines (see discussion). The soy-bean is cultivated and processed in different ways to make products from its different components, and this can have a significant effect on the pharmacokinetics and pharmacodynamics of isoflavones. For example, consumption of tempe (which contains approximately 50% aglycone) was found to result in higher serum peak levels of genistein than 15% aglycone textured vegetable protein. However, soymilk (which also contains ≈ 15% aglycone) was absorbed quicker and reached peak plasma levels faster than both tempe and textured vegetable protein (Cassidy et al. 2006). Alcohol extraction and acid precipitation reduces the isoflavone content of soy protein and the soybean can be altered in its levels of fibre, fat, phytic acid and saponin content by the processing methods used to make the end-product (Oakenfull 2001; Potter 1995)

176.7 Safety and Availability of Dietary Phytoestrogens

Currently, dietary phytoestrogens are a billion-dollar business at least partly accounted for by the fact that four out of five middle-aged women use herbal remedies and dietary supplements, with or without prescription drugs, on a regular basis in order to treat health problems associated with aging. Isoflavones are readily available, either over the counter, or as ingredients in (fortified) foods (Bloedon et al. 2002; Setchell et al. 2001).

Table 176.4   Soy food isoflavone content

Product	Aglycone (microgram per gram)			
	Daidzein	Genistein	Glycitein	Total
Traditional soy foods

This table shows the quantities of the aglycones genistein, daidzein and glycitein, in the most common soy-based foods. Please note: ns = not stated; tr = trace defined as ≤25 μg/100g (the authors minimum level of reliable detection); ♦ = data sourced from Wang and Murphy (1994); ◊ = data sourced from Horn-Ross et al. (2000)

The US Food and Drug Administration (FDA) recently allowed the food industry to state that soy protein can protect and promote a healthy heart, focusing on its isoflavone and protein content (US Food and Drug Administration 1999). This has resulted in a flooding of the food markets with soy products and supplements, as well as an expected further increase in the sale and use of these compounds. This is worrying as the full implications of soy manufacturing processes or efficacy are not fully understood. In fact, the scarce and conflicting information regarding the metabolism and bioavailability of phytoestrogens in itself should be enough to cause concern over its promotion as a 'health food'. Furthermore, a trend towards manufactured isoflavone supplements, as opposed to isoflavone in a more natural form through isoflavone-rich foods, may have further implications for health.

176.8   East Versus West: Cultural Differences in Soy Consumption and Phytoestrogen Levels

Soy-based foods have been eaten in Asian societies for over 1,000 years and are an important part of everyday diet, thus their consumption is much higher than in Western countries. Populations in Japan, China, Taiwan and Korea are estimated to consume approximately 20–150 mg/day of isoflavones,

Table 176.5 Eastern versus Western intake of isoflavones

Country	Study	Mean intake (mg/day)		
		Isoflavones	Daidzein	Genistein
Japan	Kimira et al. (1998)	39.46	4.62	52.12
Japan	Arai et al. (2000)	NR	16.4	30.1
Finland	Valsta et al. (2003)	0.79	NR	NR
USA	Horn-Ross et al. (2000)	NR	1.28	1.48
Holland	Boker et al. (2002)	NR	0.15	0.16
USA	de Kleijn et al. (2001)	1.54	0.39	0.7

NR not reported
Table gives an example of average isoflavone intake in some Eastern and Western countries as published by a selection of studies

usually from a variety of soy food sources (Murkies et al. 1998), compared to the average American who consumes only 1–3 mg/day (Barnes et al. 1995). Table 176.5 displays findings from various studies which assessed Eastern and Western soy consumption.

In Japan, soy foods and supplements are heavily promoted as "natural" sources of Es with beneficial effects for women and as having a positive influence on healthy aging, therefore soy intake in that part of the world is especially high. The most common types of soy foods eaten in Japan are tofu, miso, natto (Arai et al. 2000), and fried tofu (Wakai et al. 1999). Among the Chinese, Chen et al. (1999) found that the majority (96.7%) of women of a Shanghai sample (*n* = 60) ate soy foods at least once a week (median intake of soy foods = 100.6 g/day). Although many of these samples were small in size (less than 100 participants), the same finding was reported across studies, associating high phytoestrogen intake with East Asian communities. For instance, in our Indonesian study (*n* = 719) virtually everyone ate tofu and tempe (65% of the sample ate tofu at least once a day and 67% ate tempe at least once a day), (Hogervorst 2008).

In the West, most of the phytoestrogens consumed are lignans (de Kleijn et al. 2001; Horn-Ross et al. 2000), whereas isoflavone intake in Western countries is low compared to that in East Asian countries. Isoflavones are derived mainly from second-generation soy foods such as tofu, doughnuts, soy milk, white bread, pancakes or waffles, canned tuna and coffee (Horn-Ross et al. 2000).

176.9 Cross-cultural Dementia Prevalence

If consumption of phytoestrogens is different and if soy can affect the brain, one would expect differences in dementia prevalence in East Asian countries (such as Japan and China) and Western populations (such as the USA or Europe) in the prevalence of cognitive disorders and dementia. This is indeed found to be the case. This difference is not found for all-cause dementia, which seems to be similar across Japan, China and the West (Zhao and Brinton 2007), but specifically for the most common subtypes of dementia, AD and Vascular Dementia (VaD) (Zhao and Brinton 2007). AD rates are lower in Japan and China, and its prevalence is ~2.5 times higher in Western populations. Whereas AD is more prevalent in Western societies than VaD (~2.2 fold), AD and VaD rates in Japan and China are more similar (for an excellent review on this topic see Zhao and Brinton 2007).

The difference between East and West in AD prevalence has thus been hypothesized to be attributed to the isoflavone-rich diets in Japan and China compared to the USA and Europe and

the potential positive effects that isoflavones can have on the brain. However, other healthy lifestyles (e.g., consumption of fruit and vegetables, less alcohol consumption, more exercise and a lower body mass index, etc.) could also attribute to lower AD risks in these countries. Studies investigating the association between soy and cognition in the elderly in more detail are described below.

176.10 Observational Studies of Soy Consumption and Cognitive Function

Observational studies assessing the relationship between isoflavone and cognitive function have been few and far between, and have also reported conflicting results. These studies have investigated the relationship between phytoestrogen consumption and various aspects of cognitive function in Western countries with postmenopausal women of non-East Asian descent, older men and postmenopausal women of East Asian descent (Rice et al. 2000; White et al. 2000) as well as multi-ethnic populations younger than 50 years of age (Ostatníková et al. 2007; Huang et al. 2006; Celec et al. 2005).

176.10.1 Observational Studies in Non-Asian Western Populations

Kreijkamp-Kaspers et al. (2007) assessed the effects of habitual intake of low quantities of phytoestrogens through diet on cognition. The sample consisted of 301 Dutch postmenopausal women aged between 60 and 75 years. These were volunteers from an ongoing cohort study assessing nutrition and cancer, as well as a breast screening program, who had a wide range of phytoestrogen intake. A Food Frequency Questionnaire (FFQ) was utilized to compile information on consumption of food containing phytoestrogens. Furthermore, to evaluate approximate levels of phytoestrogens consumed, the researchers assigned a value to the various phytoestrogens (in mg per 100 g of food or drink). The foods were then divided into seven groups based on this phytoestrogen 'score' (see de Kleijn et al. 2001 for methods used), and a median phytoestrogen content was assigned to each group to avoid over- or underestimation of phytoestrogen consumption. In this sample, median intake per day of lignans ranged from 0.65 to 2.29 mg/day, whereas for isoflavones this was 0.18–14.64 mg/day, although the middle two quartiles were significantly lower than the highest (0.34 and 2.99 mg/day). The researchers reported no significant differences between the effects of various levels of isoflavone intake on cognitive tests of memory, processing speed, or executive functions. However, a significant association was found between high lignan intake and processing capacity and speed, as well as executive function.

In the same Dutch sample, Franco et al. (2005) investigated the effects of isoflavones and lignans of the levels found in a typical Western diet on cognitive performance using only the Mini Mental Status Examination (MMSE). However, in these analyses, the investigators were interested in differences between women who had experienced a longer (20–30 years) versus a shorter (8–12 years) period since menopause (postmenopausal time span). They also included natural menopause as a factor that might have affected the relationship between phytoestrogen intake and cognitive function. No significant association was found between isoflavone intake and cognitive function as measured by the MMSE. However, and more pronounced in women with longer postmenopausal time span, a significant association was found between higher lignan intake and better cognitive performance. The authors speculated that this stronger association in women with longer postmenopausal time span could be due to the older age, or other age-related mechanisms, which could have mediated the

relationship. However, it must be noted that mean isoflavone intake was very low (0.14 mg/day) in this sample and was substantially lower than those observed in Japanese and Chinese samples showing significant (negative) associations which are discussed below in 176.10.2.

176.10.2   Observational Studies in East-Asian Western Populations

Two large-scale epidemiological studies have assessed the relationship between phytoestrogen consumption, specifically tofu, and cognitive function, in Asian-Americans living in Western communities. These are the Honolulu Asia Ageing Study (HAAS) (White et al. 2000) and the Kame Project (Rice et al. 2000) although the latter has only been published as a peer-reviewed abstract, to our knowledge.

176.10.2.1   The Honolulu Asia Ageing Study

The largest study of the effect of phytoestrogen on cognitive function in both men and women has been the Honolulu Asia Ageing Study (HAAS), consisting of 3,734 Japanese-American participants, aged 70–90 years and living in Hawaii, USA (White et al. 2000). The investigators reported that (contrary to expectations based on its biological plausibility) high midlife soy consumption had a negative association with late life cognitive function. The study found that men aged 71 and above, as well as their wives, who had consumed tofu more than twice a week in midlife and in old age, had a higher risk of dementia and lower cognitive function, but also lower brain weight and more ventricular enlargement than those who consumed less tofu. For example, for men with the lowest tofu intake, the percentage of participants with cognitive impairment (CI) was identified as 4%, as compared to men with the highest tofu intake where 19% had CI. Also, in the low tofu intake group, low brain weight was seen in 12% of cases, compared to 40% of men in the highest tofu intake category. Data suggested that there may be a dose-dependent effect of tofu consumption, i.e., that increased tofu consumption was associated with poorer cognitive function.

The strength of the HAAS study lies in its' coverage of a wide time-span of dietary assessment (data were collected in two assessments, up to nine years apart). Also, some data were collected in midlife, approximately 20 years before cognitive evaluation and magnetic resonance imaging (MRI) scans. However, and as with studies using this methodology, it is unclear if tofu consumption itself was responsible for dementia risk, or whether high tofu intake was an indication of some other unfavourable exposure. For example, the men with high tofu intake, and hence a more traditional diet, were more likely to come from impoverished backgrounds and may have experienced more childhood deprivation which could be related to brain development and later life cognitive function (see also Whalley et al. 2000). In addition, a high-tofu diet could be an indication of a specific dietary pattern that may be harmful to the brain, but separating the individual elements of this diet in order to isolate the contributing factors may prove very difficult. Although these results are of great interest, they were limited, as relatively few subjects consumed very high levels of tofu and confidence intervals around the estimates of effect presented were wide, indicating little precision of results (Grodstein et al. 2000).

176.10.2.2   The Kame Project

The Kame Project (Rice et al. 2000) consisted of Japanese-American men ($n = 634$) and women ($n = 767$) living in Washington State, USA, who were aged 65 years and above. Cross-sectional results

showed an association between having a lower cognitive score, as measured by the Cognitive Abilities Screening Instrument (CASI, the same test was also used in the HAAS to identify CI), and high tofu consumption (>3 times a week) as opposed to moderate (1–2 times a week) or low consumption (<1 time a week). In stratified analyses, this negative association remained significant only for women who were hormone replacement users (but not for those who were not hormone users, elderly men or those who consumed moderate to low amounts of tofu). The investigators also found longitudinally (although no overall association was found between tofu consumption and 2 year change of CASI score), that those with modest tofu consumption showed the greatest improvements in CASI scores. These data suggest that there may be optimal levels of phytoestrogens, perhaps interacting with age, gender and E levels. It must be noted that in this and the HAAS study, the investigators did not assess total isoflavone exposure, but only estimated tofu intake. This may be problematic as the authors pointed out that tofu accounted for only approximately half of soy-based isoflavones consumed by this particular population.

176.10.3 Observational Studies in Premenopausal Women

Other observational studies have assessed the relationship between phytoestrogen consumption and cognitive function in premenopausal women. In the Study of Women's Health Across the Nation (SWAN) (Huang et al. 2006), a sub-group of 195 Japanese and 185 Chinese women who were living in the USA and were between 42 to 52 years of age were assessed for this relationship. Various tests of episodic memory, working memory and processing speed were used to assess cognitive function. The investigators found no association between genistein intake (as calculated from the FFQ) and cognitive function. The authors surmised that the effects might only be present in women who are in low-estrogenic states (i.e., postmenopausal women). Comparisons with the other studies mentioned above are difficult, as optimal genistein and daidzein levels were investigated using tertiles, rather than reported in weekly intake of tofu, as in the previous studies mentioned (Rice 2000; White 2000). Furthermore, although the participants were of Japanese and Chinese origin, with higher isoflavone intake than other Western non-Asian populations, mean genistein and daidzein intakes were still only 6.79 and 4.68 μg for Japanese women, and 3.53 and 1.74 μg for Chinese women. An intake of approximately 45,000 μg of isoflavones is needed to significantly affect follicular phase and menstrual cycle length in premenopausal women (Cassidy et al. 1995). Therefore, it is possible that the finding of no association in this study could in part be due to the levels of isoflavone not being sufficiently high enough to have an impact on cognitive function. This could also explain a lack of significant findings in the Kreijkamp-Kaspers study described above. For instance, a 100 g size serving of tofu, which is typical of an Asian diet (see Chen et al. 1999), is equivalent to 33,700 μg, which, when eaten daily, might affect human fertility, physiology and hence possibly the brain, although the exact dosage at which this occurs (if it does) is not entirely clear. This is further complicated as different sources and forms of phytoestrogens were used in the various studies.

176.10.4 Discussion of Findings from Observational Studies

It is hypothesized that the lack of any significant findings in studies assessing Western populations could thus be due to the very low levels of isoflavones consumed in these populations. The participants in Kreijkamp-Kaspers (2007) observational study had at a maximum dietary intake of 15mg/day

of soy isoflavones. This is only a quarter or half of that consumed by Japanese women living in Japan, but it was higher than that reported in other Caucasian women living in Western countries (e.g., Franco et al. 2005). This suggests there may be a dose effect and/or an effect of habitual intake, and that the lack of significance in the studies not finding an association may be due to the lower habitual intake of isoflavones consumed.

In line with previous suggestions and theory, the findings from observational studies (whether the association is a positive one, a negative one or no association has been found) thus suggest that an optimal level of phytoestrogens may be needed in order to maintain cognitive function in the middle-aged, but not in the elderly (>65 years of age) in whom high tofu consumption could be negatively associated with cognitive function. However, these studies relied on self-report FFQ, which may not be the most reliable single indicator of soy intake (especially in samples with a very low phytoestrogen intake). There is also a potential problem when comparing studies due to the differences in the type of food questionnaires used. For example, some used dietary self-report methods (recall vs. active food diary), which may cause a problem in distinguishing between cause and effect (i.e., those with cognitive impairment not remembering their intake), as well as introducing biases, such as the 'healthy-user' bias (e.g., eating soy as part of a healthy diet and/or lifestyle). In addition, in these studies, no actual endogenous phytoestrogen levels were measured.

176.11 Soy Consumption and Cognitive Function in an Elderly Indonesian Sample: Findings from our Indonesian Pilot Study

We assessed the relationship between soy intake and cognitive function in an elderly Indonesian sample. The results of the study revealed that tofu and tempe were the most common forms of soy consumed in this sample. We also measured isoflavone levels using saliva samples from the participants. See Table 176.6 for mean soy intake and salivary isoflavone levels.

In our Indonesian sample, similar to findings by White (2000) and Rice (2000), we also reported a negative association between high daily or more tofu intake and memory in participants over the age of 68 years (see Fig. 176.3) (Hogervorst et al. 2008). On the other hand, we found that participants between 52 and 68 years of age appeared to have optimal genistein levels relating to optimal memory function, whereas participants older than 68 years of age with high genistein levels exhibited lower cognitive performance and an increased risk of dementia (Hogervorst et al. 2009) (see Fig. 176.4). This suggests that the role of phytoestrogens on cognitive function may be modified by age and gender.

Another novel finding was that high tempe intake, in the same analyses, was positively associated with cognitive function. We suggested that a possible reason for this could be due to different processing methods used to make these two types of soy foods. Formaldehyde is reported to be added to tofu in Indonesia and can create oxidative damage to frontal cortex and hippocampal tissue (Gurel et al. 2005). Tempe could potentially protect against formaldehyde-induced damage through its antioxidant effects (Rilantono et al. 2000).

However, a pilot study carried out by the University of Indonesia in Jakarta, Depok recently found no trace of formaldehyde in various tofu samples bought in Jakarta (data unpublished). An alternative hypothesis is that the fermentation process used to make tempe can produce folate (Ginting and Arcot 2004) which is known to have protective effects in the brain (Smith 2002) This may be similar to findings of an interaction between estrogens and folate found before, where women who had high

Table 176.6 Frequency and quantity of soy foods eaten and salivary isoflavone levels in our Indonesian sample

Type of food eaten daily or more	Number of Participants (%)
Soy of any type	511 (71)
Tofu (daily or more)	479 (67)
Tempe (daily or more)	491 (68)
Mean Weekly Intake	Mean ± SD
Tofu	9.3 (6.9)
Tempe	9.5 (6.8)
Salivary Phytoestrogen Levels (ppm)	Mean ± SD
Genistein	0.021 (0.009)
Daidzein	0.043 (0.016)
Glycitein	0.041 (0.027)

Table shows the intake of soy foods as well as the mean salivary isoflavone levels for the whole sample. The figures show the number and percentage *[N(%)]* of participants whom eat these foods at least once a day. The table also shows the mean (and standard deviation or SD) number of times the food are eaten a week. The mean (and SD) salivary isoflavone levels are also displayed
Fig. 176.3 Weekly Tofu intake and memory Score on the Hopkins Verbal Learning Test (HVLT) in an Elderly Indonesian Population. Figure shows the quantity of tofu eaten on a weekly basis in our elderly Indonesian sample plotted against scores on the HVLT verbal memory test. As can be seen a weekly tofu intake increase was associated with lower memory scores

levels of estrogens, but also high levels of folate did not score below the cut-offs scores on the MMSE for dementia (Hogervorst and Smith 2002). These associations need to be investigated in more detail in future studies.

Clearly, observational studies can introduce systematic bias and ultimately treatment studies carry more weight in disentangling cause and effect of (dietary) phytoestrogens versus cognitive outcomes. These studies are thus discussed in more detail in the next section.
Fig. 176.4 Salivary phytoestrogen levels for the possible dementia cases and control cases in an elderly Indonesian population. Figure shows levels of the phytoestrogens daidzein, genistein and glycitein stratified by possible dementia cases and control cases. Genistein and glycitein levels were significantly higher in cases than in controls ($p < 0.05$)

176.12 Treatment/Intervention Studies in Postmenopausal Women

See Table 176.7 for a summary of all human phytoestrogen treatment studies.

There have been ten randomized placebo-controlled intervention studies (randomized controlled trials or RCTs) assessing the effects of soy isoflavone supplementation on various aspects of cognitive function (see Table 176.7). Of these, eight have assessed postmenopausal women only, of which seven were in Western populations (Fournier et al. 2007; Casini et al. 2006; File et al. 2005; Howes et al. 2004; Kreijkamp-Kaspers et al. 2004; Duffy et al. 2003), and one in a Hong Kong sample (Ho et al. 2007). Another study has assessed older men and postmenopausal women (Gleason et al. 2009) and the tenth study has been with premenopausal women and young men in a UK sample (File et al. 2001). Furthermore, two very short-term (1 week) prospective intervention studies, also with premenopausal women and young men have also been conducted (Ostatníková et al. 2007; Celec et al. 2005).

176.12.1 RCTs Reporting Positive Effects of Isoflavone Consumption on Cognitive Function

Four of the studies assessing postmenopausal women reported beneficial effects of isoflavone treatment on cognitive function (Casini et al. 2006; Duffy et al. 2003; Kritz-Silverstein et al. 2003; File 2005). Two were from the same group of investigators and separately assessed the effects of 60 mg total isoflavones per day on cognitive function, using the same cognitive test battery with postmeno-

pausal women aged 50–66 years in the UK for a duration of 6 weeks (File et al. 2005) and 12 weeks (Duffy et al. 2003). The investigators found that 60 mg/day isoflavone equivalent was beneficial for cognitive function as assessed by memory tests, as well as on tests of frontal lobe function, such as those assessing mental flexibility and planning ability.

Around the same time as the UK studies were published, the Soy and Postmenopausal Health in Aging Study (SOPHIA) (Kritz-Silverstein et al. 2003) data from the USA were disseminated. This study had also included postmenopausal women aged 55–74 years. However, a higher dose (110 mg/day) of isoflavones was used and for a much longer duration of 6 months. A learning effect was observed over time in both the placebo and isoflavone treatment group, showing improvements in all five cognitive tests used. This improvement was larger in the isoflavone groups for four tests, and significantly greater (23% as opposed to 3%) for the Category Fluency test, even after controlling for age and education. Furthermore, in analysis stratified by age, those in the younger age group (50–59 years) taking the isoflavone supplement showed a greater improvement than those on placebo on a test of visuospatial tracking and attention (Trails B). This effect was not observed in the older group (60–74 years), again suggesting that not only could isoflavones have a beneficial effect on verbal memory in postmenopausal women, but also that the effect of isoflavones may be greater for peri-menopausal women than for those who are older and had already experienced menopause. This would be in line with our observational data and those of E studies (Hogervorst et al. 2009). Similarly, another RCT (Casini et al. 2006) reported that postmenopausal women (with a mean age of 49.5 years and an average 5.7 years since menopause), who were given 60 mg/day equivalent of isofla-vones as aglycones for a duration of 6 months showed an improvement in cognitive ability, as measured by three cognitive tests, as well as improved mood. When asked, the participants also generally showed a preference for phytoestrogen over placebo (64%). This study has particular value because it provides support for the possible role of phytoestrogens in alleviating or reversing psychological ailments associated with menopause, such as mood and quality of life. Gleason et al. (2009) investi-gated the effects of 100 mg/day soy isoflavone for a duration of 6 months on cognitive function for both men and women aged 62–89 years. Cognitive function was tested at month 1, 3 and 6 and the investigators reported that the isoflavones group showed greater improvements in visual-spatial memory, construction, verbal memory and speed dexterity. However, the placebo group were faster on two tests of executive function. There was no significant effect on verbal memory for either group. Interestingly, although plasma genistein and daidzein levels showed a rise with increasing isoflavone supplementation, equol levels did not and none of the samples were equol producers. This is important as some investigators have suggested that equol, a highly estrogenic metabolite derived from daidzein in some, but not all, humans, is the most potent derivative for maintaining brain func-tion through its strong estrogenic effects. This study would suggest that this is not necessarily the case. However, the small sample size in this study ($n = 30$) must be taken into consideration.

176.12.2 RCTs Reporting No Effects of Isoflavone Consumption on Cognitive Function

Four studies failed to show any significant effect of isoflavone supplementation on various aspects of cognitive function with postmenopausal women (Fournier et al. 2007; Ho et al. 2007; Howes et al. 2004; Kreijkamp-Kaspers et al. 2004). Using aglycone isoflavone extracts from red clover, (Howes et al. 2004) investigated the effects of 25 mg/day of predominantly biochanin A (which contains less than 2 mg daidzein and genistein) for a duration of 6 months and found no significant effects on tests of visuospatial intelligence and verbal memory in postmenopausal women. The dose used may have

thus been too low and, in addition, the women included in this study were all older than 60 years of age. In a study of the longest duration of all RCTs carried out in this area, Kreijkamp-Kaspers et al. (2004) investigated the effects of 12 months of soy protein containing 99 mg equivalent of total isoflavone per day (52 mg genistein, 41 mg daidzein, and 6 mg glycitein) on cognitive function (and other health indicators) in postmenopausal women aged 60–75 years in the Netherlands. No effect of isoflavones supplementation was found on a large number of cognitive tests (see Table 176.2 for full list). However, it must be noted that compared to the earlier reported positive studies, these participants were much older on average (66 years of age), had been menopausal for longer (mean of 18 years), and 19% were also using cholesterol-lowering and antihypertensive medication. Similarly, Ho et al. (2007) did not find any effects of 6 months supplementation with 80 mg/day soy isoflavones on quality of life, as well as various cognitive functions. They had also included postmenopausal women with an average age of 63.5 years, who were also 13.8 years since menopause, on average. Interestingly, this latter study was the only study of a population who habitually ate soy as part of their daily diet (Hong Kong Chinese) and who had a mean dietary intake of 20 mg/day isoflavones. It is thus also possible that no effect was found in this study due to the higher habitual intake of soy in the sample, which could have potentially reduced group differences (Ho et al. 2007).

These data taken together would suggest that age of women, duration of treatment, habitual intake and years since menopause could explain differences found between studies. This reasoning is very similar to that for E treatment (Hogervorst et al. 2009). However, in a US-based study of postmenopausal women with a mean age of 56.1 years, and with an average of 8 years since menopause (Fournier et al. 2007), researchers also found no significant effects of either 72 mg/day total isoflavones (from soy milk) or 70 mg/day total isoflavone (via a soy isoflavone supplement) on various cognitive abilities, including selective attention, working or visuospatial short- or long-term memory when compared to placebo. On the other hand, the large variability in age since menopause (Zhao and Brinton 2007) in this group may have been responsible for a lack of significant findings.

176.13 Dose Effect of Phytoestrogens in a Pilot RCT

In a pilot RCT study (Yesufu 2009) we assessed the 24-h dose effect of phytoestrogens on verbal episodic (word lists) and semantic memory (Category Fluency) in postmenopausal women between 45 to 65 years of age. See Table 176.8 for inclusion and exclusion criteria and Fig. 176.5 for procedure. Participants had been instructed to take one of the allocated pills (half the dose) 24 hours before the morning of testing immediately upon waking, and the other half of the dose immediately before going to bed on the night before testing (10 hours before testing) to obtain maximal phytoestrogen levels. This was done to investigate the potential 24-hour dendritic sprouting effects of E (Woolley and McEwen 1993). Timing of ingestion of the dosages was based on findings by Setchell et al. (2003), who reported the terminal half-life (the interval required for the quantity to decay to half its initial value) of daidzein and genistein to be approximately 8–10 hours. In this pilot study, fifteen participants successfully completed the study. Due to subject drop out (unrelated to side effects), cells were unbalanced and there was an uneven number of participants in each treatment group (placebo $n = 6$; 30 mg, $n = 5$; 100 mg $n = 4$).

Table 176.9 below describes the sample demographics. The mean age of the participants was 55.47 ± 5.74 (range 49–65 years). Most participants had achieved secondary or university level education ($n = 6$ and $n = 8$, respectively), and only one participant had a primary level education. The majority of participants were Caucasian ($n = 12$). Nearly half the sample was currently using medication ($n = 7$), but the majority of participants did not smoke ($n = 14$) and exercised on a regular basis ($n = 14$), indicating a healthy lifestyle. No significant difference was observed between treatment

Table 176.8 Inclusion and exclusion criteria for pilot randomized controlled trial

Inclusion criteria	Exclusion criteria
Aged 45–65 years old	Use of supplementary hormones (including hormonal contraception within the last 3 months)
Good health as assessed by self-report questionnaire	
Postmenopausal (women): last menses longer than 6 months ago	Use of antibiotics in previous 6 months
Surgical or natural Menopause	Previous history of thrombosis
	Benign or malignant growths
	History of breast, ovarian or endometrial cancer
	Psychiatric disorder (e.g., clinical depression)
	Pregnancy
	Dementia (e.g., Alzheimer's disease)
	Epilepsy
	Vision/ear/hearing problems
	Dyslexia
	Premenopausal women
	Regular soy food consumers

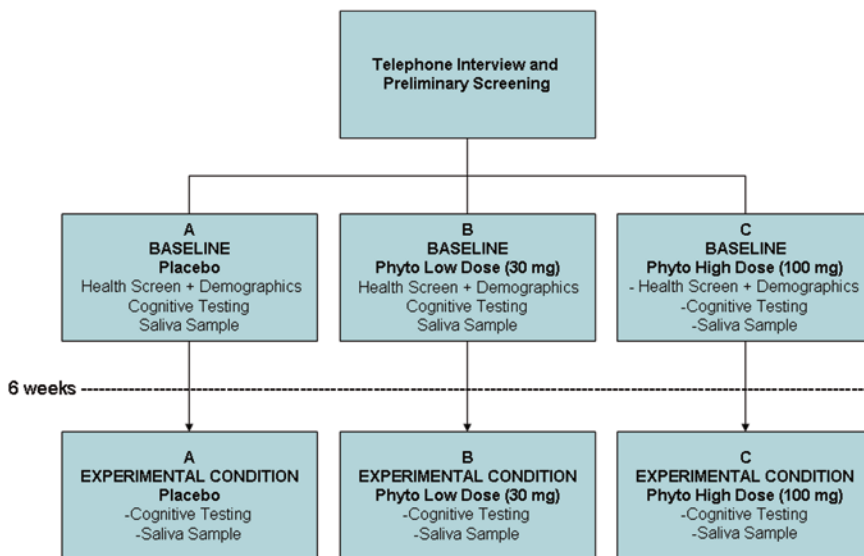
This table shows the study inclusion and exclusion criteria for participants in the pilot Randomised Controlled Trial (RCT)


Fig. 176.5 Randomized Controlled Trial (RCT) procedure. This figure shows the recruitment and test procedure for the RCT. After initial telephone screening, participants were allocated to one of the three treatment groups. Baseline data was collected. After a time period of 6 weeks, the participants consumed their treatment or placebo pills and completed the same test battery again

groups in educational attainment, ethnicity, medication use, smoking and exercise. Unfortunately, due to randomization, participants in the 30 mg group were significantly older (61 ± 4.30 years of age) than the participants in the 100 mg (50 ± 1.16 years of age) and placebo (54.50 ± 4.60 years of age) groups [$F(14) = 9.10$, df = 2, $p = 0.004$].

We found a positive effect of 100 mg total equivalent of isoflavones, as opposed to the 30 mg or placebo treatment on verbal Category Fluency (number of animals in 90 s) (see Fig. 176.6) controlling for

Table 176.9 Pilot randomized controlled trial sample demographic variables

This table displays the differences between treatment groups in demographic variables. Univariate ANOVA analyses were used to assess the differences between groups in age and chi-square analyses for all other categorical variables. NB: Critical value refers to F = ANOVA, χ^2 = chi-square; p Value = significance; df = degrees of freedom; * Correlation is significant at the 0.01 level (2-tailed); ns = correlation is not significant

age and BMI [F (14) = 4.057, df = 2, p = 0.05]. Analyses exhibited no baseline differences between groups (which had been done six weeks earlier at enrolment). The 100-mg treatment group showed more improvement than the 30-mg group, who also showed greater improvement than the placebo group ($p = 0.05$).

Women in our RCT isoflavone study (participant recruitment is ongoing) were on average younger (mean age 55 years) than those in previous studies reporting no effect or detrimental effects of phytoestrogen consumption. Due to similarities between the sex hormone E and naturally occurring phytoestrogens, this positive effect on cognitive function was expected, as this finding is in line with the 'window of opportunity' theory for estrogens (Gibbs 2006; Henderson et al. 2005; Pinkerton and Henderson 2005). This theory suggests beneficial effects of E on cognition in recently menopausal

Fig. 176.6 Change in baseline score for the Category Verbal Fluency Test (CVFT). This figure shows the 'change in baseline score' using box plots (with medians) between test session 1 and test session 2 on the CVFT for each treatment group
women only and is substantiated by basic science and human observational data. While our results reported are preliminary, they are also similar to other reports finding positive effects of phytoestrogen intake on the Category Fluency test (Kritz-Silverstein et al. 2003). Also reflective of our study was that Kritz-Silverstein et al. (2003) did not find any significant effects on other types of verbal memory either (e.g., story and verbal list recall were also assessed in our study). This may indicate that, similar to estrogenic findings, phytoestrogens may also have test-specific effects. Interestingly, the two longitudinal studies investigating menopausal change on cognition also show the largest differences on the same verbal Fluency task, which may thus be very sensitive to fluctuations in estrogenic metabolite levels (Fuh et al. 2006; Thilers et al. 2006).

176.14 Discussion

It is thought that diet and nutrition could play an important part in age-related health issues, such as cancer, cardiovascular disease, and to maintain cognitive function and prevent AD (American Institute for Cancer Research 1997). In this modern day and age we have turned to dietary supplements as a quick and easy way to obtain the nutrition we believe maintains and promotes good health. Therefore, the dietary supplement industry is now a multi-billion-dollar business based on studies such as those described in this review. However, a worrying increase in hormone-dependent health issues has been observed. Consequently, soy isoflavones have been suggested as a natural alternative to manufactured hormones, such as E, and have already been endorsed as being protective for cardiovascular health (US Food and Drug Administration 1999). The labelling of a product as 'natural' does not necessarily confirm its safety (Ernst 2002) and relatively little is known about the biological behaviours of soy isoflavones in the human body. Furthermore, the effects of a plant hormone in its natural state is not necessarily the same as that of when it is capsulated or has been extracted and processed to create a tablet form (Fitzpatrick 2003). Human phytoestrogen trials have evaluated many health issues (e.g., menopausal symptoms, cardiovascular markers, cancer, bone density and cognitive function), but clinical data remain limited and a discrepancy can be seen between studies in vitro and in vivo, across various in vivo clinical trials as well as observational studies. There are a few possible explanations for discrepancies between studies and reasons why comparing them may be complicated.

176.14.1 Differences Between Studies

176.14.1.1 Bioavailability and Metabolism of Isoflavones

Various composition and structural make-up differences between different types, products and sources of soy isoflavones may affect their in vivo pharmacodynamics in the human body (see Kano et al. 2006). This begins with the initial growth process and response to external stimuli (which may cause the molecules of the soy plant to develop in certain ways that result in more complex phytoestrogen profiles (Zhao and Brinton 2007) and ends in the processing, storage and preparation of foods. This is especially a problem as the intervention studies to date have used various different sources and types of soy isoflavones. Some studies used isolated isoflavones, while others used intact soy protein. As can be seen from Table 176.2, phytoestrogen trials vary in the make-up of their administered phytoestrogens. Variability in composition of the soy used leads to the issue of differences in bioavailability of compounds between studies and hence the possible differences in their overall effect on health. This degree of variation needs to be taken into consideration when comparing and contrasting studies, as well as when forming conclusions based on the findings of these studies.

Knowledge about the bioavailability of ingested isoflavones is of paramount importance as it enables an understanding of the way in which the chemical forms of isoflavones have a positive biological effect on the human body, i.e., their efficacy (Zubik and Meydani 2003) and allows for an evaluation of their safety. However, this knowledge, particularly in reference to the bioavailability of genistein and daidzein as a result of the form consumed (aglycone or glucoside), is in the main part incomplete, contradictory and inconclusive, particularly in human studies, making it difficult to establish firm recommendations with regards to the optimal dosage to maintain health and optimal function.

176.14.1.2 The Effects of Dose and Habitual Intake

As discussed, soy isoflavones may have different estrogenic effects, which could also be dose-dependent, but the effective dose to maintain cognitive function has not been found. Linford and Dorsa (2002) reported that very high concentrations of genistein are toxic to neurons, suggesting optimal and non linear levels. Zeng et al. (2004) reported that the neuroprotective effects of genistein are mediated by two mechanisms dependent on dose. The first one is at a nonmolar level, in which genistein protects neurons via an ER-mediated pathway. The second involves a micromolar level in which genistein behaves as an antioxidant. For instance, treatment with 50 µmol/L did not attenuate neuronal apoptosis induced by the endoplasmic reticulum calcium-ATPase inhibitor thapsigargin and actually enhanced apoptosis of cells, whilst low concentrations of genistein ameliorated apoptosis of neurons. In contrast, another study found that the same dose of genistein did protect HCN1-A and HCN2 cells from death (Sonee et al. 2004). The dose administered could thus greatly influence the efficacy and safety, by either being too low to have a noticeable effect on cognitive function, (e.g., in the SWAN study, Huang et al. 2006), or by being too high over a long exposure period and resulting in possible safety issues, which have not yet been investigated in sufficient detail. Dose, but also tissue-specific issues (see Sect. 176.3) thus need to be considered when assessing different types of health benefits of the isoflavones.

The RCTs to date all tended to use large quantities of daily administered isoflavones, which exceed the amount of daily isoflavone consumed in food in a typical Asian diet. No guidelines exist to assist in this decision and the reasons for this are not at all clear, as they are not based on any known pharmacokinetics of isoflavones. Although a possible influence of dose was found in

our RCT, confusion still exists as to whether there is a linear relationship between bioavailability and increasing dose (Setchell et al. 2003; Setchell et al. 2003; Bloedon et al. 2002). Setchell et al. (2003) and Setchell (2000) reported a positive correlation between isoflavone intake and peak concentrations of daidzein and genistein, although this was nonlinear. The same relationship has been seen between bioavailability and intake, with urine analyses showing that, over a 4-day period, a doubling of the dose of isoflavones did not double the total recovery (Setchell et al. 2003). This indicates that consuming a greater quantity of isoflavones does not necessarily result in higher quantities of isoflavones being metabolized, which may reflect a possible saturation or storage effect. Further studies assessing the optimal dosage of isoflavones in tandem with both bioavailability and cognitive function are required in order to have a clearer understanding about the relationship between these factors. The observational studies have not shed any light on this either as amount consumed was not weighted or analyzed. They did, however, suggest that intake of tofu more than 2/3 times a week could already have detrimental associations with cognitive function in the elderly.

The implication of habitual intake of isoflavones is an issue all on its own and may impact on many factors relating to bioavailability (Slavin et al. 1998; Adlercreutz et al. 1982). The regularity of isoflavone consumption could also be of some importance. Significant effects, protective or detrimental, have been reported in populations who regularly consume large amounts of isoflavones (e.g., the HAAS and Kame project), whereas no associations have been found in other sample populations treated with phytoestrogens and/or those who consumed very low and infrequent quantities of isoflavones through their diets. Setchell et al. (2003) suggests that eating soy foods regularly through the day may be more effective for maintaining high serum phytoestrogen levels, and hence may be more beneficial (or detrimental to the elderly as reflected in our Indonesian sample) than eating soy once a day or once a week. However, in a soy treatment study assessing bioavailability as a result of chronic exposure to soy isoflavones over a 10-week period, no difference was found between midpoint and endpoint concentrations of isoflavones in plasma, urine and faeces, which suggests that there were no significant effects of habitual intake (Wiseman et al. 2004). On the other hand, this study may have been too short to appropriately assess 'habitual' intake effects.

176.14.1.3   Characteristics of the Study Population: Age and Menopausal Status

Variations in some characteristics of the study participants (e.g., habitual consumption) may thus influence the effect of isoflavones on cognitive function. Similar to the findings with E, data suggest that it is also possible that age, menopausal status and endogenous hormonal profile may have an impact on the effect of soy isoflavone on cognitive function (Zhao and Brinton 2007). Interestingly, most RCTs finding no, or a negative (e.g., seen in two tests in Gleason et al. 2009), effect of isoflavone treatment on cognitive function had included participants older than 60 years of age (Ho et al. 2007; Howes et al. 2004; Kreijkamp-Kaspers et al. 2004), similar to the observational studies finding negative associations in those over 65 years of age (Rice et al. 2000; White et al. 2000; Hogervorst 2008). Beneficial effects of soy isoflavones were mainly seen for women who were within 10 years of the onset of menopause (bar Gleason et al. 2009) and/or those who had been treated for less than a year with a high dosage, which is also similar to effects seen in E treatment studies (Hogervorst 2006).

Another possible difference between the pre- and postmenopausal studies is the duration of supplementation, as the premenopausal studies tended to use much shorter treatment regimes than the postmenopausal treatment trials (Lu and Anderson 1998; Slavin et al. 1998; Lu et al. 1995). Similar to the effects of E treatment, positive effects of treatment on cognition may be limited up to 2–6 months (Hogervorst et al. 2009).

176.14.1.4 Characteristics of the Study Population: Genetics Determining Phytoestrogen Metabolism

Genetic factors could further influence the metabolism of isoflavones, i.e., due to differences in intestinal microfloral populations (Rowland et al. 1999). It is possible that the colonic microfloral environments of American participants (Zubik and Meydani 2003) may have a higher capacity to hydrolyze glucosides than those of Japanese samples (Izumi et al. 2000), and thus metabolize glucosides better, resulting in these being less bioavailable in the American participants (Zubik and Meydani 2003). Furthermore, the presence of other foods in the digestive system and the composition of those foods may also be factors to consider (Zubik and Meydani 2003). For instance, food-deprived animals were found to absorb isoflavones faster than fed animals (Piskula 2000). In the Izumi et al. (2000) and Zubik and Meydani (2003) studies, participants were fed foods with a different composition matrix before isoflavone consumption, affecting the quantities of aglycones and glucosides, which may have accounted for some of the discrepancies between the studies on cognition which were reviewed earlier.

Another factor causing variation between individuals that has relatively recently been recognized is equol. As previously stated, equol is a metabolite of the isoflavone daidzein produced by gut microflora. Equol's binding ability is of similar strength to genistein, and it has been found to be three times as estrogenic as its parent daidzein in an endometrial tumour line (Markiewicz et al. 1993). Variations exist between animals and humans, as well as between various human populations in the proportion of people who have the ability to produce equol. Due to the variability in gut microflora, only 20–35% of a Western population can produce equol (Wiseman et al. 2004; Morton et al. 1994). It is possible that the effects of isoflavones on various endogenous systems are mediated by the variable of being an equol producer or not (Zhao and Brinton 2007) and, possibly, by age affecting equol production (Frankenfeld et al. 2004). Therefore, equol may be a major player in the effect of soy consumption in the human body, and the failure of human intervention studies to account for this could result in marked differences in individuals' responses to soy consumption. On the other hand, positive effects of soy were also found in a population of non-equol producers (Gleason et al. 2009). This would suggest that other aglycones could mediate the positive effect on cognition (e.g., genistein, and daidzein itself).

176.14.1.5 Other Differences Between Studies

Another factor that needs to be considered when comparing studies and drawing conclusions from the results of RCTs is the types of cognitive tests used. The Fluency test seemed to be particularly sensitive to estrogenic effects (menopausal transition, RCTs with E and phytoestrogens), as well as possibly some specific executive function tests. However, not all studies used the same tests, which makes comparisons complicated. Again, these issues are very similar to those found in studies of the effects of E on the brain (Hogervorst 2009).

176.15 Concluding Remarks

To summarize our research, to our knowledge, we were the first to assess the intake of different types of soy products, as well as endogenous isoflavone levels, in relation to cognitive function in our Indonesian observational study (Hogervorst et al. 2008). In addition, we (Yesufu 2009) were the first to find a beneficial effect of a 24-hour high dose isoflavone supplement (100 mg equivalent of total

intake of isoflavones), as opposed to low 30 mg total intake or placebo on Verbal Fluency. Woolley and McEwen (1993) reported that the increase in dendritic sprouting as a result of high levels of Es peaked at two and three days and then decreased over the preceding 7 days. Taking these findings into consideration, with data suggesting optimal levels in the young and middle aged and negative effects of consuming tofu more than two/three times weekly in the elderly, it could be suggested that intermittent intake may be the most favourable regime to render positive effects on the brain in women who are younger than 65 years of age.

To date, most studies assessing the health effects of soy isoflavones have run into conflict and disagreement. Undeniably, there is a huge gap in our knowledge about the effects of phytoestrogens, partly due to the lack of well-controlled large clinical studies. The optimal dose at which a positive effect will be observed is unknown, as well as the toxicity of high doses of isoflavones in humans. The duration of consumption needed to detect if any effect exists, and at what point long-term intake becomes detrimental in whom, is also unclear. Other factors such as genetic/ethnic and environmental variables, isoflavone metabolism and equol production, gender, age and menopausal status, all need to be taken into consideration. Therefore, future studies should aim at addressing these issues and at arriving at a consensus about methodological standards (e.g., type of cognitive test used, isoflavones measurements, etc.) which should be used in order to make the studies more directly comparable. Taking all these points into consideration, the evidence to date is not sufficient to make any recommendations about the use of dietary intake of soy isoflavones to address any human health issues at present. Further focused research needs to be conducted in order to arrive at more definitive conclusions.

Summary Points

- Phytoestrogens are found in abundance in a variety of foods, such as fruits, vegetables and grains. However, very high concentrations can be found in soy. When consumed, they can mimic the effect of estrogens in the body.
- Phytoestrogen consumption has been promoted as beneficial on various health aspects. However, the isoflavone content can vary between different soy foods as a result of their growth process, production and the form they are consumed in. This can affect their metabolism, as well as their effect on the human body.
- It has been suggested that a diet rich in isoflavones (genistein and daidzein) could be implicated in the lower prevalence of Alzheimer's disease in East Asian countries compared to Western countries. East Asian countries consume greater quantities of isoflavones than Western countries from more traditional soy foods, such as tofu and tempe.
- Previous research assessing the relationship between isoflavones and cognition is limited and the effects are not well understood, partly due to conflicting reports from previous studies. Basic cell research has reported both neuroprotective and neurotoxic (but only in very high dosages) effects of genistein and daidzein on biological mechanisms implicated in dementia.
- Observational studies assessing the relationship between isoflavone consumption through diet and cognitive function have either found no relationship in Western populations consuming low levels of isoflavones, or a detrimental effect of high tofu consumption (>2–3/week) in older East Asian populations. This suggests that an optimal level may be required to maintain cognitive function.
- In our observational study in Indonesia, we also reported a negative relationship between high (daily) tofu intake and cognitive function. A positive relationship was observed between high tempe intake and cognitive function in the same analyses. We suggest that processing differences (formaldehyde added to tofu and folate as a by-product of tempe production) may be implicated in these findings.

- However, our results only pertained to women over 68 years of age. This suggests that the effects of phytoestrogens on cognitive function may be modified by age and gender. Participants between 52–68 years appeared to have optimal genistein levels, which was associated with better memory function. However, those over 68 years of age with high genistein levels had lower cognitive scores and a higher risk of dementia.
- Ten RCTs have also assessed this relationship in postmenopausal men and women. Some of these studies have reported beneficial effects on various cognitive functions in women and men. However, others did not find any effect. The data suggests that the duration of treatment (6 months or less), age of women (<65 years), years since menopause and possibly habitual intake could potentially explain differences found between studies.
- Preliminary results of our pilot RCT assessed the 24-hour effects of isoflavone consumption on verbal episodic and semantic memory in postmenopausal women with a mean age of 55 years. We found a positive effect of 100 mg isoflavones (compared to 30 mg or placebo) on verbal Category Fluency. This reflects previous studies reporting a protective effect of high intake in postmenopausal women.
- We propose that possible reasons for discrepancies seen between studies could be due to differences in types and sources of isoflavones (affecting bioavailability and metabolism), dose and the effect of habitual intake, duration of treatment, types of cognitive test used (not all are sensitive), as well as characteristics of the study population (age, internal hormonal status, and genetic factors affecting metabolism).
- To our knowledge, we were the first to assess soy intake and endogenous isoflavone levels in the same sample. We are also the first, to our knowledge, to find beneficial effects of isoflavones on verbal semantic memory after 24 hours. Future research is needed to identify a possible optimal dose at which a positive effect of isoflavones can be observed on cognitive function.

Definition and Explanations of Key Terms or Words

Phytoestrogen: A plant hormone which is physiologically and physiochemically similar to estrogen

Cognition: Mental capacity (Literally 'knowing'), the ability to process information; this includes perception, learning and memory, language and higher executive functions, including complex (but not simple) psychomotor reaction times

Isoflavone: A type of phytoestrogen in the form of glucosides (a sugar group attached to the main part of the molecule which makes it water soluble). When consumed isoflavones can be found in the form of aglycones (no sugar group attached)

Equol: A metabolite of the isoflavone daidzein produced by gut microflora

Estradiol: Most potent estrogen

Estrogenic: A substance which has a biological effect which is similar to that of estrogen

Anti-estrogenic: A substance which competes with estrogens to bind to receptor sites and hence blocks the activity of estrogen

Bioavailability: The part of a substance that remains after it has been digested, absorbed and metabolized by the human body

Agonist: A substance that binds to a receptor and hence affects it's functioning

Antagonist: A chemical that blocks the binding of another chemical to its receptor in an organism without binding to the receptor itself

Pharmacokinetic: The process by which a substance is absorbed, distributed, metabolized and eliminated by the body

Pharmacodynamic: The actions or effects of a substance on a living organism

Chapter 177
Nutritional Risk in the Elderly with Cognitive Impairment: A Far Eastern Perspective

Kang Soo Lee and Chang Hyung Hong

Abbreviations

AD	Alzheimer's disease
ADL	Activities of daily living
IADL	Instrumental activities of daily living
K-MMSE	Korean version of mini mental state examination
MCI	Mild cognitive impairment
NCF	Normal cognitive function
NSI	Nutrition screening initiative

177.1 Introduction

The 2005 data from the Korea National Statistical Office indicates that by 2018, Korea would become an aged society in which the elderly population, i.e., persons aged more than 65 years, would comprise 14% of the total population. As a result, problems pertaining to the welfare and health of the elderly have become a national concern. With the increase in the elderly population, the incidence of chronic geriatric diseases is also on the rise. Nutrition and diet have gradually become important from the perspective of prevention of geriatric diseases and promotion of the health of the elderly. If malnutrition refers to dietary intake in reference to dietary needs, intakes of several nutrients have been shown to be inadequate among those living in the community. However, diet is only one indicator of nutritional status of elderly people and probably not the best given the methodological assessment issues. Therefore, other indicators such as anthropometric, hematological, biochemical and immunological indices, health conditions and diseases need to be considered in addition in the evaluation of nutritional health. Many efforts have been directed to discovering factors influencing the nutritional status of elderly people to identify people with poor nutritional status or those who are at high risk of nutritional problems. Based on these factors, some simple and easy to apply nutritional assessment tools such as nutrition screening initiative checklist have been developed.

Malnutrition is one of the most prevalent problems in the elderly that is easily overlooked. The nutritional state of the elderly is threatened by several factors including the followings: tooth loss or

masticatory difficulty; deterioration of physiological functions, including the weakening of digestion and absorption; loss of gustation; effect of medications used for treating various ailments; smoking; habitual drinking; decreased activity; living alone; depression due to death of a spouse; psychological factors such as feelings of neglect; financial difficulties due to reduction in income; and environmental factors (Brownie 2006). Consequently, there is insufficient intake of food by the elderly and the utilization rate in the body also becomes lower; thus, there is a high predisposition to a nutritional risk state. Through various studies, it has been shown that the nutritional state of elderly Koreans is generally not good (Kim et al. 1997; Cho et al. 1997). In particular, the level of malnutrition is higher in the elderly residing in social welfare institutions and the low-income elderly residing at home, and it is known that the nutritional intake state is poor in the elderly who evaluate their own health as being poor or as having more clinical symptoms of diseases (Son et al. 1996; Song et al. 1995).

There is growing attention in the relationships between aging, nutritional status, and cognitive function. Research in this filed has tended to focus on advanced old age, although many of the causal pathway implicated may operate over a much longer period from early life. Nutrition has been found to be associated with cognitive impairment and dementia in older populations. The nutritional risk level of the elderly is associated with cognitive function (Pearson et al. 2001). Impairment of cognitive functions related to the basic activities of daily living (ADL) has been reported to be more rapid over a 1-year follow-up period in malnourished subjects (Vellas et al. 2005). An increased interest in this field has led to the formulation of varied hypotheses regarding the correlation between nutritional factors and cognitive impairment (Donini et al. 2007).

177.2 Nutrition and Alzheimer's Dementia

Nutrition Screening Initiative (NSI) checklist has been developed as part of the US Nutrition Screening Initiative, a collaborative effort between the American Dietetic Association, the American Academy of Family Physicians and the National Council on the Aging, Inc. The NSI checklist is the first step in a two-tiered approach to screening and assessment. The checklist is designed to enhance the older person's understanding of the determinants of nutritional well-being and promote the consideration of nutritional problems by health professionals. This self-administered awareness tool is intended for the public and may need a follow-up by professionals for further nutritional and health assessments. The checklist includes 10 Yes/No items that are given different weights associated with the nutritional well-being of older people. The checklist is not meant to be a clinical diagnostic tool but should predict overall perceived health status and identify persons whose estimated nutrient intakes fall below the recommended dietary allowances (Table 177.2).

Table 177.1 Key features of K-MMSE: Korean Mini Mental State Examination

1. The MMSE developed by Folstein et al. (1975) is the most widely used instrument for measuring global cognitive performance and for identifying individuals with cognitive dysfunction
2. The MMSE, variously modified and translated into several languages, has been used successfully in several independent cross-national studies of dementia epidemiology
3. The original MMSE was somewhat modified in the development of the K-MMSE in order to adapt it to the cultural background in Korea
4. The total K-MMSE score was calculated by summing the correct responses to all the K-MMSE sub items
5. The test scores ranged from 0 to 30
6. A Korean study in the community defined the cutoff point of K-MMSE score during the screening of dementia as 17/18 points

Table 177.2   Key features of nutrition screening Initiative checklist

1. The Nutrition Screening Initiative checklist comprises 10 questions that were designed such that their answer would be "yes" or "no."
2. Based on the evaluation standard for the nutritional risk level, 0–2 points were assigned to a good nutritional state; 3–5 points, moderate nutritional risk state; and more than 6 points, high nutritional risk state.
3. In case of good nutritional state, recheck your nutritional score in 6 months
4. If you are at moderate nutritional risk, see what can be done to improve your eating habits and life style. Recheck your nutritional score in 3 months
5. If you are at high nutritional risk, bring this checklist the next time you see your doctor or other qualified health and social service professional. Ask for help to improve your nutritional health.
6. The NSI checklist is influenced by the type of family members living together, diseases, financial condition, age, physical health condition, and its effects on cognitive function
7. Question 1 (yes = 2 point): I have an illness or condition that made me change the kind and/or amount of food I eat. Question 2 (yes = 3 point): I eat fewer than 2 meals per day. Question 3 (yes = 2 point): I eat few fruits or vegetables or milk products Question 4 (yes = 2 point): I have 3 or more drinks of beer, liquor or wine almost every day. Question 5 (yes = 2 point): I have tooth or mouth problems that make it hard for me to eat. Question 6 (yes = 4 point): I don't always have enough money to buy the food I need. Question 7 (yes = 1 point): I eat alone most of the time. Question 8 (yes = 1 point): I take 3 or more different prescribed or over-the-counter drugs a day. Question 9 (yes = 2 point): Without wanting to, I have lost or gained 10 lb in the last 6 months. Question 10 (yes = 2 point): I am not always physically able to shop, cook, and/or feedmyself.

Nutritional status is potentially important in the etiology of cognitive impairment and dementia. Dementia is associated with weight loss, which precedes the onset of the clinical syndrome and accelerates around the time of diagnosis. Specific nutritional deficits such as vitamin B12 and folate deficiency are recognized to be important potential risk factors, and other dietary factors such as caloric intake and fish consumption have also been implicated as modifying risk. Epidemiological (Masaki et al. 2000; Engelhart et al. 2002) and laboratory studies (Cotman et al. 2002; Kruman et al. 2002) have demonstrated that antioxidants, which are found in abundance in fresh fruits and vegetables, are associated with cognitive function. In addition, it has been reported that nutritional substances or food stuffs such as fish, vitamin, and a moderate amount of alcohol decrease the risk for dementia and Alzheimer's disease (AD) (Kalmijn et al. 1997, 2004; Luchsinger and Mayeux 2004). Several studies have clearly demonstrated that nutritional factors are linked with AD, both as risk or protective factors in the onset of the disease and as elements that are capable of modifying the disease course (Donini et al. 2007). Although dietary intervention is capable of minimizing or preventing weight loss (Franzoni et al. 1996), patients at particular risk of malnutrition are not detected quickly enough; therefore, nutritional screening tools should be included in the multidimensional geriatric evaluation that must be performed in every elderly patient.

177.3 Nutrition and Mild Cognitive Impairment

In 1999, Petersen et al. proposed clinical MCI criteria including essentially preserved activities of daily living. In 2003, Petersen et al. revised original criteria as one including clinical judgment for assessing people of low education and for ADL performance. In terms of the criterion of preserved activities of daily living, the CSHA study found intact ADL to be unnecessary for case definition but the validity of the ADL criterion were also challenged in the other study. These reflect that MCI represents a condition with multiple sources of heterogeneity. Key methodological factors differing

across studies of MCI include (1) the fact of MCI diagnoses being assigned on a case-by-case basis in a consensus conference of expert clinicians or assigned purely objectively using neuropsychological, functional, and medical data; (2) the extent to which non-demented older subjects with memory deficits are distinguished from those with cognitive deficits in non-memory domains; (3) the extent to which those with isolated deficits in one cognitive domain are distinguished from those with impairment in multiple cognitive domains; (4) the test score "cutoff" used to define cognitive impairment; (5) the use of norms that adjust for age and other background factors such as years of school, sex, and race/ethnicity; (6) the extent to which subjective memory complaints are considered as a requirement for the diagnosis of MCI; and finally, (7) follow-up diagnosis being made with the knowledge of prior diagnostic status.

Difficulties remain in defining the boundaries between normal ageing and MCI, and between MCI and mild dementia. An international working group on MCI formulated specific recommendations for certain criteria, including: (1) the individual is neither normal nor demented; (2) there is evidence of cognitive deterioration, shown by either objectively measured decline over time or subjective report of decline by self or informant in conjunction with objective cognitive deficits; and (3) activities of daily life are preserved and complex instrumental functions are either intact or minimally impaired. Considering the special situation that low educational level and simple life style are frequent in the Korean rural community, there are many subjects who are neither normal nor demented and whose complex instrumental functions are impaired. Findings of epidemiological studies have shown that subtle difficulties in the performance of everyday activities are common in individuals with MCI. If limitations on complex ADL were present in patients with MCI, the assessment of impairments in everyday life might provide useful complementary information to establish the diagnosis of the syndrome. The use of combined tests has shown to be a promising procedure in order to increase the accuracy of mild dementia diagnoses, as for instance the combination of a cognitive test with a functional evaluation test. An approach that combines both domains of information is often part of a comprehensive clinical assessment and appears, from the present data, to be valuable in prediction of clinical course as well. However, until now no specific instruments for evaluating complex ADL in MCI have been proposed. So, there is a need for a consensus regarding the degree of functional decline that can be considered acceptable in the frame of MCI definition.

Mild cognitive impairment (MCI) defines a transitional stage between normal aging and dementia (Petersen et al. 2001) and reflects a clinical situation where a person has complaints about memory loss and shows objective evidence of cognitive impairment but exhibits no evidence of dementia (Burns and Zaudig 2002). Not many studies have prospectively addressed the role of putative risk factors for MCI. Three short-term longitudinal studies, carried out in subjects with MCI, identified older age, low education, being African American, presence of ApoE 4, cortical atrophy at neuroimaging, signs or symptoms of vascular diseases and depression as risk factors. In a recent 3-year prospective study, the authors found that a previous diagnosis of psychosis, hip fracture and polypharmacy increased the risk of cognitive impairment in non-demented subjects, independent of subsequent development of dementia. Furthermore, three long-term prospective studies described midlife alcohol drinking, elevated serum cholesterol, high diastolic blood pressure, ApoE4, and white matter hyperintensities as risk factors for MCI in late life. In the absence of sensitive and specific biomarkers, risk profiles are of great importance in identifying individuals with the highest probability of incipient disease. To the extent that MCI represents preclinical AD, risk factors for AD should also be risk factors for MCI development or progression. That this degree of correspondence has not been found again reflects the heterogeneity of MCI. These might well represent reversible comorbid conditions, other than neurodegeneration, that caused or contributed to the cognitive impairment, for example, depression, heart failure, anticholinergic drug use (Ganguli 2006).

Over the last decade few studies have examined nutritional risk and low weight in the community-living older adult population. Multifactorial issues that contribute to nutritional risk and malnutrition make it difficult to study. It is apparent that weight loss and nutritional risk are common in this population and can be associated with adverse outcomes. The results of many studies carried out in recent years ascertained that nutritional factors are linked with dementia, especially with AD, both as risk or protective factors in the onset of the disease and elements able to modify the course of the disease (Donini et al. 2007). But in the case of MCI, antioxidant trials are underway, aiming to prove that vitamin E, selegiline, and Ginkgo Biloba slow or stop MCI to AD conversion (Brenner 2003; Mecocci et al. 2004); however, another trial (Petersen et al. 2005) failed to demonstrate a benefit from vitamin E. This approach is in line with previous studies on preceding concepts on MCI with cognitive stimulants and nootropics (Levy 1994; Lockhart and Lestage 2003). The results have been consistently disappointing and in contrast with neurobiological data, which have always been in favor of the role of free radicals and reactive oxygen species in cell death and dementia onset (Qin et al. 2006).

177.4 Nutrition and Functional Status in the Elderly

At the beginning of the disease course, there may be an alteration of nutritional status. This alteration may be explained by a change in dietary intake due to the inability to carry out complex tasks in daily life (e.g., difficulty in shopping, preparing meals, or selecting food). A change in the instrumental activities of daily living (IADL), which assesses independence in performing complex tasks in daily life, is sometimes one of the first signs of the disease. The original criteria for MCI provided for intact ADL, but the current recommendations indicate that the basic ADL should be mainly preserved, and that a "minimal impairment" in IADL may be accepted (Winblad et al. 2004). Recent data suggest that the inclusion of IADL restriction in MCI criteria improves the prediction of subsequent dementia as well as the stability of the MCI condition over time (Peres et al. 2006). Although no consensus has been reached about what composes an ADL restriction in MCI, functional impairments in MCI are focused on the area of instrumental ADL (IADL) tasks – such as managing finances or using a telephone. As IADL tasks are definitely more cognitively demanding tasks than basic ADL tasks, they are more likely to be vulnerable to early cognitive decline due to MCI. Loss in the ability to complete IADL tasks can be among the earliest signs of MCI, even though global functional impairment would still be unnoticeable. Moreover, recent studies suggest that MCI patients with IADL impairment are at higher risk of progression to dementia in the future. MCI patients have significantly worse IADL ratings compared with cognitively unimpaired controls, and those with IADL impairment experience more rapid functional decline and are more likely to convert to dementia compared with those MCI patients without IADL problems. Therefore, an assessment of the completion of IADL tasks in MCI is potentially of great interest, and could serve as a major criterion for differentiating MCI and cognitively normal elderly. Impaired IADL is a strong prognosticator of progression to dementia, with the risk increasing as a function of the number of impaired IADL tasks, particularly specific IADL tasks (e.g., telephone, transport, medication, and finances) in MCI patients, the conversion rate being almost four times higher.

Because functional and nutritional statuses are interrelated, functional impairment can also increase the risk of poor nutrition in MCI. Many of the identified nutritional risk factors of malnutrition are based on functional competencies such as mobility, depression, cognition, food shopping, and food preparation. Considering MCI has little known risk factors and minimal impairment in IADL, nutritional risk assessment will be helpful.

177.5 Nutritional Risk and Cognition: A Far Eastern Perspective

177.5.1 Nutritional Risk and Cognitive Impairment

Elderly Korean people have a low level of education because the sociopolitical circumstances during their childhood and adolescence hindered their access to formal schooling, and the availability of public education was generally lower during the time period between the Second World War and the Korean War. Although the K-MMSE equals the scoring of the MMSE reported by Folstein, considering the special situation that low educational level are frequent in the Korean rural community, the low K-MMSE scores in the MCI subjects could not suggest that these patients may meet criteria for dementia. Another normative study of the K-MMSE in the elderly showed that education level had a greater effect on the K-MMSE than age and sex (Table 177.1).

The MMSE developed by Folstein is the most widely used instrument for measuring global cognitive performance and for identifying individuals with cognitive dysfunction. The elderly exhibit a high prevalence of cognitive dysfunction that may influence their test performance, and therefore their normative data may differ from those in younger subjects. The MMSE, variously modified and translated into several languages, has been used successfully in several independent cross-national studies of dementia epidemiology. The MMSE was modified and translated into Korean by Kang, and the resulting K-MMSE has been widely used in clinical evaluations and research involving patients with dementia in Korea. The original MMSE was somewhat modified in the development of the K-MMSE in order to adapt it to the cultural background in Korea; however, the K-MMSE still shares all of the limitations of the original MMSE. Temporal orientation was assessed according to the two methods used to calculate year and time in Korea: the solar and lunar years. The words "airplane," "pencil," and "pine tree" were used in the memory assessment, with their associated sounds. Serial sevens (sequential subtraction of 7 from 100) were performed to assess the attention of each patient. The repetition phrase item, "no ifs, ands, or buts," was modified to "seeing is believing" with vowel sounds. The three-stage command was modified to "turn the paper over, fold it in half, and give it to me." The total K-MMSE score was calculated by summing the correct responses to all the KMMSE sub items. The test scores ranged from 0 to 30.

The original K-MMSE score was lower in the moderate or high nutritional risk state group of elderly subjects living in the community when compared with the good nutritional state group of elderly subjects. A Korean study in the community defined the cutoff point of K-MMSE score during the screening of dementia as 17/18 points; the sensitivity and specificity of the findings were 91% and 86%, respectively (Kim et al. 2003). Based on these results, we defined cognitive impairment as the group that had a K-MMSE score lower than 17 points, and cognitive non-impairment was defined as the group that had a K-MMSE score higher than 18 points. In the good nutritional state group, the percentage of subjects demonstrating cognitive function impairment was only 13.9%, whereas it was 27.0% in the moderate nutritional risk state group or the high nutritional risk state group. This suggests that malnutrition state is associated with an impairment of cognitive function (Tables 177.3 and Fig 177.1).

This is in agreement with the findings reported in a study of 627 elderly individuals (Pearson et al. 2001). Although the interrelationship between cognitive impairment and nutritional risk are complex and reciprocal; cognitive impairment recedes malnutrition or vice versa. Recent research demonstrates that altered nutritional status appear to predict the severity and progression of cognitive impairment (Vellas et al. 2005). These findings underscore the importance of systematic nutritional assessment at the time of diagnosis and during the follow-up of cognitive impairment cases, especially in those with dementia, in order to implement nutritional intervention as soon as it is deemed necessary (Gillette-Guyonnet et al. 2007). To examine whether cognitive function differs depending

Table 177.3 The relationship between nutritional risk and Mini Mental State Examination in the Far Eastern community elderly subjects (Reprinted from Lee et al.2009. With permission)

K-MMSE score	Good nutritional state (NSI[a] score ≤ 2), n (%)	Moderate or high nutritional risk (NSI[a] score > 2), n (%)	p^b
>17	1485 (86.1)	615 (73.0)	<0.0001
≤17	239 (13.9)	228 (27.0)	

[a]Nutritional Screening Initiative

[b]Chi-square test

Chi-square analysis was performed to assess the risk for cognitive impairment based on the presence or absence of nutritional risk. Table 177.2 shows that the relative frequency of cases with cognitive impairment was higher in the moderate or high nutritional risk level group when compared with that observed in the good nutritional state group ($x^2 = 66.1$, d.f. = 1, $p < 0.0001$)
Fig.177. 1 Estimated marginal means of Mini Mental State Examination according to the nutritional risk in the Far Eastern community elderly subjects. Multiple logistic regression analysis was performed to assess the risk for cognitive impairment based on the presence or absence of nutritional risk after adjustment for age, sex, and educational level. General Linear Model (GLM) univariate analysis was performed, and GLM profile plots were plotted as shown in this figure (Reprinted from Lee et al. 2009. With permission)

on the responses to the ten questions in the NSI checklist, we compared the response rate of NSI checklist items in the low and high K-MMSE groups. It was observed that the low K-MMSE group responded more frequently to the following two items after adjustment of age, sex, education: (1) "I have tooth or mouth problems that make it difficult for me to eat," (2) "I am not always physically able to shop, cook, and feed myself." Tooth problems are not simply limited to oral problems. Additionally, they are not limited by their association with the socio-economic and education levels, lifestyle, and smoking history; they are also related to diverse physical conditions such as the presence of cardiopulmonary diseases. It has been reported that there is an association between most oral problems and lower cognitive function (Avlund et al. 2004). However, the results cannot confirm whether the presence of tooth and other oral problems resulted in malnutrition and consequently impairment in cognitive function, whether cognitive impairment was caused by other factors that led to tooth and oral problems, or whether cognitive impairment resulted in changes in the lifestyle that induced tooth and oral problems. The same problem was also applied to other questions.

177.5.2 Nutritional Risk and Mild Cognitive Impairment

The frequency of MCI was higher in the moderate or high nutritional risk state group of elderly subjects living in a community when compared with the group of elderly subjects in a good nutritional state. In the good nutritional state group, the percentage of MCI subjects was only 47.0%, whereas it was 61.1% in the moderate or high nutritional risk state group. One study showed that the K-MMSE score was lower in the moderate or high nutritional risk state group of elderly subjects living in the community when compared with the good nutritional state group of elderly subjects. In line with this concept, the nutritional risk state is associated with an MCI (Table 177.4).

However, the interrelationships between MCI and nutritional risk are complex and reciprocal; MCI precedes malnutrition or vice versa. On the one hand, nutritional risk influences risk factors or outcomes of MCI. Recent research demonstrates that an altered nutritional status appear to predict the severity and progression of cognitive impairment (Vellas et al. 2005). These findings underline the systematic nutritional assessment in MCI. On the other hand, mild changes in discrete IADLs in MCI increase nutritional risk. By analyzing the functional characteristics of subjects with MCI collected in the ReGAl study, it was found that subjects with MCI had more severe IADL disability than cognitively healthy elderly controls, particularly with regard to shopping, self-administration of drugs, and handling finances. These IADL disabilities were significantly associated with the degree of cognitive impairment, but not with somatic comorbidity. Similarly, in another study (Perneczky et al. 2006), it was found that MCI patients are limited in everyday tasks that involve either memory (i.e., finding things at home, keeping appointments, and remembering information from a conversation or from television) or complex reasoning (i.e., checking bank account, shopping). When compared the response rate of the NSI checklist items in the MCI and NCF elderly groups to examine whether MCI results in different responses to the ten questions in the NSI checklist. The MCI group responded more frequently to the following two items after the adjustment of age, sex, and education: (1) "I do not always have enough money to buy the food I need" and (2) "I am not always physically able to shop, cook, and feed myself (Table 177.5)." Items (1) and (2) generally reflect financial abilities and physical abilities. Because the "yes" response rate to item (1) was too low, the interpretation of the result has limitations. But financial abilities cognitively demand IADLs that are vital to independent functioning in a community (Marson et al. 2000), and they are very sensitive to mild AD (Earnst et al. 2001; Wadley et al. 2003). Financial skills are multidimensional, and they encompass an array of judgmental, conceptual, and pragmatic skills. They have been shown to be affected in the early stages of dementia. The nutritional state is also not limited by the association with the socio-economic and education levels, lifestyle, and

	β (SE)	p	OR (95% CI)
Intercept	−0.28 (1.44)	0.846	–
Nutritional risk (NSI score ≥ 3)	0.12 (0.06)	0.032	1.13 (1.01–1.26)
Age (year)	0.004 (0.02)	0.849	1.14 (1.10–1.17)
Sex: male	0.24 (0.24)	0.319	1.28 (0.79–2.06)
Education (year)	−0.23 (0.08)	0.007	0.798 (0.679–0.939)
K-SGDS score	0.03 (0.03)	0.317	1.028 (0.974–1.086)

K-SGDS Korean short form Geriatric Depression Scale, *SE* standard erro, *OR* odds ratio, *CI* confidence interval

The nutritional risk increased the risk of mild cognitive impairment (OR = 1.13, 95% CI = 1.01–1.26) after the adjustment for age, sex, educational level, and geriatric depression score

Table 177.5 Relationship between mild cognitive impairment and nutrition screening initiative checklist (ten items) in the Far Eastern community elderly subjects (Reprinted from Lee et al. 2009. With permission)

Items (weighted score)		NCF elderly n (%)	MCI n (%)	p	Odds ratio (OR)
F1. I have an illness or condition that made me change the kind and/or amount of food I eat. (2)	Yes	23 (9.7)	37 (14.6)	0.10	Unadjusted OR = 0.627 (0.361–1.092)
	No	214 (90.3)	216 (85.4)		Adjusted OR = 1.563 (0.890-2.744)
F2. I eat fewer than two meals per day. (3)	Yes	2 (0.8)	3 (1.2)	0.71	Unadjusted OR = 0.709 (0.117–4.282)
	No	235 (99.2)	250 (98.8)		Adjusted OR = 1.532 (0.243–9.658)
F3. I eat few fruits or vegetables or milk products. (2)	Yes	1 (0.4)	4 (1.6)	0.20	Unadjusted OR = 3.791 (0.421–34.165)
	No	236 (99.6)	249 (98.4)		Adjusted OR = 4.717 (0.496–44.832)
F4. I have three or more drinks of beer, liquor, or wine almost every day. (2)	Yes	6 (2.5)	10 (4.0)	0.38	Unadjusted OR = 1.584 (0.567–4.429)
	No	231 (97.5)	243 (96.0)		Adjusted OR = 1.503 (0.513–4.404)
F5. I have tooth or mouth problems that make it hard for me to eat. (2)	Yes	118 (49.8)	135 (53.4)	0.43	Unadjusted OR = 1.154 (0.809–1.645)
	No	119 (50.2)	118 (46.6)		Adjusted OR = 0.963 (0.662–1.400)
F6. I don't always have enough money to buy the food I need. (4)	Yes	2 (0.8)	12 (4.7)	0.01	Unadjusted OR = 5.851(1.295–26.423)
	No	235 (99.2)	241 (95.3)		Adjusted OR = 6.006 (1.316–27.398)
F7. I eat alone most of the time. (1)	Yes	33 (13.9)	40 (15.8)	0.56	Unadjusted OR = 1.161 (0.705–1.913)
	No	204 (86.1)	213 (84.2)		Adjusted OR = 1.064 (0.635–1.782)
F8. I take 3 or more different prescribed or over-the-counter drugs a day. (1)	Yes	20 (8.4)	21 (8.3)	0.96	Unadjusted OR = 0.982 (0.518–1.862)
	No	217 (91.6)	232 (91.7)		Adjusted OR = 1.169 (0.608–2.247)
F9. Without wanting to, I have lost or gained 10 lb in the last 6 months. (2)	Yes	3 (1.3)	3 (1.2)	0.94	Unadjusted OR = 0.936 (0.187–4.684)
	No	234 (98.7)	250 (98.8)		Adjusted OR = 1.325 (0.258–6.807)
F10. I am not always physically able to shop, cook and/or feed myself. (2)	Yes	38 (16.0)	65 (25.7)	0.01	Unadjusted OR = 1.811 (1.158–2.831)
	No	199 (84.0)	188 (74.3)		Adjusted OR = 1.647 (1.025–2.648)

NCF normal cognitive function, *MCI* mild cognitive impairment

The mild cognitive impairment group responded more significantly than the normal cognitive function elderly groups in the following two items: (1) "I do not always have enough money to buy the food I need" and (2) "I am not always physically able to shop, cook, and feed myself" ($p = 0.01$; $p = 0.001$, respectively). Those participants with economic problem or physical disability were significantly more likely than those are not to develop mild cognitive impairment (with economic problem adjusted OR = 6.006, 95% CI = 1.316–27.398; with physical disability adjusted OR = 1.647, 95% CI = 1.025–2.648) after adjustment for age, sex, and education

smoking history; it is also related to diverse physical conditions such as the presence of cardiopulmonary diseases. This finding is consistent with the results of previous study that the low cognitive function group (less than the score of K-MMSE 17) responded more frequently to item (1).

177.6 Applications to Other Areas of Health and Disease

Although dietary intervention is capable of minimizing or preventing weight loss, patients at particular risk of malnutrition are not detected quickly enough; therefore, nutritional screening tools should be included in the multidimensional geriatric evaluation that must be performed in every elderly patient.

Because functional and nutritional statuses are interrelated, functional impairment can also increase the risk of poor nutrition in mild cognitive impairment (MCI). Many of the identified nutritional risk factors of malnutrition are based on functional competencies such as mobility, depression, cognition, food shopping, and food preparation. Considering MCI has little known risk factors and minimal impairment in IADL, nutritional risk assessment will be helpful.

Summary Points

- Mini Mental State Examination score was lower in the moderate or high nutritional risk state group of elderly subjects living in the community when compared with the good nutritional state group of elderly subjects.
- The frequency of Mild Cognitive Impairment was higher in the moderate or high nutritional risk state group of elderly subjects living in a community when compared with the group of elderly subjects in a good nutritional state.
- Nutritional factors are linked with Alzheimer's disease, both as risk or protective factors in the onset of the disease and as elements that are capable of modifying the disease course.
- Considering Mild Cognitive Impairment has little known risk factors and minimal impairment in Instrumental Activities of Daily Living, nutritional risk assessment will be helpful.
- Nutrition screening tools should be included in the multidimensional geriatric evaluation that must be performed in every elderly patient.

Key Terms

Mild cognitive impairment: This is a transitional stage between normal aging and dementia and reflects a clinical situation where a person has complaints about memory loss and shows objective evidence of cognitive impairment but exhibits no evidence of dementia.

Nutrition screening initiative: The checklist comprises ten questions that were designed such that their answer would be ''yes'' or ''no.'' 0–2 points were assigned to a good nutritional state; 3–5 points, moderate nutritional risk state; and more than 6 points, high nutritional risk state.

178.1 Introduction

178.1.1 Dementia and Predementia Syndromes

In westernised countries, Alzheimer's disease (AD) and vascular dementia (VaD) are the most common forms of dementia, with estimated incidences of 70% and 15% of all dementia, respectively (Table 178.1). In elderly people, AD is the primary neurodegenerative disorder defined by a loss of memory associated with a progressive deterioration of other cognitive functions that must also contribute to significant decline in a person's level of everyday functioning, eventually to disability and finally contributing to death in a period of time that can range from 2 to 20 years (Table 178.1). After the age of 60 years, the prevalence of AD doubles every 5 years, increasing from a prevalence of 1% among those 60–64 years old to about 40% among those aged 85 years and above (Vickers et al. 1999). Thus, with recent improvements in life expectancy and as a result of increased aging population, AD has become a major public health consideration because of its consequence in terms of social and emotional costs. AD is characterised by two major anatomo-pathological features, intraneuronal protein clusters composed of paired helical filaments consisting of hyperphosphorylated forms of tau protein [neurofibrillary tangles (NFTs)], and extracellular protein aggregates [senile plaques (SPs)]. The SPs contain a diverse array of constituents but the main one being a toxic amyloid β (Aβ) peptide that accumulates most likely as a result of misprocessing of the Aβ protein precursor (AβPP) by β- and γ-secretases as well as reduced levels of clearance of Aβ through the blood-brain barrier (BBB) from the brain (Bell and Zlokovic 2009) and its degradation by a variety of Aβ degrading enzymes within the brain (Miners et al. 2008; Banks et al. 1997). In turn, Aβ aggregates into a variety of molecular configurations (Irvine et al. 2008) which contribute to a pathogenic cascade ultimately leading to neuronal loss. Amongst the various molecular configurations that Aβ can

Table 178.1 Key features of dementia syndromes

1. Dementia is a syndrome definite by impairments in memory and other cognitive functions that are severe enough to cause significant decline from a previous level of social and occupational functioning

2. AD is the most common dementia and primary neurodegenerative disorder in the elderly, gradually leading to a complete psychological and physical dependency and finally to death within one to two decades

3. The diagnosis of AD is essentially a clinical one, and it is based on a typical clinical picture and findings, with a set of clinical criteria often used in research

4. Cognitive function declines over time, and the diagnosis of AD can be considered when the patient has impairments in memory and at least in one other cognitive function (executive dysfunction, agnosia, aphasia, apraxia), severe enough to cause impairment in social or occupational functioning

5. In advanced AD, common symptoms include also confusion, behavioural and gait disturbances, and the patients are increasingly dependent on others in activities of daily living

6. Another common form of dementia is VaD, its clinical presentation varies greatly depending on the causes and location of cerebral damage

7. Large-vessel disease leads commonly to multiple cortical infarcts and a multifocal cortical dementia syndrome

8. Small-vessel disease, usually resulting from hypertension and diabetes, causes periventricular white matter ischemia and lacunar strokes characterised clinically by subcortical dementia with frontal lobe deficits, executive dysfunction, slow information processing, impaired memory, inattention, depressive mood changes, slowing of motor function, Parkinsonian features, small-step gait, urinary disturbances and pseudobulbar palsy

9. The characteristic neuropsychological profile of VaD is believed to include frequently early impairment of attention and executive control function, with slowing of motor performance and information processing, while episodic memory is relatively spared compared to that in AD

This table lists the key facts of dementia syndromes including clinical pictures and criteria of Alzheimer's disease (AD) and vascular dementia (VaD), the most common dementia syndromes

form, including soluble monomers, dimers and oligomers, increasingly complex aggregations are suggested to be more toxic than monomeric forms (Permanne et al. 2002).

Although the 'amyloid cascade hypothesis' is one of the more commonly upheld and cited hypotheses, AD is also recognised to involve a combination of genetic and environmental factors. Moreover, a significant comorbidity of AD and cerebrovascular disease has been demonstrated, suggesting that cerebrovascular disruption may be an important contributor to, and feature of, AD and supporting views of possible pathological and clinical overlap between AD and VaD (Gold 2003; Jellinger 2003). In fact, it has been shown that the major forms of Aβ peptides (Aβ 1–40 and Aβ 1–42) may cause vascular lesions. Cerebral amyloid angiopathy (CAA), which involves the deposition of Aβ 1–40 in the cerebrovascular system and is a major risk factor for stroke, is one such example. CAA is normally present in the majority of AD cases but is only present (in less severe forms) in approximately 30% of non-demented elderly (Love et al. 2009). Other examples include the occurrence of Aβ associated lesions in the arterioles of some animal models (Rhodin et al. 2003), similar to those observed in the brain of AD patients and which may represent the initial phase of a vascular inflammatory response associated with CAA (Banks et al. 2006).

Recently, the term 'predementia syndrome' was proposed to describe all conditions associated with age-related deficits in cognitive function that are reported in the literature. This included a mild stage of cognitive impairment based on a model of normality and pathological characteristics that were considered to be predictive of early stages of dementia (Panza et al. 2006) (Table 178.2). Mild cognitive impairment (MCI) is, at present, the most widely used term to identify non-demented aged persons with a mild memory or cognitive impairment that is not considered to be explained by any recognised medical or psychiatric disorder and which is not severe enough to cause impairment as might be more typically attributed to dementia (Table 178.2). Moreover, 12% of MCI patients develop dementia within 1 year (Panza et al 2005) a prevalence that increases to 20% over 3 years (Petersen et al. 2001). Recently, in the Italian Longitudinal Study on Aging (ILSA), a population-based study involving a sample of 5,632 individuals aged 65–84 years, a progression rate to dementia of MCI of 3.8/100 person-years was found (Solfrizzi et al. 2004). Nevertheless, at present, it still questionable whether these entities are a manifestation of normal aging, are clinically distinguishable from dementing syndromes, or, are part of a continuum with dementia.

Table 178.2   Key features of predementia syndromes

1. The term 'predementia syndromes' identifies all conditions with age-related deficits in cognitive function reported in the literature, including a mild stage of cognitive impairment based on a normality model and pathological conditions considered predictive or early stages of dementia

2. Among predementia syndromes, MCI is, at present, the most widely used term to indicate non-demented aged persons with a mild memory or cognitive impairment that cannot be accounted for any recognised medical or psychiatric condition

3. The general criteria for MCI include: (a) memory complaint, (b) objective memory disorder, (c) absence of other cognitive disorders or repercussions on daily life, (d) normal general cognitive function, (e) absence of dementia

4. MCI definitions can be broadly classified as amnestic (aMCI) and nonamnestic (naMCI)

5. There is now ample evidence that MCI is often a pathology-based condition with a high rate of progression to AD, and aMCI, with a central role for memory disorder and with relative preservation of other cognitive domains, was identified as the predementia syndrome for AD

6. aMCI can be subdivided into a single domain subtype with a pronounced memory deficit or a multiple domain subtype that includes memory impairment along with some impairment in other cognitive domains such as language, executive function, and visuospatial skills

7. The other major MCI subtype is naMCI, which similarly can be subdivided into single and multiple domain subtypes

This table lists the key facts of predementia syndromes including diagnostic criteria and clinical classification of mild cognitive impairment (MCI), the most common predementia syndrome

Table 178.3 Key features of aluminium

1. Aluminium is a nonessential metal present in 8% of the Earth's crust
2. Aluminium has no known function in living cells and produces some toxic effects in elevated concentrations
3. The toxicity of aluminium can be traced to deposition in bone and the central nervous system, which is particularly noticeable in patients with reduced renal function
4. In very high doses, aluminium can cause neurotoxicity, and is associated with altered function of the blood-brain barrier
5. Present studies have not convincingly demonstrated a causal relationship between aluminium and AD. Nevertheless, some studies suggested aluminium exposure as a risk factor for AD, as some brain senile plaques have been found to contain increased levels of the metal

AD Alzheimer's disease

This table lists the key features of aluminium including definition, general health effects, and current research findings on the aluminium and AD

178.1.2 Neurotoxicity of Aluminium and Other Metals

Although knowledge of the pathophysiology of AD has greatly increased during recent decades, and new therapeutic approaches have been proposed, AD is still a chronic and incurable disease, and its causal mechanisms remain unclear. In recent years, interest in the potential role of metals such as iron, copper and zinc, among other trace redox-active transition metals, in the pathogenesis of AD, has grown considerably (Todorich and Connor 2004). The hypothesis that aluminium (Al) exposure is related to AD has prompted several studies and, at present, the relationship is still unresolved and under investigation (Table 178.3). The potential role of Al as a mediator of neurotoxicity was suggested more than 100 years ago after Dollken reported his work with Al in experimental studies on animals (Dollken 1897). Al neurotoxicity was first reported in humans at the beginning of the 1970s when neurodegeneration in patients undergoing chronic hemodialysis was observed (Wills and Savory 1983). The hypothesis that Al could be involved in the pathogenesis of AD arose when Al was detected in SPs and NFTs in brain tissue from AD patients (Crapper et al. 1973). Subsequently, several studies have reported that higher intake of Al increases the production of Aβ in transgenic APP mice (Praticò et al. 2002; El-Rahman 2003). Although further research supported these findings, the role of Al remains controversial, because several other investigations did not find any relationship between Al exposure and risk of AD. In this chapter, we examine the possible role of dietary exposure to Al from drinking water or foods in modulating the risk of age-related changes in cognitive function, predementia and dementia syndromes, as well as the possible molecular epidemiological mechanisms behind the observed associations.

178.2 Environmental Exposure to Aluminium, Including Drinking Water, in Cognitive Decline and Dementia

Al is a non-essential metal present in 8% of the Earth's crust. It is a lightweight, silvery white, soft, malleable metal derived from the refining and smelting of cryolite and bauxite ore (Miessler 2003). Al is omnipresent in everyday life, and may enter the human body in many ways such as the environment, diet or drugs. Several pathological conditions that involve neurobehavioral changes have been reported among the workers involved in the Al industry such as shipbuilding, petroleum processing, and rubber industry. In particular, the potential relationship between Al body burden and CNS function was studied in Al welders where a threshold level for adverse effects was suggested (Riihimäki et al. 2000). In this context, low-exposure and high-exposure groups were defined according to Al concentrations

measured in serum (S-Al) and urine (U-Al) and were examined with a neuropsychological test battery. This neuropsychological testing revealed a circumscribed negative dose-dependent effect associated with increased Al body burden, mainly in tasks demanding complex attention, the processing of information using working memory and the analysis and recall of abstract visual patterns. This study indicated that the body burden threshold for adverse effect approximates to a U-Al value of 4–6 micromol/l and an S-Al value of 0.25–0.35 micromol/l among Al welders (Riihimäki et al. 2000). Further evidence in support of the potential of Al-mediated toxicity in humans comes from observations made of the widespread practise of glue sniffing among teenagers (Akay et al. 2008). Here the investigators compared the S-Al of glue sniffing groups and healthy control adolescents and they computed Al levels of different commercial glue preparations (i.e., metal and plastic containers). The S-Al was found to be 63.29 ± 13.20 in glue sniffers compared with 36.7 ± 8.60 ng/ml in control subjects ($P < 0.001$) (Akay et al. 2008).

Unlike occupational exposures, environmental exposure to Al is inevitable or less easy to avoid. The principal route of metal exposure is through diet (food/drinking water) and inhalation of Al as fine particles. It has been estimated that the dietary intake of Al can range from 3 to 30 mg/day, and varies with the composition of the food eaten, country of residence, age and sex (World Health Organization 1997). In the USA, the total dietary Al intake estimates for adult men and women are 8–9 and 7 mg/day, respectively (Pennington and Schoen 1995). The metal can be taken from food (both naturally occurring Al and its additives), from cookware, utensils and food wrappings, containers (including Al drink cans), and from water, aerosols and dusts. However, dietary absorption of Al consumed from food is small (less than 1% of ingested Al is absorbed) if compared with the amounts consumed through the use of Al containing antacids that may provide doses of 50–1,000 mg/day (Reinke et al. 2003). Similarly, the bioavailability of Al from water is higher than from food (0.3% vs 0.1%, respectively); yet, due to differences in daily Al intake, drinking water contributes considerably less to the total Al body burden (Yokel and Florence 2006).

Since Al is used extensively as a coagulant in water treatment, to reduce the number of small particles or as a flocculation agent to remove organic substances and improve the colour of the water, the issue of safe levels of Al in drinking water is of considerable interest to public health officials and regulatory agencies (Flaten 2001). However, other elements present in drinking water, such as fluoride, copper, zinc, iron could also have an effect on cognitive impairment or influence the Al neurotoxicity. Some epidemiological studies, but not all, suggest that silica could be protective against Al damage, because it reduces the oral absorption of Al and/or enhances Al excretion (Gillette-Guyonnet et al. 2005).

The World Health Organization (1997) has recommended that Al concentrations in drinking water should not exceed 0.2 mg/l. The US Environmental Protection Agency set 0.05 mg/l as a limit in 1985, but the European Union has more recently recommended 0.05 mg/l as a guideline with a maximum permissible level of 0.2 mg/l (Shcherbatykh and Carpenter 2007). Numerous epidemiological studies reported their investigations of the relationship between exposure to Al from drinking water and risk of AD (Flaten 2001). The first attempts to relate the actual levels of Al in drinking water to AD were made in 1986, when two parallel Norwegian studies reported higher mortality from dementia (from all causes) in areas with high Al concentration in drinking water (Vogt 1986). A cross-sectional investigation conducted a few years later in England and Wales found that among all other causes of dementia the risk of AD was 1.5 times higher in districts where the mean Al concentration in drinking water exceeded 0.11 mg/l, compared to the districts where Al concentrations were less than 0.01 mg/l (Martyn et al. 1989) (Table 178.4). In the same period, another ecological study conducted in Canada reported an excess of dementia mortality from the north shore of Bonavista Bay; a phenomenon that could be explained only by high Al concentration in the drinking water (165 mg/l) and low pH (5.2) in that area, because no other differences in sex, age or other parameters could be found (Frecker 1991) (Table 178.4).

Neri and Hewitt (1991) Canada	Case-control study	2,232 patients aged 55 years or over	Water quality data from the Water Quality Surveillance Programme of the Ontario Ministry of the Environment	Hospital discharge data with a diagnosis of dementia or presenile dementia	The relative risks associated with the consumption of drinking water containing Al concentrations of <0.01, 0.01–0.1, 0.1–0.199 and >0.200 mg/l were estimated to be 1.00, 1.13, 1.26 and 1.46, respectively
McLachlan et al. (1996) Canada	Case-control study; 830 brains of healthy controls and those with neurodegenerative diseases were donated by next of kin to the CBTB between 1981 and 1991, who, at the time of death, were Ontario residents.	680 brains analyzed which 385 with pathological or clinical diagnosis of AD and 295 controls	Al of public drinking water at last residence before death at the first moment; in the second moment Al of 10-year weighted residential exposure prior to death	Histopathologically verified AD	Elevated risk for AD associated with higher levels of Al (>0.1 mg/l) (OR = 1.7, 95% CI 1.2–2.5). For an Al concentration in drinking water of 0.125 mg/l, the OR for risk of AD was 3.6 (95% CI 1.4–9.9); at 150 mg/l the OR was 4.4 (95% CI 0.98–20), and at 0.175 mg/l it was 7.6 (95% CI 0.98–61)

CBTB Canadian Brain Tissue Bank

This table lists the principal findings of cross-sectional clinical, ecological and epidemiological studies on the relationships between dietary Al from drinking water and dementia (i.e., AD), including setting, study design, and Al and cognitive assessment used. OR = Odds Ratio; 95% CI = 95% confidence internal

A case-control study conducted in Ontario, Canada, described dose–response relationships between the Al content of drinking water and risk of AD, using hospital discharge data with a diagnosis of dementia or presenile dementia (Neri and Hewitt 1991) (Table 178.4). The relative risks (RR) associated with the consumption of drinking water containing Al concentrations of < 0.01, 0.01–0.1, 0.1–0.199 and > 0.200 mg/l were estimated to be 1.00, 1.13, 1.26 and 1.46, respectively. Subsequent re-analysis of the data adjusted for age and sex confirmed a stronger dose–response relationship for those over 75 years of age (Smith 1995). Another Canadian investigation studied the relationship between Al, fluoride and other constituents in drinking water and cognitive function (Forbes et al. 1995). The research project was based on the Ontario Longitudinal Study of Aging, where 2,000 men have been followed for about 30 years. Analysis of the data showed that men living in areas with high Al and low fluoride concentrations in drinking water were about three times more likely to have some form of cognitive impairment than those individuals living in the areas with low Al and high fluoride levels (Forbes et al. 1995). The same authors in a previous analysis confirmed that both neutral pH, relatively low Al concentrations, and relatively high fluoride concentrations in drinking water decreased the odds of cognitive impairment by a factor of five (Forbes et al. 1994). Al concentration in drinking water at last residence before death was used as the measure of exposure in a case-control study conducted on autopsy-verified material comparing the patients with AD and controls without brain pathology (McLachlan et al. 1996) (Table 178.4). The results reported elevated risks for histopathologically verified AD associated with higher levels of Al [odds ratios (OR) = 1.7, 95% CI 1.2–2.5, for a level of Al > 0.1 mg/l]. For an Al concentration in drinking water of 0.125 mg/l, the OR for risk of AD was 3.6 (95% CI 1.4–9.9); for 0.150 mg/l, the OR was 4.4 (95% CI 0.98–20); and for 0.175 mg/l, it was 7.6 (95% CI 0.98–61). Despite the fact that results were seemingly biased by selection criteria, the study had several methodological strengths, including the diagnostic quality of the data (McLachlan et al. 1996) (Table 178.4).

In France, a geographic association between Al and silica and cognitive decline or dementia was reported, utilizing the data from the Personnes Agèes QUID (PAQUID) cohort study. In this study, 3,777 subjects aged 65 years and above who were living at home in either a rural or an urban area in southwestern France were followed for up to 8 years, recording all new cases of dementia and AD (Rondeau et al. 2000). In each residential area, the range and mean exposure to Al (0.001–0.459 mg/l, median 0.009 mg/l) and silica (4.2–22.4 mg/l) from drinking water were recognised. The analysis of data adjusted for age, gender, educational level, place of residence, and wine consumption revealed that the risk of dementia was higher for individuals who lived in areas with high levels of Al in water (mean concentration >0.1 mg/l) compared with people residing in areas with Al levels less than 0.1 mg/l (RR: 1.99; 95% CI: 1.20–3.28, $P = 0.007$). Higher silica concentrations (11.25 mg/l), adjusted for age and gender, were associated with a reduced risk of dementia (RR: 0.71; 95% CI: 0.56–0.91, $P = 0.007$) (Rondeau et al. 2000) (Table 178.5). The adjusted RR of AD for individuals exposed to drinking water with Al concentration > 0.10 mg/l was 2.14 (95% CI: 1.21– 3.80, $P = 0.007$). The risk of AD was reduced in the presence of high concentrations of silica (RR: 0.73; 95% CI: 0.55–0.99, $P = 0.04$), and the authors concluded that a concentration of Al in drinking water above 0.1 mg/l may be a risk factor for dementia and AD although no dose-response effect was found (Rondeau et al. 2000) (Table 178.5). Recently, the same group revisited this topic with more precise data on daily Al and silica intake in a larger cohort followed for 15 years adding 400 subjects from the Aluminum-Maladie d'Alzheimer (ALMA+) cohort to the 3,777 elderly subjects from the PAQUID study (Rondeau et al. 2009) (Table 178.5). In this recent study, two measures of exposure to Al and silica were taken into account: geographic and individual exposure from daily consumption of tap water (including water used in making tea, coffee, soup or alcoholic drinks) and bottled water (spring or mineral). Of the whole sample, only 1,925 subjects were considered because they were free of cognitive impairment at baseline and had reliable water consumption data. Whereas geographic exposure

References Longitudinal studies	Setting and study design	Subjects	Aluminium assessment	Cognitive functions assessment	Results and conclusions
Rondeau et al. (2000) France	Longitudinal study (8 years of follow-up); subjects from PAQUID study	3,777 subjects aged 65 years and older	In each residential area the range and mean exposure to Al (0.001–0.459 mg/l, median 0.009 mg/l) and silica (4.2–22.4 mg/l) from drinking water were recorded	MMSE and other cognitive tests; standardised questionnaire for dementia's diagnosis (DSM III revised criteria); NINCDS/ADRDA criteria for AD; Hachinski score for VaD	The risk of dementia was higher for individuals who lived in areas with high levels of Al in water (>0.1 mg/l) compared with people residing in areas with Al levels less than 0.1 mg/l (RR = 1.99, 95% CI = 1.20–3.28). Higher silica concentrations (>11.25 mg/l), were associated with a reduced risk of dementia (RR = 0.71, 95% CI 0.56–0.91). The adjusted RR of AD for individuals exposed to Al concentration >0.10 mg/l was 2.14 (95% CI 1.21–3.80); the risk of AD was reduced in the presence of high concentrations of silica (RR = 0.73, 95% CI 0.55–0.99). No dose-response effect was found
Gillette-Guyonnet et al. (2005) France	Cross-sectional and longitudinal study (7 years of follow-up); multicentre study (EPIDOS)	7,598 women aged >75 years	Questionnaire relative to the daily consumption of tap water and mineral water and the brand of mineral water most frequently consumed	SPMSQ considering women cognitively normal with a score >8; MMSE and Grober and Buschke test; dementia was diagnosed by DSM IV and AD diagnosed by NINCDS/ADRDA criteria.	An inverse association between silica intake from drinking water and AD was found. Women with AD were 2.7 times as likely to have a low daily silica intake (<4 mg/day). However, this study does not show any evidence for aluminium as a risk factor for AD

| Rondeau et al. (2009) France | Longitudinal study (15 years of follow-up); subjects living in 91 drinking-water districts in southern France (PAQUID Cohort), and subjects living at home in one of the 14 drinking-water areas in southwestern France (ALMA+ Cohort) | 1,677 subjects aged 65 years or over (PAQUID cohort), and 248 subjects aged 75 years or over (ALMA+ cohort) | Two kinds of drinking water indicators for Al and silica: (1) geographic exposure measure; (2) individual measure by the questionnaire on daily consumption of tap water and bottled water | MMSE and other cognitive tests; standardised questionnaire for diagnosis of dementia (DSM III revised criteria); NINCDS/ADRDA criteria for AD; Hachinski score for VaD; cognitive decline was analyzed in both the PAQUID and the ALMA+ cohorts; dementia and AD were investigated only in the PAQUID cohort | The risk of dementia was higher for subjects with a high daily Al intake (for >0.1 mg/day; $RR = 2.26$; $P = 0.049$). Conversely, an increase of 10 mg/day in silica intake reduced the risk of dementia (adjusted $RR = 0.89$; $P = 0.036$). Using the geographic measure of tap-water exposure, Al or silica concentrations were no more associated with the risk of AD, although the tendencies were similar |

This table lists the principal findings of longitudinal clinical and epidemiological studies on the relationships between dietary Al (from drinking water or foods) and dementia (i.e., AD and VaD) or predementia syndromes (i.e., ARCD) in older people, including setting, study design, and Al and cognitive assessment used

PAQUID Personnes agées Quid, *MMSE* Mini Mental State Examination, *DSM III Diagnostic and Statistical Manual of Mental Disorders, Third Edition*, *DSM III* Diagnostic and Statistical Manual of Mental Disorders, Third Edition, *NINCDS/ADRDA* National Institute of Neurological and Communicative Disorders and Stroke/Alzheimer's Disease and Related Disorders Association, *DSM IV* Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, *RR* relative risk, *EPIDOS Study* Epidemiology of Osteoporosis Study, *SPMSQ* Short Portable Mental Status Questionnaire, *ALMA+* Aluminium-Maladie Alzheimer

to Al or silica from tap water was not associated strongly with dementia, given that other territorial factors could influence cognitive decline, the conclusions of the study were that cognitive decline became greater over time in subjects with a higher daily intake of Al from drinking water (>0.1 mg/day; adjusted RR =2.26; P = 0.005). Moreover, about silica intake, an increase of 10 mg/day was associated with a reduced risk of AD (adjusted RR = 0.89, P = 0,036) (Rondeau et al. 2009) (Table 178.5).

Recently, new evidence has come to the fore in support of the Al-AD hypothesis. First, a case of a 58-year-old woman with a rapidly progressive, fatal neurological illness, who, at autopsy, showed dramatic Aβ deposition of cerebral cortical and leptomeningeal blood vessels, modest numbers of NFTs and Lewy bodies, and evidence of very high Al content in affected brain regions. This neurological injury is potentially linked to Al exposure from drinking water. In fact, this woman was exposed, along with other 20,000 people, to high concentrations of Al in their water supplies, in excess of 500–3,000 times the limit of 0.2 mg/l. (Exley and Esiri 2006). Second, a very recent report that compared baseline and follow-up composition of drinking water and the level of cognitive function and possible risk of AD in women taking part in the Epidemiology of Osteoporosis Study (EPIDOS) found that a low silica concentration was associated with low cognitive performance at baseline. Further multivariate analysis including potential confounding factors showed that women with AD appeared to have been exposed to lower amounts of silica at baseline, suggesting a protective role against AD of silica in drinking water (Gillette-Guyonnet et al. 2005) (Table 178.5).

On balance, all epidemiological studies of Al in drinking water are more or less open to critique, particularly considering the difficulty in producing high-quality data for exposure and especially for the disease (Lovell et al. 1996). A fundamental difficulty in the interpretation of the epidemiological studies indicating increased risk for AD with increased Al concentrations in drinking water is that even at high concentrations (0.1–0.4 mg/l), drinking water accounts for less than 5% of total daily Al intake. Moreover, in contrast with the findings of these epidemiological studies and evidence against the Al-AD hypothesis is the fact that many studies examining antacid exposure that involves 1000-fold higher exposure to Al compared to drinking water or diet and AD, have been largely negative (Lione 1985). Similarly, other studies did not support any association between Al in drinking water and AD. Wettstein and colleagues (1991) compared the cognitive functions of two groups of elderly, long-term residents of Zurich, who lived in two different areas: one, with high Al concentration in drinking water (> 0.10 mg/l), and the other with relatively low Al levels (<0.01 mg/l). The authors found no substantial differences in cognitive impairment between these two groups (Wettstein et al. 1991). However, a limitation of this study was that the methodology relied on only two sources of drinking water, and thus the bioavailability of Al was likely different in the two water sources. Another study that compared 106 men with AD, 99 men with other dementias, 226 men with brain cancer, and 441 men with other diseases of the nervous system reported no association between the prevalence of AD and higher Al concentrations in drinking water (Martyn et al. 1997). In this context, all subjects aged up to 75 years old and the analysis performed employed three different measurements of exposure. No association between AD and either higher Al or lower silica concentrations in drinking water was found and this study represents perhaps some of the strongest evidence against the idea of causal relationship between Al exposure and AD.

178.3 Aluminium in Food and Cognitive Decline

Unlike a lot of studies about drinking water and AD, little investigations have attempted to measure the possible association between Al in food and cognitive decline, most likely due to significant variability in Al content in food and the difficulty to accurately measure levels of exposure and in turn absorption

from food. Yet, dietary intake of Al remains the largest route of exposure, since Al consumption from foods is typically ten-fold greater than that from drinking water (Saiyed and Yokel 2005). Al in the food supply comes from natural sources including the natural composition of the food itself, water used in food preparation, and food additives. Some foods, known as Al accumulators (e.g., herbs, tea leaves) may naturally contain more than 5 mg/g of this metal. Intake of dietary Al is higher in the USA than in other countries due to widespread use of Al-containing food additives (Flaten 2001; Saiyed and Yokel 2005). One pilot study that interviewed close relatives about dietary intake of patients in a geriatric centre, with special attention to foods high in Al (such as American cheese, chocolate pudding, doughnuts, pancakes or muffins), showed the crude OR of 2.0 (*P* value = 0.19) for daily intake of any such high-Al foodstuffs and OR of 8.6 adjusted for total caloric intake, body mass index, education and intake of vitamins A, C and E (Rogers and Simon 1999). Some subcategories of food containing Al additives were also examined; however, due to the smaller samples in these subgroups, the resulting ORs were not statistically significant, except for one food category containing waffles, pancakes, biscuits, muffins and cornbread or corn tortillas. Although interesting, these results require reproducing in other studies with larger samples sizes and more rigorous design.

Several studies have explored the link between tea consumption and risk of AD since it has been known that Al is naturally present in tea leaves. The reported concentration of Al is 0.3% in older leaves and about 0.01% in younger ones (Rao 1994). Typical tea infusions contain 50 times as much as Al as do infusions from coffee. Levels of Al in tea infusions are commonly in the range of 2–6 mg/l (Rao 1994), and thus may contribute up to 50% of the total daily Al intake in the countries with high consumption and small intake of Al from other sources (Pennington1987; Saiyed and Yokel 2005). In a case-control study (Forster et al. 1995), comparing cases of clinically diagnosed presenile dementia of the Alzheimer's type and controls matched for age and sex, exposure to Al from tea was not a significant risk factor for dementia (the OR for dementia among people consuming more than four cups of tea a day was 1.4; 95% CI: 0.8–2.6). Similarly, no relationship was found between exposure to Al from drinking water, or medicinal sources. A case-control study completed in Canada produced a similar OR for the risk of AD (1.4; 95% CI: 0.86–2.28); however, the serving amount of tea was not specified (Canadian Study of Health and Aging 1994). An Australian case-control study (Broe et al. 1990), also reported an OR of 1.42 (95% CI: 0.93–2.17) while another study found no significant relationship between tea consumption and AD (adjusted OR: 0.7, *P*-value = 0.69). In the latter there was a suggestion that the absence of association may be due to loss of Al during the tea processing and binding of Al to organic compounds, possibly lemon juice (Rogers and Simon 1999). In summary, it would seem that despite relatively high Al content and high dietary consumption, the role of tea as a dietary source of Al in development of AD or similar pathologies remains controversial.

178.4   Possible Mechanisms of Aluminium Neurotoxicity

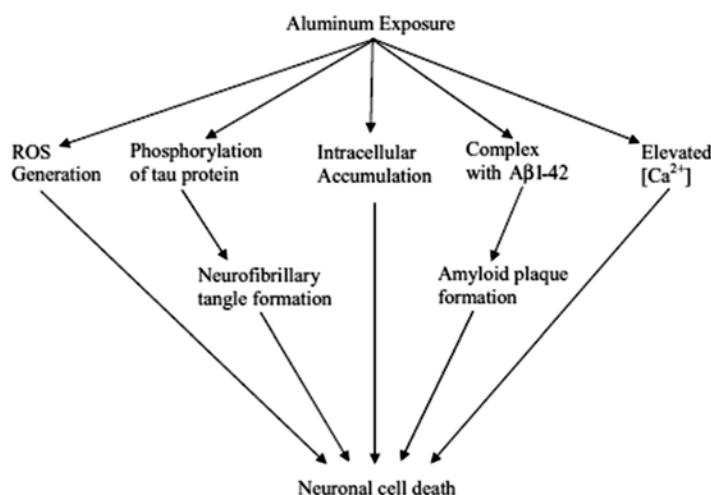
Although there is compelling evidence in support of a central role of Aβ (including from genetic studies) and tau protein in the pathogenesis of AD, there have been some residual questions whether these abnormalities are causative of the disease or secondary to another etiologic factor (Neve and Robakis 1998). Many lines of evidence have focused on the role of oxidative stress mechanisms and free radical damage in AD pathogenesis (Grant et al. 2002) (Fig. 178.1). Whether oxidative damage increases Aβ peptide production or vice versa is still unresolved. There is ambiguous evidence on the hypothetical molecular mechanisms that might explain Al involvement in the aetiology and pathogenesis of AD. Several experimental models have strongly supported the involvement of Al as a secondary modifying factor or risk factor in the pathogenesis of AD (Bharathi et al. 2008) (Fig. 178.2). There is


Fig. 178.1 Possible mechanisms whereby aluminium exposure causes neuronal cell death and lead to Alzheimer's disease. This figure shows major hypothesised pathways whereby aluminium exposure leads to neuronal cell death and Alzheimer's disease including aluminium-induced oxidative stress, accumulation of amyloid β (Aβ), phosphorylation of tau protein, elevation of [Ca²⁺], complex with Ab1–42 peptide, and intracellular accumulation of aluminium (From Shcherbatykh and Carpenter 2007. With permission)

also evidence that Al may alter the normal processing of AβPP and as such the dynamics of Aβ production (Garruto and Brown 1994), via reduced solubility of aluminium-Aβ 1–42 complexes, as well as increased precipitation of β-sheets (Exley 2006) and facilitated Aβ transport across the BBB (Yokel 2006). Several studies suggest that Aβ and oxidative stress are causally linked and Al enhances Aβ production leading to Aβ aggregation into oligomeric forms (Bondy and Kirstein 1996) which might influence the early-onset of AD or its progression (Fig. 178.1).

An appealing feature of the oxidative stress hypothesis for neurodegenerative diseases is that cumulative oxidative damage over time could account for the late-life onset and the slowly progressive nature of such disorders (Shcherbatykh and Carpenter 2007). With the development of transgenic techniques in neuroscience, new research approaches have emerged. It has been demonstrated that chronic dietary administration of Al can increase Aβ levels and accelerate SP deposition in an animal model of AD-like amyloidosis with an exacerbation of brain lipid peroxidation (Praticò et al. 2002). This phenomenon could be limited by addition of the antioxidant addition (vitamin E). Other investigators have shown that exposure to Al affects different neuronal areas, and that melatonin protects against the Al-induced cellular damage (Esparza et al. 2003).

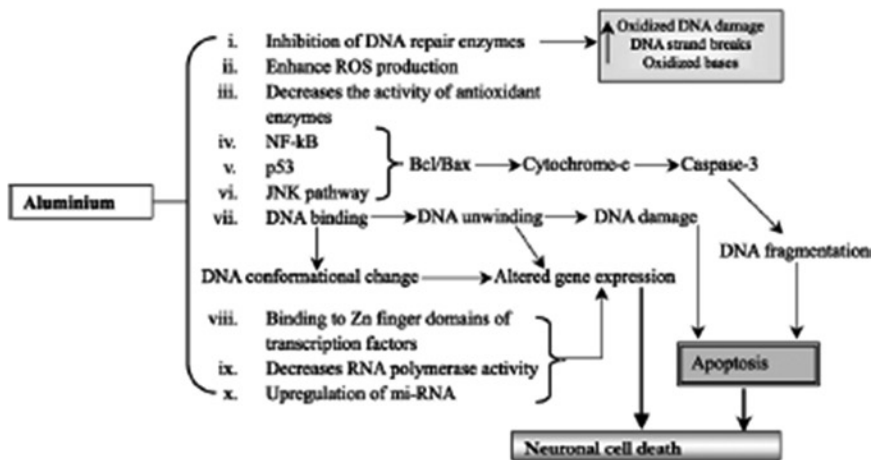
Various mechanisms have been suggested to explain the Al toxicity, taking into account that many biological reactions, if altered, can have profound cellular consequences, eventually contributing to neuronal cell death. The major sites of localisation of these important reactions are mitochondria, lysosomes and the nucleus in the cell; therefore Al toxicity can be mediated across a number of cellular compartments (Dobson et al. 1998). Al could play a role in neurodegeneration by increasing oxidative stress because as a non-redox active metal it may increase the redox active iron concentration in brain, mainly through a Fenton reaction. Al is simultaneously an activator of superoxide dismutase (SOD) and an inhibitor of catalase, and this leads to an increase in the production of hydroxyl radicals (Good et al. 1996). Apoptosis or programmed cell death, which plays a role in normal development and maintenance of tissue homeostasis, is also believed to be the general mechanism by which Al toxicity is mediated in cells. Mitochondrial changes


Fig. 178.2 Synopsis of principal mechanisms of neurotoxicity linked to aluminium exposure. This figure shows aluminium (Al) to be one of the principal causes of neurotoxicity, including modulation of inhibition of DNA repair enzymes, enhancement of ROS production, decrease of the activity of antioxidant enzymes, alteration of NF-kB, p53, JNK pathway, DNA binding. Al also binds to Zn finger domains of transcription factors, thereby decreasing RNA polymerase activity and upregulating mi-RNA. All these events lead to genomic instability and cell death (From Bharathi et al. 2008. With permission)

following cytotoxic stimuli represent a primary event in apoptotic cell death. Al has also been demonstrated to accumulate in neurons, where it inhibits the sodium $(Na)^+$/calcium $(Ca)^{2+}$ exchange mechanisms and thereby mediates the accumulation of mitochondrial Ca^{2+} (Bharathi et al. 2008) (Fig. 178.1). This increase in intra-mitochondrial Ca^{2+} levels in turn leads to an opening of the mitochondrial transition pore (MTP), with cytochrome c (an important apoptotic factor) release and subsequent apoptosis resulting from the activation of the caspase family of proteases (Dewitt et al. 2006) (Fig. 178.2).

Although mitochondrial alterations may represent an important step in the apoptotic process, other evidence supported the endoplasmic reticulum (ER) role in regulating this cell death and ER homeostasis changes due to Al. The ER is the major reservoir for calcium and is the main site of the apoptotic mediators including members of the Bcl-2 family of proteins, Bcl-2 and Bcl-XL. Al induces a redistribution of the apoptosis-regulatory proteins within the ER, resulting in Bax being elevated in the ER compared with the cytosol and mediating the reduction of Bcl-2 (D'mello et al. 1994) (Fig. 178.2). Therefore, Al mediates a specific type of apoptosis which is independent from other mitochondrial-targeted apoptotic signals. Moreover, since Al is a Lewis base, it might bind to oxygen donors generated in the cell and binds to vital biomolecules such as nucleic acids, phosphate groups of ATP and/or phosphorylated proteins and carboxylic groups of the molecules (Lankoff et al. 2006). Thus, Al could facilitate genotoxicity, through modification of DNA repair processes and conformational changes that cause DNA to unwind all of which increase the likelihood of DNA damage and changes to gene expression that might lead to neuronal cell death in AD. Further evidence in support of this are reports of Al-mediated decrease of the levels of mRNA from genes of endogenous antioxidant enzymes (Gonzalez-Muñoz et al. 2008). This may be the result of interference with the binding of transcription factors, such as factor IIIA to its corresponding zinc finger domains and in turn inhibition of gene expression (Hanas and Gunn 1996)

The biogenesis of NFTs remains an important question in understanding Alzheimer's neuropathology. Al promotes phosphorylation of the tau protein, the microtubular-associated protein that

accumulates into NFTs making it less soluble and increasing the likelihood that the protein will aggregate (Li et al. 1998) (Fig. 178.1). Thus, Al could act to promote the development of NFTs. However, an important consideration is that NFTs are associated with a number of diseases such as dementia pugilistica and other diseases where the causes remain unclear (Bharathi et al. 2008). Furthermore, studies have reported that Al kills isolated neurons secondary to its intracellular accumulation, and that the cell death is neither secondary to generation of reactive oxygen species (ROS) nor accumulation of intracellular calcium. This is despite the capability of Al to cause an elevation in both (Tuneva et al. 2006), suggesting that Al could be directly toxic to some intracellular processes. Considering numerous studies about Al neurotoxicity, Kawahara proposed a comprehensive hypothesis regarding the implications of Al and other trace metals in the pathogenesis of AD (Kawahara 2005) (Fig. 178.3).

Recently, a study investigated the effects of Al on behaviour, neurological function and morphology, using Al-maltolate administered to rabbits via the intracisternal route (Bharathi et al. 2008). The authors concluded that Al caused neurotoxicity in a multifaceted way by modulating the inhibition of DNA repair enzymes, the enhancement of ROS production, the decrease in the activity of antioxidant enzymes, and the alteration in apoptotic pathways as NF-kB, p53 and JNK (Fig. 178.2). Al was also found to bind to Zn finger domains of transcription factors, thereby decreasing RNA polymerase activity and gene expression and also upregulating micro-RNA. All these events lead to genomic instability and cell death. Common mechanisms such as failure in protein folding mechanisms have not yet been fully explored but offer possible models for further testing, particularly where circulating or intracellular forms of these proteins, complexed to Al may be toxic, and work in addition to other primary causes of the neuronal cell death (Bharathi et al. 2008).

178.5 Possible Alzheimer's Disease Treatment Linked to the Aluminium Hypothesis

Metal ligand-based therapeutic approaches for the treatment of AD have been suggested, given the growing number of epidemiological investigations that have identified Al and other metals (especially zinc and copper) as possible risk factors for this disease (Fig. 178.4). Therefore, if metals play a potential role as a cofactor in the pathogenesis of AD, removal of these from the brain might hypothetically modulate neuronal damage and progression of the AD process (Domingo 2006). Among these drugs, the use of fluoride and chelating agents were strong candidates. It was well known that fluoride ions bind with high affinity to Al, while desferrioxamine, an iron chelator, was also shown to be an effective chelating agent for Al.

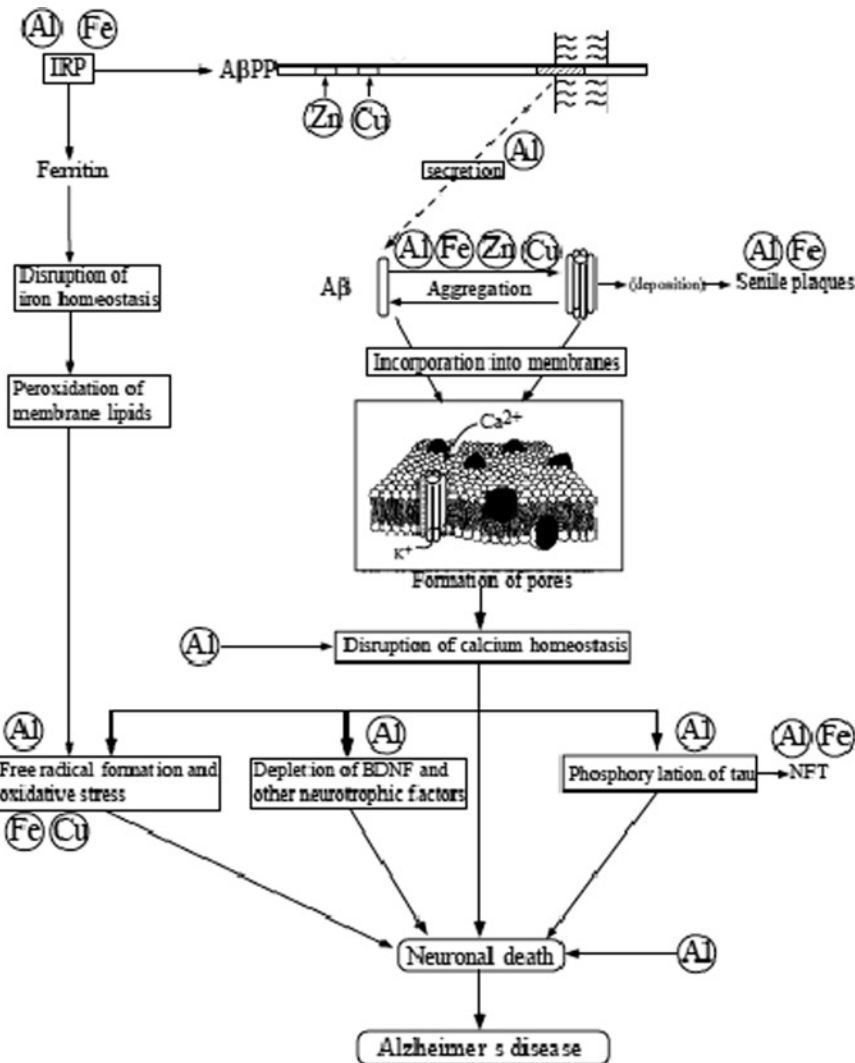
Desferrioxamine (deferoxamine, DFOA) usually used for the treatment of iron overload, was first employed to enhance Al removal in 1980, and it has been the most effective and safest Al chelator for long-term use and has produced a striking improvement in a patient with severe dialysis encephalopathy (Ackrill et al. 1980). However, the authors noted that both fluoride and chelating agents could have systemic side effects. Due to the high affinity of DFOA for Al ($K = 1,022$), this chelating agent has also been successfully applied to the therapy of Al overload, including the treatment of dialysis encephalopathy (Swartz 1985; Milne et al. 1983), however, important side effects have been reported, including increased susceptibility to infectious diseases, ocular and auditory toxicity, audiovisual neurotoxicity and developmental toxicity if used for prolonged periods at excessive doses (Domingo 1996). The hypothesis that DFOA might slow the clinical progression of the dementia associated with AD was tested in a small study, which


Fig. 178.3 Hypothesis regarding the implications of aluminium (Al) and other trace metals in the pathogenesis of Alzheimer's disease (AD). Al binds to iron regulatory protein (IRP) and influences the expression of amyloid β protein precursor (AβPP) as well as ferritin. Abnormal expression of AβPP will lead to the increased amount of amyloid β (Aβ). Normally secreted Aβ is degraded by various proteases. However, Aβ which is aggregated in the presence of trace metals, including Al, zinc (Zn), iron (Fe), and copper (Cu), could be resistant to proteases and accumulates in the brain. The aggregated Aβ could be easily incorporated into membranes resulting in the formation of ion channels. The abnormal calcium influx through amyloid channels cause the phosphorylation of tau, the depletion of neurotrophic factors such as brain-derived neurotrophic factor (BDNF), and the formation of free radicals, and finally induces neuronal death. Al implicates these neurodegenerative pathways by inhibition of BDNF-induced increase in intracellular calcium levels, by accelerating the phosphorylation of tau, and by stimulating iron-induced lipid peroxidation. Meanwhile, abnormal expression of ferritin caused an altered concentration of free iron ions, and thus, will cause oxidative damage and membrane lipid peroxidation. These events also finally lead to neuronal death. Various genetic and environmental factors may contribute to these pathways. It is possible that Al and other metals are implicated in various stages of these degenerative processes and finally link to the pathogenesis of AD (From Kawahara 2005. With permission)
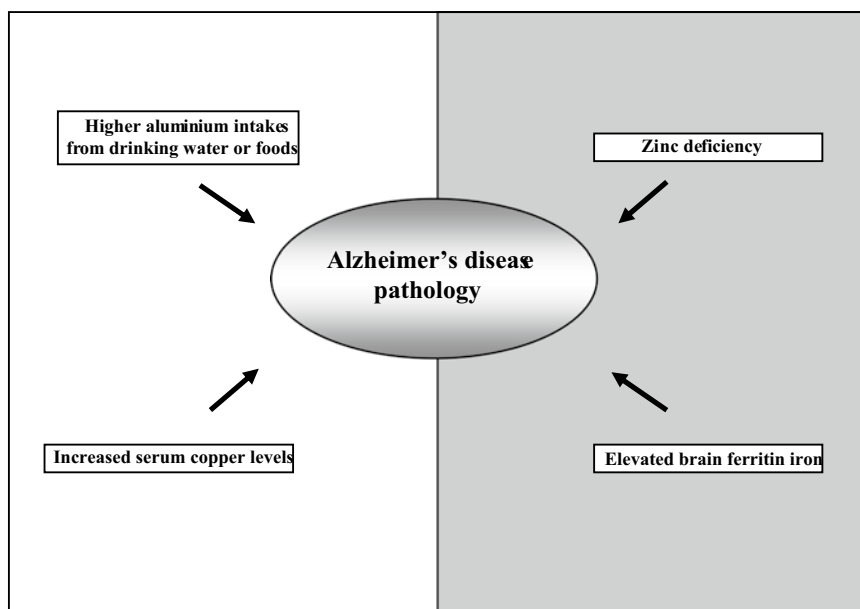

Fig. 178.4 Synopsis of the evidence on the possible effects of metals on Alzheimer's disease pathology. This figure shows the suggested impact of various metals on Alzheimer's disease pathology including aluminium, zinc, copper and iron

investigated 48 patients with probable AD, who were randomly assigned to receive DFOA (125 mg intramuscularly twice daily, 5 days per week, for 24 months), oral placebo (lecithin), or nontreatment (i.e., normal care) (McLachlan et al. 1991). No significant differences in baseline measures of intelligence, memory or speech ability existed between the groups. Activities of daily living were also assessed and video recorded at 6, 12, 18 and 24 month intervals. DFOA administration was associated with a significant reduction in the rate of decline of daily living skills as assessed by both group means and variances, while differences in the rate deterioration of patients receiving either placebo or nontreatment were noted. The mean rate of decline was twice as rapid for the nontreatment group while appetite and weight loss, which was found to be reversible by temporary suspension of DFOA, were the only reported side effects (Kruck et al. 1990). These findings (McLachlan et al. 1991) proved controversial, particularly in relation to the statistical analyses of the results as well as the use of lecithin as placebo, which was administered orally while DFOA was injected intramuscularly (Domingo 2006). Experimental studies on rabbits showed that although a partial reversal of Al-induced neurodegeneration by DFOA was observed, pretreatment of the animals with this chelator was not protective against Al-induced NFT-associated pathology. One possible explanation could also be that the therapeutic effects of DFOA were partly due to mechanisms other than chelation, such as inhibition of free radical formation or inflammation (McLachlan et al. 1991).

To date, ten natural and synthetic Al(III) ligands and chelators (fluoride, maltol, citrate, EDTA, hydroxyurea, dihydroxyacetone, salicylate, ascorbate, DFOA and Feralex-G), have been investigated alone or in combination (Kruck et al. 2004) for their ability to remove Al(III) from intact human brain cell nuclei, following preincubations with the respective compounds. Although nuclear-bound Al(III) was found to be resistant to removal, the combination of ascorbate plus Feralex-G was found to be particularly effective in removing Al(III) from the nuclear matrix. The mechanism proposed by

authors (Kruck et al. 2004), called molecular shuttle chelation, might provide a useful pharmacotherapy in the potential treatment of Al(III) overload. Nonetheless, DFOA has been the only Al chelator successfully tested in the palliative treatment of AD and while it is the main stay of iron and Al chelation therapy, the high cost of this drug, the need for parenteral administration, and various side effects observed have been considered reasonable justification to pursue an orally effective, cheaper and less toxic chelating agent than DFOA where BBB permeability of the compound would be particularly useful in AD.

There are, however, many other effective chelators of trivalent ions available that might already be exerting protective effects through the chelation of Al (House et al. 2004). Among a number of these chelating agents tested in animal models, the most promising were the 1-alkyl-3-hydroxy-2-methylpyrid- 4-ones, and particularly the compound 1,2-dimethyl-3- hydroxypyrid-4-one (deferiprone, L1) (Domingo 1996). Until recent years, aminoacridines have been the group of drugs most frequently used to improve cognitive functions in AD patients. It was even hypothesised that, in addition to the enhancement in cholinergic transmission, their metabolite might chelate Al, thereby offering an additional benefit by diminishing the Al body burden, but these claims have not been substantiated (Domingo 1996).

The possible effects of combined treatments using chelating agents to remove Al from the body have also been investigated based on the rationale that they might be more efficient than monotherapy. In a study of rats, the therapeutic efficacy of combined administration of citric acid and *N*-2 hydroxyethylethylenediaminetriacetic acid (HEDTA) was measured on the extent to which blood and brain Al concentrations and parameters indicative of haematological disorders as well as brain oxidative stress were altered (Flora et al. 2003). In contrast to DFOA, which is unable to enter the brain, HEDTA which is BBB-permeable resulted in a moderate decrease in rat brain Al concentration. The authors concluded that HEDTA could be a potential antidote for Al overload. However, in order to achieve an optimum effect of chelation therapy, administration of citric acid and HEDTA would be recommended (Flora et al. 2003). In previous studies, injection of citrate following parenteral Al administration depleted tissue Al concentrations (Domingo 2006); however, citrate may be able to increase or decrease Al accumulation, depending on the relative concentrations of Al and citrate within different compartments in the organism (Yokel et al. 1996). Research into this topic continues but it remains to be seen whether this possible therapeutic route might be of any practical importance.

178.6 Applications to Other Areas of Health and Disease

Al, as a known environmental toxicant, has been linked to a variety of pathological conditions such as dialysis encephalopathy, osteomalacia as well as AD. However, its precise role in the pathogenesis of these disorders is not fully understood. Studies using hepatocytes as a model system have examined the impact of Al on aerobic energy production and found that Al-exposed hepatocytes were characterised by lipid and protein oxidation and a dysfunctional tricarboxylic acid (TCA) cycle. Thus Al toxicity was suggested to promote a dysfunctional TCA cycle and impede ATP production, events that may contribute to various Al-induced abnormalities (Mailloux et al. 2006). Al has also been associated with other neurodegenerative diseases and, along with decreased levels of Ca and magnesium (Mg), is suspected to contribute to the pathogenesis of amyotrophic lateral sclerosis (ALS) and Parkinson's disease–related dementia (Shiraki and Yase 1991). The existence of Al in NFTs of patients with ALS/Parkinsonism dementia was also reported at the beginning of the 1960s, when epidemiological surveys in both Kozagawa and Hobara foci

revealed the characteristics of Kii ALS as follows: younger age at onset, especially men, familial clustering and presence of Alzheimer's NFTs (Kawahara 2005). Other environmental studies showed that extremely low levels of Ca and Mg in rivers adjacent to the birthplaces of ALS patients inversely and significantly correlated with high mortality rates, Al content, and densities of hippocampal NFTs (Kawahara 2005). Similarly, in experimental animals, low Ca and Mg, but high Al content in diet led to a neuronal loss with axonal swellings and chromatolysis (Kawahara 2005). Recently, a significant loss of dopaminergic neurons was identified exclusively in the substantia nigra of 1-year-old rats derived from colonies fed a low Mg diet over two generations (Kawahara 2005). Overall, some of these interactions may point to a predisposition to develop ALS/Parkinsonism dementia but which are precipitated by their environmental exposures and supporting suggestions that the aetiologies of these conditions are the result of gene-environment interactions (Kawahara 2005).

Dialysis encephalopathy was found to be caused by Al in dialysis solution or Al-containing pharmacological compounds in hemodialysis patients (Alfrey et al. 1976). A more recent case report has demonstrated that Al-containing cement used in bone reconstruction surgery caused fatal encephalopathy (Reusche et al. 2001). There have also been cases of encephalopathy that have developed in dialysis patients after they took Al-containing antacids. The Japanese Ministry of Health, Labour and Welfare recommended that patients on dialysis or with kidney failure should not use Al-containing antacids.

The lipophilic nature of the organic Al salt is a critical determinant of toxicity (Campbell et al. 2001). Human cell lines of neural origin were utilised to study the effect of lipophilic Al acetylacetonate and non-lipophilic Al sulfate on cell proliferation and viability. Although analysis of Al species in the cell culture media demonstrated that there are positively charged Al species present in solutions prepared with both Al salts, only the Al acetylacetonate salt caused changes in cell proliferation and viability. Neuroblastoma (SK-N-SH) cells were also more susceptible to decreased cell proliferation although the lipophilic Al salt was more toxic to the glioblastoma (T98G) cells. While the toxicity of Al acetylacetonate was inhibited in the T98G cells by the addition of phosphate, the same treatment did not reverse cell death in the SK-N-SH cells. Thus, the mechanism of Al toxicity appears to be different in the two cell lines and it is possible that the most susceptible cell type for Al is glial but when these cells are compromised, then there may be a secondary impact upon the neuronal population that eventually leads to neurodegeneration (Campbell et al. 2001).

The Al contamination of total parenteral nutrition (TPN) solutions is a matter of great concern. Bishop et al. reported that the neurological development of premature infants who had received a TPN solution containing a high level of Al was impaired compared with infants who had received an Al-depleted TPN solution (Bishop et al. 1997). Considering that Al in TPN solutions is highly bioavailable and that the renal function of infants is impaired, the Al contamination of TPN solutions could cause serious brain damage. The US Food and Drug Administration (FDA), the North American Society for Pediatric Gastroenterology and Nutrition (Klein et al. 1998), and other societies have recommended the reduction of the contamination of Al in parenteral solutions.

178.7 Conclusions

AD is widely accepted as a multifactorial disease, and genetic as well as environmental factors play significant roles in its pathogenesis. The involvement of Al in the pathogenesis of AD cannot be discarded, especially when there are many reports suggesting links between Al and the Aβ hypothesis

Table 178.6 Key points of clinical and epidemiological studies on the relationships between dietary aluminium (Al) and dementia or predementia syndromes

A. In recent years, an increasing body of epidemiological evidence suggested potential role of metals in the pathogenesis of Alzheimer's Disease (AD). In particular, the aluminium (Al) neurotoxicity has been established, beginning from its presence discovered in the senile plaques and neurofibrillary tangles, the principal histopathological hallmarks of AD
B. Al may enter the human body from several sources, especially from drinking water and food consumption. The epidemiological evidence supporting this association is somewhat stronger for exposure to Al from drinking water, as compared to food. However, other elements present in drinking water, such as fluoride, copper, zinc or iron could also have an effect on cognitive impairment or influence the Al neurotoxicity
C. Metal ligand-based therapeutic approaches for treatment of AD have been suggested, given the growing number of epidemiological investigations that have identified Al and other metals (especially zinc and copper) as possible risk factors for this disease, opening a new route to disease-modifying treatment of AD

This table lists the principal features of clinical and epidemiological studies on the relationships between dietary Al and dementia (i.e., AD), or predementia syndromes (i.e., age-related cognitive decline)

in AD. Overall, the results of molecular epidemiological investigations have suggested an association between chronic exposure to Al and risk of AD. This possible association is biologically plausible and likely to be of moderate significance and may be modified by other inorganic substances, like silica (Rondeau et al. 2000). The evidence supporting this association is stronger for exposure to Al from drinking water, compared to food (Table 178.6). However, this association does not yet satisfy all of Hill's criteria for causation (Hill 1965). Therefore, future studies require stronger methodological designs in order to fully test the validity of previous positive findings and to demonstrate dose–response relationships between Al and AD risk. This might provide new routes to the treatment of AD, with a disease-modifying effect, as opposed to the predominantly symptomatic approaches currently in use.

Summary Points

- An increasing body of molecular epidemiological evidence suggests the potential role of metals in the pathogenesis of Alzheimer's Disease (AD).
- Aluminium (Al) neurotoxicity, in particular, has been identified due to its presence in the senile plaques and neurofibrillary tangles that are the principal neuropathological hallmarks of AD.
- Epidemiological evidence supporting association between Al and AD is stronger for exposure to Al from drinking water, compared to exposure from food, although other elements present in drinking water, such as fluoride, copper, zinc or iron could also have an effect on cognitive impairment or influence any Al-mediated neurotoxicity.
- Metal ligand–based therapeutic approaches that might offer treatment for AD have been suggested, following the epidemiological evidence supporting the involvement of Al and other metals (especially zinc and copper) as possible risk factors for this disease
- The therapeutic efficacy of combined administration of citric acid and N-2 hydroxyethyl-ethylenediaminetriacetic acid (HEDTA) in decreasing blood and brain Al concentrations, other adverse haematological parameters, and brain oxidative stress has been investigated but further research is required to identify whether it can truly offer practical or clinical application.

Definitions

Aluminium: is a nonessential metal present in 8% of the Earth's crust. Despite its natural abundance, aluminium has no known function in living cells and produces some toxic effects in elevated concentrations. Its toxicity can be traced to deposition in bone and the central nervous system, which is particularly noticeable in patients with reduced renal function. In very high doses, aluminium can cause neurotoxicity, and is associated with altered function of the blood-brain barrier

Dementia: is a syndrome defined by impairments in memory and other cognitive functions that are severe enough to cause significant impairment and decline from a previous level of social and occupational functioning

Alzheimer's disease neuropathology: Alzheimer's disease is characterised by a number of pathological hallmarks, the most common being intraneuronal protein clusters composed of paired helical filaments including hyperphosphorylated tau protein (neurofibrillary tangles), and extracellular protein aggregates (senile plaques). The senile plaques are the result of either increased processing of the amyloid-β (Aβ) protein precursor by β- and γ-secretases or reduced degradation of clearance of the resultant toxic Aβ peptide that forms and in turn aggregates and initiates a pathogenic cascade that leads to neuronal loss

Predementia syndrome: this term identifies all conditions with age-related deficits in cognitive function, including a mild stage of cognitive impairment based on a model of normality or also due to pathological conditions considered predictive or early stages of dementia

Mild cognitive impairment (MCI): is a clinical label that includes non-demented aged persons with memory impairment that is more pronounced than what would be expected normal for that age but not severe enough as to cause significant disability

Chapter 179
Dietary Fatty Acids, Cognitive Decline, and Dementia

Vincenzo Solfrizzi, Vincenza Frisardi, Cristiano Capurso, Alessia D'Introno,
Anna M. Colacicco, Gianluigi Vendemiale, Antonio Capurso, and Francesco Panza

Abbreviations

AD   Alzheimer's disease
VaD   Vascular dementia
MCI   Mild cognitive impairment
ARCD   Age-related cognitive decline
AACD   Aging-associated cognitive decline
UFA   Unsaturated fatty acids
MUFA   Monounsaturated fatty acids
PUFA   Polyunsaturated fatty acids
LA   Linoleic acid
ALA   α-linolenic acid
DHA   Docosahexaenoic acid
EPA   Eicosapentaenoic acid
APOE   Apolipoprotein E
ARA   Arachidonic acid

179.1 Introduction

179.1.1 Dementia and Predementia Syndromes

Dementia is estimated to affect approximately 6% of the population aged 65 and older, the prevalence increasing exponentially with age, to 40–70% at the age of 95 years and over. In Western countries, the most common forms of dementia are Alzheimer's disease (AD) (Table 179.1) and vascular dementia (VaD) (Table 179.2), with respective frequencies of 70% and 15% of all dementias (Qiu et al. 2007). AD is an age-related progressive neurodegenerative disorder with an enormous unmet medical need, characterized by relatively slow chronic but progressive impairment in cognition, behavior, and functionality. The number of people suffering from AD is rising quickly because there are no effective

Table 179.1 Key features of Alzheimer's disease (AD)

1. AD is the most common dementia and primary neurodegenerative disorder in the elderly
2. AD gradually leads to a complete psychological and physical dependency and finally to death within one to two decades
3. The neuropathology of AD involves aberrant protein processing and is characterized by the presence of both intraneuronal protein clusters composed of paired helical filaments of hyperphosphorilated tau protein (NFTs), and extracellular protein aggregates (SPs)
4. The diagnosis of AD is essentially a clinical one, and it is based on a typical clinical picture and findings, with a set of clinical criteria often used in research
5. From a clinical point of view, AD is a slow, progressive disease that most often starts with episodic memory impairment. However, the patients with preclinical AD show deficits in several cognitive areas, including executive function, verbal and visuospatial abilities, attention, and perceptive speed
6. Cognitive function declines over time, and the diagnosis of AD can be considered when the patient has impairments in memory and at least in one other cognitive function (executive dysfunction, agnosia, aphasia, apraxia), severe enough to cause impairment in social or occupational functioning
7. In advanced AD, common symptoms include also confusion, behavioral and gait disturbances, and the patients are increasingly dependent on others in activities of daily living

NFTs neurofibrillary tangles, *SPs* senile plaques
This table lists the key facts of AD including neuropathological hallmarks, clinical criteria for diagnosis, and the natural history of the disease

Table 179.2 Key features of vascular dementia (VaD)

1. The clinical presentation of VaD varies greatly depending on the causes and location of cerebral damage
2. Large-vessel disease leads commonly to multiple cortical infarcts and a multifocal cortical dementia syndrome
3. Small-vessel disease, usually resulting from hypertension and diabetes, causes periventricular white matter ischemia and lacunar strokes characterized clinically by subcortical dementia with frontal lobe deficits, executive dysfunction, slow information processing, impaired memory, inattention, depressive mood changes, slowing of motor function, Parkinsonian features, small-step gait, urinary disturbances and pseudobulbar palsy
4. The term Vascular Cognitive Disorder (VCD) has been recently proposed and it would become the global diagnostic category for cognitive impairment of vascular origin
5. VCD would include the group of syndromes and diseases characterized by cognitive impairment resulting from a cerebrovascular etiology
6. The main categories of VCD are Vascular Cognitive Impairment (VCI) (i.e., vascular CIND and vascular MCI), VaD, and mixed AD plus CVD. previously termed "mixed dementia"
7. Dementia is defined as executive control deficit producing loss of function for instrumental activities of daily living, while mixed AD plus CVD is defined as preexisting AD worsened by stroke (equivalent to prestroke dementia)
8. VCI is a term referred to all forms of mild to severe cognitive impairment associated with CVD, including vascular CIND and vascular MCI, e.g., predementia syndromes with a presumed primary vascular basis
9. The characteristic neuropsychological profile of VCI is believed to include frequently early impairment of attention and executive control function, with slowing of motor performance and information processing, while episodic memory is relatively spared compared to that in AD

CIND cognitive impairment no dementia, *MCI* mild cognitive impairment, *AD* Alzheimer's disease, *CVD* cerebrovascular disease
This table lists the key features of VaD including clinical and neuropathological classification, and the clinical picture of the disease

treatments for the disorder available. Clinical and epidemiological research has also focused on the identification of risk factors that may be modified in predementia syndromes, at a preclinical or early clinical stage of dementing disorders. The umbrella term "predementia syndromes" includes the transitional phase between mild nondisabling cognitive decline and disabling dementia, an ambiguous diagnostic period during which it is unclear whether mild cognitive deficits predict incipient dementia or not. In fact, the clinical label identifies all conditions with age-related deficits in cognitive function reported in the literature, including a mild stage of cognitive impairment based on a normality model

and pathological conditions considered predictive of early stages of dementia (Panza et al. 2005). Such predementia syndromes have been defined for AD and partly for VaD, but have not yet been operationalized for other specific forms of dementia. Therefore, the term "predementia syndromes" includes different conditions and, among them, MCI is at present the most widely used term to indicate non-demented aged persons with no significant disability and a mild memory or cognitive impairment, which cannot be explained by any recognized medical or psychiatric condition (Panza et al. 2005). At present, the term mild cognitive impairment and its abbreviation MCI have frequently been used in studies on the preclinical phases of dementia, although with differing and inconsistent definitions (Petersen et al. 1999, 2001; Winblad et al. 2004) (Table 179.3). There is now ample evidence that MCI is often a pathology-based condition with a high rate of progression to AD (Panza et al. 2005). Therefore, MCI has also been identified as the predementia syndrome for AD. The more recently proposed multiple subtypes of MCI were intended to reflect the heterogeneity of different types of dementia. Actually, the recent subclassifications of MCI according to its cognitive features [dysexecutive MCI and amnestic-MCI (aMCI), or aMCI and non-amnestic MCI (naMCI): single-domain aMCI and multiple-domain aMCI or single-domain naMCI and multiple-domain naMCI] (Winblad et al. 2004), clinical presentation [MCI with parkinsonism, cerebrovascular disease (CVD), depressive symptoms, behavioral and psychological symptoms], or probable etiology (MCI-AD, vascular MCI, or MCI-Lewy body dementia) (Gauthier et al. 2006) all represent an attempt to control this heterogeneity. A critical review has recently made in Stockholm and then in Montreal, in order to define a new consensus on MCI (Winblad et al. 2004). Furthermore, different diagnostic criteria have been proposed for other predementia syndromes, and the terms age-related cognitive decline (ARCD) (American Psychiatric Association 1994) (Table 179.4) and aging-associated cognitive decline (AACD) (Levy 1994) (Table 179.5) have been recently proposed to distinguish individuals with mild cognitive disorders associated with aging, also non-pathological, from noncognitively unimpaired individuals.

Table 179.3 Key features of mild cognitive impairment (MCI)

1. MCI is, at present, the most widely used term to indicate non-demented aged persons with a mild memory or cognitive impairment that cannot be accounted for any recognized medical or psychiatric condition
2. The general criteria for MCI include: a) memory complaint, b) objective memory disorder, c) absence of other cognitive disorders or repercussions on daily life, d) normal general cognitive function, e) absence of dementia
3. MCI definitions can be broadly classified as amnestic (aMCI) and nonamnestic (naMCI)
4. There is now ample evidence that MCI is often a pathology-based condition with a high rate of progression to AD, and aMCI, with a central role for memory disorder and with relative preservation of other cognitive domains, was identified as the predementia syndrome for AD
5. aMCI can be subdivided into a single domain subtype with a pronounced memory deficit or a multiple domain subtype that includes memory impairment along with some impairment in other cognitive domains such as language, executive function, and visuospatial skills
6. The other major MCI subtype is naMCI, which similarly can be subdivided into single and multiple domain subtypes

AD Alzheimer's disease
This table lists the key features of MCI including diagnostic criteria, and clinical classification

Table 179.4 Key features of age-related cognitive impairment (ARCD)

1. ARCD is defined by the DSM-IV as "an objectively identified decline in cognitive functioning consequent to the aging process that is within normal limits given the person's age
2. At present, there are no defined diagnostic criteria for ARCD or other operational definition
3. Few epidemiological studies using this definition have been conducted

DSM IV Diagnostic and Statistical Manual of Mental Disorders, fourth edition
This table lists the key features of MCI including definition, and current research issues on this clinical entity.

Table 179.5 Key features of aging-associated cognitive decline (AACD)

1. In 1994 a task force of the International Psychogeriatric Association (IPA) in collaboration with the World Health Organization (WHO) proposed diagnostic criteria for AACD

2. In these clinical diagnostic criteria, patients score at least one SD below age and education-based standards (e.g., by reference to norms for elderly people) on neuropsychological tests assessing multiple cognitive abilities (memory and learning, attention and concentration, thinking, language, and visuospatial functioning)

3. In the AACD criteria there is no age restriction: though the cognitive decline is more prevalent in old age, its onset may occur earlier in life

SD standard deviation

This table lists the key features of AACD focusing on clinical diagnostic criteria

179.1.2 *Possible Prevention of Dementia and Predementia Syndromes*

The causes of predementia syndromes and dementia are at present unknown. However, some studies have suggested that these conditions may be prevented (Solfrizzi et al. 2006a, 2008). The role of the diet in cognitive decline has not been extensively investigated, with a few data available on the role of macronutrient intake in the pathogenesis of predementia and dementia syndromes (Solfrizzi et al. 2006a, 2008). Since several dietary factors affect the risk of cardiovascular disease, it can be assumed that they also influence the risk of dementia. Some recent studies have suggested that dietary fatty acids may play a role in the development of cognitive decline associated with aging or dementia (Solfrizzi et al. 2005). This concept is further supported by recent evidence that certain diets have been associated with a lower incidence of AD. In fact, antioxidants, dietary fatty acids, and micronutrients appear to have a role, and evidence is at least suggestive that diets rich in fruits and vegetables and other dietary approaches may permit a beneficial effect on the risk of dementia (Solfrizzi et al. 2006a, 2008).

Fatty acids can be categorized briefly into saturated fatty acids (SFA) and unsaturated fatty acids (UFA). SFA, such as stearic acid, is present in products such as meat, dairy products, cookies, and pastries. Monounsaturated fatty acids (MUFA) are most frequently consumed in olive oil. The principal series of polyunsaturated fatty acids (PUFA) are *n*-6 [i.e., linoleic acid (LA)] and *n*-3 [i.e., α-linolenic acid (ALA), docosahexaenoic acid (DHA), and eicosapentaenoic acid (EPA)]. In our Mediterranean dietary pattern, the main sources of *n*-6 PUFA are vegetable oils, while the principal sources of *n*-3 PUFA are fatty fish (salmon, tuna, and mackerel). In fact, olive oil contains 70–80% MUFA (oleic acid) and 8–10% PUFA (6–7% linoleic acid and 1–2% a-linolenic acid) (Solfrizzi et al. 2005). In this chapter, we examine the possible role of dietary fatty acids in modulating the risk of age-related changes in cognitive function, predementia, and dementia syndromes, as well as the possible mechanisms behind the observed associations. Furthermore, we review current evidence on dietary fatty acid supplementation in predementia and dementia syndromes.

179.2 Dietary Fatty Acids in Predementia Syndromes

179.2.1 *Cross-sectional Studies*

Recently, an increasing number of epidemiological and clinical studies have addressed the link between UFA intake and cognitive function, most being cross-sectional (Solfrizzi et al. 2005). In the last years, the study approach was to associate single micro- or macronutrients to ARCD, MCI, AD, or VaD. In this picture, several hallmarks of the Mediterranean diet were linked to increased risk or to a protective effect against cognitive impairment (Panza et al. 2004). The typical dietary pattern of a Mediterranean

diet is characterized by high intakes of vegetables, fruits and nuts, legumes, cereals, fish, and MUFA, relatively low intakes of meat and dairy products, and moderate consumption of alcohol. In fact, higher levels of consumption of olive oil are considered the hallmark of the traditional Mediterranean diet.

In a cross-sectional French study, a positive relationship was found in elderly women between lipid intake and the Mini Mental State Examination (MMSE) score, which evaluates global cognitive functions. A positive relationship was also found between PUFA intake and mobility in elderly men, and between functional variables and alcohol intake in the whole sample. The response rate of this study was very low (around 50%) and these findings, contradictory to the results of the subsequent studies, were explained by the authors with the fact that high intakes of these dietary factors can be considered as an indicator of a better health status (Pradignac et al. 1995) (Table 179.6). Another cross-sectional study from Spain showed that the older subjects with a lower intake of MUFA, SFA, and cholesterol, and higher intakes of total calories, fresh fruit, carbohydrate, thiamine, foliate, vitamin C, and minerals (iron and zinc) had the best performance in global cognitive tests, with a statistical significance after adjustment for age and sex (Ortega et al. 1997) (Table 179.6).

As seen above, MUFA, consequent to the high consumption of extra-virgin olive oil, represent the most important fats in the Mediterranean diet. Cumulative evidence suggests that extra-virgin olive oil may have a role in the protection against cognitive decline, besides coronary disease and several types of cancer, because of its high levels of MUFA and polyphenolic compounds. In the older subjects of the Italian Longitudinal Study on Aging (ILSA), which followed a Mediterranean dietary pattern, total fat is 29% of energy, with a high consumption of olive oil (46 g/d), an MUFA energy intake of 17.6% of total energy, 85% of which is derived from olive oil, and an SFA intake of only 6% (Solfrizzi et al. 1999) (Fig. 179.1). The cross-sectional association between dietary macronutrients and cognitive impairment was examined in elderly subjects aged 65–84 years from the ILSA. After adjustment for educational level, the odds ratios (ORs) of cognitive decline (MMSE score < 24) decreased exponentially with the increase of MUFA energy intakes. Furthermore, selective attention performances were independently associated with MUFA intake (Solfrizzi et al. 1999) (Table 179.6). Recently, in another Northern Italian cross-sectional study on older subjects, the Progetto Veneto Anziani (Pro.V.A. study), in a multiple regression analysis, age and educational level accounted for 29.6% of the MMSE variance, while the contribution of the other variables considered [low-density lipoproteins (LDL) cholesterol, diastolic blood pressure, MUFA, and PUFA] was almost negligible. The authors acknowledged that these results were limited by the fact that total energy intake, which is known to be reduced in patients with cognitive impairment, was not considered, and by the fact that the study was a cross-sectional survey (Manzato et al. 2003). Recently, in the Doetinchem Cohort Study, after adjusting for age, gender, education, alcohol consumption, smoking, and energy intake, higher dietary cholesterol was associated with an increased risk of impaired memory function and cognitive flexibility cognitive function, whereas higher SFA intake was associated, although not significantly, with a 15% to 19% increased risk of impairment in memory function, psychomotor speed, and cognitive flexibility. Fatty fish and marine *n*-3 PUFA consumption were significantly associated with a 19% to 28% decreased risk of global cognitive function impairment and psychomotor speed. These associations appeared to be independent of differences in cardiovascular risk factors (Kalmijn et al 2004) (Table 179.6).

179.2.2 Longitudinal Studies

To our knowledge, there is an increasing number of longitudinal epidemiological studies on the association between fatty acids and cognitive functioning (Kalmijn et al. 1997a; Hende et al. 2003; Morris et al. 2004, 2005a; Solfrizzi et al. 2005, 2006a, b; Psaltopoulou et al. 2008; Eskelinen et al. 2008;

Table 179.6 Principal cross-sectional studies on the relationships between dietary fatty acids and predementia syndromes in older people

Cross-sectional studies

Reference	Setting and study design	Subjects	Dietary assessment	Cognitive outcomes	Results and conclusions
Pradignac et al. (1995)	Cross-sectional, population based	441 subjects aged >65 years	Evaluation of dietary intake	MMSE, Geronte scale for the assessment of daily living activities	In men, alcohol intake was associated with improved functional and cognitive parameters, while PUFA intake only with functional status. In women, lipid intakes were related to better cognitive performance. Overweight in both sexes was associated with an improvement in functional status
Ortega et al. (1997)	Cross-sectional	260 subjects aged 65–90 years	Evaluation of dietary intake with a weighed-food record for 7 consecutive days, and biochemical assays	MMSE, PMSQ	A diet poor in fatty acids, saturated fatty acids, and cholesterol, but rich in carbohydrates, fibers, vitamins (folates, vitamins C and E, and β-carotene, and minerals [zinc and iron) seems to improve cognitive skills
Solfrizzi et al. (1999)	Cross-sectional, population based	278 subjects, 65–84 years old	Evaluation of dietary intake with a 77-item FFQ	MMSE, DCT, and BSRT	Inverse relationship between MUFA intake and cognitive decline. Significant inverse association between MUFA intakes and selective attention. No association was found between nutritional variables and episodic memory
Manzato et al. (2003)	Cross-sectional, population based	191 subjects aged □ 65 years	Evaluation of plasma phospholipid fatty acid composition	MMSE: subjects with a score between 10 and 17 versus subjects with a score between 28 and 30	Cognitive functioning are affected mainly by age and education, not by dietary fatty acids
Kalmijn et al. (2004)	Cross-sectional, population based	1,613 subjects, 45–70 years old	Evaluation of fatty fish, total fat, cholesterol, SFA MUFA, PUFA (n-6 and n-3) dietary intakes with a 178-item FFQ	Concurrent to the dietary assessment, the VVLT, the CST, an abbreviated SCWT, the LDST, a CFT were administrated	Fatty fish and marine n-3 PUFA consumption was associated with a reduced risk and intake of cholesterol and saturated fatty acids with an increased risk of impaired cognitive function in this middle-aged population

Nurk et al. (2007)	Cross-sectional, population based	2,031 subjects, 70–74 years old	Evaluation of dietary intakes with a 169-item FFQ	Six cognitive tests were administered: m-MMSE, m-DST, m-BD; KOLT; TMT-A, and the S-task of the COWAT	Consumers of fish and fish products had better cognitive function than did non-consumers. The associations between fish and fish product intake and cognition were dose-dependent. The effect of fish on cognition differed according to the type of fish and fish product consumed
Dangour et al. (2009)	Randomized clinical trial (24 months)	867 subjects, 70–79 years old from 20 general practices in England and Wales.	Evaluation of fish consumption variable that took into account both frequency and type of fish consumption	A standardized battery of cognitive tests: CVLT; subjective memory assessment; 3 tests of prospective memory; story recall (immediate and delayed); verbal fluency; letter cancellation; location memory (immediate and delayed); symbol-letter substitution; digit span forwards and backwards; simple and choice reaction time	High levels of fish consumption are associated with better cognitive function in later life. Furthermore, there was an apparent linear trend for increased cognitive function across the five-item fish consumption variable, with highest cognitive function levels found in those individuals who report eating the largest amount of fatty, as opposed to white fish

This table lists the principal findings of cross-sectional clinical and epidemiological studies on the relationships between dietary fatty acids and predementia syndromes (i.e., age-related cognitive decline, ARCD, and mild cognitive impairment, MCI) in older people, including the setting and study design, and the dietary and cognitive assessment used. *FFQ* food frequency questionnaire, *MMSE* Mini-Mental State Examination (global cognitive functioning), *PMSQ* Pfeiffer's Mental State Questionnaire (global cognitive functioning), *DCT* Digit Cancellation Test (selective attention), *PUFA* = polyunsaturated fatty acids, *MUFA* = monounsaturated fatty acids; *SFA* = saturated fatty acids; *VVLT* = Visual Verbal Learning Test (verbal memory), *CST* Concept Shifting Task (mental processing speed), *SCWT* Stroop Color Word Test (selective attention), *LDST* Letter Digit Substitution Test (perceptual-motor speed), *CFT* Category Fluency Test (semantic memory), *m-MMSE* modified Mini-Mental State Examination (global cognitive functioning), *m-DST* modified Digit Symbol Test (perceptual speed), *m-BD* modified Block Design (visuo-spatial and motor skills), *KOLT* Kendrick Object Learning Test (episodic memory), *TMT-A* Trail Making Test, part A (executive function), S-task of the *COWAT* the abridged version of the Controlled Oral Word Association Test (access to semantic memory), *CVLT* Californian Verbal Learning Test (verbal memory)
Fig. 179.1 Mean energy intakes from the Italian Longitudinal Study on Aging (*ILSA*). This figure shows the distribution of mean energy intakes (%), stratified for age and gender of the ILSA (Casamassima, Bari, Italy), first prevalence Survey, 1992–1993

Vercambre et al. 2009) (Table 179.7), indicating a crucial need for prospective studies that could confirm initial observations. In particular, one of these prospective studies, the Zutphen Study of 476 men aged 69–89 years, found that high linoleic acid intake was positively associated with cognitive impairment in elderly subjects only in one cross-sectional study after an adjustment for age, education, cigarette smoking, alcohol consumption, and energy intake. High fish consumption, tended to be inversely associated with cognitive impairment and cognitive decline at 3-year follow-up, but not significantly (Kalmijn et al. 1997a) (Table 179.7). Furthermore, in the cohort of the Etude du Viellissement Arteriel (EVA) Study, moderate cognitive decline (a > 2-point of MMSE decrease) and erythrocyte membrane fatty acid composition were evaluated in 264 elderly subjects aged 63–74 years, during a 4-year follow-up. In this study, a lower content of *n*-3 PUFA was significantly associated with a higher risk of cognitive decline. After adjusting for age, gender, educational level and initial MMSE score, stearic acid and total *n*-6 PUFA were consistently associated with an increased risk of cognitive decline. Moreover, a lower content of *n*-3 PUFA was significantly associated with cognitive decline, but after adjustment, this association remained significant only for DHA, and not for EPA (Hende et al. 2003) (Table 179.7). Findings from the CHAP on 2,560 persons aged 65 years and older, showed that in a large population-based sample, a high intake of saturated and trans-unsaturated fat was associated with a greater cognitive decline over a 6-year follow-up. Intake of MUFA was inversely associated with cognitive change among persons with good cognitive function at baseline and among those with stable long-term consumption of margarine, a major food source. Slower decline in cognitive function was associated with higher intake of PUFA, but the association appeared to be due largely to its high content of vitamin E, which shares vegetable oil as a primary food source and which is inversely related to cognitive decline. Finally, cognitive change was not associated with intakes of total fat, animal fat, vegetable fat, or cholesterol (Morris et al. 2004) (Table 179.7). In the same CHAP sample on 3,718 persons aged 65 years and older, high copper intake was associated with a significantly faster rate of cognitive decline but only among persons who also consumed a diet that was high in saturated and trans fats in a 6-year follow-up (Morris et al. 2005a) (Table 179.7). Moreover, in a total of 732 men and women aged 60 years or older, participating

Table 179.7 Principal longitudinal studies on the relationships between dietary fatty acids and predementia syndromes in older people

Reference	Setting and study design	Subjects	Dietary assessment	Cognitive outcomes	Results and conclusions
Longitudinal studies					
Kalmijn et al. (1997a)	Longitudinal, population based (3 years)	476 subjects, aged 69–89 years	Evaluation of dietary intake with the cross-check dietary history method	Cognitive impairment defined as a MMSE score <25 points and cognitive decline as a drop of >2 points of MMSE over a 3-year period	High linoleic acid intake (PUFA) was positively associated with cognitive impairment. High fish consumption was inversely associated with cognitive impairment
Hende et al. (2003)	Longitudinal, population based (4 years)	246 subjects aged 63–74 years	Evaluation of fatty acid composition in erythrocyte membranes	MMSE score with a >2-point of decrease in a 4-year follow-up	Inverse association between cognitive decline and the ratio of *n-3* to *n-6* PUFA in erythrocyte membranes
Morris et al. (2004)	Longitudinal, population based (6 years)	2,560 subjects, aged 65 years and older	Evaluation of dietary intake with a 139-items FFQ	Cognitive change at 3-year and 6-year follow-ups measured with the EBT of Immediate and Delayed Recall, the MMSE, and the SDMT	A diet high in saturated and *trans*-unsaturated fat or low in non-hydrogenated unsaturated fats may be associated with cognitive decline among older people
Morris et al. (2005a)	Longitudinal, population based (6 years)	3,718 subjects, aged 65 years and older	Evaluation of dietary intake with a 139-items FFQ	Cognitive change at 3-year and 6-year follow-ups measured with the EBT of Immediate and Delayed Recall, the MMSE, and the SDMT	High copper intake was associated with a significantly faster rate of cognitive decline, but only among persons who also consumed a diet that was high in saturated and trans fats
Morris et al. (2005b)	Longitudinal, population based (6 years)	3,718 subjects, aged 65 years and older	Evaluation of dietary intake with a 139-items FFQ	Cognitive change at 3-year and 6-year follow-ups measured with the EBT of Immediate and Delayed Recall, the MMSE, and the SDMT	Dietary intake of fish was inversely associated with cognitive decline over 6 years. There were no consistent associations with the *n-3* fatty acids, although the effect estimates were in the direction of slower decline

Table 179.7 (continued)

Reference	Setting and study design	Subjects	Dietary assessment	Cognitive outcomes	Results and conclusions
Solfrizzi et al. (2006a)	Longitudinal, population based (8.5 years)	278 subjects, 65–84 years old from a cohort of 5,632 subjects	Evaluation of MUFA and PUFA dietary intakes with a 77-item FFQ	MMSE	High MUFA, PUFA, and total energy intake were significantly associated with a better cognitive performance in time. The association between high MUFA, PUFA intakes and cognitive performance remained robust even after adjustment for potential confounding variables such as age, sex, educational level, CCI, BMI, and total energy intakes
Solfrizzi et al. (2006b)	Longitudinal, population based (2.6 years)	278 subjects, 65–84 years old from a cohort of 5,632 subjects	Evaluation of MUFA and PUFA dietary intakes with a 77-item FFQ	Incident MCI. Diagnostic criteria for MCI: 1.5 SDs below mean age and education adjusted on the MMSE and 10th percentile below age and education adjusted on memory test, without SMC and intact ADL/IADL	Dietary fatty acids intakes were not associated with incident MCI. However, high PUFA intake appeared to have borderline nonsignificant trend for a protective effect against the development of MCI that may be important.
van Gelder et al. (2007)	Longitudinal, population based (5 years)	210 subjects,70–89 years old	Information about habitual food consumption was collected using the cross-check dietary history method	MMSE	Fish consumption was associated with less subsequent 5-y cognitive decline than was no fish consumption. Furthermore, a dose-response relation was noted between the combined intake of EPA and DHA and cognitive decline, which suggests that a higher intake of EPA plus DHA was associated with less cognitive decline
Psaltopoulou et al. (2008)	Longitudinal, population based (median 8 years)	732 subjects, 60 years or older	Evaluation of dietary intakes with a 150-item FFQ. A dietary composite score (MeDi score) evaluated adherence to Mediterranean diet	MMSE	No significant association between MeDi score and MMSE scores, whereas a statistically significant inverse association was found between MMSE performance and some individual dietary components, such as seed oil or PUFA intakes

| Vercambre et al. (2008) | Longitudinal, population based (13 years) | 4,809 elderly women, 76–82 years old | Evaluation of dietary intakes with a 208-item FFQ | DECO and IADL | Elderly women that were reported by informants to have undergone recent cognitive decline, 13 years previously, lower intakes of poultry, fish, and animal fats, as well as higher intakes of dairy desserts and ice-cream. They had lower habitual intakes of dietary fiber and n-3 PUFA, but a higher intake of retinol. Elderly women that were reported by informants to be functionally impaired had, in the past, lower intakes of vegetables and vitamins B2, B6 and B12 |
| Eskilinen et al. (2008) | Longitudinal, population based (21 years) | 1,449 subjects aged 65–80 years | Evaluation of dietary intakes with a 208-item FFQ | The Mayo Clinic AD Research Center criteria were applied for diagnosing MCI; MMSE, CFT, PPBt, LDST, episodic memory with immediate word recall tests; executive function with the Stroop test, and prospective memory with a task by Einstein | Elevated SFA intake at midlife was associated with poorer global cognitive function and prospective memory and with an increased risk of MCI. High intake of PUFA was associated with better semantic memory. Frequent fish consumption was associated with better global cognitive function and semantic memory. Higher PUFA/SFA ratio was associated with better psychomotor speed and executive function |

This table lists the principal findings of longitudinal clinical and epidemiological studies on the relationships between dietary fatty acids and predementia syndromes (i.e., age-related cognitive decline, ARCD, and mild cognitive impairment, MCI) in older people, including the setting and study design, and the dietary and cognitive assessment used

MMSE Mini-Mental State Examination (global cognitive functioning), *PUFA* polyunsaturated fatty acids, *FFQ* food frequency questionnaire, *EBT* East Boston Memory test (immediate and delayed episodic memory), *SDMT* Symbol Digit Modalities Test (perceptual-motor speed), *MUFA* monounsaturated fatty acids, *CCI* Charlson comorbidity index, *BMI* body mass index, *SMC* subjective memory complaint, *ADL* activities of daily living, *IADL* instrumental activities of daily living, *EPA* eicosapentaenoic acid, *DHA* docosahexaenoic acid, *DECO* DEtérioration Cognitive Observée scale (observed cognitive deterioration), *CFT* Category Fluency Test (semantic memory), *PPBt* Purdue Peg Board task (psychomotor speed), *LDST* Letter Digit Substitution Test (perceptual-motor speed)

in the European Prospective Investigation into Cancer and Nutrition (EPIC), Greece cohort, and residing in the Attica region, 6–13 years follow up showed that seed-oil consumption may adversely affect cognition, whereas adherence to the Mediterranean diet, as well as intake of olive oil, MUFA, and SFA exhibited weakly positive but not significant associations (Psaltopoulou et al. 2008) (Table 179.7). Finally, 4.809 elderly women (born between 1925 and 1930) were studied in a French longitudinal cohort, the Etude Epidémiologique de Femmes de la Mutuelle Générale de l'Education Nationale (E3N) study. Elderly women participating in the E3N cohort who were reported by informants to have undergone recent cognitive decline had, 13 years previously, lower intakes of poultry, fish, and animal fats, as well as higher intakes of dairy desserts and ice-cream. They had lower habitual intakes of dietary fiber and *n*-3 PUFA, but a higher intake of retinol. Furthermore, elderly women who were reported by informants to be functionally impaired had, in the past, lower intakes of vegetables and vitamins B2, B6, and B12 (Vercambre et al. 2009) (Table 179.7). More recently, in the Cardiovascular Risk Factors, Aging and Dementia (CAIDE) Study from eastern Finland, abundant SFA intake from milk products and spreads at midlife was associated with poorer global cognitive function and prospective memory and with an increased risk of MCI in average follow-up period of 21 years after adjusting for demographic and vascular factors, other fats, and apolipoprotein E (APOE). On the contrary, high PUFA intake was associated with better semantic memory. Also frequent fish consumption was associated with better global cognitive function and semantic memory. Further, higher PUFA/SFA ratio was associated with better psychomotor speed and executive function (Eskelinen et al. 2008) (Table 179.7).

Therefore, on the basis of the previous significant suggestions (Solfrizzi et al. 2005), we tested further the hypothesis that high MUFA and PUFA intakes may protect against the development of cognitive impairment over time in a median follow-up of 8.5 years of the ILSA. The major finding of this study was that high MUFA, PUFA, and total energy intake were significantly associated with a better cognitive performance in time (Figs. 179.2 and 179.3). Total energy intake should be considered

Fig. 179.2 Cognitive profile across time for total energy intake from the Italian Longitudinal Study on Aging (*ILSA*). This figure shows the mean observed Mini-Mental State Examination (*MMSE*) score profile across time for total energy intake (<11,330 kJ/day and ≥11,330 kJ/day at the beginning of the study), ILSA, 1992–2001. The *squared symbols* and *solid line* represent the mean observed MMSE scores for total energy intake, respectively, computed using all observations (*n* = 278 subjects), while the squared symbols and short dashed line represent the mean MMSE scores for total energy intake, computed data from 95 subjects with complete observations
Fig. 179.3 Cognitive profile across time for monounsaturated fatty acids (*MUFA*) intake from the Italian Longitudinal Study on Aging (*ILSA*). This table Mean observed MMSE score profile across time for daily MUFA intake (<53.1 g/day and ≥53.1 g/day at the beginning of the study), ILSA, 1992–2001. The *circle symbols* and *solid* represent the mean observed MMSE scores for MUFA intake, respectively, computed using all observations (*n* = 278 subjects), while the circle symbols and short dashed line represent the mean MMSE scores for MUFA intake, computed data from 95 subjects with complete observations
an important confounder of diet-ARCD relationships and, as we proposed in our methodological approach, suggesting that association between macronutrient intake and cognitive decline should be adjusted by total energy intake. No other individual dietary component of our study population was significantly associated with cognitive impairment in time (Solfrizzi et al. 2006a) (Table 179.7). The association between high MUFA, PUFA intakes, and cognitive performance remained robust even after adjustment for potential confounding variables such as age, sex, educational level, Charlson comorbidity index, body mass index, and total energy intakes (Solfrizzi et al. 2006a). Finally, recent findings from the ILSA demonstrated that while dietary fatty acids intakes were not associated with incident MCI, high PUFA intake appeared to have a borderline nonsignificant trend for a protective effect against the development of MCI (Solfrizzi et al. 2006b) (Table 179.7).

179.2.3 Fish Consumption and Cognitive Decline

Epidemiological observational studies reporting associations of fish consumption with cognitive function have shown mixed results; some cross-sectional and longitudinal studies have reported a positive association with higher fish consumption (Morris et al. 2005b; van Gelder et al. 2007; Nurk et al. 2007; Dangour et al. 2009), while others have found no association (Kalmijn et al. 1997a) (Tables 179.6 and 179.7). Fish, particularly fatty fish (e.g., herring, mackerel, salmon, or trout), is the principal source of *n*-3 PUFA in the Mediterranean diet. Very recently, the baseline data from the Older People And *n*-3 Long-chain polyunsaturated fatty acid (OPAL) study, a double-blind randomized placebo-controlled trial examining the effect of daily supplementation with 700 mg *n*-3 PUFA on cognitive performance in healthy older persons aged 70–79, suggested that higher fish consumption is associated with better cognitive function in later life (Dangour et al. 2009) (Table 179.6).

In the Chicago Health and Aging Project (CHAP), dietary intake of fish was inversely associated with cognitive decline over 6 years of follow-up. In this cohort, there was little evidence that the *n*-3 PUFA were associated with cognitive change (Morris et al. 2005b) (Table 179.7). Furthermore, in the Zutphen Elderly Study, fish consumers had significantly less 5-year subsequent cognitive decline than did non-consumers. A linear trend was observed for the relation between the intake of EPA + DHA and cognitive decline, and an average difference of 380 mg/day in EPA plus DHA intake was associated with a 1.1-point difference in cognitive decline (van Gelder et al. 2007) (Table 179.7). Finally, findings from the Hordaland Health Study suggested that subjects whose mean daily intake of fish and fish products was >10 g/day had significantly better mean test scores and a lower prevalence of poor cognitive performance than did those whose intake was <10 g/day. The associations between total intake of seafood and cognition were strongly dose dependent; and the effect was more pronounced for non-processed lean fish and fatty fish (Nurk et al. 2007) (Table 179.6).

179.3 Dietary Fatty Acids and Dementia

179.3.1 Cross-sectional Studies

In 1997, for the first time, a strong dietary link to AD was suggested (Grant 1997) (Table 179.8). The primary finding of this cross-sectional ecological study was that fat and total caloric supply have the highest correlations with AD prevalence rates. In addition, a combination of fat and fish consumption is found to reduce the prevalence of AD in the European and North American countries, i.e., one calorie of fish was found to counter the effects of approximately 4.3 calories of fat. As with most studies of this type, there are a number of potential caveats. In particular, the results of analyses of food supply data with prevalence data that are applied to specific populations should be viewed with caution. However, these ecological evidences were in agreement with various recent epidemiologic studies (Grant 1999).

One of the most interesting findings of a recent study on VaD risk factors conducted on the cohort of the Honolulu-Asia Aging Study (HAAS), in 3,385 older Japanese subjects, was the protective effect of a Western diet against the development of VaD (Ross et al. 1999) (Table 179.8). Oriental populations from Asian countries are known to be more prone to stroke and VaD. A traditional Western diet is high in animal fat and protein and low in complex carbohydrates, compared to the traditional Japanese diet, which is high in complex carbohydrates and low in animal fat and protein. This is an interesting approach in which dietary patterns, not only single micro- or macronutrients, are considered in explaining the possible role of diet in cognitive decline. The mechanism by which an oriental diet leads to VaD remains speculative. The higher risk of stroke could probably be referred to the lower intake of animal fat and protein. As these findings do not allow analysis of separate nutrients, a hypothesis could be that more fat intake may stabilize the integrity of smaller intracranial arterioles, while the quantity and quality of dietary protein may affect small vessel pathology. Furthermore, the increased risk of VaD and stroke in Japan may well be due to the high sodium intake, in the form of soy sauce, pickled fish, etc.

179.3.2 Longitudinal Studies

The possible relationship between dietary fatty acids intake and risk of dementia and AD has been evaluated in a series of longitudinal studies. In fact, the finding that total dietary fat is a possible risk factor for the development of AD has been reported in the Rotterdam Study, although not at a

Table 179.8 Principal cross-sectional studies on the relationships between dietary fatty acids and dementia, or vascular dementia (VaD), or Alzheimer's disease (AD)

Reference	Setting and study design	Subjects	Dietary assessment	Dementia diagnosis	Results and conclusions
Cross-sectional studies					
Grant (1997)	Ecological cross-sectional	18 community-wide studies conducted after 1979 (≥65 years old)	Evaluation of the components of the national diets	Prevalence of AD diagnosed with various clinical criteria	The primary finding is that fat and total caloric supply have the highest correlations with AD prevalence rates. In addition, fish consumption is found to reduce the prevalence of AD in the European and North American countries
Ross et al. (1999)	Cross-sectional, population based	3,734 Japanese American men aged 71 to 93	Evaluation of vascular risk factors, dietary habits, and questionnaire on supplementary vitamin E and C use and alcohol intake	Diagnosis of dementia, VaD (ADDTC criteria), and stroke without dementia	The antioxidant vitamin E and unknown factors related to a Western diet, high in animal fat and protein and low in complex carbohydrates, as opposed to an Oriental diet may be protective against developing VaD

This table lists the principal findings of cross-sectional ecological and epidemiological studies on the relationships between dietary fatty acids and dementia, or VaD, or AD, including the setting and study design, and the dietary and cognitive assessment used
ADDTC California Alzheimer's Disease Diagnostic and Treatment Centers

statistically significant level. In the same study, fish consumption was confirmed to reduce AD risk and LA was inversely correlated with AD. This study suggested that an elevated intake of lipids and saturated fat increased the risk for dementia with a cerebrovascular component (Kalmijn et al. 1997b) (Table 179.9). The cohort of the Rotterdam Study was reexamined in a 6-year follow-up, and a high intake of total fat, saturated fat, trans fat, and cholesterol and low intake of MUFA, PUFA, *n*-6 PUFA, and *n*-3 PUFA were not associated with an increased risk of dementia or its subtypes (Engelhart et al. 2002) (Table 179.9). The discrepancy in comparison with the results of the first study was explained by the authors by the shorter follow-up (2.1 years) and a consequent smaller number of incident cases of dementia. Moreover, other limitations of the Rotterdam study included the potential for confounding by intake of other types of fat (e.g., intake of trans fat is associated with both intakes of MUFA and SFA), and the potential for nonlinear associations, with associations of the extremes of intake.

Finally, the findings of the reexamined cohort of the Rotterdam Study are at odds with several recent studies (Luchsinger et al. 2002; Barberger-Gateau et al. 2002; Morris et al. 2003a, b; Laitinen et al. 2006; Barberger-Gateau et al. 2007) (Table 179.9). In fact, a 4-year cohort study in New York, the Washington Heights-Inwood Columbia Aging Project, found that dietary fat was an important risk factor for AD for those with the APOE ε4 allele, but not for those without that allele (Luchsinger et al 2002). Luchsinger and colleagues did not find associations with individual types of fat, but like the Rotterdam study, failed to control for other types of fat, which may have confounded the observed findings. They also confirmed previous ecological findings on the possible role of cereals as a risk reduction factor (Grant 1997).

Furthermore, findings coming from the Personnes Agees QUID (PAQUID) study, a population-based study conducted in France on 1,674 subjects aged 68 years and over, with no apparent dementia at baseline, showed that participants who ate fish or seafood at least once a week had a significantly lower risk of dementia (age and sex adjusted hazard ratio of 0.66, 95% CI: 0.47–0.93) in the 7 subsequent years. After adjusting for education, the hazard ratio was almost unchanged (0.73), but the 95% CI (0.52–1.03), slightly overlapping 1.00, indicated that higher education regarding regular consumption explains in part the protective effect of weekly fish or seafood consumption against dementia. Moreover, in this study no significant association between meat consumption and the risk of dementia was found for weekly consumers, with only a borderline significance for developing AD (hazard ratio: 0.68, 95% CI: 0.47–1.01) (Barberger-Gateau et al. 2002) (Table 179.9).

More recently, two studies from the cohort of the CHAP, increased the evidence of a strict linkage between dementia and fatty acid intake (Morris et al. 2003a, b) (Table 179.9). In fact, in this cohort of 815 subjects, aged 65 years and older, after a mean follow-up of 3.9 years, 131 persons developed AD. A high intake of saturated fat and trans-unsaturated fat may be associated with a higher risk of AD; while a high intake of *n*-6 PUFA and MUFA may be protective against AD (Morris et al. 2003a). Furthermore, in the same cohort, a higher intake of *n*-3 PUFA and weekly fish consumption may reduce the risk of incident AD. In fact, in this study, people who ate fish once or more times in a week had a relative risk for AD of 0.4: the absolute risk reduction was about 9.5% (Morris et al. 2003b). More recently, in the CAIDE Study, after an average follow-up of 21 years, moderate intake of PUFA at midlife decreased the risk of dementia, whereas SFA intake was associated with an increased risk, only among the APOE ε4 carriers (Laitinen et al. 2006) (Table 179.9) (Fig. 179.4). Finally, data from the Three-City Study demonstrated that a diet rich in fish, *n*-3 rich oils, fruits, and vegetables could contribute to decreasing the risk of dementia and AD in older persons whereas consumption of *n*-6 rich oils could exert detrimental effects when not counterbalanced by sufficient *n*-3 intake. These effects seem more pronounced among APOE ε4 non-carriers (Barberger-Gateau et al. 2007) (Table 179.9).

Table 179.9 Principal longitudinal studies on the relationships between dietary fatty acids and dementia, or vascular dementia (VaD), or Alzheimer's disease (AD)

Reference	Setting and study design	Subjects	Dietary assessment	Dementia diagnosis	Results and conclusions
Longitudinal studies					
Kalmijn et al. (1997b)	Longitudinal, population based (2.1 years)	5,386 subjects aged 55 and older	Evaluation of dietary intakes with a 170-item FFQ	Diagnosis of AD (NINCDS-ADRDA criteria), VaD (NINDS-AIREN criteria), or dementia with a vascular component	High intakes of total fat, saturated fat, and cholesterol were associated with an increased risk of dementia. Dementia with a vascular component was most strongly related to total fat and saturated fat. Fish consumption was inversely related to incident dementia, and in particular to AD
Engelhart et al. (2002)	Longitudinal, population based (6 years)	5,395 subjects aged 55 and older	Evaluation of dietary intakes with a 100-item FFQ	Diagnosis of dementia (DSM-III-R criteria), AD (NINCDS-ADRDA criteria), and VaD (NINCDS-AIREN criteria)	High intakes of total fat, saturated fat, trans fat, and cholesterol and low intake of MUFA, PUFA, n-6 PUFA, and n-3 PUFA were not associated with an increased risk of dementia, AD, or VaD
Luchsinger et al. (2002)	Longitudinal, population based (4 years)	980 subjects, mean age: 75.3±5.8 years	Evaluation of dietary intake with a 61-item FFQ	Diagnosis of prevalent dementia (DSM-IV criteria) and incident AD (NINCDS-ADRDA criteria)	Higher intake of calories and fats may be associated with higher risk of AD in subjects carrying the apolipoprotein E □4 allele
Barberger-Gateau et al. (2002)	Longitudinal, population based (7 years)	1,674 subjects aged 68 years and over	Evaluation of frequency of consumption of meat and fish and seafood: from daily to never	Diagnosis of incident dementia, including AD (DSM-III-R criteria)	Elderly people who consumed fish [rich in PUFA] or seafood at least once a week are at lower risk of dementia, including AD
Morris et al. (2003a)	Longitudinal, population based (3.9 years)	815 subjects, aged 65 years and older	Evaluation of dietary intake with a 154-item FFQ	Incident diagnosis of AD (NINCDS-ADRDA criteria)	High intake of saturated and trans-unsaturated fats may be associated with higher risk of AD; while high intake of n-6 PUFA and MUFA may be protective against AD
Morris et al (2003b)	Longitudinal, population based (3.9 years)	815 subjects, aged 65 years and older	Evaluation of dietary intake with a 154-item FFQ	Incident diagnosis of AD (NINCDS-ADRDA criteria)	Higher intake of n-3 PUFA and weekly fish consumption may reduce the risk of incident AD

(continued)

Table 179.9 (continued)

Reference	Setting and study design	Subjects	Dietary assessment	Dementia diagnosis	Results and conclusions
Huang et al. (2005)	Longitudinal, population based (5.4 years)	5,201 participants, aged 65 years and older	Evaluation of dietary intake with a 99-item FFQ	Incident diagnosis of dementia (DSM-IV criteria) and AD (NINCDS-ADRDA criteria)	Fatty fish, such as tuna or "other fish" was associated with a lower risk of developing dementia and AD with a dose-response relationship, whereas lean, fried fish was not. Those without an APOE ε4 allele had a 35–45% lower risk with consumption of fatty fish, whereas there was little or no difference for APOE ε4 allele carriers
Schaefer et al. (2006)	Longitudinal, population based (9.1 years)	488 participants from a sample of 899 individuals, median age: 76.0 years	Evaluation of dietary intake with a 125-item FFQ and plasma phosphatidylcholine DHA content	Incident diagnosis of dementia (DSM-IV criteria) and AD (NINCDS-ADRDA criteria)	Higher dietary intakes of DHA and fish did not result protective against all cause dementia and AD. A protective effect of higher plasma DHA was observed against the risk of all cause dementia but not for AD
Laitinen et al. (2006)	Longitudinal, population based (21 years)	1,449 subjects aged 65–80 years	Evaluation of dietary intake with a 154-item FFQ	Incident diagnosis of AD (NINCDS-ADRDA criteria)	Moderate intake of PUFA at midlife was protective, whereas a moderate intake of SFA may increase the risk of dementia and AD, especially among APOE ε4 carriers.
Barberger-Gateau et al. (2007)	Longitudinal, population based (4 years)	9,294 subjects, aged 65 years and older	Evaluation of dietary intakes with a FFQ	Incident diagnosis of dementia (DSM-IV criteria) and AD (NINCDS-ADRDA criteria)	Frequent consumption of fruits and vegetables, fish, and n-3 rich oils may decrease the risk of dementia and AD, especially among APOE ε4 non-carriers

This table lists the principal findings of longitudinal clinical and epidemiological studies on the relationships between dietary fatty acids and dementia, or VaD, or AD, including the setting and study design, and the dietary and cognitive assessment used.

FFQ food frequency questionnaire, *NINCDS-ADRDA* National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association, *NINCDS-AIREN* National Institute of Neurological and Communicative Disorders and Stroke and the Association Internationale pour la Recherche at l'Enseignement en Neurosciences, *DSM-III-R* Diagnostic and Statistical Manual of Mental Disorders, third edition revised, *PUFA* polyunsaturated fatty acids, *MUFA* monounsaturated fatty acids, *DSM-IV* Diagnostic and Statistical Manual of Mental Disorders, fourth edition, *APOE* apolipoprotein E, *DHA* docosahexaenoic acid
Fig. 179.4 Combined effects of apolipoprotein E (*APOE*) ε4 carrier status and midlife polyunsaturated fatty acids (*PUFA*), monounsaturated fatty acids (*MUFA*), and saturated fatty acids (*SFA*) consumptions in spreads and the risk of dementia (**a**) and Alzheimer's disease (*AD*) (**b**). This figure lists analyses adjusted for age, sex, education, follow-up time, other subtypes of fat from spreads and milk, APOE ε4 and midlife systolic blood pressure (*SBP*), body mass index (*BMI*), cholesterol, smoking, and late-life history of myocardial infarction, stroke and diabetes; *$p < 0.05$, **$p < 0.01$ when compared to the reference group (first fat quartile and APOE ε4 non-carrier); = APOE ε4 non-carriers; = APOE ε4carriers (Reprinted from Laitinen et al. 2006. With permission)

179.3.3   Fish Consumption and Dementia

A lower risk of incident dementia in subjects consuming more fish has nevertheless been reported in several other independent prospective cohort studies (Barberger-Gateau et al. 2002; Morris et al. 2003b; Huang et al. 2005; Barberger-Gateau et al. 2007) (Table 179.9). In particular, data from the Cardiovascular Health Cognition Study (CHCS) showed that consumption of fatty fish more than twice per week was associated with a reduction in risk of dementia by 28%, and AD by 41% in comparison to those who ate fish less than once per month. Stratification by APOE ε4 showed this effect to be selective to those without the ε4 allele (Huang et al. 2005) (Table 179.9). Only one prospective study has not shown a significant benefit of higher fish intake and risk of AD (Schaefer et al. 2006) (Table 179.9). This study was based on a subsample of 488 participants representing about 25% of the main cohort of the Framingham Heart Study in which both dietary DHA intakes were

calculated and plasma DHA measurements made. A protective effect of higher plasma DHA was observed against the risk of all cause dementia but not for AD. Higher dietary intakes of DHA and fish did not result protective against dementia and AD. This negative finding for AD per se may have been due to a lack of statistical power because the 50% risk reduction for AD in subjects who consumed fish more than twice a week was almost statistically significant (95% CI 0.20–1.27; P=0.14). Furthermore, several studies suggest that APOE polymorphism may inhibit or prevent the beneficial effect of fish in reducing the risk of cognitive decline in the elderly. Two recent prospective studies indicate that ApoE4 carriers are not protected against dementia by higher fish intake (Huang et al. 2005; Barberger-Gateau et al. 2007) (Table 179.9). Therefore, despite these contrasting findings, there is now considerable evidence suggesting that fatty acid intake and fish consumption may influence dementia and AD risk, but the direction (protection or risk) and the level of this effect remain unclear. In fact, based on the current evidences from human and animal studies, it is not possible to make definitive dietary recommendations in relation to the AD risk on fish consumption and the lower intake of saturated fat from meat and dairy products. Furthermore, individuals who consume a diet high in fruits and vegetables as well as nuts or fish would probably have other lifestyle characteristics that might be effective in reducing AD or VaD risk (e.g., physical activity). However, a high consumption of fats from fish, vegetable oils, vegetables, and nuts should be encouraged because this dietary advice is in accordance with recommendations for lowering the risk of cardiovascular disease, obesity, diabetes, and hypertension.

179.4 Dietary Fatty Acid Supplementation in Predementia and Dementia Syndromes: Is It the Case for a Treatment?

The increasing epidemiological evidence of an association between a reduced risk of AD and a diet high in *n*-3 PUFA and fish consumption (Panza et al. 2004), is further supported by recent findings that certain diets have been associated with a lower incidence of predementia syndromes (Solfrizzi et al. 2006a, b). Two randomized clinical trials (RCT), using an *n*-3/*n*-6 fatty acid compound on 100 AD patients and a supplementation with DHA on 20 nursing home residents with VaD found improvements in mood, cooperation, appetite, sleep, ability to navigate in the home, and short-term memory in the AD-treated group (Yehuda et al. 1996) and improved cognitive scores in the VaD-treated group (Terano et al. 1999) (Table 179.10).

Recently, Freund-Levi and colleagues found that, in 204 patients with moderate AD, the supplementation with DHA and EPA (for a total dose of 1,720 mg DHA/600 mg EPA) for 6 months (OmegAD Study) did not delay the rate of cognitive decline but, in the group of 32 patients with the most mild AD (MMSE >27, Clinical Dementia Rating Score 0.5–1), *n*-3 PUFA supplementation slowed the decline in MMSE scores (Freund-Levi et al. 2006) (Table 179.10). After the treatment period, all the subjects received open label *n*-3 PUFA for another 6 months. The subjects in the placebo group of these very mild AD patients also showed a statistically significant slowing of decline when they were switched to treatment between 6 and 12 months, suggesting that *n*-3 PUFA might be of benefit to slow the progression of the disease in MCI or very mild AD (Freund-Levi et al. 2006). Furthermore, this supplementation did not result in marked effects on neuropsychiatric symptoms in mild to moderate AD patients except for possible positive effects on depressive symptoms and agitation symptoms in subgroups. In fact, there were positive effects on depressive symptoms in non-APOE ε4 carriers and in non-APOE ε4 carriers on agitation symptoms (Freund-Levi et al. 2008) (Table 179.10).

At present, the effect of arachidonic acid (ARA) and DHA (240 mg/day), after a 90-day supplementation, on MCI, organic brain lesions, or AD showed a significant improvement of the immediate

Table 179.10 Principal clinical trials on polyunsaturated fatty acid (PUFA) supplementation in patients with mild cognitive impairment (MCI), vascular dementia (VaD), Alzheimer's disease (AD), and age-related cognitive decline (ARCD)

Reference	Participants	Intervention and duration of exposure	Outcome measures	Effects of interventions
Terano et al. (1999)	20 elderly nursing home residents with VaD	A single dose of 4.3 g of DHA was administered; dose effect was not assessed. The duration of exposure was 12 months	Cognitive functioning was evaluated using HDS-R and MMSE scores at baseline, and after 3, 6, and 12 months	Baseline HDS-R and MMSE scores were 15 to 22, consistent with mild to moderate dementia. HDS-R and MMSE scores improved in the DHA-treated group but not among patients who were not treated with DHA. Comparisons between groups were significant at 3 and 6 months for the HDS-R and at 6 months for the MMSE
Freund-Levi et al. (2006)	204 patients with mild to moderate AD and with acetylcholine esterase inhibitor treatment and a MMSE >15 points	A single dose of 1.7 g of DHA plus 0.6 g of EPA was administered. The duration of exposure was 6 months placebo-controlled and 6 months open for both groups	Primary outcome measures: MMSE and ADAS-cog. Secondary outcome measures: was global function as assessed with the CDR	Administration of n-3 PUFA in patients with mild to moderate AD did not delay the rate of cognitive decline according to the MMSE or ADAS-cog. However, positive effects were observed in a small group of patients with very mild AD (MMSE >27 points)
Kotani et al. (2006)	21 patients with mild cognitive dysfunction (12 MCI patients with supplementation and 9 MCI patients with placebo), 10 patients with organic brain lesions, and 8 patients with AD	A single dose of 240 mg/day of ARA and DHA, or 240 mg/day of olive oil (placebo). The duration of exposure was 3 months	The cognitive functions were evaluated using Japanese version of RBANS at two time points: before and 90 days after the supplementation	The MCI group with supplementation showed a significant improvement of the immediate memory and attention score. Organic group showed a significant improvement of immediate and delayed memory. However, there were no significant improvements of each score in AD and MCI placebo groups
Freund-Levi et al. (2008)	204 patients with mild to moderate AD and with acetylcholine esterase inhibitor treatment and a MMSE >15 points	A single dose of 1.7 g of DHA plus 0.6 g of EPA was administered. The duration of exposure was 6 months placebo-controlled and 6 months open for both groups	Neuropsychiatric symptoms were measured with NPI and MADRS. Care givers' burden and activities of daily living (DAD) were also assessed.	No significant overall treatment effects on neuropsychiatric symptoms, on activities of daily living or on caregiver's burden were found. However, significant positive treatment effects on the scores in the NPI agitation domain in APOE ε4 carriers and in MADRS scores in non-APOE ε4 carriers were found.

Table 179.10 (continued)

Reference	Participants	Intervention and duration of exposure	Outcome measures	Effects of interventions
Chiu et al. (2008)	23 patients with mild to moderate AD and 23 patients with MCI	n-3 PUFA 1.8 g/day in monotherapy or placebo (olive oil). The duration of exposure was 24 weeks	Global clinical function measured with CIBIC-plus, cognitive function with ADAS-cog and MMSE, depressive symptoms with HDRS	This supplementation may improve global clinical function (CIBIC-plus) in MCI patients relative to placebo. No associations were found between randomization group and ADAS-cog, MMSE or HDRS scores
Van de Rest et al. (2008a)	Independently living individuals (n = 302) aged ≥ 65 years CES-D score < 16 MMSE score > 21	A single dose of 1,800 mg/day EPA+DHA (n = 96), 400 mg/day EPA+DHA (n = 100), or placebo capsules (n = 106); the duration of exposure was 26 weeks	Changes in mental well-being were assessed as the primary outcome with the CES-D, MADRS, GDS-15, and HADS-A	Treatment with neither 1800 mg nor 400 mg EPA+DHA differentially affected any of the measures of mental well-being after 13 or 26 weeks of intervention compared with placebo
Van de Rest et al. (2008b)	Independently living individuals (n = 302) aged ≥ 65 years CES-D score < 16 MMSE score > 21	A single dose of 1,800 mg/day EPA+DHA (n = 96), 400 mg/day EPA+DHA (n = 100), or placebo capsules (n = 106); the duration of exposure was 26 weeks	Cognitive performance was assessed using an extensive neuropsychological test battery that included the cognitive domains of attention (SC-WT; fWDST), sensorimotor speed (TMT-A), memory (WLT; bWDST), and executive function (TMT-B; VFT)	There were no significant differential changes in any of the cognitive domains for either low-dose or high-dose fish oil supplementation compared with placebo; an effect of EPA–DHA supplementation in subjects who carried the APOE ε4 allele was also found, but only on the cognitive domain of attention

This table lists the principal findings of clinical trials on PUFA supplementation in patients with MCI, VaD, AD, and ARCD, including the intervention and duration of exposure, and the outcome measures used

DHA docosahexaenoic acid, *HDS-R* Hasegawa's Dementia rating scale, *MMSE* Mini-mental State Examination, *EPA* eicosapentaenoic acid, *ADAS-cog* cognitive portion of the Alzheimer Disease Assessment Scale, *CDR* Clinical Dementia Rating Scale, *ARA* arachidonic acid, *RBANS* Repeatable Battery for Assessment of Neuropsychological Status, *NPI* Neuropsychiatric Inventory, *MADRS* Montgomery Asberg Depression Scale, *DAD* Disability Assessment for Dementia, *APOE* apolipoprotein E, *CIBIC-plus* Clinician's Interview-Based Impression of Change Scale, *HDRS* Hamilton Depression rating Scale, *DRS-2* Dementia Rating Scale 2, *CDT* Clock Drawing Tests, *ADCS-ADL* Alzheimer's Disease Cooperative Study–Activities of Daily Living, *CES-D* Center for Epidemiologic Studies Depression Scale, *GDS-15* 15-item Geriatric Depression Scale, *HADS-A* Hospital Anxiety and Depression Scale, *SC-WT* Stroop Color–Word Test, *fWDST* forward test of the Wechsler Digit Span Task, *TMT-A* Trail Making Test version A, *WLT* Word Learning Test, *bWDST* backward test of the Wechsler Digit Span Task, *TMT-B* Trail Making Test version B, *VFT* Verbal Fluency Test

memory and attention score for MCI patients, and a significant improvement of immediate and delayed memories for patients with organic brain damages (Kotani et al. 2006) (Table 179.10). Finally, the preliminary results from a 24-week, randomized, double-blind placebo-controlled study on 23 participants with mild or moderate AD and 23 with MCI randomized to receive *n*-3 PUFA 1.8 g/day or placebo (olive oil), suggested that his supplementation may improve global clinical function, as measured by Clinician's Interview-Based Impression of Change scale which included caregiver-supplied information (CIBIC-plus), relative to placebo. No associations were found between the randomization group and ADAS-cog, MMSE, or Hamilton Depression rating Scale scores. Levels of EPA on erythrocyte membrane, were associated with cognitive function, measured by ADAS-cog, in these patients (Chiu et al. 2008) (Table 179.10). However, in a secondary analysis, participants with MCI showed more improvement of ADAS-cog than those with AD associated with *n*-3 PUFA administration (Chiu et al. 2008), which support recent reports showing that PUFA supplementation could be more beneficial on cognition in people with very mild AD (Freund-Levi et al. 2006) or MCI Kotani et al. 2006) than in AD patients (Table 179.10).

A few years ago, a Cochrane review concluded that there was a growing body of evidence from biological, observational, and epidemiological studies that suggested a protective effect of *n*-3 PUFA against dementia. However, the Cochrane review team was unable to locate a single published randomized controlled trial on which to base recommendations for the use of dietary or supplemental *n*-3 PUFA for the prevention of cognitive impairment or dementia (Lim et al. 2006). However, very recently, a randomized, double-blind, placebo-controlled trial on 302 cognitively healthy (MMSE score > 21) individuals aged 65 years or older investigated the possible impact of *n*-3 PUFA on the mental well-being and cognitive performance of nondepressed (CES-D score < 16), older individuals (van de Rest et al. 2008a, b) (Table 179.10). In this RCT, participants were randomly assigned to 1.800 mg/d EPA–DHA, 400 mg/d EPA–DHA, or placebo capsules for 26 weeks. In older Dutch subjects, no effect of daily supplementation with low or high doses of EPA-DHA on mental well-being as assessed by depression and anxiety questionnaires was found (van de Rest et al. 2008a). Furthermore, there were no significant differential changes in any of the cognitive domains (attention, sensorimotor speed, memory, and executive function) for either low-dose or high-dose fish oil supplementation compared with placebo (van de Rest et al. 2008b). However, an effect of EPA–DHA supplementation in subjects who carried the APOE-ε4 allele was found, but only on the cognitive domain of attention (van de Rest et al. 2008b). Fish oil may be beneficial in these subjects who are most sensitive to developing dementia. These two substantially negative studies on ARCD may be explained by the samples investigated (nondepressed and noncognitively impaired older subjects). Further trials in depressed patients or ε4-carriers with MCI are needed. Finally, there is another ongoing RCT with cognitive endpoints of *n*-3 PUFA supplementation in healthy cognitively intact older persons. The OPAL study is a double-blind randomized placebo-controlled trial examining the effect of daily supplementation with 700 mg *n*-3 PUFA (500 mg DHA and 200 mg EPA) for 24 months on cognitive performance in healthy older persons aged 70–79 with good cognitive function (MMSE equals or greater than 24 out of 30 points at baseline), who are recruited from 20 primary care practices (Dangour et al. 2006). The OPAL study was completed at the end of 2007 and its findings will be published shortly. Thus, epidemiological evidence has suggested a possible association between PUFA (particularly, *n*-3 PUFA) and reduced risk of cognitive decline and dementia. However, due to the small number of studies that inform this topic, further research is necessary before a strong conclusion can be drawn. Some recent RCTs assessed the cognitive or functional effect of *n*-3 PUFA supplementation on patients with VaD, AD, MCI, or ARCD in cognitively unimpaired older subjects. These RCTs suggested a positive effect of this intervention only in very mild AD or MCI patients, or in subgroups (e.g., APOE-e4 carriers) for cognitive performance in nondemented subjects or for neuropsychiatric symptoms in mild to moderate AD patients. On the basis

of these evidences, we strongly suggest also for predementia syndromes, a high-risk condition for progression to dementia of vascular and degenerative origin, intervention trials using measures of dietary supplementation similar to the OmegAD Study to determine if such supplements will slow cognitive decline.

179.5 Dietary Unsaturated Fatty Acids and Cognitive Decline: Possible Mechanisms

179.5.1 Monounsaturated Fatty Acids and Cognitive Decline

Different pathways could contribute to the neuroprotective as well as the neurotrophic properties of UFA. As seen above, in the older subjects of the ILSA, there was a high consumption of olive oil, with an MUFA energy intake of 17.6%, 85% of which was derived from olive oil (Solfrizzi et al. 1999) (Fig. 179.1). In our population, the prolonged protection of MUFA intake against age-related changes in cognitive functions may be linked to the relevant quota of antioxidant compounds in olive oil, including low-molecular-weight phenols (Solfrizzi et al. 2005). In fact, animal studies suggested that diets high in antioxidant-rich foods, such as spinach, strawberries, and blueberries, rich in anthocyanins and other flavonoids may be beneficial in slowing age-related cognitive decline (Solfrizzi et al. 2005). The possible role of antioxidant compounds from olive oil do not diminish or otherwise alter the argument concerning the fatty acids, because this is only a possible explanation of the role of MUFA on age-related cognitive changes in our population, in which MUFA intake derived for a large part from olive oil.

The neuroprotective effects of dietary UFA could rely on their impact on membrane architecture. In fact, UFA have an important role in maintaining the structural integrity of neuronal membranes, determining the fluidity of synaptosomal membranes and thereby regulating neuronal transmission. Furthermore, essential fatty acids can modify the activity of certain membrane-bound enzymes (phospholipase A2, protein kinase C, and acetyltranferase), and the function of the neurotransmitters' receptors. Finally, free fatty acids, lipid metabolites, and phospholipids modify the function of membrane proteins including ion channels (Solfrizzi et al. 2005). Moreover, fatty acid composition of neuronal membranes in advancing age demonstrated an increase in MUFA content and a decrease in PUFA content (Solfrizzi et al. 2005). *n*-3 PUFA increase membrane fluidity by replacing *n*-6 PUFA and cholesterol from the membrane (Solfrizzi et al. 2005) maintaining an optimal membrane fluidity as obligatory for neurotransmitter binding and signaling within the cell (Solfrizzi et al. 2005). There is also evidence associating a dietary deficiency of *n*-3 PUFA with changes in cortical dopoaminergic function (Solfrizzi et al. 2005) (Fig. 179.5).

179.5.2 Polyunsaturated Fatty Acids and Cognitive Decline

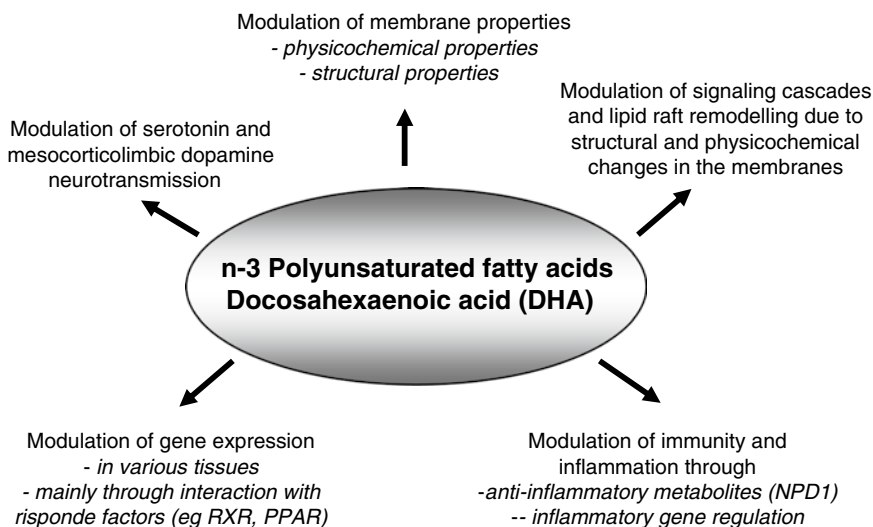
In adult rats, learning and cognitive behavior are related to brain DHA status, which, in turn, is related to the levels of the dietary *n*-3 PUFA (Moriguchi et al. 2000). In fact, administration of DHA seems to improve learning ability in β-amyloid (Aβ)-infused rats (Hashimoto et al. 2005) and inhibit decline in avoidance learning ability in the AD model rats, associated with an increase in the cortico-hippocampal *n*-3/*n*-6 ratio, and a decrease in neuronal apoptotic products (Hashimoto et al. 2002).


Fig. 179.5 Synopsis of the neuroprotective properties of *n*-3 polyunsaturated fatty acids (*PUFA*) and docosahexaenoic acid (*DHA*). This figure lists various possible molecular mechanisms of *n*-3 PUFA and DHA linked to their neuroprotective properties including modulation of membrane properties, serotonin, and dopamine neurotransmission, signaling cascades and lipid raft remodeling, gene expression, and immunity and inflammation (Modified from Florent-Béchard et al. 2007. With permission)

Similarly, recent studies showed that dietary DHA in an aged AD mouse model could be protective against Aβ production, deposition in plaques and cerebral amyloid angiopathy (Lim et al. 2005; Hooijmans et al. 2007), and increases cerebral blood volume (Hooijmans et al. 2007). In other transgenic AD mouse models, DHA also protects against dendritic pathology (Calon et al. 2004) and prevents neuronal apoptosis induced by soluble Aβ peptides (Florent et al. 2006), increases synaptic protein and phospholipid densities (Cole et al. 2005; Wurtman et al. 2006), and inhibits degradative endopeptidase activities (Park et al. 2003). Some experimental evidence has suggested that essential *n*-3 PUFA effectively lower Aβ production in transgenic mice, as reported in studies from several laboratories (Lim et al. 2005; Cole et al. 2005; Oksman et al. 2006). Yet, plaque burden was reduced in only one study using aged transgenic mice, following 3 months DHA enriched diet (Lim et al. 2005), but not in several other studies that started dietary intervention at a much younger age (Oksman et al. 2006; Hooijmans et al. 2007).

Furthermore, DHA, given its unique structural properties, could allow of the modification of the architectural properties of the membrane, especially the distribution and the abundance of lipid raft microdomains (Florent-Béchard et al. 2007). Lipid rafts are liquid ordered sphingomyelin-rich cholesterol-rich PUFA-poor microdomains. DHA and PUFA enrichment is known to be accompanied by lateral phase separation and local lipid redistribution, subtle membrane remodeling and selective displacement of proteins (Florent-Béchard et al. 2007) (Fig. 179.5). By changing the organization and/or composition of the lipid rafts, DHA could directly modify many signaling pathways such as those initiated at the plasma membrane (Florent-Béchard et al. 2007) (Fig. 179.5).

It is well known that PUFA of both *n*-3 and *n*-6 families control gene expression in a variety of tissues including liver and adipose tissue. However, the underlying mechanisms of the direct effects of dietary PUFA-induced differential gene expression pattern in the brain have been addressed by few studies (Florent-Béchard et al. 2007). Gene regulation by PUFA can occur through interactions with specific or nonspecific ligands such as transcription factors like peroxysome proliferator-activated

receptors (PPAR) or retinoid X receptor (RXR) that directly modulate the expression of target genes (Florent-Béchard et al. 2007) (Fig. 179.5). The direct effects of PUFA on gene regulation might be one of the clues to understand the beneficial effects of the *n*-3 PUFA on the nervous system.

Several clinical and epidemiological studies have identified beneficial effects of PUFA for a variety of inflammatory diseases, yet without mechanistic explanations for these beneficial effects. Resolvins and protectins are recently identified molecules that are generated from *n*-3 PUFA precursors and can orchestrate the timely resolution of inflammation in model systems. In fact, DHA also serves as a precursor for the biosynthesis of additional bioactive counter-regulatory lipid mediators. For (neuro)protectin D1 (N)PD1 formation, DHA is rapidly released for conversion to 17S-hydroxy-DHA that serves as a biosynthetic precursor (Serhan et al. 2006). In AD, NPD1 biosynthesis is activated by soluble APP-α (Lukiw et al. 2005). In this disorder, levels of DHA, NPD1, and 15-lipoxygenase (15-LOX) are selectively decreased in the hippocampus, providing a plausible mechanism for decreased neuroprotection in AD: less inhibition of apoptosis and subsequently, increased neuronal cell death (Lukiw et al. 2005) (Fig. 179.5). In a placebo-controlled randomized trial, the OmegAD study, AD patients treated with DHA-rich dietary supplements had reduced release of interleukin (IL)-1b, IL-6 and granulocyte colony-stimulating factor from peripheral blood mononuclear cells (Vedin et al. 2008).

The *n*-3 PUFA from fish may be inversely associated with dementia because it lowers the risk of thrombosis, stroke, cardiovascular disease, and cardiac arrhythmia, reducing the risk of thromboembolism in the brain and consequently of lacunar and large infarcts that can lead to VaD and AD (Solfrizzi et al. 2005). Furthermore, the *n*-3 PUFA may be important as lipids in the brain, particularly for the possible influence of DHA on the physical properties of the brain that are essential for its function (Solfrizzi et al. 2005). Furthermore, fish oil was a better source than α-linolenic acid for the incorporation of *n*-3 PUFA into rat brain phospholipid subclasses (Solfrizzi et al. 2005). On the contrary, high linoleic acid intake (*n*-6 PUFA) may increase the susceptibility of LDL cholesterol to oxidation, which makes it more atherogenic, even if the association between linoleic acid and atherosclerosis is controversial (Solfrizzi et al. 2005). Therefore the ratio of dietary *n*-3/*n*-6 PUFA intake may influence the potential role of PUFA on cognitive decline and dementia, the optimal ratio of *n*-6/*n*-3 should be <5:1 (de Lorgeril et al. 1998). Finally, a high dietary intake of SFA and cholesterol increases the risk for cardiovascular disease, and therefore for cognitive decline, VaD, and AD (Solfrizzi et al. 2008). On the contrary, treatment for 4 weeks with a Mediterranean-inspired diet rich in *n*-3 PUFA decreased blood lipids in healthy individuals with a low-risk profile for cardiovascular disease, with a beneficial effect also on vascular function and oxidative stress (Ambring et al. 2004).

179.6 Applications to Other Areas of Health and Disease

About 50–60% of the dry weight portion of the human brain consists of lipids. PUFA constitute approximately 35 percent of that lipid content (Lauritzen et al. 2001). *n*-3 PUFA, particularly EPA and DHA, play important roles in the development and maintenance of normal central nervous system structure and function. Along with the *n*-6 PUFA, ARA, DHA is a major constituent of neuronal membranes, making up about 20% of the brain's dry weight (Yehuda et al. 1999). Synapses contain a high concentration of DHA, which appears to play a role in synaptic signal transduction (Jones et al. 1997). The metabolic pathways of the essential fatty acids that play an important role in neuronal signal transduction and release of these fatty acids is involved in the phospholipase A2 cycle following activation of various neurotransmitter receptors. DHA is also important for normal cognitive development. In addition, the anti-inflammatory compounds for which DHA is a precursor may

function in the brain to protect against ischemic damage. PUFA in general play important roles in structural and functional maintenance of neuronal membranes, neurotransmission, and eicosanoid biosynthesis (Lauritzen et al. 2001; Tapiero et al. 2002), as well as in the maintenance of membrane fluidity and flexibility and in the modulation of ion channels, receptors, and ATPases. The importance of PUFA in the maintenance of adequate membrane rigidity is evidenced by the loss of fluidity that follows decrease in PUFA (Bourre et al. 1991), leading to changes in the orientation and function of receptors and ion channels, such as calcium and sodium channels.

Several lines of research have suggested that the high ratio of *n*-6 PUFA to low levels of *n*-3 PUFA currently consumed in occidental countries promotes a number of chronic diseases. Whether or not the relatively high intake of *n*-6 PUFA independently contributes to this problem is currently uncertain (Richardson 2003). Because of the slow rate of elongation and further desaturation of the essential fatty acids, the importance of PUFA to many physiological processes, and the overwhelming ratio of *n*-6 PUFA to *n*-3 PUFA in the average occidental diet, nutrition experts are increasingly recognizing the need for humans to augment the body's synthesis of *n*-3 PUFA by consuming foods that are rich in these compounds. According to data from two population-based surveys, the major dietary sources of *n*-3 PUFA in the US population are fish, fish oil, vegetable oils (principally canola and soybean), walnuts, wheat germ, and some dietary supplements, and the primary dietary sources of *n*-6 PUFA are meats and dairy products. These surveys, the Continuing Food Survey of Intakes by Individuals 1994–98 (CSFII) and the third National Health and Nutrition Examination (NHANES III) 1988–94 surveys, are the main sources of dietary intake data for the US population.

Other studies specifically addressed the association of *n*-3 PUFA consumption with risk or incidence of particular neurological diseases other than dementia, e.g., the incidence of multiple sclerosis (MS) (Ghadirian et al. 1998; Zhang et al. 2000), the risk of Parkinson's disease (PD) (Chen et al. 2003), and the risk of cerebral palsy (Petridou et al. 1998). The relationship between dietary intake of *n*-3 PUFA and incidence of MS was assessed in two reports; one pooled data from two large cohorts of women from the Nurses' Health Study (NHS) and the Nurses' Health Study II (NHS II) (Zhang et al. 2000), and the other used a case-control design (Ghadirian et al. 1998). The prospective cohort study assessed the effect of *n*-3 PUFA in terms of fish consumption, fish *n*-3 PUFA, ALA, EPA, and DHA. ALA was associated with a reduced risk of MS in both cohorts that did not reach statistical significance. Intakes of *n*-3 PUFA, EPA, or DHA were not associated with MS incidence. The case-control study evaluated 197 incident MS cases and 202 age-, sex- and neighborhood-matched controls and found no significant association between fish consumption and risk of MS overall. However, fish consumption was significantly associated with a lower risk of MS in females only (Ghadirian et al. 1998).

The relationship between dietary intake of *n*-3 PUFA and incidence of PD was assessed in one report that pooled data from two large prospective cohorts, the Health Professionals Follow-up Study and the NHS (Chen et al. 2003). This study assessed the effect of *n*-3 PUFA in terms of *n*-3 fats from fish, ALA, EPA, and DHA over a 6- to 8-year period. There was no significant association between fish *n*-3 PUFA, ALA, EPA, or DHA intake and risk of PD. In a pooled analysis of men and women across two cohorts, ALA was associated with a reduced risk of developing PD (RR = 0.65, 95% CI 0.46, 0.91 for comparison of highest to lowest quintiles of risk). Among women, there was a significant trend but no significant risk reduction for any individual quintile of consumption. This finding is particularly noteworthy given the statistical power of the Health Professionals Follow-up Study and the NHS and the longitudinal analysis of dietary intake in these studies.

One study evaluated the effects of maternal dietary intake on the risk of cerebral palsy in offspring in a case-control study of 91 cases of cerebral palsy identified from statistics of hospitals and rehabilitation centers in Greece and 246 neighborhood controls (Petridou et al. 1998). Mothers of cases and controls were interviewed about their dietary habits during pregnancy using a food-frequency

questionnaire. Consumption of fish once a week throughout pregnancy was associated with a lower risk of cerebral palsy compared with no fish intake.

In the Mediterranean countries, the principal source of MUFA is olive oil, probably the most representative food in the traditional Mediterranean diet. The hypocholesterolemic effect of the isoenergetic substitution of dietary MUFA for SFA first generated interest in MUFA-rich fats, which include olive, canola, and high-oleic sunflower oils. However, olive oil has additional biological effects, related in part to MUFA but also to minor components, particularly antioxidant phenolics. Virgin olive oil, a pure olive juice, is particularly rich in phenolics. Increasing epidemiologic and clinical evidences suggest that MUFA as a nutrient, olive oil as a food, and the Mediterranean diet as a food pattern have beneficial effects on obesity, the metabolic syndrome, and diabetes (Perez-Jimenez et al. 2005). A Mediterranean diet rich in virgin olive oil and virgin olive oil per se have been shown to improve classical and novel cardiovascular risk factors, such as lipid profiles, blood pressure, postprandial lipemia, endothelial dysfunction, oxidative stress, inflammation, and thrombosis (Perez-Jimenez et al. 2005). Limited epidemiologic evidences from Mediterranean countries suggest that dietary MUFA and/or olive oil intake might protect against breast, colorectal and prostate cancer. Experimental cellular studies have provided new evidences on the potential protective effect of virgin olive oil on cancer (Perez-Jimenez et al. 2005).

179.7 Conclusions

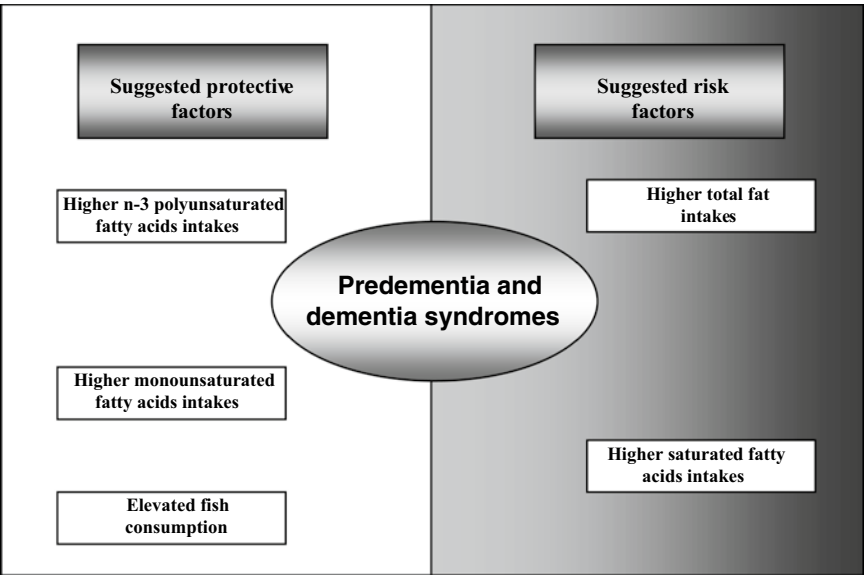
Recently, several studies have suggested that an increase of SFA could have negative effects on cognitive functions. Furthermore, a clear reduction of risk for cognitive decline has been found in population samples with elevated fish consumption, high intake of MUFA and PUFA, particularly *n*-3 PUFA (Fig. 179.6). Recent findings have demonstrated that while dietary fatty acid intakes were not associated with incident MCI, high PUFA intake appeared to have a borderline nonsignificant trend


Fig. 179.6 Synopsis of the evidence on the possible effects of dietary fatty acids on predementia and dementia syndromes. This table lists the key possible effects of dietary fatty acids on predementia and dementia syndromes including *n*-3 polyunsaturated fatty acids, monounsaturated fatty acids, saturated fatty acids (*SFA*), and fish consumption

Table 179.11 Key points of studies on the relationships between dietary fatty acids and predementia and dementia syndromes

A. An increasing body of epidemiological evidence suggests that elevated saturated fatty acids (SFA) could have negative effects on age-related cognitive decline (ARCD). On the contrary, a reduction of risk for dementia and mild cognitive impairment (MCI) has been found in population samples with elevated fish consumption, high intake of monounsaturated fatty acids (MUFA) and polyunsaturated fatty acids (PUFA), particularly *n*-3 PUFA

B. Recent findings from clinical trials with *n*-3 PUFA supplementation have shown efficacy on depressive symptoms in non-apolipoprotein E (APOE) ε4 carriers, and on cognitive symptoms only in very mild Alzheimer's disease (AD) subgroups, MCI patients, and cognitively unimpaired subjects non-APOE ε4 carriers

C. The evidence coming from clinical trials together with epidemiological findings support the idea that *n*-3 PUFA may play a role in maintaining adequate cognitive functioning in predementia syndromes, but not when the AD process has already taken over. Therefore, at present, no definitive dietary recommendations on fish and unsaturated fatty acids consumption or lower intake of saturated fat in relation to the risk for predementia and dementia syndromes are possible

This table lists the principal features of clinical and epidemiological studies on the relationships between dietary fatty acids and predementia (MCI and ARCD) and dementia syndromes (AD and vascular dementia), including findings of clinical trials on PUFA supplementation in these patients

for a protective effect against the development of MCI. Nonetheless, at present, no definitive dietary recommendations on fish and UFA consumption or lower intake of saturated fat in relation to the risk for dementia and cognitive decline are possible (Table 179.11). In fact, in a recent randomized controlled trial, *n*-3 PUFA supplementation did not influence cognitive functioning during a follow-up of 6 months except in a small group of patients with very mild AD and for possible positive effects on depressive symptoms in non-APOE ε4 carriers. These data together with epidemiological evidence support the idea that *n*-3 PUFA may have a role in the primary and maybe secondary prevention of the disease but not when the disease process has already taken over. However, high levels of consumption of fats from fish, vegetable oils, and vegetables should be encouraged because this dietary advice is in accordance with recommendations for lowering the risk of cardiovascular disease, obesity, diabetes, and hypertension. Therefore, epidemiological studies on the association between diet and cognitive decline suggested a possible role of fatty acids intake in maintaining adequate cognitive functioning and possibly in preventing or delaying the onset of dementia, both of degenerative or vascular origin. Appropriate dietary measures or supplementation with specific macronutrients might open new ways for the prevention and management of cognitive decline and dementia (Solfrizzi et al. 2008).

On the other hand, Scarmeas and colleagues, using an inclusive dietary score (MeDi score) but studying a population with a substantial difference in dietary habits in comparison with Greek (EPIC) (Psaltopoulou et al. 2008) and Italian (ILSA) (Solfrizzi et al. 2006a, b) cohorts, found that higher adherence to the Mediterranean diet is associated with a trend for reduced risk of incident MCI and with reduced risk of MCI progression to AD (Scarmeas et al. 2009). The use of diet-scoring systems such as the MeDi score has undeniable advantages in understanding the role of diet in chronic disease (Solfrizzi et al. 2006c). They may account for the complex biological interactions between different components of a composite dietary pattern, such as a Mediterranean diet, that may be difficult to detect in analyses focusing only on individual components (Trichopoulou et al. 2006). These contrasting findings about the impact of MeDi score or individual macronutrients on ARCD or MCI may suggest an approach not confined only to cognitive skills but extended to functional status and comorbidity. However, we should not renounce a priori the work for a correct estimate of the validity of the MeDi score for cognitive impairment as a criterion. In fact, the evidence about the role of the whole Mediterranean diet on cognitive decline are still scarce (Psaltopoulou et al. 2008; Scarmeas et al. 2009). Therefore, in future studies, it would be indicated, along with measuring this effect by a dietary composite score, also to report the estimates and the impact of the individual components

of the diet. In a very recent re-analysis from the ILSA cohort, we showed that high PUFA were associated with reduced risk of incident MCI among who consumed a low MUFA/SFA ratio intake (Solfrizzi et al. 2009). Therefore, it should be advisable to include PUFA in the MeDi score as individual macronutrient (such as MUFA/SFA ratio), among the components presumed to be beneficial, in evaluating the relationship between adherence to Mediterranean diet and ARCD or MCI. In fact, while an increasing body of evidence suggested that elevated fish consumption and high intake of *n*-3 PUFA may be protective against ARCD and MCI, the traditional Cretan diet, although strongly dependent on high olive oil intake, was never centered on fish consumption. In this context, *n*-6 PUFA could potentially exert some health benefits. In fact, in a Mediterranean diet, some foods are rich in *n*-6 PUFA (e.g., walnuts, almonds, hazelnuts), while other foods, although poor in *n*-6 PUFA, are highly consumed such as cereals, legumes, and, in less amount, some types of meat (pork), and poultry. Furthermore, olive oil contains n–6 and n–3 PUFA in a ratio of 10:1. Therefore, it should be advisable to include PUFA in the MeDi score as individual macronutrient (such as MUFA/SFA ratio), among the components presumed to be beneficial, in evaluating the relationship between adherence to Mediterranean diet and ARCD or MCI (Solfrizzi et al. 2009).

Summary Points

- Dietary and vascular factors are associated with increasing risk of predementia and dementia syndromes.
- Among different dietary patterns, adherence to a traditional Mediterranean diet was associated with a significant reduction in risk for Alzheimer's disease (AD).
- Among dietary factors, a clear reduction of risk of cognitive decline has been found in a population sample with a high intake of polyunsaturated fatty acids (PUFA) and monounsaturated fatty acids (MUFA).
- Cumulative evidence has suggested that elevated saturated fatty acids (SFA) could have negative effects on age-related cognitive decline (ARCD).
- Recent findings have demonstrated that while dietary fatty acids intakes were not associated with incident mild cognitive impairment (MCI), high PUFA intake appeared to have a borderline non-significant trend for a protective effect against the development of MCI.
- Recent findings from clinical trials with *n*-3 PUFA supplementation, showing efficacy on cognitive and depressive symptoms only in very mild AD subgroups or MCI, suggest a possible role of fatty acid intake in maintaining adequate cognitive functioning and possibly for the prevention and management of cognitive decline and dementia.

Definitions

Unsaturated and saturated fatty acids: Unsaturated fat is fat or fatty acid in which there are one or more double bonds in the fatty acid chain. A fat molecule is monounsaturated if it contains one double bond, and polyunsaturated if it contains more than one double bond. Whendouble bonds are formed, hydrogen atoms are eliminated. Thus,saturated fat is "saturated" with hydrogen atoms.

Dementia: This is a syndrome defined by impairments in memory and other cognitive functions that are severe enough to cause significant decline from a previous level of social and occupational functioning.

Predementia syndrome: This term identifies all conditions with age-related deficits in cognitive function, including a mild stage of cognitive impairment based on a normality model and pathological conditions considered predictive of early stages of dementia

Mild cognitive impairment (MCI): This is a clinical label that includes non-demented aged persons with memory impairment and no significant disability.

Age-related cognitive decline (ARCD): This is defined as an objectively identified decline in cognitive functioning consequent to the aging process that is within normal limits given the person's age, but there are no defined diagnostic criteria, and few epidemiological studies using this definition have been conducted.

Chapter 180
Nutritional Issues for Older People and Older People with Dementia in Institutional Environments

180.1 Introduction

Nutrition has always been a factor in the care of ill people and chapters on nutrition were commonplace, and still are, in nursing textbooks. In the field of gerontology, authors such as Potter and Perry (1993:1094) suggest that when treatments or therapies were lacking, care relied heavily on the *preparation and administration* of food to maintain the body's strength and fight disease. Later nursing texts, for example, Ebersole et al. (2008), devote a chapter to nutrition and again emphasize the importance of ensuring that patients take adequate fluids and diet. The authors stress the problems associated with poor nutrition and provide strategies to ensure that all patients have the opportunity to eat well by giving them assistance and by providing them with an atmosphere conducive to eating. It appears to be simple; people need adequate food and fluids to maintain and to restore health. However, on further exploration of factors affecting the nutritional needs of older people, providing an environment conductive to eating and making mealtimes special are an essential part of nutritional care.

    This chapter highlights the problems of poor nutrition for an ever increasing ageing population who are in institutions (hospital or care home). It goes on to examine why, when there are so many directives for, and standards on, good nutritional care, frail older people and people with dementia are failing to have their nutritional needs met. The conclusion centres on the fact that directives and standards are aimed at managers and qualified staff, yet the direct care of serving food and assisting with meals is carried out by care assistants who have no knowledge of best practices (Table 180.1).

Table 180.1 Key facts of ageing

- Ageing is a complex, natural process potentially involving every molecule, cell and organ in the body.
- In its broadest sense, ageing merely refers to changes that occur during the lifespan and is marked by time.
- Chronological ageing is not a disease, but biological ageing involves internal and external factors that negatively impact on an individual's system
- As individuals grow older, they do lose functional reserve, which means that their bodies do lose the ability to compensate when threatened by disease or hardship
- The term Frailty is common, but there is no consensus on its definition, apart from that it is caused by many factors including anorexia and weight loss and is a state of vulnerability
- Poor nutrition is recognised as one of the physical factors leading to frailty

This table illustrates the difference between chronological age, marked by years, and biological age, marked by factors that negatively impact on an individual's bodily functions. It highlights the important of maintaining an older person's nutritional status as poor nutrition can compromise an individual's ability to combat disease

Table 180.2 Three calls to action from the European Nutrition for Health Alliance (2005)

Action	Recommendation
1	Malnutrition is 'alive and killing'. It must be recognised as a disease in its own right
2	The high prevalence of malnutrition can no longer be tolerated. It is a serious social and economic issue with significant repercussions for individuals and society as a whole
3	Every stakeholder needs to take ownership and action to address the problem. Malnutrition occurs across all settings. Targeted actions are needed to address the root causes of malnutrition and empower individuals to foster 'well nutrition' for themselves

The calls to action were drawn from discussions and recommendations from the ENHA 2005 conference. In identifying malnutrition as a disease, the onus is on stakeholders to see this as a condition that needs treating as much as any other disease or disorder

180.2 The Extent of the Problem of Poor Nutrition in Older People

There is high incidence of malnutrition in the older age groups. This is a cause for major concern and more worryingly, not a new concern. Addressing poor nutrition has been on the health and social care agenda for many years. The statistics make depressing reading.

In 2005, the European Nutrition for Health Alliance (ENHA) published an inaugural conference report which stated that 46% of all hospitalized patients in Europe are malnourished on admission to hospital. The figure rises to 50% for those over the age of 60. The report stated that as one third of all Europeans will be over 60 in 2050, malnutrition is a serious problem and a critical issue for Europe. The recommendations from the conference are presented in Table 180.2.

Statistics from Age Concern England (2006) show a higher incidence, with estimates that 60% of people over 60 are at risk of becoming malnourished.

Prevalence of malnutrition does increase with age (ENHA 2005) but malnutrition is not a normal part of ageing. For those who are not in ill health, a healthy diet can result in many years of active life into old age (Department of Health 2001). Indeed, many people over the age of 65 are healthy and living full lives, with only 7% being classed as "frail" (Fried et al. 2004).

180.3 The Increase in the Numbers of Frail Older People in the UK

The prevalence of frailty increases up to 40% in persons aged 85 and over, and given the dramatic increase of the oldest-old population (those 85 and over), frailty is becoming increasingly common (Table 180.3).

Table 180.3 The ageing population

Year	Population over 65 (%)	Those aged 65–74 (%)	Those aged 75–84 (%)	85 years or older (%)
2006	16.4	8.9	5.5	2
2021	19.2	10.4	6.3	2.5
2051	24.4	10.7	8.8	4.9

Figures from the Office of Health Economics (2009) to illustrate the projected percentage increase in the numbers of frail older people in the United Kingdom (UK)

The incidence of dementia also increases with age. Approximately 2% of persons aged over 65 have some form of dementia, but prevalence rises to 20% in those over 80. In terms of numbers, this means there are currently 670,000 people with dementia in the UK, and this figure is expected to rise to nearly 1,000,000 by 2021 (Barratt 2004). If the above projections are realized, this figure is set to double in 2050.

These statistics have serious implications when coupled with the statistics on the number of older people thought to be malnourished.

180.4 Malnutrition in Institutions

In the early 1990s attention was paid to the fact that older people in institutional care were not having their nutritional needs met. A wealth of publications resulted. In 1991, the Committee on Medical Aspects of Food Policy [COMA] found that nearly 50% of people in care had nutrient deficiencies. In 1992 COMA reported that further research needed to be carried out on the nutritional needs of frail older people. The King's Fund Centre report (Lennard-Jones 1992) suggested the benefit of treating poor nutritional states would only be realised when nutritional assessment on every patient was routine.

In 1995, the Caroline Walker Trust recommended that all older people entering residential care accommodation should have their nutritional needs assessed in the first week after admission, and should be monitored regularly thereafter. This recommendation was reiterated in 1996 by BAPEN. In 1997 the publication *Hungry in Hospital* by the Association of Community Health Councils in England and Wales (ACHEW) identified the need for nurses to assess nutritional status and ensure that frail older people received adequate nutrition. Yet a National study by Finch et al. (1998) reported that of 412 people over the age of 65 living in institutions, 16% of men and 15% of women were underweight.

Currently, there are many recommendations of how to address the problem of poor nutrition of older people in institutions. In 2003, BAPEN developed a valid and reliable nutritional screening tool to identify people who were underweight and those at risk of under-nutrition; the Malnutrition Universal Screening Tool (MUST). Standards to address the nutritional needs of older people in institutions were published by the Nutrition Advisory Group for Elderly People (NAGE) (2005), the Food Standards Agency (2006) and the Commission for Social Care Inspection (2006) in England and NHS Quality Improvement Scotland (2003) and the Care Commission in Scotland (2009).

Best practices and standards for good nutritional care, *all* include the need for qualified and unqualified staff to recognize both the physical and psychosocial aspects of mealtimes and the importance of food and fluids. These have been outlined in Table 180.4 and expanded below.

However, life in institutions frequently centre on the routine tasks to be performed, and rather than be seen as an enjoyable way to break up an otherwise long day, mealtimes are treated as a task to be accomplished at certain times.

Table 180.4 Intrinsic and extrinsic risk factors for malnutrition in care

Domain	Examples of intrinsic risk factors	Examples of extrinsic risk factors
Physical	Arthritic	Fasted prior to surgery
	In pain	Inability to use utensils
	Xerostomia (dry mouth)	Medicines given prior to mealtimes
	Oral thrush or mouth ulcers	Food not hot/cold enough
	Poorly fitting dentures	
	Sensory loss	
	Constipated	
	Nauseated	
	Side effects of medication	
	Difficulties with chewing/swallowing	
Psycho-social	Depression	Dislikes people sharing the table
	Confusion	Poor relationship with staff
	Delirium	Noisy environment
	Dementia	Untrained staff
	Feeling rushed/anxious, frightened/ withdrawn/stressed/agitated	Dislikes food
		Food not suitable for the individual
	Not able to recognize food	Meal served in unsuitable surroundings such as a clinical area with urinals/vomit bowls in sight
	Unable to move food from plate to mouth	
	Unable to accept current situation	
	Dining area not conducive to eating	No sense of occasion

Physical and psychosocial considerations as risk factors for malnutrition

180.5 Meals in Institutions

The recommendations and standards of good nutritional care stress the importance of the intrinsic and extrinsic factors associated with mealtimes and food, yet meals served in institutions are still reported to be an unpleasant experience. Sadly, early literature of life in institutions such as Goffman (1961) on *block treatment* and Miller and Gwynne (1971) on *warehousing* is found in more current literature such as institutional disrespect (Kitwood 1997) and lack of personalised care (Kydd 2006; Kerr et al. 2008).

180.5.1 The Social Environment

The social aspect of meals should not be underestimated, yet mealtimes in some institutions can be anti-social. Staff can appear like wardens, overseeing patients eating, and the environment can be noisy and alarming. Studies (e.g., Mathey et al. 2001; Desai et al. 2007) have shown that when institutionalised mealtimes were changed to more homely environments, the results showed improved food consumption and therefore improved nutritional status in older people. Providing a homely environment includes providing a set dining area, matching crockery, a nicely set table, with glasses for water and a water jug.

180.5.2 Institutional Food

Whilst the social environment of mealtimes is important, so are the food and fluids. Some foods served in institutions can be difficult to eat and fluids are not always offered or available. Some food might be unpalatable or culturally inappropriate for the individual (Kayser-Jones 2000), the

Table 180.5 Personalised strategies to promoting eating

Strategies to increase appetite	Reason
Provide balanced meals	To avoid constipation
Offer a favourite alcoholic drink before the meal (if medications permit)	To stimulate appetite
Do not give medications directly before a meal	The taste can put individuals off their food
Allow the person to eat when hungry	Food is more enjoyable
Encourage physical activity where possible	To work up an appetite
Find out what the individual's favourite foods are	To enhance enjoyment
Encourage the individual to eat one type of food before moving on to the next	To avoid confusion when tastes and textures change
To ascertain which meal should be the largest	To fit in with the individuals pattern of eating
Allow enough time to help individuals to the table or to sit alone if that is their preference	To avoid individuals feeling rushed
Ensure that individuals have their dentures and their mouth is clean	
Ensure that each individual has assistance at hand should they require it	To avoid people becoming frustrated with the effort of trying to manage their food
Provide seasonal food and temperature appropriate foods	Soups are more appetising in the winter and ice-cream in the summer

The above strategies are basic requisites to provide a person-centred approach to care

packaging may be difficult to open (Healthcare Commission 2007), or the portions too big (Vivanti et al. 2008). Antecedents to meals such as medications given just before meals can negatively affect food consumption (de Graaf 1994; Stratton et al. 2003) and strategies to enhance appetite, such as an aperitif before main meals are a rare occurrence. Examples of such strategies are given in Table 180.5.

180.5.3 Institutional Living

Routines within institutions can pose threats to promoting each individual's nutritional status. For example, staff shortages at mealtimes can mean that the individuals who need assistance may not get the help they require (Crogan and Scultz 2000). Timing of meals is also important. Food is usually prepared in one main kitchen and meals are given at set times. Unless such foods are prescribed, it is not easy for staff to provide fortified foods or snacks outside of the normal routine mealtimes. Individuals have different times of day to have their main meals and may not be able to eat a large meal at the times served in the institution. Many older people will have lived alone before being admitted into an institution and will have developed eating habits to suit themselves. Focussing on an individual's past routines and personalising care needs should be at the heart of good care and this has to include nutritional care, which must be person centred and have the explicit aim of helping individuals to maintain their own nutritional needs (European Nutrition for Health Alliance 2005). This can be a problem especially at night time when food is not usually available (Kerr et al. 2008).

Table 180.6 outlines some of the considerations necessary to ensure that individuals get the maximum benefit from meals within an institutional setting.

Table 180.6 Considerations at mealtimes

Area	Action	Examples of evidence
Personal care	Well fitting dentures, mouth care, choice of menu, choice of person to sit with (if appropriate)	Barratt (2004)
The social environment of mealtimes	The environment should be homely, the table set nicely and the environment should be calm and non confrontational	Mathey et al. (2001); Desai et al. (2007)
Communal eating	Consideration given to those people who wish to eat alone and those who prefer company	Barratt (2004)
Crockery and cutlery	Disabilities should be minimized. Cutlery and crockery designed to help people eat their food	Marshall (1996); Bartlett (2000)
The food	The food should be identifiable and culturally appropriate for the individual. It should be easy for the individual to eat. Small and nutrient rich	Kayser-Jones (2000); Healthcare Commission (2007); Vivanti et al. (2008)
Time of meal	Personal preferences for meals or snacks	Barratt (2004)
Time of and type of medications	Medications should not be given immediately before meals if possible. Knowledge of drugs/side effects that may affect appetite needs to be included in nutritional assessment and reviewed regularly	de Graaf et al. (1994); Stratton et al. (2003)
The Assistance required	Help should be available to give time to all patients who require assistance	Crogan and Scultz (2000)
Staff training	Staff need to be trained in how to ensure patients receive adequate nutrition	Castellanos et al. (2000); Chang and Lin (2005)

The areas of concern are not exhaustive but serve to illustrate the multifactorial nature of the antecedents to meals and mealtimes

180.5.4 Staff Attitudes

Institutionalised ageism, explained by Bender (2003: 121) as a way of treating everyone in the same manner, serves to devalue the individual. Bender (2003) states that any expressions of preference or individuality are seen as complaints and patients' requests are frequently ignored. People who are physically dependent are more vulnerable to being treated this way and yet these are the people in most need of help. A study by Sormunen et al. (2007) found that the greater the dependence of the resident in a care home, the greater the number of inappropriate treatments they received, and of the inappropriate treatments, a quarter of these occurred during mealtimes, with staff talking over patients and performing tasks for people that the individuals could still do for themselves if given time.

180.6 The Extent of the Problem of Poor Nutrition in People with Dementia

All of the issues of poor nutrition as described above are all relevant to people with dementia living in institutions, but this client group are at greater risk from dehydration and malnutrition (Castellanos et al. 2003). One of the symptoms of dementia is weight loss and is associated with the disease

process, poor quality of life and morbidity and mortality (Smith and Greenwood 2008). However, weight loss is also associated with age-related physical problems and psychosocial behaviours of people with dementia in care, and the behaviours and attitudes of staff.

180.7   The Need to Train Frontline Staff

In order to identify people who need extra calories, staff need to be trained and frontline staff who give direct help with meals are usually care assistants, who have little training in the nutritional care of frail older people and older people with dementia (Watson 1997). Training care staff has been shown to have positive effects on the nutritional status of older people with dementia, as staff need to be aware of the multiple factors involved in presenting, serving and assisting people to eat the food offered (Chang and Lin 2005). The challenges in providing adequate nutrition to people with dementia can lie in knowledge of how dementia affects a person's neuromuscular ability to take food to their mouths, chew and swallow (Ikeda et al. 2002), their perceptual difficulties of recognizing food and/or utensils (apraxia), or their ability to identify objects by name (aphasia). They may also lack the cognitive ability to initiate and/or maintain an effective way of eating (Chang and Roberts 2008). This can make following instructions impossible for them, and may lead to confrontations between staff and the individual at mealtimes. Such individuals can have difficulty communicating their likes, dislikes and their lack of comprehension verbally, which can cause them to feel frustrated and incapable, resulting in them communicating their dislikes with aggressive behaviours. In turn, staff who have no training in caring for people with dementia will not view the distress, but will view the individual as a 'problem'. This lack of understanding of what the person with dementia is experiencing can lead to negative attitudes and negative or diminished social interaction with the individual. This treatment depersonalises the individual, leading to what Kitwood (1998) termed 'malignant social psychology'.

Person-centred care, espoused by Kitwood (1997), centres on seeing the person and not the dementia. Promoting independence in eating is preferable and various strategies can be used to promote food intake. Marshall (1996), in writing on mealtimes in institution, speaks of disabling environments and suggests that people could be given greater assistance with eating independently if they had utensils and crockery that compensated for their disabilities.

Table 180.7 illustrates activities and actions to promote an individual's nutritional status.

180.8   Applications to Other Areas of Health and Disease

People who are ill have a compromised nutritional status. Poor nutrition can be the cause of health problems, ranging from relatively minor ailments such as constipation to more serious problems such as anaemia, osteoporosis, coronary heart disease and declining mental health (The Caroline Walker Trust 2004). Malnutrition can exacerbate illness (British Association for Parenteral and Enteral Nutrition [BAPEN] 2006) and prevent recovery from illnesses. The human cost of malnutrition is high, resulting in lengthy hospital stays, poor quality of life and malnutrition can have serious consequences for frail older people (Crogan and Pasvogal 2003). The public cost on disease-related malnutrition is also high; with a projected spend of over £7 billion per annum in 2007 in the UK (BAPEN 2009).

Table 180.7 Activities and actions to ensure adequate nutrition

Activity	Action
Valid nutritional assessment	Medical and nursing staff to ascertain any causes for poor appetite that can be treated, such as pain, illness, side effects from medications, depression
Educating staff, especially those involved in direct care	To provide staff training on food and nutrition for older people and older people with dementia
Providing easy to eat foods at regular times that individual patients like	The social aspects of mealtimes help people orientate to time of day and mix with other residents
Provide high calorie snacks at regular intervals between meals	Foods such as muffins, cakes scones, malt loaf, cheese and biscuits
Provide finger foods	Foods and for people who have compromised manual dexterity and that can be eaten independently. These foods are also suitable for people who find it difficult to sit still while eating.
Offer fortified foods or food supplements when adequate food cannot be taken	Food should always be offered first, food can be fortified and supplements given but not instead of meals.

Assessment is essential in order to follow through on the actions. Meals should be treated as an enjoyable experience. Food should be acceptable, fortified if necessary and supplements given to augment calorific intake

180.9 Conclusion

This chapter highlights that the importance of providing good nutritional care for older people has been well documented in the many recommendations and standards written by experts in Europe and the UK. However, if these standards are to be implemented, they have to be taught to those involved in the direct care of mealtimes. Frontline staff who deal with meals have to not only be aware of the importance of maintaining an individual's nutritional status, but they need to be taught that ensuring good nutrition is more than a physical requirement, it involves knowing that the psychosocial aspects of meals play a major part in helping older people and older people with dementia to maintain dignity, independence and a sense of enjoyment at mealtimes.

Summary Points

- Malnutrition in older people and older people with dementia is a critical issue.
- Recommendations and standards are not being carried out in many institutions.
- Training is essential for staff who provide meals to people in institutional care.
- Frontline staff are usually untrained people who have little knowledge of the strategies that can be used to ensure adequate nutrition.
- Mealtimes involve physical and psychosocial interventions.

Definitions of Key words

Malnutrition: The cellular imbalance between the supply of nutrients and energy and the body's demand for them to ensure growth, maintenance and specific functions. This can result in weight gain or weight loss

Nutrients: Foods that contain the elements necessary for bodily functions. The six categories of nutrients are water, carbohydrates, proteins, lipids, vitamins and minerals.

Undernutrition: When nutrient intake falls below that necessary to sustain health and well-being and results in weight loss.

Fortified drinks: Fluids that have extra nutrients in them.

Finger foods: Foods that can be eaten without the need for crockery or cutlery.

Nutritional screening tool: An assessment carried out to assess people at risk of undernutrition and/or malnutrition.

181.1 Introduction

Fetal alcohol syndrome (FAS) is a condition referring to a specific set of growth, cognitive, behavioral and facial abnormalities associated with prenatal alcohol exposure. It was first described in the late 1960s and early 1970s (Jones and Smith 1973; Lemoine et al. 1968), and is now estimated to affect anywhere between 0.3 and 2 individuals per 1,000 live births (Abel and Sokol 1986; May and Gossage 2001; Sampson et al. 1997). Individuals with FAS demonstrate characteristic facial abnormalities such as a smooth philtrum, short palpebral fissures, and a thin upper lip (Astley 2004; Sampson et al. 1997). Common brain malformations revealed by postmortem studies include microcephaly, ventriculomegaly, a small cerebellum, and malformations or agenesis of the corpus callosum (Clarren et al. 1978; Jones and Smith 1973; Peiffer et al. 1979). Children and adults with FAS may also demonstrate a wide variety of cognitive and behavioral problems including motor delays, and deficits of executive functioning, attention, memory, reading, and mathematics (Jacobson and Jacobson 2002; Mukherjee et al. 2006).

However, not all individuals with prenatal alcohol exposure demonstrate the same extent of symptoms, and it is now known that there is a wide range of outcomes associated with prenatal alcohol exposure. Although poorly understood, the extent and timing of prenatal alcohol consumption likely plays a major role in creating this spectrum; there are also differences in genetic susceptibility (Streissguth and Dehaene 1993). Fetal alcohol spectrum disorder (FASD) is the umbrella term used to describe the various developmental disorders associated with prenatal alcohol exposure. The prevalence of FASD is higher than FAS since it includes additional disorders, and is estimated at up to 1% of live births in North America (May and Gossage 2001; Sampson et al. 1997). FASD is the leading known cause of mental retardation (Abel and Sokol 1986).

There are a variety of methods for diagnosing the various disorders falling under the FASD umbrella; however, the 4-digit diagnostic code is an increasingly popular technique due to its consistency and reproducibility (Astley 2004). The 4-digit diagnostic code ranks diagnostic information in the areas of growth deficiency, facial phenotype, brain dysfunction, and alcohol use. The magnitude of expression of each feature is ranked independently on a 4-point Likert scale: 1 reflects complete absence of the typical FAS feature, 4 reflects a strong "classic" presence of the FAS feature. To meet the criteria for FASD, individuals must have a brain dysfunction score of 2 or higher and confirmed alcohol exposure, as indicated by alcohol use scores of 3 (some risk) or 4 (high risk). Diagnoses falling under the FASD umbrella can be grouped into four broad categories, which are (in order of most severe to least severe): FAS, partial FAS (pFAS), static encephalopathy: alcohol-exposed (SE:AE), and neurobehavioral disorder: alcohol-exposed (NBD:AE). Individuals diagnosed with FAS, the most severe end of the FASD spectrum, display serious structural and functional brain abnormalities (brain code of 3 or 4), growth deficiencies (rank 2–4), and the full FAS phenotype of thin upper lip, smooth philtrum, and short palpebral fissures. SE:AE is the diagnosis given to subjects who have significant structural and/or functional brain abnormalities at a level of 3 or 4, but are lacking the growth deficiencies and facial features of FAS. When individuals have static encephalopathy and most, but not all, of the growth deficiencies and facial features of FAS, they are given the diagnosis of partial FAS (pFAS). Subjects with NDB:AE still have brain abnormalities, but they are ranked 2 and are less severe than for those with static encephalopathy. The accurate diagnosis and characterization of FASD subjects is challenging, yet is a key part of imaging studies to ensure appropriate analysis and interpretation of quantitative brain parameters.

181.2 Brain Abnormalities in FASD

Early studies of children with prenatal alcohol exposure used autopsies to identify several structural brain abnormalities caused by neuronal and glial migration errors (Clarren et al. 1978; Jones and Smith 1973; Peiffer et al. 1979). These malformations include microcephaly, a small cerebellum, agenesis of the corpus callosum, and ventriculomegaly. However, autopsy studies are limited by the number of available subjects and represent a skewed sample, since only the most severely alcohol-affected subjects die during infancy or early childhood. Brain imaging techniques such as magnetic resonance imaging (MRI) make it possible to noninvasively assess the teratogenic effects of alcohol in vivo, thus allowing for much larger sample sizes with a wide range of severities. Also, since MRI does not use ionizing radiation, it is a safe modality to investigate children.

MRI and other neuroimaging studies have shown many different structural abnormalities in individuals with FASD (Riley and McGee 2005). Conventional MRI can provide excellent contrast among the major brain tissues (white matter, cortical gray matter and deep gray matter) and allows for measurements of volume, thickness, and density. Individuals with FASD demonstrate total brain volume reductions, as well as reductions of all major tissue components (Archibald et al. 2001; Astley et al. 2009). Children with FASD have thicker cortical gray matter than healthy children, particularly in the parietal and temporal lobes (Sowell et al. 2008b). Deep gray matter structures have been shown to be particularly affected in FASD, demonstrating especially reduced volumes (Archibald et al. 2001; Astley et al. 2009) and abnormal metabolic rates (Cortese et al. 2006; Fagerlund et al. 2006). Abnormalities in the corpus callosum, the largest brain white matter tract, are common across imaging studies, with a variety of malformations reported (Bookstein et al. 2001; Peiffer et al. 1979). Diffusion tensor imaging provides an excellent way of further studying the white matter, as it provides measures of microstructure not available via conventional imaging methods, and diffusion tensor imaging studies have revealed widespread brain abnormalities in individuals with FASD, highlighting many of the same regions identified by previous MRI studies and suggesting even more widespread damage.

181.3 Diffusion Tensor Imaging

Diffusion tensor MRI (DTI) is an advanced imaging technique that uses the mobility of water molecules to infer the state of the underlying tissue microstructure (Basser et al. 1994; Le Bihan 2003); its key features are summarized in Table 181.1. While the concept was first described 15 years ago, its applications have greatly expanded to study a myriad of brain disorders over the last 5 years (Assaf and Pasternak 2008; White et al. 2008). DTI is sensitive to the Brownian motion of water molecules (i.e., so-called diffusion). When the diffusion of water molecules is unhindered, or encounters randomly oriented barriers, motion occurs equally in all directions and is termed isotropic diffusion (see Fig. 181.1a). However, oriented barriers asymmetrically hinder diffusion, imposing a directionality on water motion; this is termed anisotropic diffusion (see Fig, 181.1b). The axonal membranes and myelin sheaths contained in the highly ordered fiber bundles of brain white matter form barriers to diffusion perpendicular to axons, while allowing water diffusion to occur unhindered parallel to the axons (Beaulieu 2002). A direct relationship between a specific tissue compartment (e.g., myelin) and a measured diffusion parameter, while desirable, is fraught with difficulty given the complexity of neural fibers (the reader is referred to the review article by Beaulieu (2002), for a more in-depth discussion).

Table 181.1 Key features of diffusion tensor imaging (DTI)

1. Diffusion tensor imaging (DTI) is a noninvasive, quantitative magnetic resonance imaging technique sensitive to the Brownian motion (i.e., diffusion) of water molecules.
2. Diffusion occurs differently in an unrestricted medium (e.g., cerebrospinal fluid), tissue with randomly oriented barriers to diffusion (e.g., gray matter), and tissue with highly oriented barriers to diffusion (e.g., white matter). DTI can measure the diffusion in different brain areas and provide information about tissue microstructure.
3. DTI is typically conduced on MRI scanners with magnetic field strengths of 1.5 or 3 T.
4. Typical DTI sequences range from 5 to 10 min in length and measure diffusion along 6–30 different directions.
5. Raw DTI images are processed to provide important quantitative measures of tissue microstructure, including fractional anisotropy (FA) and mean diffusivity (MD).
6. DTI can be used to investigate healthy development, as well as abnormalities in many different diseases and conditions.

This table lists the key features of diffusion tensor imaging (DTI), including how images are acquired and why they are useful
Fig. 181.1 Isotropic and anisotropic diffusion. Isotropic diffusion occurs in a fluid either without barriers (e.g., in a cup of coffee or cerebrospinal fluid), or one with randomly oriented barriers to diffusion, (e.g., gray matter). Anisotropic diffusion occurs when there are oriented barriers to diffusion, such as brain white matter, in which the axonal membranes and myelin sheaths hinder diffusion perpendicular to axons

In cerebrospinal fluid (CSF), there are no barriers and diffusion is rapid and isotropic. Brain gray matter, which contains dendrites, neuronal cell bodies, and glial cells, presents barriers to diffusion that are mostly randomly oriented. However, deep gray matter structures such as the thalamus and putamen exhibit some degree of anisotropy. Figure 181.1 shows examples of isotropic diffusion (e.g., in CSF or gray matter) and anisotropic diffusion (in white matter).

DTI allows for the characterization of diffusion in all directions in each voxel within the brain. DTI measures diffusion in at least six noncollinear directions using diffusion-sensitizing gradients to create a tensor model that fully characterizes diffusion within a voxel. From this tensor, three eigenvalues may be calculated, representing the magnitude of diffusion in the primary diffusion

direction (assumed to be oriented along the white matter tract) called parallel or axial diffusivity, and the magnitude of diffusion in two directions orthogonal to that called perpendicular or radial diffusivity. While it is possible to calculate the primary diffusion direction regardless of its orientation relative to the diffusion-sensitizing gradients, one of the major weaknesses of the tensor model occurs in areas where two or more white matter fiber bundles oriented in different directions overlap.

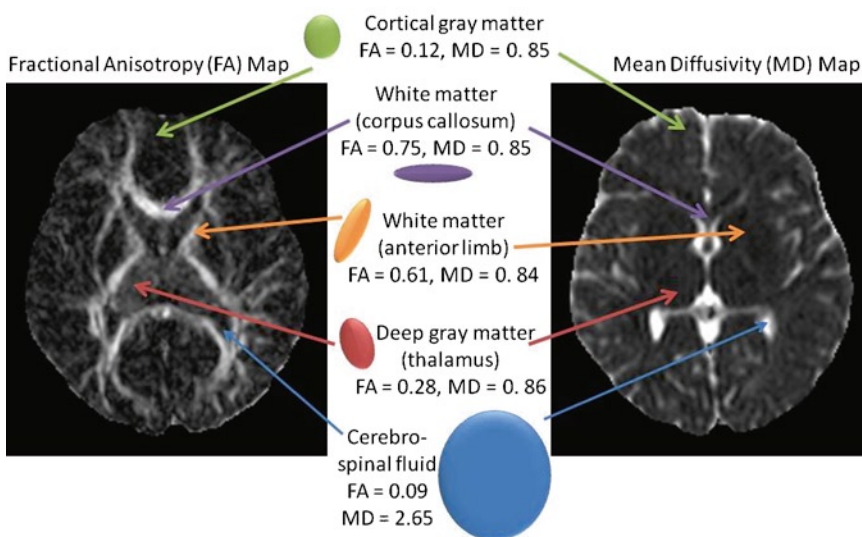
The two most commonly used DTI parameters are fractional anisotropy (FA) and mean diffusivity (MD). The overall magnitude of diffusion is measured by MD, which is simply the average of the three eigenvalues. The directionality, or anisotropy, of diffusion is most often assessed using FA (Basser 1995). FA varies from 0 to 1, with 0 representing completely isotropic diffusion and 1 representing highly anisotropic diffusion. FA is generally thought of as a measure of white matter integrity, with lower FA values indicative of reduced myelination, less densely packed axons, or some combination of the two. One method of visualizing isotropic and anisotropic diffusion is an ellipsoid. The three eigenvalues of the diffusion tensor (representing diffusivity in the primary direction and two orthogonal directions) form the three axes of the ellipsoid and the overall size of the ellipsoid gives an indication of MD. Isotropic diffusion is represented as a sphere, while more anisotropic diffusion is represented as a more elongated ellipsoid. Figure 181.2 shows an FA map and an MD map, and gives the diffusion ellipsoids and FA and MD values for several different brain regions. In general, anisotropy is high within brain white matter due to its highly ordered nature (white matter appears bright in Fig. 181.2a), while CSF exhibits virtually no anisotropy (appears dark in Fig. 181.2a). The deep gray matter structures exhibit some anisotropy, albeit to a much lesser degree than brain white matter. MD is generally quite uniform across the non-infant brain parenchyma (Fig. 181.2b), but is much higher in the CSF.


Fig. 181.2 Fractional anisotropy and mean diffusivity maps. Fractional anisotropy (*FA*, *left*) and mean diffusivity (*MD*, units of 10^{-3} mm^2/s, *right*) maps are shown for two axial slices in a 9-year-old boy with Fetal alcohol spectrum disorder (*FASD*). On the FA map, structures with high FA (white matter) appear bright, indicating greater directionality of water diffusion, while those with low FA (gray matter and cerebrospinal fluid) appear dark. On the MD map, regions with more rapid diffusion (i.e., molecules displace further in the same amount of time) are bright. Diffusion ellipsoids demonstrating the probability of diffusion in each direction are shown for voxels in five different areas reflecting a range of FA values as well as a much higher MD for cerebrospinal fluid than the brain tissue whose MD is rather uniform between gray and white matter (unlike FA)

longitudinal fasciculus, the
superior and inferior
fronto-occipital fasciculi and
the uncinate fasciculus
There are three primary techniques for analyzing DTI data: region-of-interest (ROI) analysis, tractography, and voxel-based morphometry (VBM). With ROI analysis, the investigator manually defines areas on two-dimensional images to extract diffusion parameters for specific structures. ROI analysis is generally quite straightforward to conduct, and can be performed on any structure that is readily visible on two-dimensional images. Tractography is a method of virtually reconstructing and visualizing white matter fiber tracts, essentially creating three-dimensional volumes of interest (Basser et al. 2000; Conturo et al. 1999; Jones et al. 1999; Mori et al. 1999). With tractography, the user defines seeding and target regions to start and constrain the fiber tracts, and then an algorithm uses the primary direction of diffusion within each voxel and the FA values to trace out white matter fibers in the brain. Once the fiber bundles have been delineated, FA and MD can be measured along the entire tract, or any smaller portion of it. Figure 181.3 shows an example of some of the white matter pathways that can be reconstructed using tractography.

The third commonly used analysis method for DTI data is VBM, which examines the entire brain without relying on user-defined regions for ROI analysis or tractography (Ashburner and Friston 2000). VBM normalizes each subject's brain to a template and looks at each voxel individually across the group. VBM allows for both group comparisons and correlations with other variables. Tract-based spatial statistics (TBSS) is a form of VBM specifically designed for analysis of DTI data, which examines only the central portion of white matter fibers (Smith et al. 2006). The sensitivity of DTI to microstructural changes within brain tissue makes it an excellent method for studying brain differences in FASD. The following section discusses the published studies that have used DTI to investigate brain abnormalities within FASD.

181.4 DTI Studies of FASD

Although DTI cannot yet be used as a diagnostic tool, it can nonetheless provide valuable information about brain abnormalities in FASD. There are seven previously published DTI studies of FASD or prenatal alcohol exposure (Fryer et al. 2009; Lebel et al. 2008a; Li et al. 2009; Ma et al. 2005; Sowell et al. 2008a; Wozniak et al. 2006, 2009), using a variety of methods and including subjects with a range of ages and disorders related to prenatal alcohol consumption. Table 181.2 summarizes the key details for each of the seven studies. Six studies compared one group of children or young

Table 181.2 DTI studies of prenatal alcohol exposure

Study	Number of subjects	Age range	DTI protocol	Analysis method	Findings
Fryer et al. (2009)	15 alcohol-exposed (9 FAS, 6 unspecified alcohol-exposed) 12 control	8–18 year	3 T GE 7 min 15 directions $b = 2,000$ s/mm²	TBSS of white matter ROI of CC	↓FA in ant, post, sup CR, forceps major, R SLF; R UF; R SFO; ↓FA in body CC ↑FA in R PLIC, R cing ↑MD in L ALIC, L sup frontal lobe ↓MD in R ant CR, R forceps major Alcohol-exposed compared to controls

[a]No scan time provided

The seven previous studies examining the effects of prenatal alcohol exposure on brain structure using DTI are outlined below

adults prenatally exposed to alcohol ($n = 9$–33) to healthy controls ($n = 7$–95) whereas one study subdivided participants into three groups: alcohol-exposed with dysmorphia, alcohol-exposed without dysmorphia, and controls ($n = 28, 29, 25$, respectively). In total, the previous studies cover an age range of 5–27 years. It is not surprising that there are no studies examining older individuals with FASD, since FASD disorders are relatively new and the diagnosis of adults is more difficult and less common than in children. One advantage of studying children is that it provides a glimpse of brain abnormalities that are more likely to be caused by prenatal alcohol exposure rather than by a lifetime of adaptation to particular difficulties.

One of the most important things to consider in a study of FASD is the severity of the subjects included. Structural brain abnormalities have been shown to vary with the severity of diagnosis, with subjects classified as FAS or pFAS having more severe abnormalities than those with SE:AE, who have more abnormalities than those with NBD:AE (Astley et al. 2009). Most studies included a mix of subjects, although one study (Ma et al. 2005) included only subjects with FAS, the most severe disorder on the FASD spectrum, and another (Wozniak et al. 2006) included only subjects with less severe FASD (no subjects in their study had FAS). The study by Li et al. (2009) subdivides the 57 subjects with prenatal alcohol exposure into those with dysmorphia (the facial features associated with FAS) and those without. The subjects in the Li et al. (2009) study were never formally assessed for diagnosis of FASD; however, those in the dysmorphic group had characteristic FAS facial abnormalities, as well as confirmed prenatal alcohol exposure, suggesting that they are likely to fall under either the FAS or pFAS diagnostic categories, depending on the severity of the growth, brain, and facial abnormalities. Although the non-dysmorphic subjects had confirmed alcohol exposure, they were not assessed for the other features of FASD (growth deficiency and central nervous system abnormalities), so they may have symptoms meeting the criteria for diagnoses of SE:AE or NBD:AE, or may not. The study by Fryer et al. (2009) included nine subjects (60%) with FAS, and mentions that all subjects had substantial prenatal alcohol exposure, but does not confirm an FASD diagnosis for the remaining six subjects. The remaining studies used only subjects with a confirmed diagnosis of FASD, but with varying levels of severity; the percentage of subjects with full-blown FAS ranged from 8–60%. Thus, there is a wide range of symptom severity among studies, which should be taken into account when comparing the findings. In addition, confounds such as other drug use during pregnancy and abuse or neglect may be of particular concern in an FASD population. Unfortunately, information about these potential confounds, as well as exact timing and amount of alcohol use during pregnancy, is often unavailable.

Although it is not possible to assess image quality when studies do not show raw diffusion images or the processed FA maps from which they are measuring diffusion parameters, the imaging protocols used by all the DTI FASD studies appear adequate. In general, the protocols were fairly similar, with the number of diffusion encoding directions ranging from 6–30 (with 6 of 7 studies using 15 or fewer), the DTI protocols were 5–10 min in length, and all but one used a b-value of 1,000 s/mm^2. The magnetic field strength was 1.5 T for two of the studies; 3 T MRI scanners were used for the other five studies. The image analysis methods varied, with several studies using a combination of methods. Five studies used ROI analysis on select regions, three used VBM (two of those using TBSS specifically) of all the white matter, and two used tractography of a priori defined white matter tracts.

Three of the DTI studies of FASD (Ma et al. 2005; Wozniak et al. 2006, 2009) examined only the corpus callosum, likely because it is a large, important, and straightforward-to-measure structure that is known from autopsy and conventional imaging studies to be affected in FASD. Three of the studies examined all brain white matter using VBM (Fryer et al. 2009; Li et al. 2009; Sowell et al. 2008a), and one (Lebel et al. 2008a) used tractography to study 10 major white matter tracts and ROI analysis to examine 4 deep gray matter regions. All studies measured FA changes, and all but one (Sowell et al. 2008a) also assessed MD values.

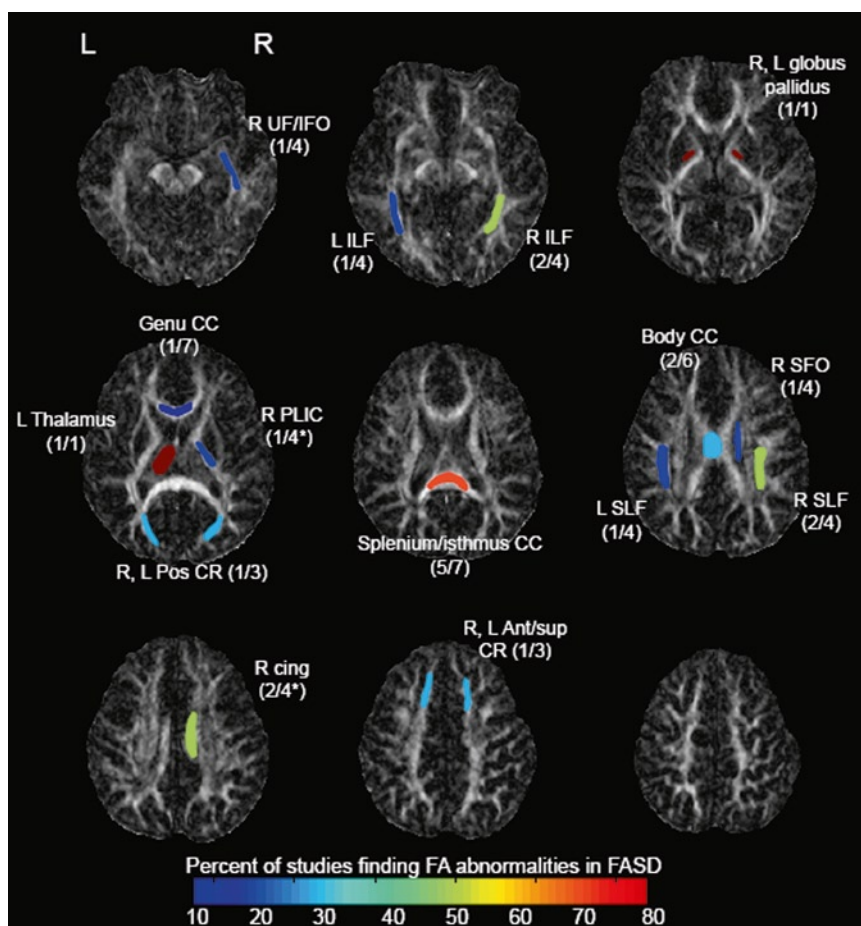
Although there have been relatively few studies of FASD using DTI, there are some convergent results. The findings common to several studies likely point to the most consistently affected structures across individuals with FASD regardless of age, diagnosis severity, etc. Figure 181.4 shows the regions observed to have significantly different FA values between subjects with prenatal alcohol exposure and healthy controls. The corpus callosum, particularly the posterior portion, is consistently reported to be highly affected by FASD. The posterior corpus callosum (the splenium and isthmus were defined differently among the studies, so they have been lumped together for the purpose of this review) had significantly lower FA values in FASD subjects in five of seven studies.


Fig. 181.4 Structures demonstrating fractional anisotropy abnormalities in Fetal alcohol spectrum disorder (*FASD*). Structures that have shown significant fractional anisotropy (*FA*) differences between subjects with prenatal alcohol exposure and healthy controls are shown overlaid on an FA map of a 9-year-old boy with FASD. Structures are colored according to the percentage of studies that has shown differences in that particular area. Structures are also listed with the number of studies showing differences and the total number of studies examining that particular area. For all regions, the alcohol-exposed group showed lower FA than controls, except for regions marked with an asterisk (*, the right PLIC and R cingulum), for which one of the studies showed increased FA in the alcohol-exposed group. *ALIC/PLIC* anterior/posterior limb of the internal capsule, *ant* anterior, *CC* corpus callosum, *cing* cingulum, *CR* corona radiata, *IFO/SFO* inferior/superior fronto-occipital fasciculus, *ILF/SLF* inferior/superior longitudinal fasciculus, *sup* superior, *UF* uncinate fasciculus, *WM* white matter

Other consistent FA abnormalities include three temporal connections: the right inferior and superior longitudinal fasciculi, and the right cingulum, which were each significantly different in two studies (out of the four that examined these areas). Several studies have demonstrated an anterior-to-posterior trend of maturation in the corpus callosum during healthy childhood development, with the splenium maturing later than the genu (Giedd et al. 1999b; Thompson et al. 2000). Also, the white matter in the temporal lobe is known to be late-developing, in terms of both white matter volume (Giedd et al. 1999a), and diffusion parameters of white matter tracts that connect there (Lebel et al. 2008b; Zhang et al. 2007). Therefore, it appears that the latest maturing structures in the brain seem to be the most affected by prenatal alcohol consumption. It is not clear why these regions may be more vulnerable to the teratogenic effects of alcohol.

Other portions of the brain display less consistent FA abnormalities. Two of six studies observed lower FA in the body of the corpus callosum (Wozniak et al. (2009) found differences specifically in the posterior midbody), while the remaining structures pictured in Fig. 181.4 were found to be abnormal in only one of the three to four studies investigating them. The deep gray matter structures were only measured by Lebel et al. (2008a), so it is impossible to assess the consistency of these DTI findings. The structures found to be abnormal in only one study, or those that were only examined by one study, will need to be further investigated to determine whether they are consistent among those with FASD or perhaps a unique feature of the particular population of subjects used in one study.

Abnormalities of MD are shown in Fig. 181.5. Although many of the same regions were highlighted in the FA findings, including the corpus callosum, inferior longitudinal fasciculus, and several deep gray matter structures, the MD results seem less consistent than the abnormal FA findings. The only structures observed to have abnormal MD values in more than one study were the genu and splenium of the corpus callosum. There are some conflicting reports, such as one study observed higher MD in the genu of adolescents with FAS (Ma et al. 2005), while another observed lower MD in the genu of FASD children (Lebel et al. 2008a).

Analysis of Figs. 181.4 and 181.5 suggests the right hemisphere of the brain is more affected than the left hemisphere. Although some structures demonstrate bilateral differences between subjects with FASD and controls (the globus pallidus for FA and MD, anterior and posterior corona radiata for FA, inferior fronto-occipital fasciculus for MD), and some demonstrate differences only in the left hemisphere (thalamus for FA differences, superior frontal white matter, anterior and posterior limbs of the internal capsule, and left inferior longitudinal fasciculus for MD only), more abnormalities are apparent in the right hemisphere. Figures 181.4 and 181.5 show ten structures for which the differences are either present only in the right hemisphere, or are more consistent there (i.e., detected by more studies). While most volumetric studies do not report hemispheric differences, an earlier study using conventional T_1-weighted MRI reported more prominent differences in the left hemisphere of children and adolescents with FASD (Sowell et al. 2001). The development of brain asymmetry is poorly understood, although it can be affected by many different genes and drugs (Levin 2005). Clearly, there are some interesting asymmetries present in FASD, but the reasons for this are not clear at present.

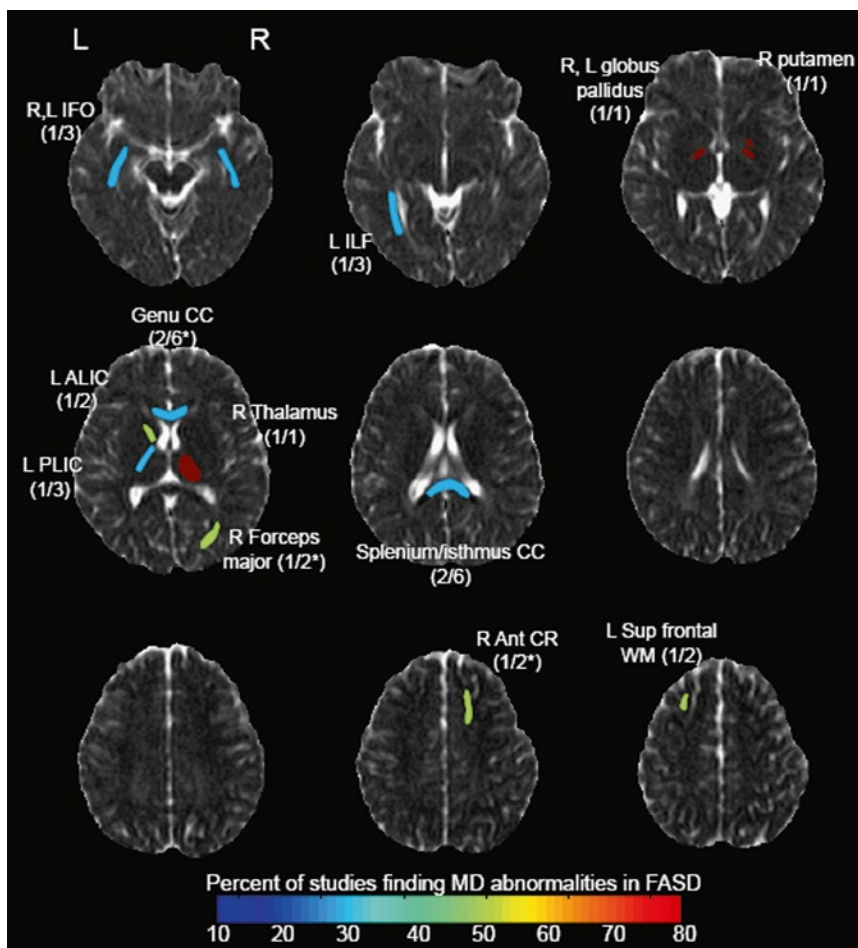
Previous studies have reported temporal and parietal lobe abnormalities in FASD populations, showing increased cortical gray matter thickness (Sowell et al. 2008b) and decreased volume in the parietal lobe (Archibald et al. 2001). Although the parietal area did not have an unusually large number of regions demonstrating diffusion abnormalities (only the superior longitudinal fasciculus, a frontal-parietal-temporal connection showed FA differences between FASD and controls), the temporal lobe shows many changes. In fact, three of the four studies examining the temporal lobe found differences here. Three temporal areas or connections to them were found to be abnormal in at least two studies: the superior longitudinal fasciculus (SLF), the inferior longitudinal fasciculus (ILF, an occiptial-temporal connection), and the cingulum (frontal-temporal). The uncinate fasciculus (UF), another frontal-temporal connection was found to be abnormal by one study. Another region that


Fig. 181.5 Structures with mean diffusivity abnormalities in Fetal alcohol spectrum disorder (*FASD*). Structures that have shown significant mean diffusivity (*MD*) differences between subjects with prenatal alcohol exposure and healthy controls are shown overlaid on an MD map of a 9-year-old boy with FASD. Structures are colored according to the percentage of studies that has shown differences in that particular area. Structures are also listed with the number of studies showing differences and the total number of studies examining that particular area. For all regions, the alcohol-exposed group showed higher MD than controls, except for regions marked with an asterisk (*, the genu CC, forceps major, anterior coronal radiata), for which one of the studies showed decreased MD in the alcohol-exposed group. Abbreviations are the same as for Fig. 181.4.

seems to be commonly different amongst these studies is the frontal region: the UF, SLF, cingulum, inferior and superior fronto-occipital fasciculi (IFO, SFO), and the anterior corona radiata, all connect to this area. Since the frontal lobe is involved in impulse control and executive functioning, both of which many FASD individuals have difficulty with, these frontal connection abnormalities make sense.

Volumetric and metabolic imaging studies have reported major changes in the deep gray matter structures, which are the relay stations of the brain; in particular the caudate nucleus has been implicated (Archibald et al. 2001; Cortese et al. 2006; Mattson et al. 1996). However, only one DTI study to date has examined the deep gray matter structures, where it was demonstrated that the thalamus, putamen, and globus pallidus had significant differences of diffusion parameters in FASD. In contrast to the volumetric and metabolic studies, significant DTI differences were not observed in the caudate nucleus between groups (Lebel et al. 2008a). Further studies are needed to determine whether these
Fig. 181.6 Regions commonly reported to be abnormal in DTI studies of FASD. Abnormalities in the corpus callosum, temporal lobes, and the right hemisphere of individuals with fetal alcohol spectrum disorder (*FASD*) have been reported by many, but not all, diffusion tensor imaging (*DTI*) studies of FASD

diffusion differences are robust and appear in other FASD populations, which would be interesting given the sensitivity of deep gray matter structures to prenatal alcohol exposure in terms of their size and function. Agreement of diffusion changes with volumetric and functional abnormalities in these areas would suggest that they are highly sensitive to prenatal alcohol exposure in many ways, while a disparity between volumetrics and diffusion parameters may indicate a preservation of tissue microstructure, even while overall volume was reduced.

One interesting line of study will be age-related changes within FASD populations. It is well known that diffusion parameters across the brain change with age during childhood and adolescence (Lebel et al. 2008b; Schmithorst et al. 2002); however, the developmental trajectory for FASD is unknown. To date, the DTI studies of children with FASD (age-related DTI changes will be most prominent in children and adolescents) have had relatively small sample sizes ($n = 14$–24), which limit their ability to detect possible changes. Large sample sizes, wide age ranges, and an assortment of analysis techniques will be required to accurately model development trajectories, which are often nonlinear and contain considerable scatter. Lebel et al. (2008a) conducted an exploratory analysis to examine age-related changes of diffusion parameters in FASD compared to the trajectory of development in healthy controls. While there were insufficient FASD subjects to properly fit a curve, in structures with significant differences between children with FASD and healthy controls, the FASD group seemed to follow a similar pattern to the healthy controls, but with most FASD subjects located on one side of the best-fit curve. Another study tested correlations between FA and age in all subjects (FASD group and controls combined) and found no significant correlations (Fryer et al. 2009); however, this may not be unexpected given the small sample size ($n = 15$ FASD, $n = 12$ control).

Despite the relatively small number of studies examining diffusion parameters in FASD, the corpus callosum, temporal lobe, and right hemisphere emerge as consistently abnormal (see Fig. 181.6). Future studies may highlight additional areas and may help elucidate reasons as to why these particular areas are most affected by prenatal alcohol exposure.

181.5 Links to Cognition and Behavior

Children, adolescents, and adults with FASD often have a variety of cognitive and behavioral impairments that may include motor delays, attention deficits, and difficulties with language, learning, memory, and mathematics (Jacobson and Jacobson 2002; Mattson and Riley 1998). Many studies have linked cognitive abilities to brain microstructure as assessed by DTI in healthy populations and

Table 181.3 DTI studies examining correlations with cognitive measures

Study	Number of subjects	Cognitive measures	Brain regions	Findings
Lebel et al. (2008a)	24 FASD	NEPSY (6 subtests) WMTB: Digit, Block Recall WJ III: Quantitative Concepts WRMT: Word ID CREVT	10 white matter tracts 4 deep gray matter structures	No significant correlations
Ma et al. (2005)	9 FAS 7 controls	WISC-III Full-scale IQ	Genu CC Splenium CC	Full-scale IQ – FA in genu and splenium Processing speed – FA in genu and splenium (correlations were across entire group, not in the FAS group alone)
Sowell et al. (2008a)	17 FASD	WRAT reading scores Visuomotor integration	7 regions in temporal lobe, splenium, brainstem	Visuomotor integration – splenium FA
Wozniak et al. (2009)	33 FASD	WISC-IV or WAIS-III: Verbal Comprehension, Perceptual Organization, Working Memory, Processing Speed	Genu CC Splenium CC	Working memory – FA genu and MD splenium Perceptual organization - MD splenium

This table outlines details of the four previous studies that have tested for correlations between cognitive measures and DTI parameters in subjects with prenatal alcohol exposure

other abnormal conditions (Barnea-Goraly et al. 2005; Deutsch et al. 2005; Schmithorst et al. 2005). However, little is known about the relationship between brain structure, cognition, and behavior in FASD. Out of the seven previous studies examining FASD using DTI, four report looking at correlations between brain structure, as assessed by DTI parameters, and cognitive measures. The results of the correlations in these studies are presented in Table 181.3. Although FA is a nonspecific measure, lower FA is suggestive of reduced myelination and/or decreased axonal density; basically, lower FA is interpreted or hypothesized to be linked with weaker white matter integrity. Since white matter forms the brain connections necessary for proper and efficient cognitive function, it is logical that weaker connections would be associated with cognitive deficits. Therefore, positive correlations are expected between cognition and/or behavior scores and FA measures. Brain regions where correlations occur may indicate some degree of specificity related to a certain cognitive task. Significant correlations imply that the variety of cognitive and behavioral difficulties in individuals with FASD is associated with the level of brain abnormalities, and that the more difficulties an individual has with the task, the more abnormal their brain structure is likely to be. Similarly, negative correlations of cognitive scores with MD would be expected, given the higher MD in children with FASD (i.e., freer water diffusion, reflecting fewer microstructural barriers). However, correlations are not causal and may also simply be due to the fact that both the brain area and cognitive measure in question are particularly affected by prenatal alcohol exposure, rather than that they are related to each other. Therefore, although correlations between brain structure and cognition can be extremely useful for understanding FASD, they must be interpreted with caution.

Lebel et al. (2008a) examined correlations between FA and MD in ten different white matter tracts identified with tractography and four deep gray matter structures (ROI) of children with FASD and ten

different cognitive measures: six subtests of the NEPSY measuring neuropsychological functioning, Working Memory Test Battery (WMTB) digit and block recall tests, the Woodcock-Johnson III Tests of Achievement Quantitative Concepts subtest, and the WRMT Word ID, and the Comprehensive Receptive and Expressive Vocabulary Test. None of the correlations between diffusion parameters and cognitive measures were significant after correction for multiple comparisons. However, given the high number of comparisons (10 cognitive scores × 14 brain regions), the correction was strict and more targeted analyses may be needed. Furthermore, correlations between cognitive scores and diffusion parameters are most often found in small areas that are a subsection of a tract, and averaging over an entire white matter tract may mask correlations that exist in smaller subsections of the tract.

Ma et al. (2005) correlated both FA and MD with the WISC-III full-scale IQ and processing speed scores. A significant linear relationship was observed for both processing speed and full-scale IQ measures with FA in the corpus callosum (both genu and splenium). These correlations, however, were only observed across the entire group (nine FAS, seven controls) and were not present in the FAS group alone. Two caveats must be noted,however: first, the sample size was quite small ($n = 9$ for FAS subjects), so the absence of significant correlations may be simply due to reduced power; and second, the cognitive scores used in the correlations were obtained approximately 5 years prior to imaging. Although the authors mention that these types of scores tend to be stable over adolescence, this is a potential confound.

In a study of 33 children and adolescents with FASD, Wozniak et al. (2009) correlated diffusion parameters in the genu and splenium of the corpus callosum with verbal comprehension, perceptual organization, working memory, and processing speed. A significant positive correlation was observed between working memory and FA in the genu; significant negative correlations were reported between splenium MD and both perceptual organization and working memory.

Another study examined correlations between FA and visuo-motor integrations and Wide Range Achievement Test (WRAT) reading scores (Sowell et al. 2008a). FA values were measured in the splenium, bilateral brainstem, and two regions of the temporal lobe in each hemisphere. Significant positive correlations were observed between the visuomotor integration scores and FA in the splenium within the FASD group. No significant correlations were observed between FA and reading scores.

Clearly, connecting diffusion abnormalities with cognitive difficulties in FASD is an important area of research and very little is currently known. Ultimately, linking specific structural brain abnormalities in FASD with cognition, behavior, and brain function will provide clues as to the causes of certain deficits and may lead to more effective treatments of such difficulties in the future.

181.6 Summary

In summary, the seven previous DTI studies of FASD point to several consistent structural brain abnormalities between children, adolescents, and young adults with FASD and healthy controls: the corpus callosum, in particular the posterior region; the temporal lobes, and the right hemisphere. The corpus callosum and temporal lobe findings are in good agreement with other imaging and autopsy studies. To date, only a few studies have examined cognition-brain structure correlations within individuals with FASD, but they do point to relationships between the cognitive and behavioral deficits observed in FASD and the underlying brain microstructure. Future research examining brain abnormalities, cognitive score-diffusion parameter correlations, and developmental trajectories within FASD will provide a much more detailed understanding of this unfortunately prevalent but preventable disorder.

Summary Points

- Fetal alcohol spectrum disorder (FASD) is a developmental disorder associated with prenatal alcohol exposure.
- Individuals with FASD have a variety of cognitive, behavioral, and neurological brain deficits, including structural brain damage.
- Diffusion tensor imaging (DTI) is an excellent method of examining tissue microstructure, especially in white matter tracts.
- DTI has been used in seven previous studies to examine abnormalities in children, adolescents, and young adults prenatally exposed to alcohol.
- Consistent findings of these studies include abnormalities of the corpus callosum (especially the posterior section), temporal lobes, and right hemisphere
- Four of these studies have examined correlations between cognitive measures and DTI parameters, demonstrating significant relationships between brain structure and visuomotor integration, perceptual organization and working memory in individuals with FASD.

Definitions

Fractional anisotropy (FA): An important diffusion tensor imaging parameter reflecting the directionality of diffusion. FA varies from 0 (isotropic diffusion) to 1 (completely anisotropic diffusion). FA is often considered to be a measure of "white matter integrity".

Mean diffusivity (MD): Another important diffusion tensor imaging parameter representing the average diffusivity (i.e., mobility) of water occurring in the tissue.

Tractography: A diffusion tensor image analysis technique that uses the primary diffusion direction and anisotropy to trace out white matter connections and provide visualization of the pathways in vivo. Tractography is often used to analyze the FA and MD of specific white matter tracts.

White matter tracts: Bundles of axons connecting spatially segmented brain regions. These are necessary for efficient brain communication and proper cognitive function. One or more white matter tracts are often abnormal in various diseases or conditions.

Fetal alcohol spectrum disorder (FASD): The umbrella term describing the various disorders associated with prenatal alcohol exposure. Individuals with FASD may have a variety of behavior, cognitive, and brain abnormalities.

Chapter 182
Neuronal Cell Migration in Fetal Alcohol Syndrome

Tatsuro Kumada, Yutaro Komuro, Ying Li, Yoav Littner, and Hitoshi Komuro

Abbreviations

FAS	Fetal alcohol syndrome
FASD	Fetal alcohol spectrum disorders
EGL	External granular layer
ML	Molecular layer
PCL	Purkinje cell layer
IGL	Internal granular layer
WM	White matter
NMDA	N-methyl-D-aspartate
cAMP	Cyclic AMP
cGMP	Cyclic GMP
AC	Adenylyl cyclase
PKA	Protein kinase A
PDE	Cyclic nucleotide phosphodiesterases
PKC	Protein kinase C
CaMKII	Ca^{2+}/calmodulin-dependent protein kinase II
PP1	Protein phosphatase 1
MAPK	Mitogen-activated protein kinase
PI$_3$K	Phosphoinositide 3-kinase
BrdU	5-bromo-2′-deoxy-uridine

182.1 Introduction

Prolonged exposure to alcohol during gestation and lactation correlates with a pattern of abnormal development in newborns (Lemoine et al. 2003; Sokol et al. 2003; Goodlett et al. 2005). Jones and Smith (1973) called this developmental disturbance "fetal alcohol syndrome" (FAS). The disturbance of the central nervous system is the most serious feature of FAS (Marcus 1987; Riley and

H. Komuro (✉)
Department of Neurosciences/NC30, Lerner Research Institute,
The Cleveland Clinic Foundation, 9500 Euclid Avenue, Cleveland, OH 44195, USA
e-mail: komuroh@ccf.org

McGee 2005). For example, microencephaly is common among FAS patients (Wisniewski et al. 1983). Several aspects of the developmental program are involved in the alcohol-induced malformation of the brain (Jones 1988; Coulter et al. 1993; Guerri 2002). Among them, the most striking abnormalities appear to involve the impairment of neuronal cell migration (Miller 1986, 1993). Recent studies indicate the role of the Ca^{2+} and cyclic nucleotide signaling pathways in the alcohol-induced abnormal migration of immature neurons (Kumada et al. 2006). In this chapter, we focus on cellular mechanisms by which alcohol impairs the migration of immature neurons in the developing brain.

182.2 Maternal Alcohol Exposure Affects Brain Development of Fetuses and Children

Alcohol is presently the most common chemical teratogen causing malformation and mental deficiency in humans (Clarren and Smith 1978; Clarren et al. 1978). Maternal exposure to alcohol may not lead to full expression of FAS but rather may result in a variety of less pronounced dysmorphic, cognitive, and behavioral effects, often termed "fetal alcohol spectrum disorders" (FASD). The world incidence of FAS is estimated as approximately 1.9 per 1,000 live births, while the incidence of FASD is thought to be as high as 1 in 100 live births (Committee on Substance Abuse 1993). The most serious feature of FAS is disturbance of the central nervous system (Clarren and Smith 1978; Clarren et al. 1978, 1990). Microcephaly is present in nearly all cases, and this reflection of disturbed brain growth is accompanied by delayed neurologic development in approximately 90% of the cases (Wisniewski 1983). Particular defects of speech and language development are also evident (Marcus 1987). In addition to serious cognitive deficits, a far-reaching and pervasive state of disability is induced by behavioral disturbances, impaired communication skills, and maladaptive social function, manifested by lack of reciprocal friendships, impulsive behavior, anxiety and dysphoria. Children with FAS also show neurological signs associated with cerebellar damage such as delayed motor development, problems with fine tasks, and ataxia (Coffin et al. 2005; Manzardo et al. 2005). The most common abnormality observed in the brain of FAS patients is a leptomeningeal neuroglial heterotopia that assumes the form of a sheet of aberrant neuronal and glial cells covering portions of the cerebral, cerebellar, and brain stem surfaces (Clarren and Smith 1978; Clarren et al. 1978). Aberrations of brain stem and cerebellar development, in large part related to faulty cell migration, have also been especially frequent, along with the migrational disturbances of schizencephaly and polymicrogyria (Peiffer et al. 1979). Disordered midline prosencephalic formation – e.g., agenesis of the corpus callosum, septo-optic dysplasia, and incomplete holoprosencephaly – has also been documented (Coulter et al. 1993). Therefore, multiple aspects of central nervous system development can be affected by alcohol exposure, including proliferation, migration, differentiation, and synapse formation.

182.3 Animal Models for Studying the Effects of Alcohol Exposure on Brain Development

Due to the obvious limitations on human studies, animal models of FAS have been used to further document the phenomenon of alcohol-induced defects in brain development and to study underlying mechanisms. Pre- and/or neonatal exposure to alcohol also induces long-term neuromorphologic, neurochemical and behavioral changes in experimental animals (Sakata-Haga et al. 2001;

Dikranian et al. 2005). Some of these changes were observed in humans, and thus led to the identification of FAS. In mice and rats, the early postnatal period is equivalent to fetal development in humans, and alcohol exposure causes a reduction of their brain weight, especially in the cerebellum (Kornguth et al. 1979; Sakata-Haga et al. 2001; Dikranian et al. 2005). The alcohol-exposed rats are hypoactive during treatment and exhibit a reduction in cerebellar Purkinje cell numbers, especially in the early maturing lobules (Bauer-Moffet and Altman 1975). Furthermore, the number of granule cells in the internal granular layer (IGL) of the cerebellum is significantly reduced in the alcohol-treated animals (Borges and Lewis 1983), suggesting that alcohol affects the migration of cerebellar granule cells to the IGL. Moreover, prenatal exposure of alcohol-induced morphological defects in the rat cerebral cortex, including heterotopia and disorganized cortical architecture, suggest abnormal migration (Kotkoskie and Norton 1988). In the rat cerebrum, prenatal alcohol exposure delays the migration of early generated neurons to the deep cortical layers by 2 days, and the migration of late generated neurons to the upper cortical layers by 4–6 days (Miller 1993). Alcohol exposure also reduces the speed of neuronal cell migration in the rat cerebrum (Siegenthaler and Miller 2004).

182.4 Migration of Cerebellar Granule Cells as a Model of Neuronal Cell Migration

To examine mechanisms by which alcohol affects neuronal migration, the cerebellum of the early postnatal mouse is used as a model system, since exposure to alcohol induces quantitative morphological changes in the rodent cerebellum (Bauer-Moffet and Altman 1975; Borges and Lewis 1983). Furthermore, the defined neuronal cytoarchitecture and the small number of neuronal types in the cerebellum provide an ideal system for determining cellular and molecular mechanisms of neuronal migration (Komuro and Rakic 1998b; Komuro and Yacubova 2003). Specifically, the migration of granule cells has been intensively examined, and it has become apparent that the mechanisms underlying granule cell migration are utilized during the migration of immature neurons in other brain regions (Yacubova and Komuro 2003; Komuro and Kumada 2005). Therefore, this review is based on studies of the migration of cerebellar granule cells. Interestingly, cerebellar granule cells alter the mode, rate and direction of migration as they traverse different cortical layers of the cerebellum (as schematically presented in Fig. 182.1).

At the top of the external granular layer (EGL), granule cell precursors proliferate every 18–20 h. After their final mitosis, granule cells remain in the EGL for 24–48 h before initiating their radial migration across the molecular layer (ML) (Komuro et al. 2001). During this latent period, granule cells tangentially migrate within the middle and bottom of the EGL (Komuro et al. 2001). At the middle of the EGL, coinciding with the extension of two uneven horizontal processes oriented parallel to the longitudinal axis of the folium, granule cells start to migrate tangentially in the direction of the larger process. Their morphology and speed of movement change systematically with their position within the EGL (Komuro et al. 2001). The speed of movement is fastest (~14.8 μm/h) in the middle of the EGL, when granule cells have two short horizontal processes. As granule cells elongate their somata and extend longer horizontal processes at the bottom of the EGL, they move at a reduced speed (~12.6 μm/h). At the interface of the EGL and the ML where granule cells migrate at the slowest speed (~4.1 μm/h), their somata round, and then begin to extend couples of descending processes into the ML. After the stationary period, granule cells abruptly extend a single vertical process and initiate the transition from tangential to radial migration, reshaping their rounded somata into a vertically elongated spindle.
Fig. 182.1 A three-dimensional representation of granule cell migration from their birthplace, the external granular layer (*EGL*), to their final destination, the internal granular layer (*IGL*), in the developing cerebellum. 1, Extension of two uneven horizontal processes near the top of the EGL; 2, Tangential migration in the middle of the EGL; 3, Development of vertical processes near the border between the EGL and the molecular layer (*ML*); 4, Initiation of radial migration at the EGL-ML border; 5, Bergmann glia-associated radial migration in the ML; 6, Stationary state in the Purkinje cell layer (*PCL*); 7, Glia-independent radial migration in the IGL; 8, Completion of migration in the middle or bottom of the IGL. Abbreviations: *P* Purkinje cell, *B* Bergmann glia, *G* Golgi cell, *g* postmigratory granule cell, *cf* climbing fiber, *mft* mossy fiber terminal

In the ML, granule cells have vertically elongated cell bodies, thin trailing processes, and more voluminous leading processes, and migrate radially along Bergmann glial processes (Komuro and Rakic 1995). In this layer, the speed of granule cell movement depends critically on the age of the cerebellum (Komuro and Rakic 1995). The average speed of migration in the ML increases systematically from 9.6 μm/h in the cerebellum of postnatal 7-day-old mice to 18.0 μm/h in postnatal 13-day-old mice. Consequently, granule cells traverse the developing ML within a relatively constant time period (10–11 h) despite the doubling in width of the layer during the second week of postnatal life. The movement of granule cells in this layer is characterized by alternations of short stationary phases with movement in a forward or backward direction. The net displacement of granule cells depends on the duration and frequency of these phases as well as on the speed of movement.

Upon entering the Purkinje cell layer (PCL), granule cells detach from the processes of Bergmann glial cells, and the shape of their cell bodies abruptly transforms from a vertically elongated spindle to a sphere (Komuro and Rakic 1998a). The rounded somata significantly slow their movement, and stop completely in the PCL. The somata remain stationary in the PCL for an average of 115 min, with times ranging from 30–220 min (Komuro and Rakic 1998a). However, highly motile lamellipodia and filopodia develop at the distal portion of the leading process, suggesting that the tips of leading processes actively search for potential guidance cues. After a prolonged stationary period, granule cells in the PCL begin to re-extend their somata and leading processes. During this transformation, granule cells gradually accelerate the speed of migration and cross the border between the PCL and the internal granular layer (IGL).

In the IGL, granule cells migrate radially toward the bottom of the IGL without an association with glial cells at a speed comparable to that observed in the ML (Komuro and Rakic 1998a). The long axis of their somata remains oriented perpendicular to the PCL-IGL boundary line during this radial migration. Interestingly, once the tip of a leading process approaches the IGL-white matter (WM) border, their somata become rounded again. Thereafter, granule cells gradually slow their

migration and stop movement near the IGL-WM border (Komuro and Rakic 1998a). In early postnatal mouse cerebella, the majority of granule cells complete their migration at the bottom stratum of the IGL.

In vitro studies with the use of real-time observation of granule cell migration in acute cerebellar slices reveal that in the P10 mouse cerebellum, granule cells first move tangentially about 220 μm in the EGL, and then migrate radially about 250 μm to reach their final position in the IGL (Komuro and Yacubova 2003). The average transit time of granule cells is 25.0 h in the EGL, 9.8 h in the ML, 5.2 h in the PCL, and 11.1 h to attain their final position in the IGL (Yacubova and Komuro 2003). Therefore, granule cells move from the top of the EGL through the ML and PCL to their final position in the IGL within about 2 days (average, 51 h).

182.5 Alcohol Exposure Reduces the Speed of Granule Cell Migration In Vitro

To determine whether and how alcohol exposure affects the migration of cerebellar granule cells, first, the relation between the doses of alcohol exposure and the effects on granule cell migration was examined. Real-time observation of cell movement in cerebellar slices obtained from postnatal (P) 10-day-old mice indicate that the administration of 100 mM ethanol immediately slows the tangential migration of granule cells in the EGL (Kumada et al. 2006). Pharmacologically relevant concentrations of ethanol are based on blood-ethanol concentrations attained by alcohol consumption in humans (Jones 1988). Since ethanol readily crosses the placental and blood brain barriers, and diffuses rapidly into all aqueous compartments of the body, these levels would readily be found in cases of alcohol consumption during pregnancy (West et al. 1994). The effects of ethanol on the speed of granule cell migration in the cerebellar slices of P10 mice are dose dependent (Fig. 182.2). Although 2.5 mM ethanol fails to alter the speed of granule cell movement, 10 mM ethanol (equivalent to blood ethanol level <50 mg/dL) significantly decreases the speed to 62% (EGL), 76% (ML), and 82% (IGL) of the control value. In the presence of 50 mM ethanol, the speed is further reduced to 40% (EGL), 55% (ML), and 62% (IGL) of the controls. Finally, when 100 mM ethanol is added, movement declines to 35% (EGL), 50% (ML), and 56% (IGL) of the control. It is noteworthy that the vulnerability of granule cells to ethanol exposure decreases as granule cells migrate from the

Fig. 182.2 Ethanol slows the migration of granule cells in the acute slices of the early postnatal mouse cerebella. Effects of different doses (0–100 mM) of ethanol on the speed of granule cell migration among three different cortical layers (the EGL, ML and IGL) of the early postnatal mouse cerebellum. Bar is S.D.
Fig. 182.3 Ethanol directly inhibits the migration of isolated granule cells in the microexplant cultures of the early postnatal mouse cerebella. Dose-dependent reduction of the speed of granule cell migration in the microexplant cultures of P3 mouse cerebella by an acute exposure of ethanol (0–200 mM). Bar is S.D.
EGL to the IGL (Fig. 182.2). The changing vulnerability suggests that the stage of differentiation (or maturation) is critical in producing the harmful effects of ethanol on granule cell migration.

Ethanol may alter the motility of granule cells directly or indirectly by modifying the surrounding environment. For example, ethanol exposure affects the development and functions of glia, which in turn may alter granule cell motility (Shetty and Phillips 1992). To determine whether ethanol directly affects granule cell migration, microexplant cultures of P0-P3 mouse cerebella, in which isolated granule cells actively migrate in the absence of cell–cell contact, are used (Yacubova and Komuro 2002; Kumada et al. 2009). The addition of 100 mM ethanol slowed the migration of isolated granule cells from 43.2 to 18.3 μm/h, even though ethanol did not affect the extension of the leading process or the morphological features of the process (Kumada et al. 2006). Furthermore, application of ethanol at concentrations ranging from 25 to 200 mM appreciably slows the movement of isolated granule cells (Fig. 182.3). The average speed of granule cell movement is reduced to 85% (25 mM ethanol), 71% (50 mM ethanol), 63% (100 mM ethanol), and 46% (200 mM ethanol) of the control (Kumada et al. 2006). These results indicate that ethanol directly acts on granule cell migration in a dose-dependent manner.

182.6 Alcohol Exposure Reduces the Frequency of Spontaneous Ca^{2+} Spikes in Migrating Granule Cells

How does alcohol slow the migration of granule cells? Although the effects of alcohol are initially believed to arise from alcohol-induced perturbations in the order of membrane lipids, the effects on membrane lipids are actually quite small at clinically relevant concentrations (Peoples et al. 1996).

However, even low levels of alcohol can modulate the functions of voltage-gated and ligand-gated Ca^{2+} channels by binding to a hydrophobic pocket on the proteins (Walter and Messing 1999). This suggests that alcohol may affect the intracellular Ca^{2+} levels of migrating granule cells. This is intriguing because granule cell migration is highly sensitive to changes in intracellular Ca^{2+} levels and Ca^{2+} signaling (Komuro and Rakic 1992, 1993, 1996; Kumada and Komuro 2004; Komuro and Kumada 2005). Indeed, the use of a Ca^{2+} indicator dye revealed that administration of ethanol significantly

Fig. 182.4 Ethanol action on Ca^{2+} spikes in migrating granule cells. Histograms showing the reduction of the frequency of spontaneous Ca^{2+} spikes in the somata of migrating cerebellar granule cells by ethanol (0–200 mM). Bar is S.D.
lowers the frequency of spontaneous Ca^{2+} spikes in the granule cell somata in a dose-dependent manner (Kumada et al. 2006). For example, the average number of spontaneous Ca^{2+} spikes in the granule cells was reduced to 88% (25 mM ethanol), 73% (50 mM ethanol), 48% (100 mM ethanol), and 35% (200 mM ethanol) of the control after administration of ethanol (Fig. 182.4). These results suggest that one of the cellular mechanisms underlying ethanol action on neuronal migration is the alteration of Ca^{2+} signaling.

182.7 Enhancing Ca^{2+} Signaling Reverses Alcohol Action on Granule Cell Migration

If ethanol slows granule cell migration by inhibiting Ca^{2+} signaling, enhancing Ca^{2+} release from internal Ca^{2+} stores or Ca^{2+} influxes across the plasma membrane may reduce the effect of ethanol on granule cell migration. To test this possibility, (1) caffeine, which increases internal Ca^{2+} release through the ryanodine receptors, (2) *N*-methyl-*D*-aspartate (NMDA) and (3) nicotine, which both induce Ca^{2+} influxes through the NMDA type glutamate receptors and the nicotinic acetylcholine receptors, are applied with ethanol. Intoxicating levels of ethanol have been reported to alter the activity of these receptors (Narahashi et al. 1999; Kumada et al., 2006). In the absence of ethanol, the addition of nicotine or caffeine to the culture medium does not appreciably change the speed of granule cell migration, whereas addition of NMDA significantly increases the speed of migration (Fig. 182.5). Interestingly, when caffeine or NMDA is added to the culture medium with ethanol, the effects of ethanol on the speed of granule cell migration are noticeably reduced at all dose levels (25–100 mM) (Fig. 182.5). In contrast, when nicotine is added to the culture medium with low doses (25 and 50 mM) of ethanol, nicotine has little effect on the rate of migration (Fig. 182.5). In the presence of a high dose (100 mM) of ethanol, the application of nicotine significantly amplifies the effects of ethanol on granule cell migration (Fig. 182.5). These results suggest that ethanol affects the migration of granule cells by altering multiple and distinct components of Ca^{2+} signaling (Kumada et al. 2006). Furthermore, these results demonstrate that the action of ethanol may be ameliorated by controlling Ca^{2+} signaling.
Fig. 182.5 Alterations of the Ca^{2+} signaling change the effect of ethanol on granule cell migration. An application of caffeine (1 mM), nicotine (1 μM), and NMDA (30 μM) alters the effects of four different doses (0, 25, 50, and 100 mM) of ethanol on the speed of granule cell migration. Bar is S.D.

182.8 cAMP Signaling Reciprocally Affects Alcohol Action on Granule Cell Migration

Ca^{2+} signaling pathways interact with numerous other signaling systems (Berridge et al. 2003). Among them, cyclic nucleotide pathways, such as those involving cyclic AMP (cAMP) or cyclic GMP (cGMP), are of particular interest, because alterations of these systems affect the motility of various types of cells (Howe et al. 2005; Veltman et al. 2005). Accordingly, the use of the cAMP enzyme immunoassay reveals that intraperitoneal injection of ethanol (5 g/kg body weight) into P10 mice increases cAMP levels but decreases cGMP levels in the cerebellum 1 h after injection (Kumada et al. 2006), suggesting that cAMP and cGMP signaling also play a role in the effects of ethanol on granule cell migration. To test the role of cyclic nucleotide signaling, first, cAMP signaling pathways are stimulated or inhibited. In the absence of ethanol, the stimulation of adenylyl cyclase (AC) with forskolin, which is upstream of cAMP signaling, markedly reduces the speed of granule cell movement; however, the inhibition of protein kinase A (PKA) with PKI, which is downstream of cAMP signaling, markedly increases the speed (Fig. 182.6). Similarly, without ethanol, application of a competitive cAMP agonist, Sp-cAMPS, reduces the speed of granule cell migration, whereas a competitive cAMP antagonist, Rp-cAMPS, increases the speed (Fig. 182.6). These results demonstrate that without ethanol, the stimulation of cAMP signaling slows down granule cell migration, whereas the inhibition of cAMP signaling accelerates migration. Importantly, the inhibition of PKA activity with PKI significantly reduces the effects of 25–50 mM ethanol on the speed of granule cell migration, but fails to change the action of 100 mM ethanol on the migration (Fig. 182.6). Application of Rp-cAMPS completely reverses the effects of 25–100 mM ethanol on the speed of granule cell migration (Fig. 182.6). Moreover, the inhibition of the activity of AC with 9CP-Ade significantly reduces the effects of 100 mM ethanol (Fig. 182.6). In contrast, the stimulation of AC activity with forskolin significantly enhances the effects of 25 mM ethanol on the speed of granule cell migration (Fig. 182.6). These results demonstrate that alcohol action on granule cell migration is highly sensitive
Fig. 182.6 cAMP signaling plays a key role in the ethanol-induced inhibition of granule cell migration. Altering cAMP signaling with Sp-cAMPS (20 μM), Rp-cAMPS (100 μM), PKI (5 μM), forskolin (30 μM), or 9CP-Ade (30 μM) changes the action of four different doses (0, 25, 50, and 100 mM) of ethanol on the speed of granule cell migration

to changes in the activity of cAMP signaling pathways: stimulating cAMP signaling amplifies alcohol action on granule cell migration, whereas inhibiting cAMP signaling reduces action (Kumada et al. 2006). Because the application of ethanol increases cAMP levels, ethanol may slow granule cell migration by stimulating cAMP signaling pathways.

182.9 Stimulation of cGMP Signaling Pathways Reduces Alcohol Action on Granule Cell Migration

In the case of the cGMP signaling pathway, without ethanol, stimulating cGMP signaling with a cGMP analogue, Br-cGMP, slightly increases the speed of granule cell movement, whereas inhibiting cGMP signaling with cGMP antagonist, Rp-8-pCPT-cGMPS, slightly decreases the speed (Fig. 182.7). Furthermore, inhibiting guanylyl cyclase with ODQ does not affect the speed of granule cell migration (Fig. 182.7). Interestingly, when the cGMP signaling pathway is stimulated with Br-cGMP, the effects of ethanol on granule cell migration are markedly reduced at all dose levels (25–100 mM) (Fig. 182.7). In contrast, inhibiting the cGMP signaling pathway with Rp-8-pCPT-cGMPS or ODQ does not change ethanol action on the speed of granule cell migration (Fig. 182.7). Cumulatively, these results demonstrate that cGMP signaling is also targeted by ethanol action in granule cell migration (Kumada et al. 2006). Application of ethanol may slow granule cell migration by reducing the activity of cGMP signaling pathways.

182.10 Alterations of Hydrolysis of cAMP and/or cGMP by PDE Modify Alcohol Action on Granule Cell Migration

If alcohol affects granule cell migration by altering the cAMP and cGMP signaling pathways, one mechanism controlling alcohol action might be the degradation of these cyclic nucleotides. Indeed, the alterations of the activity of cyclic nucleotide phosphodiesterases (PDE), which catalyze the
Fig. 182.7 Stimulation of cGMP signaling reduces the effects of ethanol on granule cell migration. Altering cGMP signaling with Br-cGMP (100 μM), Rp-8-pCPT-cGMPS (5 μM), or ODQ (1.5 μM) changes the action of four different doses (0, 25, 50, and 100 mM) of ethanol on the speed of granule cell migration

hydrolysis of cAMP and/or cGMP, change alcohol action on granule cell migration (Kumada et al. 2006). For example, application of EHNA, a PDE2 inhibitor that blocks the cGMP-dependent cleavage of cAMP and cGMP, significantly reduces ethanol action on granule cell migration (Kumada et al. 2006). In contrast, 8-MM-IBMX, a PDE1 inhibitor that blocks the Ca^{2+}/calmodulin-dependent cleavage of cAMP and cGMP, does not significantly change the effects of ethanol on granule cell migration (Kumada et al. 2006). These results indicate that alcohol may affect granule cell migration by altering the amplitude and duration of cyclic nucleotide signals by modifying the activity of a specific PDE family.

182.11 Ca^{2+} Spike-Dependent and Spike-Independent Mechanisms Underlying the Reversal of Alcohol Action on Granule Cell Migration

Changes in the frequency of Ca^{2+} transients positively correlate with changes in the speed of granule cell migration (Komuro and Rakic 1996; Kumada and Komuro 2004). Do caffeine, NMDA, cAMP antagonists, and cGMP agonists reduce alcohol action on granule cell migration by increasing the frequency of Ca^{2+} spikes? The use of a Ca^{2+} indicator dye reveals that without ethanol, the application of NMDA significantly increases the frequency of Ca^{2+} spikes in migrating granule cells, whereas caffeine does not affect the frequency (Fig. 182.8). Importantly, application of NMDA or caffeine markedly reduces the effects of ethanol on the frequency of Ca^{2+} spikes in granule cells (Fig. 182.8). In the case of cAMP signaling pathways, without ethanol, the stimulation of AC activity with forskolin significantly reduces the frequency of Ca^{2+} transients, while the inhibition of cAMP signaling
Fig. 182.8 Effects of caffeine, NMDA, forskolin and Rp-cAMPS on the ethanol-induced reduction of the frequency of Ca^{2+} spikes in the granule cell somata. Effects of caffeine (1 mM), NMDA (30 μM), forskolin (30 μM), Rp-cAMPS (100 μM), BAPTA-AM (10 μM), and Rp-cAMPS (100 μM)+BAPTA-AM (10 μM) on the frequency of spontaneous Ca^{2+} spikes in the granule cell somata in the presence and absence of ethanol (0, 50, and 100 mM)

with Rp-cAMPS significantly increases the frequency (Fig. 182.8). It is also noteworthy that the application of Rp-cAMPS completely eliminates the effects of ethanol on the frequency of Ca^{2+} transients (Fig. 182.8). Such effects of Rp-cAMPS on the frequency of Ca^{2+} transients are significantly reduced by a coadministration of an intracellular Ca^{2+} chelator, BAPTA-AM (Fig. 182.8b). In contrast, neither stimulating cGMP signaling with Br-cGMP nor inhibiting the activity of PDE2 with EHNA changes the effects of ethanol on the frequency of Ca^{2+} transients (Kumada et al. 2006). These results indicate that Ca^{2+} signaling and cAMP signaling may reverse alcohol action on granule cell migration by increasing the frequency of Ca^{2+} transients in their somata, whereas cGMP signaling and cyclic nucleotide phosphodiesterases may reduce alcohol action on migration without altering Ca^{2+} transients (Kumada et al. 2006).

182.12   Multiple Downstream Targets Are Involved in Reversing Alcohol Action on Granule Cell Migration

What downstream effectors are involved in the reversal of alcohol action on granule cell migration by altering Ca^{2+}, cAMP, or cGMP signaling? Although these signals interact with large varieties of downstream targets, protein kinase C (PKC), Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII), calcineurin, protein phosphatase 1 (PP1), Rho GTPase, mitogen-activated protein kinase (MAPK), and phosphoinositide 3-kinase (PI_3K) are potential targets. This is because these molecules are involved in controlling the motility of various types of cells. The use of pharmacological tools reveals that the reversal of alcohol action on granule cell migration by controlling the Ca^{2+} and cAMP/cGMP signaling pathways requires the activities of multiple but distinctive downstream effectors. For example, (1) caffeine needs the activities of CaMKII, calcineurin, PP1, Rho GTPase, MAPK and PI_3K; (2) NMDA needs the activities of PKC, CaMKII, calcineurin, PP1, MAPK and PI_3K; (3) Rp-cAMP needs the activities of PKC, CaMKII, calcineurin, PP1, Rho GTPase and PI_3K; (4) Br-cGMP needs the activities of PP1, Rho GTPase, MAPK and PI_3K (Kumada et al. 2006).

182.13 Alcohol Action on Granule Cell Migration In Vivo Is Reversed by Caffeine, Rp-cAMPS and Br-cGMP

The effects of alcohol on granule cell migration in vitro are significantly reduced by controlling the Ca^{2+}, cAMP and cGMP signaling pathways (Kumada et al. 2006). Could controlling the Ca^{2+}, cAMP and cGMP signaling pathways also reduce the effects of alcohol on granule cell migration in vivo? A single intraperitoneal injection of ethanol (5 g/kg body weight) into P10 mice raises blood ethanol levels to approximately 80 mM (equivalent to blood ethanol level <400 mg/dL) within 1 h after injection (Kumada et al. 2006), and decreases both the average distance of BrdU-labeled granule cells from the EGL-ML border and the number of BrdU-labeled granule cells in the ML, PCL, and IGL (Fig. 182.9a and b). These results demonstrate that a single injection of ethanol prevents granule cells from entering the ML and slows radial migration in the ML, PCL, and IGL (Kumada et al. 2006).

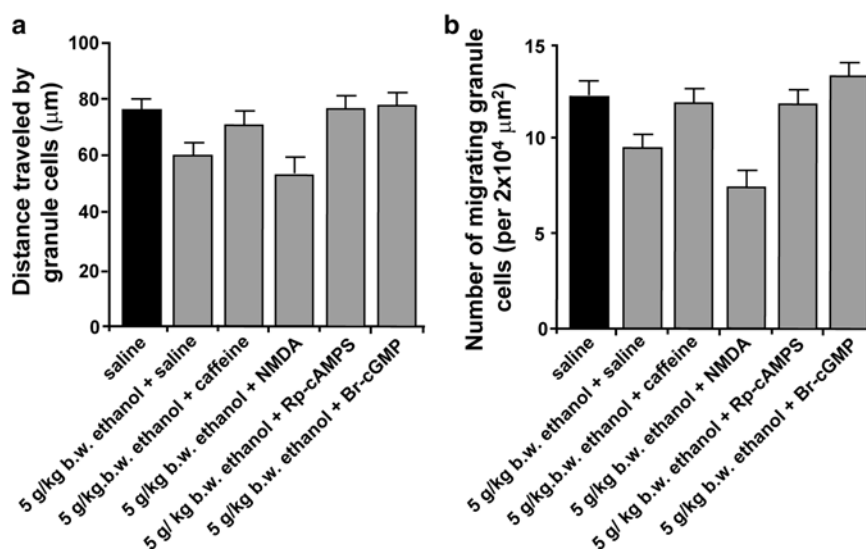
Most importantly, the injections of caffeine (2 mg/kg body weight), Rp-cAMPS (0.4 mg/kg body weight) or Br-cGMP (0.4 mg/kg body weight) into the subarachnoid space between the skull and the surface of the P10 mouse cerebellum with a single intraperitoneal injection of ethanol (5 g/kg body weight) completely reverses the effects of ethanol on granule cell migration in vivo (Fig. 182.9a and b). In contrast, the administration of NMDA (more than 0.01 mg/kg body weight) into the subarachnoid space between the skull and the surface of the cerebellum does not reduce the effect of ethanol on granule cell migration in vivo (Fig. 182.9 a and b), and often causes the death of injected pups, possibly from neurotoxic effects of high doses of NMDA. These results demonstrate that the effects of alcohol on granule cell migration in vivo can be reduced by controlling the Ca^{2+}, cAMP and cGMP signaling pathways (Kumada et al. 2006).


Fig. 182.9 Effects of ethanol on granule cell migration in vivo are reversed by an administration of caffeine, Rp-cAMPS and Br-cGMP. (**a** and **b**) The effects of the injection of 5 μl of saline, caffeine (2 mg/kg body weight), NMDA (0.01 mg/kg body weight), Rp-cAMPS (0.4 mg/kg body weight), and Br-cGMP (0.4 mg/kg body weight) into the subarachnoid space between the skull and the surface of the cerebellum of P10 mice on the ethanol (5 g/kg body weight)-induced changes in (**a**) the distance of the BrdU-labeled granule cells from the EGL-ML borders and (**b**) the number of BrdU-labeled cells in the ML, PCL, and IGL. Bar is S.D. P9 mice were injected intraperitoneally with 5-bromo-2'-deoxy-uridine (BrdU, 50 mg/kg body weight). One day after BrdU injection (at P10), mice were injected with saline, caffeine, NMDA, Rp-cAMPS, or Br-cGMP with or without ethanol injection (5 g/kg body weight, 25%, v/v mixed in saline). Two days after BrdU injection (at P11), mice are euthanized. The distribution of BrdU-labeled granule cells in the ML, PCL, and IGL was examined

182.14 Applications to Other Areas of Health and Disease

Recent studies reveal that Ca^{2+} signaling and cyclic nucleotide signaling are the central targets of alcohol action in neuronal cell migration. These results suggest two new directions of research regarding how diets, including alcohol, affect the development of brain, especially the migration of immature neurons. One direction is to determine what kinds of food worsen or ameliorate the effect of alcohol on neuronal cell migration in the developing brain. For example, drinking coffee or tea may reduce the effects of alcohol on neuronal cell migration because caffeine reduces the effect of alcohol on granule cell migration. Having foods or drinks which stimulate the Ca^{2+} and cGMP signaling pathways or inhibit the cAMP signaling pathways in immature neurons may ameliorate the effect of alcohol on neuronal cell migration, leading to the normal development of the fetal brain.

The other direction is to determine the potential risk of foods and drinks in influencing the migration of immature neurons. For example, foods which contain chemicals that inhibit Ca^{2+} release from intracellular Ca^{2+} stores of immature neurons may inhibit the migration of immature neurons. Likewise, foods which contain chemicals that stimulate the cAMP signaling pathways, such as AC or PKA, may slow down neuronal cell migration, leading to ectopic neurons in the brain.

In conclusion, elucidating the mechanisms underlying the alcohol-induced abnormal migration of immature neurons helps us to determine whether and how diets play a role in establishing neuronal cytoarchitecture and function in the developing brain by controlling neuronal cell migration.

182.15 Key Points of Cellular Mechanisms Underlying the Alcohol-Induced Inhibition of Neuronal Cell Migration

1. Recent studies suggest the involvement of the Ca^{2+}-PKC, cAMP-PKA, and cGMP-PKG signaling pathways in the alcohol-induced impairment of granule cell migration (Kumada et al. 2006, 2007; Jiang et al. 2008). These three signaling pathways interact with each other (schematically shown in Fig. 182.10). For example, the activity of adenylate cyclase 7 (AC7) is modified by PKC, and alcohol potentiates AC7 activity by altering the activity of PKCδ. The stimulation of PKA and PKG enhances the activity of voltage-dependent N-type and L-type Ca^{2+} channels, which in turn affects the Ca^{2+} signaling pathway. The activation of cAMP signaling pathways alters internal Ca^{2+} release through PKA-mediated phosphorylation of inositol 1,4,5-triphosphate receptors and ryanodine receptors. Moreover, the activity of PKA regulates NMDA receptor activity through an interaction with A-kinase anchoring protein 79. Therefore, it may be worth examining whether and how the interactions between the cAMP-PKA, Ca^{2+}-PKC, and cGMP-PKG signaling pathways play roles in controlling alcohol action on granule cell migration.
2. Alcohol also directly and indirectly induces alterations in the activity of other signaling molecules (such as Rho GTPase, MAPK/ERK). There is a functional link between the activity of Rho GTPase and the activities of Ca^{2+}- and PKA signaling. The changes in intracellular Ca^{2+} levels regulate Rho GTPase activity in various types of cells, although how the changes in Ca^{2+} levels modulate Rho GTPase activity is essentially unclear. Furthermore, cAMP/PKA is involved in controlling cell migration and cytoskeletal organization via activation of Rho GTPase. Interestingly, alcohol decreases the activity of MAPK/Erk in immature neurons. The reduction of MAPK/Erk activity may be involved in the alcohol-induced impairment of granule cell migration. This is because the reduction of phosphorylated Erk1 and Erk2 by inhibition of mitogen-activated protein kinase inhibits neurite outgrowth in cerebellar granule cells. Moreover, PKC and PKA alter the phosphorylation of Erk. Whether alcohol impairs granule cell migration via altering the activity of Rho GTPase and/or MAPK/Erk remains to be examined.
Fig. 182.10 Schematic drawing showing how ethanol affects the cAMP-PKA, Ca^{2+}-PKC, and cGMP-PKG signaling pathway in migrating granule cells. Abbreviation: *c.g.c.* cerebellar granule cells, *GPCR* G-protein coupled receptors, *NOS* nitric oxide synthase, *NO* nitric oxide, *sGC* soluble guanylyl cyclase

Summary Points

- Alcohol exposure inhibits the migration of cerebellar granule cells in vitro as well as in vivo.
- Alcohol exposure inhibits Ca^{2+} spikes in cerebellar granule cells.
- Alcohol exposure reduces intracellular cGMP levels of cerebellar granule cells but increases cAMP levels.
- Ca^{2+} signaling and cyclic nucleotide signaling are the central targets of alcohol action in neuronal cell migration. For example, stimulating Ca^{2+} and cGMP signaling or inhibiting cAMP signaling completely reverses the action of alcohol on cerebellar granule cell migration in vitro as well as in vivo.
- Aberrant migration of immature neurons in the fetal brain caused by maternal alcohol consumption may be corrected by controlling the activity of Ca^{2+} signaling and cyclic nucleotide signaling pathways.

Definitions and Explanations

Fetal alcohol syndrome: Fetal alcohol syndrome refers to a wide range of neuronal and extraneuronal anomalies that occurs in infants born to chronically alcoholic women.

Neuronal cell migration: In the developing brain, immature neurons migrate from their birthplace to their final destination. This active movement of immature neurons is essential for the formation of neuronal cytoarchitecture and proper differentiation. Excitatory neurons and inhibitory neurons originate from different regions of the brain, and exhibit different modes of migration.

Cerebellar granule cells: Cerebellar granule cells are glutamatergic excitatory interneurons, and the most abundant type of neurons in the mammalian brain. They receive synaptic input from the mossy fibers and Golgi cell axons, and send synaptic output to Purkinje cells, stellate cells, basket cells and Golgi cells.

Ca^{2+} spikes: Ca^{2+} spikes are transient increases of the intracellular Ca^{2+} levels of cells. The average frequency of Ca^{2+} spikes of migrating granule cells are 10–20 per hour. Alterations of frequency of Ca^{2+} spikes affect the speed of granule cell migration.

Speed of migration: Speed of migration is calculated by the total distance traveled by granule cells divided by the period of observation during the entire time-lapse session.

Key Facts of Neurological Features of Fetal Alcohol Syndrome (FAS)

1. FAS is one of the most common causes of mental retardation worldwide.
2. Microcephaly is present in nearly all cases of FAS.
3. Delayed neurologic development is in approximately 90% of cases of FAS.
4. Defects of speech and language development are evident in FAS.
5. The severity of the mental deficiency in FAS correlates most closely with the severity of the dysmorphic features. In one series, infants with the most severe dysmorphic manifestations of FAS had a mean IQ of 55, those with moderate manifestations had a mean IQ of 68, and those with mild manifestations had a mean IQ of 82.
6. Hypoplasias of the corpus callosum, the optic nerve and the cerebellum as well as hydrocephalus and abnormalities of the corticospinal tracts are common in FAS.

Chapter 183
Folate and the Effects of Prenatal Alcohol on the Brain

Yajun Xu and Jie Zhao

Abbreviations

BDNF	Brain-derived neurotrophic factor
BRFSS	Behavioral Risk Factor Surveillance System
CNS	Central nervous system
DNA	Deoxyribonucleic acid
dUMP	Deoxidized uridine monophosphate
dTMP	Deoxidized thymidine monophosphate
FAD	Flavine adenine dinucleotide
MS	Methionine synthetase
MTHF	Methyltetrahydrofolate
MTHFR	Methylenetetrahydrofolate reductase
RBC	Red blood cell
RNI	Recommended nutrient intake
RNA	Ribonucleic acid
SAH	S-adenosyl homocysteine
SAM	S-adenosyl methionine
THF	Tetrahydrofolate
TS	Thymidylate synthetase
UNG	Uracil DNA glycosylase
VB_{12}	Vitamin B_{12}

183.1 Introduction

Alcohol consumption during pregnancy can cause a wide array of disorders in the fetal brain, from subtle changes in intelligence to profound mental retardation (Sharpe et al. 2004). These effects can be manifested as severe damage in learning capabilities or impaired adaptation abilities for their environments. Prenatal alcohol exposure has become one of the leading causes of mental retardation in the Western world (Green 2007). On the severe end of the disorder spectrum is fetal alcohol syndrome

Y. Xu (✉)

e-mail: xuyajun@bjmu.edu.cn

(Sharpe et al. 2004), affecting from 1 to 7 per 1,000 live-born infants (Niccols 2007). The impairments in this syndrome are irreversible, therefore most people with fetal alcohol syndrome are not able to live independently (Sharpe et al. 2004), which causes a heavy load for their families and society.

Much effort has been made to prevent fetal alcohol syndrome, especially in western countries. In addition to avoiding drinking, other measures have also proved effective, such as folate supplementation. In this review, we focus on the impairment effects of prenatal alcohol exposure on the fetal brain and the protective effects of folate.

183.2 Prenatal Alcohol on Fetal Brain Development

183.2.1 Prenatal Alcohol Exposure

Alcohol is popular with people and there is no exception with women at the ages of childbearing. Recent data from the 2002 Behavioral Risk Factor Surveillance System (BRFSS) showed that more than half of women of childbearing age reported drinking alcohol, including an estimated 12.4% who reported binge drinking, which can be interpreted as no less than five drinks in the past month on any occasion (Centers for Disease Control and Prevention 2004). Alcohol is easily absorbed by stomach and intestines and quickly reaches the tissues through the blood circulation. The alcohol that mothers intake can transit the placenta into the fetus, which gives the infants exposure to alcohol before they are born. This is called prenatal alcohol exposure. Alcohol is a toxic agent which can cause oxidative stress on many embryonic tissues, especially the central nervous system (CNS), and is therefore a potent teratogen.

Although many studies have associated maternal alcohol consumption with birth defects, no definitive level of ingestion has been established as the threshold level beyond which congenital anomalies will result. Moreover, the perceived safety level of alcohol consumption during pregnancy has been lowered continuously as further studies have been conducted. Complete abstinence during pregnancy is recommended, because alcohol consumption in each trimester has been associated with abnormalities, and the lowest innocuous dose of alcohol is still not known.

183.2.2 Brain Malformation and Dysfunctions Caused by Prenatal Alcohol Exposure

The brain is one of the most susceptible organs to prenatal alcohol exposure. Fetuses exposed to alcohol during development can be born as children with a wide array of brain disorders, from subtle changes in intelligence to profound mental retardation (Sharpe et al. 2004), which can be understood as severe damage in learning capabilities or impaired adaptation abilities for their environments. Prenatal alcohol exposure has been previously reported to result in behavioral and cognitive deficits that continue into adulthood. These deficits are often manifested by poor performance on higher-order cognitive motor tasks, difficulties in maintaining postural balance, slower reaction times, and deficits in fine motor performance. The most severe disorder is called fetal alcohol syndrome, which is the sum of conditions that result from prenatal alcohol exposure, including microcephaly (defined as reduced brain weight relative to body weight), brain malformation and the impairment of behavior, intelligence, and cognition.

The mechanisms of brain damage induced by prenatal alcohol exposure are still not so clear. There are many hypotheses regarding this, such as alterations of neurotransmitters and receptors, brain-derived neurotrophic factor (BDNF), CNS cells and expressions of cell factors. In our researches, we found that the maturation of mitochondria in embryonic brain was affected by prenatal alcohol exposure (Xu et al. 2005a), and also that the expression of some of the mitochondrial protein was changed (Xu et al. 2005b), implying that drinking during pregnancy could further affect the oxidative phosphorylation function of mitochondrion, resulting in the lack of energy in fetal cerebral cells and finally the retardation of fetal cerebral development. As the fetal mice we selected were all without apparent brain malformations, our results suggested that the development of inner tissues may be disturbed even when the fetus seemed normal when born, and this is consistent with the clinical condition of children with fetal alcohol syndrome, most of whom have no defects in appearance, but have impairment of behavior when they are grown up.

183.3 Folate and Its Role in Human Health

183.3.1 Folate and Folic Acid

Folate is a water-soluble B-vitamin, also known as Vitamin B_9. Folate gets its name from the Latin word "folium" for leaf. In 1931, a researcher named Lucy Wills demonstrated that anemia in pregnancy could be corrected by using a yeast extract. Folate was identified as the corrective substance in yeast extract in the late 1930s, and was extracted from spinach leaves in 1941.

The name "folic acid" is widely acknowledged today, so what's the difference between folate and folic acid? Folate is the natural form of this vitamin existing in food; however folic acid is the man-made form of folate, which is also known as synthetic folic acid and often found in supplements and added to fortified foods. In January 1998, the US Food and Drug Administration introduced mandatory fortification of cereal-grain products with folic acid at a concentration of 140 µg/100 g (Food and Drug Administration 1996). In the UK, the Department of Health proposed fortification of flour with folic acid at 240 µg/100 g flour (Wright et al. 2001).

In fact, the bioavailability of folic acid is higher than that of folate; therefore, the dietary folate equivalent system was established: 1 µg dietary folate equivalent is defined as 1 µg of dietary folate, or 0.6 µg of folic acid supplement. This is reduced to 0.5 µg of folic acid if the supplement is taken on an empty stomach.

183.3.2 Physiological Functions of Folate

Folate is vital in the transferring of single carbon units in our bodies. It is reduced into tetrahydrofolate (THF) in intestinal mucous cells through twice reduction with the help of dihydrofolate reductase before entering the blood. THF is the active form of folate in our body, which can be transformed into methyltetrahydrofolate (MTHF), the carrier of single carbon units.

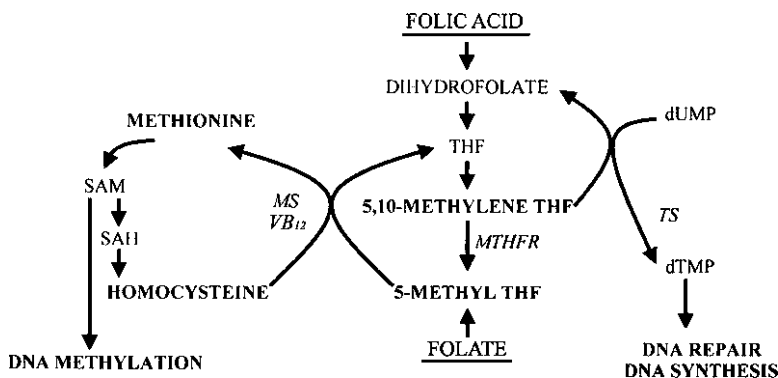
The metabolism of many substances important for life, including nucleic acid synthesis, amino acid metabolism and protein synthesis, can be affected in this way. Let us take two of the most important and well-accepted conversions, for example. One is that folate acts as a cofactor for enzymes that are essential in deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) synthesis by


Fig. 183.1 Key functions of folate in human body. The *left part* of the figure illustrates the processes of methionine synthesis and SAM-mediated methylations including DNA methylation, from which we can see that the synthesis of methionine depends on the methyl radical transfer mediated by 5-methyl-THF. The *right part* of the figure demonstrates the process of thymidylate synthesis which is related to DNA repair and synthesis and 5,10-methylene-THF is vital in the process. *dUMP* deoxidized uridine monophosphate, *dTMP* deoxidized thymidine monophosphate

providing single carbon units for the de novo synthesis of nucleotide bases. The other is that folate is required in the transfer of methyl groups in the amino acid methylation cycle, an essential step in the recycling of homocysteine back to methionine (Fig. 183.1). It is notable that the conversion of homocysteine into methiomine with the help of 5-methyl-THF which provides the methyl radical is the only way to make use of 5-methyl-THF in humans.

As the metabolic process of folate is easily saturated, large amounts of unreduced folate exist in the blood and urine when too much folate is ingested. THF, especially 5-methyl-THF, is the main form of existence in the blood. It reaches the liver through the portal circulation and turns into polyglutamate folate to store in the liver. When needed, polyglutamate folate in storage can be released into the bloodstream and decomposed into monoglutamate folate. This binds with the plasma protein and reaches the target tissues that need it for use.

183.3.3 Homocysteine

Homocysteine is derived from *S*-adenosyl homocysteine (SAH) that is formed after *S*-adenosyl methionine (SAM) has donated a methyl group to be used in many methylation reactions (including that of DNA). Homocysteine is then remethylated to methionine by methionine synthetase (MS), which requires Vitamin B_{12} (VB_{12}) as a cofactor, and 5-methyltetrahydrofolate (5-methyl-THF) as substrate (Fig. 183.2). 5-methyl-THF is formed by the action of the flavine adenine dinucleotide (FAD)-dependent enzyme 5,10-methylenetetrahydrofolate reductase (MTHFR). MTHFR is at a crucial metabolic point, directing 5,10-methylenetetrahydrofolate (5,10-methylene-THF) to homocysteine remethylation instead of toward the enzyme thymidylate synthetase (TS) and the creation of thymidylate for DNA de novo synthesis or repair.

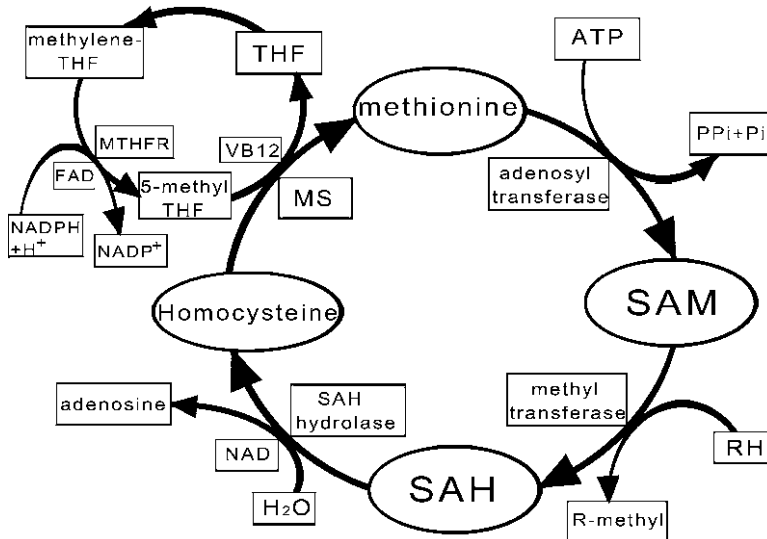
Homocysteine cannot turn into methionine if folate is deficient and so the homocysteine concentration in the body rises. Therefore, homocysteinemia can occur and disorders associated with homocysteine excess will be caused. Additionally, Vitamin B_{12} acts as the coenzyme in the reaction mentioned above and folate cannot fully play its role without it.


Fig. 183.2 Folate and methionine cycle. *MS* represents methionine synthetase. *RH* in the figure refers to biochemicals that can receive methyl group from SAM. For example, RH can be glycine and it changes to methyl-glycine after getting the methyl group from SAM which is denoted as R-methyl in the figure. The transformation of THF into methylene-THF is catalyzed by methylene-THF reductase which is not shown in the figure because of the lack of space. *VB₁₂* Vitamin B$_{12}$, *MTHFR* methylenetetrahydrofolate reductase

183.3.4 Absorption of Folate and Factors Affecting Its Concentration in the Body

In humans, folate is mainly stored in the liver, which is assumed to contain 50% of the normal total body folate content of 5–20 mg. Folate undergoes substantial enterohepatic recirculation, that is, much of the folate which undergoes biliary excretion is reabsorbed by the small intestine (Weir et al. 1985). However, the efficiency of this reabsorption may be influenced by dietary composition if digestion of foods happens to be occurring concurrently.

Naturally occurring dietary folate has a reduced pteridine ring and a polyglutamate polypeptide that must be hydrolyzed to a monoglutamate form before being absorbed by the intestinal cell. Fully oxidized folic acid is a synthetic form of folate and is found only in food that has been fortified with it. Folic acid is absorbed to a greater degree than the naturally occurring food folate (Johnson 2007). Intracellular folate concentrations are saturable and independent of excess exogenous folate supply and the threshold for intracellular folate accumulations is limited by the folate-binding capacity of the cell (Suh et al. 2001).

The absorption of folic acid can be influenced by a series of factors. For example, chronic alcoholism is often associated with impaired folate status. Intestinal malabsorption is one of the reasons for ethanol-induced folate deficiency. In addition, the use of oral contraceptive agents has been associated with low serum and red blood cell (RBC) folate levels in women 20–44 years of age. The use of anticonvulsant drugs, such as primidone and carbamazepine, also has an impact on tissue folate concentrations in rats (Suh et al. 2001).

183.3.5 Genetic Aspects of Folate Metabolism

As mentioned above, the enzyme MTHFR has received much attention in recent years because a thermolabile enzyme variant inherited as an autosomal recessive trait, later identified as a 677 C→T mutation resulting in an alanine to valine substitution, was found associated with increased plasma homocysteine levels and possible increased risk of cardiovascular disease. The MTHFR enzyme is involved directly in VB_{12}-dependent remethylation of homocysteine to methionine in which it provides the 5-methyl-THF necessary for this methylation. It is a crucial enzyme as it can direct the folate pool towards homocysteine remethylation at the expense of DNA and RNA biosynthesis. MTHFR is also flavin-adenine dinucleotide, a co-enzyme of VB_2 (riboflavin), dependent. The prevalence of the MTHFR 677 C→T variant, which results in an enzyme activity of about 50% of the normal value, and has distinctive thermolability under specific conditions of heat inactivation (Kang et al. 1991), is related to ethnicity: the frequency of homozygosity for the T allele (abnormal TT genotype) is relatively high throughout the world, around 10–15% in the UK, 20–30% in some Italian populations but only a few percent in Afro Americans (Schneider et al. 1998).

183.3.6 The Role of Folate in Reproduction and Development

Folate is necessary for fertility in both men and women. In men, it contributes to spermatogenesis. In women, it contributes to oocyte maturation, implantation and placenta formation. It is most important for women who may become pregnant since it is necessary for the production and maintenance of new cells, especially important during periods of rapid cell division and growth such as the embryonic stage. It has been shown that some kinds of birth defects are closely related to folate deficiency (Czeizel and Dudas 1992; Bailey et al. 2003), such as neural tube defects, congenital heart diseases, cleft lip, palate, etc. (Czeizel and Dudas 1992; Bailey et al. 2003;Cogswell et al. 2003). Among these, the relationship between folate deficiency and neural tube defects was first defined. Neural tube defects are usually separated into two main categories: (1) malformations of the spine (meningomyelocele or spina bifida) and (2) abnormalities of the skull and brain (anencephaly, acrania, and encephalocele). In spina bifida, the fetal spinal column does not close completely during the first month of pregnancy. There is usually nerve damage that causes at least some paralysis of the legs. In anencephaly, much of the brain does not develop. Babies with anencephaly are either stillborn or die shortly after birth. Investigations around the world have indicated that periconceptional supplementation with folic acid is able to decrease the rates of neural tube defects. As a result of this supplementation, a 19% reduction of neural tube defects prevalence occurred (Honein et al. 2001).

Another birth malformation associated with folate is Down's syndrome, which is the most common genetic cause of human mental retardation, with an incidence of approximately 1 in 600–1,000 live births (Zintzaras 2007). Down's syndrome has been linked with the abnormal metabolism of homocysteine, which is led by variants in a critical folate metabolizing enzyme. A thermolabile variant of MTHFR has been described in which a cytosine-to-thymine nucleotide (C677T) occurs, causing relatively reduced enzyme activity.

183.3.7 Folate Deficiency–Related Mental Diseases

Serum levels fall within days when intake is diminished, and as body stores are relatively low, folic acid deficiency can develop within 1–6 months, dependent upon nutritional status and the rate of utilization (Paul et al. 2004).

Folate deficiency and resultant increased homocysteine levels have been linked experimentally and epidemiologically with neurodegenerative conditions like stroke and dementia. Moreover, folate deficiency has been implicated in the pathogenesis of psychiatric disorders, most notably depression (Kronenberg et al. 2008). However, Balk et al. (2006) reported that deficiencies in Vitamins B_1 or folate generally cause neurological dysfunction, and supplementation with B_6, B_{12}, or folate may improve neurocognitive function in animal studies, but their effects are unclear in human studies. Overall, studies do not support an association between B vitamin status and age-related neurocognitive disorders (Balk et al. 2006) but the causal relationship between folic acid deficiency and neural tube defects is widely accepted and that is why mandatory folic acid supplementation is enforced in some countries.

183.3.7.1 Cognitive Impairments

Researchers have shown that low blood folate and raised homocysteine concentrations are associated with poor cognitive function. Folic acid supplementation is beneficial in improving cognitive function (D'Anci and Rosenberg 2004; Das 2008). However, Ellinson et al. (2004) pointed out that the present evidence did not support a correlation between serum VB_{12} or folate and cognitive impairment in people aged over 60 years and there is little evidence to justify treating cognitive impairment with VB_{12} or folate supplementation.

183.3.7.2 Schizophrenia

Psychiatric disorders are common among the elderly. The overall prevalence of depression in the USA is approximately 17% for women and 10% for men, and is increased more than twofold in individuals over the age of 65 (Mattson et al. 2002). The hypothesis that folic acid plays a role in the predisposition toward schizophrenia is biologically plausible, as folate levels have been shown to be involved in neurodevelopmental processes (Picker and Coyle 2005). Folate deficiency and subsequent elevated homocysteine levels increased the risk of schizophrenia, whereas risk was not increased in individuals with low folate levels, but normal homocysteine levels, indicating that the association between folate deficiency and schizophrenia may be caused by the alteration of homocysteine level induced by folate deficiency (Mattson et al. 2002). However, some researchers pointed out that folate deficiency has been associated with schizophrenia in affected patients independent of other factors such as homocysteine. But at the fetal stage, folate deficiency appears to exert its teratogenic effect primarily through elevating plasma homocysteine (Picker and Coyle 2005). Although the mechanism is still unclear and more research is needed to support the results mentioned above; the potential role of maternal folate deficiency and hyperhomocystinemia in the genesis of schizophrenia would extend the range of their known teratogenic effects and folate supplementation may benefit many psychiatric patients (Mattson et al. 2002).

183.3.7.3 Depression

Folate deficiency has been implicated in the pathogenesis of psychiatric disorders, most notably depression (Kronenberg et al. 2008). There is now substantial evidence of a common decrease in serum/red blood cell folate, serum VB_{12} and an increase in plasma homocysteine in patients with depression (Coppen and Bolander-Gouaille 2005). Deficits of both folate and VB_{12} are associated with a greater risk of depression during adulthood (Black 2008). Some studies have confirmed the

link between folate deficiency and depression and have provided evidence for a mechanism involving homocysteinemia and altered methylation reactions (Mattson et al. 2002). Furthermore, the MTHFR C677T polymorphism that impairs the homocysteine metabolism is shown to be overrepresented among depressive patients, which strengthens the association (Coppen and Bolander-Gouaille 2005).

However, another study showed that serum and red blood cell folate levels were associated with depression in younger individuals, but the relationship was less clear in older people (D'Anci and Rosenberg 2004).

A large literature has documented a role for folate in modifying the symptoms of depression (Mattson et al. 2002; Morris 2002). Among depressed patients, higher folate status has been linked to shorter and less frequent, depressive episodes as well as a better antidepressant response, while folate deficiencies may lead to poorer antidepressant treatment outcomes (Mischoulon and Raab 2007). Although it is unclear at present whether low folate status causes depression, antidepressant trials have demonstrated the benefits of higher folate status or folate supplementation relative to decreasing symptoms in depressed patients undergoing antidepressant therapy (Morris 2002).Therefore, it is suggested that oral doses of both folic acid (800 μg daily) and VB_{12} (1 mg daily) should be tried to improve treatment outcomes in depression (Coppen and Bolander-Gouaille 2005)

183.3.8 Possible Mechanism of Folic Acid on Mental Diseases

Black (2008) summed up that disruptions to myelination and inflammatory processes were the two possible mechanisms that associated folic acid or VB_{12} deficiency with abnormal behavior and development in infants. In the meantime, variants of several genes of folate-related metabolic pathways have been found to be significantly associated with the risk of neural tube defects in many studies (De Marco et al. 2006). Kronenberg et al. (2008) showed that whereas folate deficiency alone did not confer a clearly despair-like phenotype, folate-deficient mice lacking uracil DNA glycosylase (UNG) demonstrated significantly increased immobile time and reduced latency to float, indicating that impaired uracil repair was involved in neurodegeneration and neuropsychiatric dysfunction induced by experimental folate deficiency (Table 183.1).

Table 183.1 Key facts of folate and/or folic acid

1. Folate is a water-soluble B-vitamin. It is the natural form of this vitamin existing in food. Folic acid is the man-made form of folate and often found in supplements and added to fortified foods.

2. The bioavailability of folic acid is higher than that of folate; therefore, a dietary folate equivalent system was established.

3. The metabolisms of many processes important for life, including nucleic acid synthesis, amino acid metabolism and protein synthesis, can be affected by folate.

4. Folate is necessary for fertility in both men and women. In men, it contributes to spermatogenesis. In women, it contributes to oocyte maturation, implantation and placenta formation.

5. The absorption of folate/folic acid can be influenced by a series of factors, such as chronic alcoholism.

6. Maternal folate deficiency is related to fetal birth defects, especially neural tube defects.

7. Folate deficiency and resultant increased homocysteine levels have been linked with the pathogenesis of psychiatric disorders such as depression, and neurodegenerative conditions like stroke and dementia.

This table lists the key facts of folate/folic acid including the difference between folate and folic acid, roles of folate and/or folic acid in human metabolism, reproduction and development, and metal disorders related to folate/folic acid deficiency

183.4 Folic Acid Supplementation on Prenatal Alcohol Exposure Impairments

183.4.1 Folic Acid and Prenatal Alcohol Exposure

Investigations (Muldoon and McMartin 1994; Halsted et al. 2002) have indicated that alcohol exposure impairs folate absorption by inhibiting the expression of reduced folate carrier and decreasing the hepatic uptake and renal conservation of circulating folate, resulting in decreased serum folate levels. One of our studies (Xu et al. 2006a) has also shown that alcohol exposure during pregnancy caused a significant increase of maternal serum homocysteine, which might be responsible for brain malformations related to prenatal-alcohol-exposure, and folic acid supplementation during the organogenesis period showed protective effects against prenatal alcohol exposure. Our study (Xu et al. 2008) also indicated that folic acid supplementation could reverse the expression of alcohol-altered proteins related to energy production (some of which were mitochondria origin), signaling pathways and protein translation in the fetal brain, which were all important for embryonic development. This might explain the probable pathway through which folic acid functioned against alcohol's teratogenic action on fetal brain. Another study (Wang et al. 2009) demonstrated a suppression of ethanol-induced teratogenesis by folic acid supplementation, accompanied by a down-regulation of miR-10a expression and miR-10a has been found to be significantly up-regulated in the fetal mouse brain after prenatal ethanol exposure in this study.

As we mentioned above, folic acid plays an important part in the amino acid methylation cycle, an essential step in the recycling of homocysteine back to methionine as well as DNA and RNA synthesis because of its role in the transfer of single carbon units. The requirements of nucleic acid and protein synthesis are at their peak during the stages of embryogenesis and rapid fetal growth, so the demand for folic acid increases during pregnancy. However, alcohol ingestion inhibits folic acid absorption and oxidizes the pteridine ring of folic acid which may lead to folic acid deficiency (Suh et al. 2001).When folic acid deficiency reaches a certain degree, inhibition of the methylation cycle might impair the synthesis and function of specific proteins. This may contribute to the decreased expression of some proteins including the mitochondrial proteins found in our research (Xu et al. 2008). However, when enough folic acid is supplemented, the organic nucleic acid and protein synthesis can return to physiologic levels, therefore the malformation and dysfunction caused by alcohol can be reversed. In addition, folic acid may also play a role in the regulation of gene expression to change the expressions of enzymes or other proteins vital in brain development, which are altered by prenatal alcohol exposure (Wang et al. 2009). Also, folic acid deficiency can induce the increased level of homocysteine which can also be the cause of damage. Animal experiments showed that concurrent folic acid administration prevented homocysteine effects, possibly by its antioxidant and DNA stability maintenance properties (Matté et al. 2009) (Fig. 183.3).

183.4.2 Combined Effect of Folic Acid and VB_{12} on Prenatal Alcohol Exposure

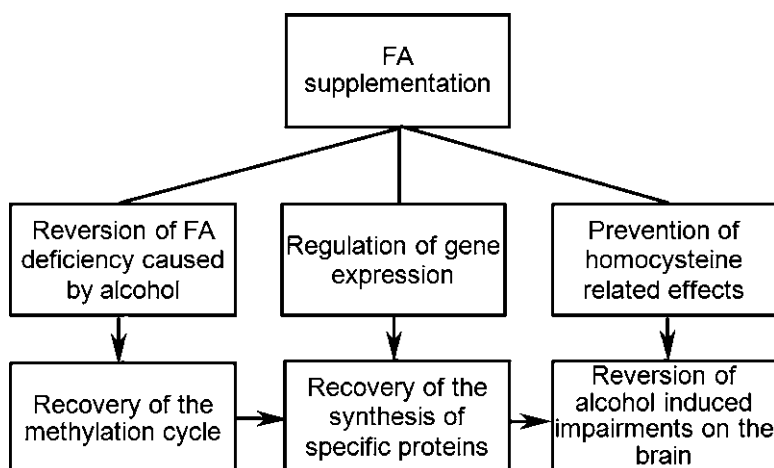
An interesting phenomenon found in our studies (Xu et al. 2006a, b) was that folic acid and VB_{12} together could protect mouse embryos against ethanol-induced development toxicity better than folic acid alone at relatively low concentrations, both in vitro and in vivo. Since folic acid and VB_{12} are metabolically interdependent (see Fig. 183.1), additional supplementation of VB_{12} may enhance


Fig. 183.3 Possible mechanisms of the antagonism of folic acid supplementation against prenatal alcohol exposure induced impairments. Three possible mechanisms of the antagonism of folic acid supplementation against prenatal alcohol exposure induced impairments which are mentioned in the text are illustrated in the figure. However, the exact mechanisms are not so clear at present

the utilization and biologic effects of folic acid. As a result, the embryonic DNA, RNA and protein synthesis might be enhanced, which could better make up the losses caused by ethanol toxicity. Also, the process of DNA methylation might be enhanced, which could suppress the expression of mutated genes caused by ethanol exposure, thereby decreasing the incidence of malformations.

183.5 The Recommended Intake of Folate and Food Resources

183.5.1 The Recommended Intake of Folate

Since the discovery of the link between insufficient folate and neural tube defects, governments and health organizations worldwide have made recommendations concerning folic acid supplementation for women intending to become pregnant. The recommended nutrient intake (RNI) for men and women from the age of 14 years to over 70 years is 400 µg dietary folate equivalent, which is equal to 400 µg of folate in natural foods or about 240 µg of folic acid in fortified foods (Johnson 2007). For women planning to conceive or those already pregnant and lactating mothers, the RNI is 600 and 500 µg dietary folate equivalent, respectively (Table 183.2). There has been some concern about the interaction between VB_{12} and folic acid. Folic acid supplements can correct the anemia associated with VB_{12} deficiency. Unfortunately, folic acid will not correct changes in the nervous system that result from VB_{12} deficiency. Permanent nerve damage could theoretically occur if VB_{12} deficiency is not treated. Therefore, intake of supplemental folic acid should not exceed 1,000 micrograms (1,000 µg or 1 mg) for adults aged 19 years and older, and 800 µg for pregnant and lactating women less than 18 years of age per day to prevent folic acid from masking symptoms of VB_{12} deficiency.

However, women who have had one pregnancy affected by a birth defect of the brain or spine are recommended to take 4,000 µg (4.0 mg) of folic acid each day at least 1 month before getting pregnant and during the first few months of being pregnant (Table 183.2). This is ten times the amount of

Table 183.2 Recommended intake of folate for different subjects

Subjects	RNI (µg dietary folate equivalent)
People from 14 to over 70 years old	400
Women planning to conceive or already pregnant	600
Lactating mothers	500
Women who had one pregnancy affected by a birth defect of the brain or spine	4,000 micrograms of folic acid each day at least 1 month before getting pregnant and during the first few months of being pregnant

Dietary folate equivalent is defined as 1 µg of dietary folate, or 0.6 µg of folic acid supplement. Folic acid listed in the last row refers to folic acid supplements

Table 183.3 Folate content in common food (µg/100 g)

Food	Folate content
Liver (pig)	236.4
Liver (chicken)	80.0
Spinach	347.0
Red amaranth	330.6
Tomato	132.1
Lettuce	49.6
Badish	22.5
Bean curd	66.1
Dried bean curd	57.9
Citrus	52.9
Banana	29.7
Strawberry	33.3
Peanut	104.9
Rice	32.7
Flour	24.8

This table lists some foods commonly available in different countries or areas. There is usually a slight difference in folate content in the listed food because the values can be influenced by food varieties, growing areas, seasons, measuring methods and so on

RNI for the general population. Studies have shown that the risk of neural tube defects is significantly reduced when supplemental folic acid is consumed in addition to a healthy diet prior to and during the first month following conception (Honein et al. 2001; Picker and Coyle 2005).

183.5.2 Food Resources of Folate

Unlike most bacteria and yeast, mammals cannot synthesize folate in vivo, and therefore require folate in the diet (Suh et al. 2001). Luckily, folate exists widely in foods from plants and animals. It is richly present in green leafy vegetables such as spinach, turnip greens, lettuces, dried beans and peas, citrus fruits, fortified cereal products, sunflower seeds, and certain other fruits and vegetables. Liver and liver products also contain high amounts of folate, as does baker's yeast (Table 183.3).

183.5.3 Folate Loss in Storage and Cooking Process

Folate is easily broken down by heat, light, and acid; therefore, it can be lost from foods during storage, preparation, or cooking. Long storage time at high temperatures, boiling the vegetables, washing vegetables after slicing, immersion in water for a long time and heating the leftover dishes repeatedly can all cause great loss of folate in vegetables.

The following will help preserve folate in foods as much as possible:

- Store vegetables and fruits in cool temperatures or in a refrigerator
- Wash vegetables before slicing them
- Cook with high heat for only a short time
- Steam or boil vegetables in a minimal amount of water
- Do not heat leftover dishes repeatedly
- Serve fruits and vegetables raw whenever possible

Of course, the best way to preserve folate in vegetables is to take them raw, but the problem of food hygiene arises at the same time. Folate-fortified foods, such as bread and flour, may meet the needs of both nutrition and food hygiene. Taking folate supplements according to biological need is also an option.

Interestingly, there are some ways to enrich the folate content of some kinds of foods, especially staple foods, which have been adopted in many countries. Studies indicate that the process of fermentation with yeast can somehow increase the total folate content in bread to more than that in the original flour (Osseyi et al. 2001; Kariluoto et al. 2004). Gujska and Majewska (2005) found that for both wheat and rye bread products, there was a 12% and 21% decrease of added folic acid from flour to bread stage, respectively, but there were almost no changes in the total endogenous folate content. This has confirmed some conclusions obtained by earlier studies that folate is produced during the leaving of dough with baker's yeast.

183.6 Supplementation with Folic Acid: Arguments Continue

Supplementation of pregnant human mothers with folate significantly decreases the incidence of developmental defects, including neural tube defects, conotruncal heart defects and cleft lip/palate (Picker and Coyle 2005). The results of Das (2008) suggested that a combination of eicosapentaenoic acid, docosahexenoic acid, arachidonic acid, and folic acid could be of significant benefit in dementia, depression, Alzheimer's disease, and impaired cognitive functions.

One big problem is whether or not we should use folic acid-fortified foods. In the USA and Canada, after folic acid fortification, the estimated total intake is approximately 800 μg/day for those taking multivitamins containing folic acid and this number may be an underestimation (Kim 2007). Although the toxicity of high folate levels in the body is unclear, there are many concerns about it. For one thing, folic acid supplementation and fortification may promote the progression of already existing undiagnosed preneoplastic and neoplastic lesions (Kim 2007). For another, high levels of folic acid may exacerbate the neurological consequences of a VB_{12} deficiency (D'Anci and Rosenberg 2004).

Besides the problem of supplementation amounts, when and how to supplement are also the focus of research. Some researchers (Morris 2002) presented that the greatest effects of folate supplementation occur in those with the lowest folate concentrations and the highest homocysteine levels. The current recommendation is to take extra folate, not just food fortification, through the first trimester of pregnancy, but this recommendation is seriously inadequate if folate and homocysteine are involved in disrupting neurodevelopment during the second trimester (Picker and Coyle 2005).

It has been reported that it may be more effective to supplement with methyltetrahydrofolate, which is the active form of folate and more readily absorbed, for the prevention and treatment of both depression and dementia (Mischoulon and Raab 2007).

To sum this up, the evidence to support supplementation with folic acid is not clear and some scientists are cautious on the subject (Morris 2002). There are still arguments on whether or not to supplement with folic acid during pregnancy or in elderly people, as well as how and when to do it to be beneficial. As a result, more research regarding this is needed.

183.7 Prevention of Prenatal-Alcohol-Exposure-related Abnormalities

Since prevention is of the greatest importance in our lives, current medical guidelines recommend that no alcohol should be consumed over the period of conception and throughout pregnancy (Tough et al. 2006). A study on prenatal alcohol exposure (Abate et al. 2008) also demonstrated that there was no so-called safe dose of alcohol ingestion. Low to moderate levels of prenatal ethanol exposure do not generate evident morphologic or neurobehavioral alterations in the offspring, but they exert a significant impact upon later ethanol-seeking and intake behaviors.

Since there is no safe dose, is there a safe period for drinking alcohol during the pregnancy? The answer is no to either. Although it has been found that prenatal alcohol exposure causes damage to the development of the brain at specific times in both animal studies and epidemiological results, agreement on the precise critical exposure time has not been agreed upon by scientists. The results of a birth cohort study (Sun et al. 2009) have also indicated that the association between prenatal ethanol exposure and the occurrence of some types of seizures reflecting underlying brain dysfunction is only observed from the 11th to the 16th week of gestation. Another review (Guerri et al. 2009) has shown that alcohol affects the embryonic stage of gastrulation and the ontogenetic stages of brain development that occurs in humans from the 7th to the 20th week of gestation. In conclusion, the most sensible behavior is to be far away from alcohol for the whole duration of a pregnancy.

There are still problems concerning alcohol intake in pregnancy. For example, the majority of women reduce alcohol consumption when they realize they are pregnant, but this recognition may not occur until well into the first trimester, potentially impacting embryonic development (Tough et al. 2006). There are also data revealing that a large proportion of women are not changing their drinking behaviors when pregnant, including the average amount of alcohol consumed per occasion while trying to conceive, thus putting their developing child at risk for alcohol exposure during the early stages of embryonic development (Tough et al. 2006).Taking all the problems above into consideration, we can see that the prevention of impairments that prenatal alcohol exposure causes is easier said than done and more attention and efforts are needed to do this.

183.8 Applications to Other Areas of Health and Disease

Supplementation with folic acid may reverse some of the effects of ethanol toxicity on the brain, which has been illustrated in detail above. In fact, the benefits of folic acid supplementation are much broader than that. Folate deficiency in adults can increase the risk of coronary artery disease, stroke, several types of cancers, and possibly Alzheimer's and Parkinson's diseases (Mattson et al. 2002). Folate supplementation may be of benefit for the treatment of these diseases but consensus regarding this has not been reached.

183.8.1 Cancers

Animal models of carcinogenesis have suggested that folate deficiency facilitates cancer formation, according to the results of case-control studies (Mattson et al. 2002). Folate may be helpful for the prevention of breast and cervical cancers. The occurrence of neoplastic processes, such as acute lymphoblastic leukemia in children is also likely to be associated with folate supplementation, but it remains to be confirmed (Eichholzer et al. 2006). Although folate appears to be preventive in the development of new cancers in persons without preexisting premalignant lesions, folic acid supplementation and fortification may promote the progression of already existing, undiagnosed preneoplastic and neoplastic lesions (Cornel et al. 2005; Kim 2007). However, the present research is not conclusive; hence, whether or not folic acid promotes the progression of cancer is still not clear. Long-term follow-up studies are warranted to determine the effect of folic acid on the incidence of cancer and on DNA methylation and other epigenetic regulatory mechanisms (Cornel et al. 2005).

183.8.2 Cardiovascular Disease and Stroke

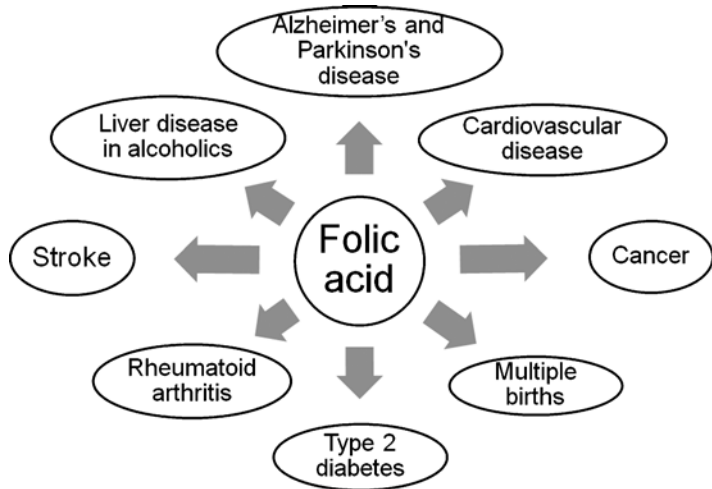
Folate deficiency may induce increased levels of homocysteine. The association between hyper-homocysteine and atherosclerotic cardiovascular disease has been found in populations with different genetic backgrounds and lifestyles. Possible links between homocysteine metabolism and stroke have been examined and animal studies support a cause–effect relationship between elevated homocysteine levels, vascular pathology and stroke (Mattson et al. 2002). 5-methyltetrahydrofolic acid (5-MTHF), when given intra-arterially, not only improved flow-mediated dilatation without altering plasma homocysteine concentrations but also abolished homocysteine-induced increases in intracellular superoxide generation, thus is beneficial for cardiovascular diseases (Das 2003; Eichholzer et al. 2006).

183.8.3 Multiple Births

The results of research have shown an increase in twinning rates associated with the use of multivitamin supplements containing folic acid. Positive associations may in part be explained by residual confounding of in-vitro fertilization and ovarian stimulation, or by the effect of other vitamins in the multivitamins consumed (Eichholzer et al. 2006). Although the available evidence is not conclusive, a large study from China, which included many young mothers and where the use of ovarian stimulation is not common, did not show an increased risk of twinning after periconceptional folic acid use (Cornel et al. 2005).

183.8.4 Type 2 Diabetes

Studies showed that homocysteine levels are also associated with exacerbation of type 2 diabetes, rheumatoid arthritis and some other vascular events (Mattson et al. 2002). In addition, it is likely that elevated homocysteine levels, which can be induced by folate deficiency, contribute to the various organic pathologies in alcoholics, including liver disease, and cognitive and motor dysfunction (Mattson et al. 2002) (Fig. 183.4).

Fig. 183.4 Applications of folate to other diseases. Although the association between folate and the diseases listed here remains to be confirmed, it provides new insights into the studies of mechanisms and the treatment of these diseases


Summary Points

- Alcohol consumption during pregnancy, which is also termed as prenatal alcohol exposure, can cause a wide array of disorders in the fetal brain, from subtle changes in intelligence to profound mental retardation. The mechanisms of prenatal alcohol exposure induced brain damage are still not clear.
- Folate is a water-soluble B-vitamin, which is the natural form of this vitamin existing in food. Folic acid is the man-made form of folate, which is also known as synthetic folic acid and is often found in supplements or added to fortified foods.
- Chronic alcoholism is associated with impaired folate status and excess ethanol intake is often associated with folate deficiency. Folic acid administration during pregnancy shows protective effects against prenatal alcohol exposure induced brain malformation or mental disorders.
- Folate/Folic acid is vital in the transferring of single carbon units in our body, which is important for the metabolism of many substances, including nucleic acid synthesis, amino acid metabolism and protein synthesis. Since folic acid and VB_{12} are metabolically interdependent, additional supplementation of VB_{12} may enhance the utilization and biologic effects of folic acid.
- A dietary folate equivalent system is identified since the bioavailability of folic acid is higher than that of folate. The recommended nutrient intake (RNI) for men and women from the age of 14 years to over 70 years is 400 µg dietary folate equivalent.
- Foods that are rich in folate content are green leafy vegetables, dried beans and peas, citrus fruits, fortified cereal products, sunflower seeds and certain other fruits and vegetables. Liver and liver products also contain high amounts of folate, as does baker's yeast.
- Folate is easily inactivated by heat, light and acid, therefore can be lost from foods during storage, preparation or cooking. However the process of fermentation with yeast can somehow increase total folate content in breads to levels greater than the original flour.

Definitions and Explanations

Fetal alcohol syndrome: the sum of conditions that result from fetal alcohol exposure, including brain malformations and the impairment of behavior, intelligence, cognition, etc.

Mental retardation: severe damage in learning capabilities or adaptation abilities for environments.

Neural tube defects: serious birth defects of brain and/or spine due to the failure of the neural tube to close completely during fetal development, induced by folic acid deficiency, resulting in anencephaly and spina bifida.

Prenatal alcohol exposure: the behavior of drinking during pregnancy inducing alcohol exposure of children before they are born.

Recommended nutrient intake: This value is a goal for individuals; it is the daily dietary intake level that is sufficient to meet the nutritional requirements of 97–98% of all healthy individuals in a population.

Tetrahydrofolate: the active form of folate in the body. Folic acid that we intake is first transformed into tetrahydrofolate before becoming active in the body. A cycle exists between tetrahydrofolate and methyl-tetrahydrofolate, which is the provider of one-carbon units.

Chapter 184
Decreased Appetite for Food in Alcoholism

Anna Kokavec

Abbreviations

ADX	Adrenalectomy/Adrenalectomized
ARC	Arcuate nuclei located in the hypothalamus
DHEAS	Dehydroepiandrosterone sulphate
GABA	γ-aminobutyric acid
GABA$_A$	γ-aminobutyric acid receptor/chloride ionophore
HPA	Hypothalamic-pituitary-adrenal axis
K$^+$	Potassium ion
mRNA	Messenger ribonucleic acid
Na$^+$	Sodium ion
NMDA	*N*-methyl-D-aspartate
NPY	Neuropeptide Y
PVN	Paraventricular nuclei located in the hypothalamus

184.1 Introduction

Alcohol consumption can induce the development of nutritional disorders as alcohol ingestion often replaces food intake (Orozco and De Castro 1991). While alcohol contains a large number of calories, these calories are classed as 'empty' calories because alcohol contains little nutritional value (Pirola and Lieber 1972). Alcoholic beverages may account for up to 50% of the total calorie intake in chronic alcoholics, which over time can lead to the development of a severely malnourished state (Lieber 1991). The nutritional content of alcoholic beverages is presented in Table 184.1.

Assessment of the behavioural effects of alcohol on appetite has often included some investigation of meal size (e.g. Strbak et al. 1998) and meal composition (e.g., Colditz et al. 1991). It appears that while short-term alcohol intake has little effect on meal size (Poppitt et al. 1996), long-term alcohol consumption can decrease the total amount of food consumed when food is freely available

Table 184.1 Nutritional breakdown of alcoholic beverages[a]

	Light beer (285 ml)	Regular beer (285 ml)	Red wine (120 ml)	White wine (120 ml)	Spirits (30 ml)
Calories	47	105	80	75	66
Kilojoules	195	440	335	315	275
Carbohydrate (g)	6	8	0	1.5	0
Protein (g)	.8	.8	0	0	0
Fat (g)	0	0	0	0	0
Cholesterol (g)	0	0	0	0	0
Sodium (mg)	43	43	12	12	0
Potassium (mg)	42	42	Unknown	Unknown	0
Calcium (mg)	28.5	28.5	12	12	0
Iron (mg)	0	0	.4	.4	0

[a] Figures shown may vary between manufacturers

This table lists the nutritional breakdown of the most common commercially available alcoholic beverages. The nutritional content of the common alcoholic beverages is not the same. Spirits and white wine contain virtually no nutritional benefit to the individual, while on the other hand beer not only contains carbohydrate but also a large amount of salts

(Strbak et al. 1998). Further assessment of meal composition has highlighted that moderate–heavy alcohol drinkers when compared to controls consume significantly less food containing carbohydrate (Colditz et al. 1991), and more food containing fat and protein (Herbeth et al. 1988), and fat and salt (Caton et al. 2004).

The aim of this chapter is to explore the importance of this very specific alcohol effect (i.e. decrease in appetite for carbohydrate). In the next few sections evidence from a number of human studies conducted in our laboratory will be provided in order to highlight that a decreased appetite for carbohydrate may be a physiological *consequence* of alcohol consumption.

184.2 Alcohol as an Energy Source

184.2.1 Alcohol Pharmacology

Alcohol contains a high number of calories, but how the body uses energy from these calories is very complex. Animal studies have shown that alcohol lacks some characteristics of a nutrient in that alcohol does not promote optimum growth (Guthrie et al. 1990). Similarly, human data has confirmed that when alcohol is substituted for other food stuffs (e.g. carbohydrates) on a calorie-by-calorie basis, alcoholic individuals lose rather than gain weight (Colditz et al. 1991).

Alcohol is the end product of sugar metabolism formed from pyruvate in yeast and other microorganisms. The conversion of glucose to alcohol is an anaerobic process termed *alcoholic fermentation* and the sequence of reactions involved in the conversion of glucose to alcohol begins with the conversion of glucose into pyruvate. Pyruvate is then decarboxylated in a reaction catalyzed by pyruvate decarboxylase to form acetaldehyde, which in turn is reduced to alcohol by reduced nicotinamide adenine dinucleotide in a reaction catalyzed by alcohol dehydrogenase. When alcohol enters the body, alcohol dehydrogenase, with oxidized nicotinamide adenine dinucleotide acting as cofactor, converts alcohol to acetaldehyde and nicotinamide adenine dinucleotide in the liver. As the initial reduction of pyruvate to acetaldehyde is a nonreversible step, acetaldehyde rather than being converted back to pyruvate, is converted to acetate by aldehyde dehydrogenase, primarily in the mitochondria, before final oxidization into carbon dioxide and water (Berg et al. 2007).

184.2.2 Is Alcohol a Food?

In the past, we have drawn attention to the fact that alcohol may not be a food for the human body (for review see Kokavec and Crowe 2002). The known human energy systems are not able to utilize alcohol as an energy source because pyruvate cannot be produced from alcohol. In contrast, plants and anaerobic organisms are able to utilize the stored energy in alcohol via activation of the glyoxylate cycle, a gluconeogenic pathway responsible for the conversion of fat into carbohydrate. The human citric acid cycle and glyoxylate cycles at first appear similar. However, a major difference between the two energy pathways is that the glyoxylate cycle omits the steps in the citric acid cycle, which require activation of thiamine-dependent enzymes (Berg et al. 2007).

When alcohol enters the body, the ability of cells to maintain the store of thiamine is severely compromised (Zimatkin and Zimatkina 1996). Furthermore, extended periods of alcohol consumption can cause thiamine deficiency (Martin et al. 1985), even in well-nourished individuals (Rathanaswami and Sundaresan 1991). Thus, given that thiamine is required for the biosynthesis of insulin and alcohol can promote thiamine deficiency (Rathanaswami and Sundaresan 1991; Zimatkin and Zimatkina 1996), an alcohol-induced decrease in insulin may occur when alcohol is consumed alone after food (Kokavec and Crowe 2003).

The glyoxylate cycle may have a role in intermediary metabolism in the human liver. The key enzymes associated with the glyoxylate cycle can become active in the human liver after 3–4 days' fasting (Masters 1997), allowing lipid to be converted into carbohydrate. Thus, under conditions where activation of the glyoxylate pathway occurs, a decreased appetite for carbohydrate would also be expected.

184.2.3 Effect of Alcohol on Appetite for Carbohydrate

Investigations have shown that appetite for carbohydrate is hormonally regulated and largely dependent on the efficient performance of cortisol, a steroid under the control of the hypothalamic-pituitary-adrenal (HPA) axis, and insulin a pancreatic peptide hormone. Moreover, the effects of cortisol and insulin may be mediated through the regulation of hypothalamic neuropeptide Y (NPY), a 36-amino sequence pancreatic polypeptide, synthesis and release (Strack et al. 1995). A low–moderate level of cortisol stimulates appetite (Cohn et al. 1955) by promoting NPY release (Dean and White 1990), which in turn promotes insulin release (Rebuffe-Scrive et al. 1992) in order to stop feeding (Woods and Porte 1975).

NPY-induced feeding behaviour in the PVN appears to specifically increase carbohydrate intake (Stanley and Leibowitz 1984), and a lack of glucocorticoids by inhibiting NPY release in the PVN notably decreases carbohydrate intake (Tempel and Leibowitz 1989). Cortisol can increase the transcription rate of NPY mRNA (Dean and White 1990) and a sufficient release of cortisol may be necessary for NPY-stimulated insulin release (Wisialowski et al. 2000). NPY is synthesized by neurons in the hypothalamic arcuate nucleus (ARC) and while these neuronal axons can project to a number of areas (O'Donohue et al. 1985), projections to the paraventricular nuclei (PVN) have been strongly associated with stimulation of feeding (Muroya et al. 1999).

Fasting promotes an elevation in glucocorticoids and NPY gene expression (Hanson et al. 1997). In contrast, the level of insulin in nondiabetic individuals is reduced. Insulin acts locally to inhibit NPY gene expression in the ARC (Schwartz et al. 1992a) and a decrease in food intake is observed with insulin and adrenalectomy (ADX) due to a reduction in ARC NPY mRNA levels (White et al. 1990). The insulin-mediated inhibition of NPY gene expression in the ARC may be mediated through

GABAergic systems (Sato et al. 2005). There is co-localization of NPY and GABA in various brain areas (Deller and Leranth 1990) and NPY can inhibit potassium-stimulated glutamate release (Wang 2005). Alternatively, NPY protein and mRNA levels are increased by glutamatergic stimulation (Kim et al. 2000).

184.2.4 Effect of Alcohol on Receptor Systems

NPY-induced feeding in the hypothalamus may be dependent on activation of *N*-methyl-D-aspartate (NMDA) glutamate receptors (Lee and Stanley 2005). In the absence of glutamate excitation, NPY in the ARC has little influence on hypothalamic neuronal activity but instead has a modulatory role by either reducing glutamate release at presynaptic terminals or modulating the postsynaptic response to glutamate (Belousov and van den Pol 1997).

Chronic ethanol exposure can produce a significant reduction in NPY protein levels (Roy and Pandey 2002), and suppress NPY gene expression in the ARC (Kinoshita et al. 2000). Thus, these findings provide support for the behavioural data claiming that alcohol may alter appetite for carbohydrate. Moreover, this is also consistent with the accepted view that acute alcohol administration impairs functioning of excitatory NMDA glutamate receptors (Lustig et al. 1992) and potentiates the function of inhibitory $GABA_A$ receptors (Givens and Breese 1990). The key features of appetite behaviour in alcoholism are summarized in Table 184.2.

In the next few sections, we investigate the effect of commercially available alcohol on hormonal factors thought to be associated with appetite regulation in order to determine whether commercially available alcohol products promote a decrease in carbohydrate intake.

184.2.5 White Wine Before Food

In the brain, steroid hormones such as cortisol and dehydroepiandrosterone sulphate (DHEAS) act as modulators of synaptic events and salivary steroids can provide some indication of the level of cortisol and DHEAS in CSF (Guazzo et al. 1996). Cortisol may alter the binding of γ-aminobutyric acid (GABA) to inhibitory $GABA_A$ receptors in a biphasic fashion, with potentiation of GABA occurring at nanomolar levels and a reduction occurring at micromolar ones (Majewska et al. 1985). Alternatively, DHEAS modulates the action of cortisol (Guazzo et al. 1996), by acting as a GABA antagonist at the $GABA_A$ receptor (Demirgoren et al. 1991), in order to potentiate the function of excitatory NMDA glutamate receptors (Baulieu 1996). The key features of salivary cortisol is summarized in Table 184.3.

Table 184.2 Key features of feeding behaviour in long-term chronic alcoholics

1. Alcohol consumption usually replaces food intake
2. The alcoholic individual is often blamed for their highly irregular feeding behavior
3. Alcoholics usually consume less food when food is freely available
4. Alcohol can at times account for 50% of daily calories in long-term chronic alcoholics
5. Alcohol contains few nutrients and malnutrition is commonly associated with alcoholism
6. There is a preference for foods containing salt and protein during alcohol consumption
7. A decreased appetite for carbohydrate has been noted in long-term chronic alcoholics while consuming alcohol
8. Alcohol can alter biochemical processes associated with the regulation of appetite for carbohydrate

This table lists the key findings associated with impaired appetite for food in alcoholism. A decreased appetite for carbohydrate is one of the main factors associated with alcohol consumption

Table 184.3 Key features of salivary cortisol

1. Plasma-free cortisol is the most reliable measure of adrenal activity as plasma total cortisol values may be affected by the alteration of its carrier protein, corticosteroid-binding-globulin

2. It is not unusual in psychoneuroendocrinology for cortisol to be assessed in saliva

3. Amount of cortisol in saliva is highly correlated with the level of plasma free cortisol

4. Amount of cortisol in saliva has been found to be highly correlated with the level of cortisol in cerebrospinal fluid (i.e. in the brain)

5. Cortisol concentration in saliva is not dependent on saliva flow rate

6. No dilution effects have been observed. Thus, readings are highly accurate

7. As cortisol is released in response to stress, salivary measure of cortisol may offer a more accurate noninvasive measure of adrenal activity

Cortisol is the body's major stress hormone and stress associated with the blood taking procedure can falsely increase cortisol values making blood taking results at times difficult to interpret. Saliva sampling offers a convenient, noninvasive, and more reliable method for assessment of adrenal hormones

Fig. 184.1 Effect of white wine on salivary cortisol and salivary DHEAS before a meal. Mean salivary cortisol and salivary DHEAS before food (0 g), during ingestion of white wine containing 40 g alcohol (13–40 g), and after food. The level of cortisol and DHEAS data was measured in eight nondiabetic males aged 18–22 years across a 180-min period. Error bars have been included to show the average deviation from the Mean at each 45-min assessment point. The results showed a significant decrease in cortisol and DHEAS over time when white wine is consumed. The consumption of food promoted some recovery in cortisol but the level of DHEAS continued to decrease

The consumption of white wine significantly decreases salivary cortisol and DHEAS when consumed alone under fasting conditions (Kokavec et al. 2009). The cortisol-DHEAS relationship when white wine is consumed prior to food is shown in Fig. 184.1. While an absence of cortisol in CNS could indicate that glucose transport and glutamate uptake is promoted in astrocytes (Virgin et al. 1991) the significant reduction in DHEAS highlights that NMDA receptor activity is not promoted. Moreover, as NPY protein and mRNA levels in the ARC are increased by glutamatergic stimulation (Kim et al. 2000) the steroid data could support previous claims that an alcohol-induced reduction in NPY mRNA in ARC (Kinoshita et al. 2000) and NPY in PVN (Roy and Pandey 2002) occurs.

During fasting, insulin is usually reduced in order to promote feeding, and insulin administration during fasting may prevent the fasting-induced increase in NPY in PVN and NPY mRNA in ARC (Schwartz et al. 1992a). White wine prior to food does not increase plasma insulin (Kokavec and
Fig. 184.2 Effect of white wine on plasma insulin and salivary cortisol prior to a meal. Mean plasma insulin and salivary cortisol before food (0 g), during ingestion of white wine (13–40 g alcohol) and after food is presented. The level of insulin and cortisol was measured in eight nondiabetic males across a 180-min period. Error bars have been included to show the average deviation from the mean at each 45-min assessment point. The results showed no change in insulin when white wine is consumed prior to food. However, the consumption of food promoted a significant and abnormally large increase in insulin immediately

Crowe 2006) and ketone production is maintained (Kokavec 2000). Taken together, this would suggest that white wine prior to food does not promote an elevation in plasma glucose and raises the possibility that an increase in NPY mRNA in ARC could occur under these conditions.

184.2.6 Effect of Alcohol-induced Dehydration

The expression of NPY in the ARC is influenced by both feeding and hydration factors. Moreover, a combination of ADX and chronic osmotic stimulation can increase NPY mRNA expression in neurons of the ARC (Larsen et al. 1993). Similarly, a combination of ADX and fasting can increase NPY gene expression in the medial basal hypothalamus (Hanson et al. 1997) and an increase in ARC NPY mRNA has also been observed in food (Johnstone et al. 2005) and calorie (Shimokawa et al. 2003) restricted animals.

Chronic osmotic stimulation can deactivate the HPA axis (Jessop et al. 1990) and alcohol may promote the development of a dehydration condition (Linkola et al. 1979). Similarly, we noted a significant alcohol-induced reduction in urinary Na^+ and K^+ excretion and reduced urine flow when white wine is consumed prior to food (Kokavec 2000). However, when we compared the level of urinary K^+ and urinary Na^+ in our study with urinary electrolyte data collected after several days fasting in non-obese individuals (Elia et al. 1984), we were surprised to find that the electrolyte data was very similar after 40 g alcohol despite participants being only mildly fasted prior to alcohol consumption.

Consuming white wine prior to food, despite promoting a significant reduction in steroid hormones (Kokavec and Crowe 2001a), may, therefore, increase NPY mRNA in the ARC (for review see Kokavec and Crowe 2001b), due to impaired salt and water balance. Although, inactivation of NMDA

receptors could prevent NPY in the ARC from influencing hypothalamic neuronal activity and instead may reduce glutamate release at presynaptic terminals and/or promote glutamate resistance. Therefore, the DHEAS and insulin data together may suggest modulation of NPY in PVN due to glutamate resistance (Belousov and van den Pol 1997). Similarly, a lack of glucocorticoids will also notably decrease carbohydrate intake (Tempel and Leibowitz 1989). Thus, the hormonal data suggests that ingesting white wine prior to a meal could reduce appetite for carbohydrate. The cortisol-insulin interaction when white wine is consumed alone before a meal is presented in Fig. 184.2.

184.2.7 Food After White Wine

The consumption of food after white wine can significantly reduce DHEAS and promote an increase in salivary cortisol concentration (Kokavec and Crowe 2001a). Laboratory investigations have demonstrated that ethanol administration prior to ingestion of a glucose load (McMonagle and Felig 1975) can potentiate the glucose stimulating properties of insulin and promote a rapid release of insulin (O'Keefe and Marks 1977). Similarly, we observed a significant elevation in plasma insulin when food was consumed after a moderate amount of white wine had already been ingested (Kokavec 2000).

The rapid release of insulin that was noted when food is consumed after white wine (Kokavec 2000) could reduce NPY gene transcription in ARC (Schwartz et al. 1992a). Furthermore, the significantly reduced level of DHEAS that was observed when food is consumed after white wine (Kokavec and Crowe 2001a) could promote a cascade of events commencing with increased GABA uptake at the GABA$_A$ receptor and then may involve inhibition of NPY in the ARC on hypothalamic neuronal activity, reduced glutamate release, and promotion of glutamate resistance (Belousov and van den Pol 1997). Therefore, the DHEAS, insulin and cortisol data could be highlighting that an NPY deficient state develops when food is consumed after white wine. Thus, when white wine is consumed prior to food appetite for carbohydrate could be inhibited when food is finally presented, which would encourage less food to be consumed.

184.2.8 White Wine After Food

A meal high in carbohydrate will usually promote a sudden increase in plasma glucose, which then stimulates insulin release by the β-cells in the pancreas. Circulating insulin levels in nondiabetic individuals usually rise with feeding (Schwartz et al. 1992a) and the level of plasma insulin remains elevated until the plasma glucose level begins to drop, which often can take several hours (Berg et al. 2007). In contrast, during fasting, insulin secretion is markedly reduced (Schwartz et al. 1992b) and cortisol is elevated in order to reduce glucose utilization and transport, and promote gluconeogenesis. While the relationship between cortisol and insulin is usually antagonistic elevations in cortisol and insulin can occur simultaneously in response to food intake. The role of cortisol in this instance is to modulate the effects of insulin on glucose utilization in order to ensure that energy stores are replenished (Goldstein et al. 1993).

The effect of white wine on steroid hormones may be dependent on the prior nutritional status of the individual. Consuming white wine alone after a meal can promote a significant elevation in DHEAS together with a significant decrease in cortisol (Kokavec and Crowe 2001a), plasma insulin (Kokavec and Crowe 2003), urinary K$^+$ excretion (Kokavec 2000) and a trend for a lowering of
Fig. 184.3 Effect of white wine on salivary cortisol and salivary DHEAS after a meal. Mean salivary cortisol and salivary DHEAS before food (pre-food), after food, and during ingestion of white wine containing 40 g alcohol (13–40 g) in a group of eight nondiabetic males aged 18–22 years across a 180-min period. Error bars have been included to show the average deviation from the mean for the group at each 45-min assessment point. The results showed a significant decrease in cortisol and significant increase in DHEAS as soon as white wine was consumed alone after the meal
Fig. 184.4 Effect of white wine on salivary cortisol and plasma insulin after a meal. Mean salivary cortisol and plasma insulin before food (pre-food), after food, and during ingestion of white wine containing 40 g alcohol (13–40 g) in a group of eight nondiabetic males aged 18–22 years across a 180-min period. Error bars have been included to show the average deviation from the mean for the group at each 45-min assessment point. The results showed a significant decrease in insulin as soon as white wine is consumed. The level of insulin was similar to that observed prior to food intake despite individuals having consumed a high carbohydrate meal

plasma glucose (Kokavec and Crowe 2003). The cortisol-DHEAS and cortisol-insulin relationship is shown in Figs. 184.3 and 184.4, respectively. Our findings are consistent with rodent studies where it has been shown that ethanol treatment following glucose administration can promote a marked inhibition of glucose-induced insulin secretion (Tiengo et al. 1981). Therefore, this together could highlight that white wine may alter glucose utilization and metabolism.

The alcohol-induced elevation in DHEAS by inhibiting GABA uptake at the $GABA_A$ receptor could promote an increase in NPY mRNA in ARC and NPY level in PVN via potentiation of NMDA receptors (Kim et al. 2000). Moreover, a significant decrease in insulin (Kokavec and Crowe 2003) adds further support for an alcohol-induced increase in NPY mRNA in ARC. However, a significant alcohol-induced decrease in cortisol was also observed (Kokavec and Crowe 2001b), which could modulate the transcription of NPY in ARC (Dean and White 1990) and reduce the level of NPY in PVN (Sato et al. 2005).

184.2.9 Is All Alcohol the Same?

The effect of alcohol on the HPA axis may be dependent on the type of alcoholic beverage consumed. In the past, we have assessed a number of commercially available alcoholic beverages and found that the consumption of red wine and white wine under similar experimental conditions does not necessarily produce the same effect on the HPA axis. The effect of alcohol on the HPA axis may be dependent on not only the prior nutritional status of the individual but also the nutritional content of the alcoholic product being tested.

While most alcoholic beverages contain varying amounts of histamine (Lonvaud-Funel 2001), red wine is unique in that it contains a higher level of histamine when compared to other alcoholic products (Wantke et al. 1994) and (unlike other alcoholic beverages) can also promote histamine release (Intorre et al. 1996). Therefore, given that histamine can promote ACTH release (Knigge et al. 1988), the precursor for steroidgenesis (Endoh et al. 1996), it would not be unreasonable to assume that red wine may also influence the HPA axis differently than other alcoholic beverages.

184.2.10 Red Wine Prior to Food

When we assessed the effect of red wine on the HPA axis prior to food intake, it became clear that the amount of red wine being ingested was a very important factor. We observed that consumption of red wine can promote a significant decrease in salivary cortisol and salivary DHEAS. In contrast, ingestion of 2–3 standard units of red wine (20–30 g alcohol) can promote a trend for an increase in salivary DHEAS, but salivary cortisol remains lowered. After ingestion of four standard units of red wine (40 g alcohol), the concentration of salivary cortisol remains lowered and DHEAS continues to increase slightly (Fig. 184.5) (Kokavec et al. 2009).

Thus, the red wine data suggests that activation of $GABA_A$ receptors is promoted when red wine is consumed prior to food (Demirgoren et al. 1991). Alternatively, ingestion of 2–3 standard units of red wine (20–30 g alcohol) may promote the activation of NMDA receptors due to the inhibition of GABA. Following ingestion of four standard units of red wine (40 g alcohol), activation of NMDA receptors may continue to be promoted and NPY mRNA in ARC and NPY release in PVN may increase (Kim et al. 2000). We also noted a significant decrease in insulin when red wine is consumed prior to food, which further suggests that an alcohol-induced increase in NPY mRNA occurs in ARC. Therefore, the red wine data could suggest caution when consuming red wine prior to food with more than three standard units of red wine (>30 g alcohol) prior to food possibly decreasing carbohydrate intake. The cortisol-insulin interaction when red wine is consumed prior to a meal is presented in Fig. 184.6.
Fig. 184.5 Effect of red wine on salivary cortisol and salivary DHEAS before a meal. Mean salivary cortisol and salivary DHEAS before food (0 g), during ingestion of red wine containing 40 g alcohol (13–40 g), and after food in a group of eight nondiabetic males aged 18–22 years across a 180-min period. Error bars have been included to show the average deviation from the mean for the group at each 45-min assessment point. The results showed a significant decrease in cortisol and significant increase in DHEAS over time as more red wine is consumed
Fig. 184.6 Effect of red wine on salivary cortisol and plasma insulin before a meal. Mean salivary cortisol ($n = 8$) and plasma insulin ($n = 8$) was assessed before food (0 g) and during ingestion of red wine containing 40 g alcohol (13–40 g) on two separate occasions. A total of 16 nondiabetic males aged 18–22 years participated in one of the two 180-min testing sessions. Error bars have been included to show the average deviation of scores from the mean at each 45-min assessment point. The results showed a significant decrease in cortisol and insulin when red wine is consumed prior to food

184.2.11 Beer Before Food

Consuming beer, a product containing alcohol, various minerals, and approximately 8 g carbohydrate prior to food can promote a significant elevation in the level of fasting salivary DHEAS after only one standard unit of regular beer (i.e. 10 g alcohol) is ingested. Cortisol is significantly lowered and an increase in cortisol is only observed after 40 g alcohol is consumed. The consumption of three standard units of regular beer (30 g alcohol) can promote a further decrease in salivary cortisol with the level of DHEAS also being shown to become lowered. However, consumption of 40 g alcohol in the form of beer can promote an elevation in cortisol and no change in salivary DHEAS (Fig. 184.7). We compared the effects of light beer (2.3% alcohol per 100 ml) and heavy beer (4.9% alcohol per 100 ml) and found there to be no significant alcohol-induced differences in salivary cortisol or salivary DHEAS when trials were compared across time. Therefore, the effect of beer on salivary cortisol and salivary DHEAS was found to be the same regardless of alcohol content (Kokavec et al. 2009).

Simultaneous administration of ethanol and glucose can decrease the insulin response (Singh et al. 1980). Alternatively, consuming alcohol with carbohydrate (Marks 1978) can elevate insulin (O'Keefe and Marks 1977). An antagonistic relationship is known to exist between insulin and DHEAS, and it may be that when beer is consumed, the carbohydrate content of beer exerts some influence on the level of fasting insulin. An absence of ketone bodies was noted after 30 g alcohol, which could suggest that sufficient energy is available to meet the needs of the system.

Therefore, the steroid data when combined with early insulin findings could suggest that consuming alcohol with carbohydrate may decrease NPY gene expression in ARC, which could promote NPY deficiency by subsequently reducing NPY in PVN (Schwartz et al. 1992a). An elevation in insulin could reduce appetite for carbohydrate (Tempel and Leibowitz 1989) and NPY deficiency may promote alcohol consumption. Therefore, consuming alcohol with sufficient carbohydrate to alter insulin should probably not be promoted.
Fig. 184.7 Effect of beer on salivary cortisol and salivary DHEAS before a meal. Mean salivary cortisol and salivary DHEAS before food (0 g), during ingestion of high-alcohol beer containing 40 g alcohol (13–40 g) and after food in a group of eight nondiabetic males aged 18–22 years across a 180-min period. Error bars show the average deviation from the mean for the group at each 45-min assessment point. The results showed a significant decrease in cortisol and a significant but highly variable increase in DHEAS

184.3 Summary

Alcohol may not be a fuel for the human body. The known energy pathways cannot utilize alcohol as an energy source and it is unlikely that humans can convert the calories contained in alcohol to fuel using the usual energy pathways. The biochemical evidence presented above confirms that an alcohol-induced alteration in appetite for carbohydrate may occur when a range of commercially available alcohol products are ingested. Moreover, consuming alcohol prior to food can decrease the amount of food consumed when food is finally presented. Therefore, consuming commercially available alcohol alone before or after a meal should probably not be encouraged.

The material presented in this chapter is by no means extensive and has merely focussed on some of the more established biochemical aspects of carbohydrate intake regulation. There are several other biochemical factors associated with food intake (e.g. cholecystokinin, leptin, ghrelin) that have not been mentioned, and probably many more factors that remain to be discovered. However, this serves as a good starting point to perhaps make us start to question why alcoholics prefer to consume alcohol rather than food. It is possible that a consequence of alcohol consumption under certain conditions may be to promote an alteration in the way the body processes energy such that carbohydrate intake is discouraged and a malnourished state is encouraged.

184.4 Application to Other Areas of Health and Disease

Malnutrition is a common finding in the alcoholic population and the alcoholic individual is often blamed for his or her irregular feeding behaviour. While long-term alcohol abuse has been linked to a number of serious health conditions, steatosis or fatty liver is the primary cause of illness and death in alcoholics. The material presented here provides an explanation as to why the liver is often damaged in alcoholics, by suggesting that a consequence of alcohol consumption may be a reduced appetite for carbohydrate due to an alteration in energy metabolism. This information will be invaluable to a large number of health professionals and researchers who are working toward improving the health status of alcoholics.

Summary Points

- Alcohol consumption often replaces food intake in alcoholics.
- Alcohol is a high caloric substance but whether humans can generate any energy from alcohol is unknown.
- Alcohol can promote dehydration and may promote the development of a malnourished state.
- The known human energy systems are not able to utilize alcohol as an energy source.
- Alcohol may promote thiamine deficiency even in well-nourished individuals.
- Alcohol, if consumed alone, may alter appetite for carbohydrate regardless of whether alcohol is consumed before or after a meal.
- Consuming alcohol alone before a meal could result in less food being consumed when food finally becomes available.

Key Terms

Alcoholic fermentation: Series of chemical reactions involved in the conversion of glucose to alcohol.

Cortisol: A steroid hormone. The body's major glucocorticoid, synthesized and released by the hypothalamic–pituitary–adrenal axis.

Dehydroepiandrosterone sulphate: A steroid hormone. The body's major androgen synthesized and released by the hypothalamic-pituitary-adrenal axis.

Glyoxylate cycle: gluconeogenic pathway that allows fat to be converted to carbohydrate.

Hypothalamic–pituitary–adrenal axis: Hormonal pathway responsible for the synthesis and release of steroid hormones.

Insulin: Pancreatic peptide hormone that allows glucose to gain entry into cells located outside of the brain.

Neuropeptide Y: 36-amino sequence pancreatic polypeptide, which when released increases appetite for carbohydrate.

Chapter 185
Gender Aspects in the Comorbidity of Eating Disorders and Alcohol Use Disorders

Tahany M. Gadalla

185.1 Introduction

Both eating disorders and alcohol use disorders are prevalent in men and women. However, while eating disorders are more prevalent in women, alcohol use disorders are more prevalent in men. Comparisons between clinical attributes of eating disorders, such as age of onset, frequency of various symptoms or duration of illness in men and women revealed no significant gender differences (Barry et al. 2002; Woodside 2002). Similar to women with eating disorders (Gruber et al. 2001), men with eating disorders were found to have an exaggerated perception of their body fat compared to controls (Mangweth et al. 2004). Barry and colleagues (2002) found no differences between men and women with binge eating disorders on measures of eating-related features such as eating concerns, shape, or weight concerns. These authors also found that women with a binge eating disorder experienced significantly greater body image dissatisfaction and drive for thinness compared to men with the same disorder (Barry et al. 2002).

Gender differences in risk factors for eating disorders and body dissatisfaction, such as self-esteem, perfectionism, and mass-media, have been suggested (Elgin and Pritchard 2006). Specifically, self-esteem, perfectionism, and mass-media were related to disordered eating behavior in women, whereas only perfectionism and mass-media were related to disordered eating behavior in men. Additionally, self-esteem and mass-media were related to body image dissatisfaction in women, whereas perfectionism and mass media were related to body image dissatisfaction in men (Elgin and Pritchard 2006). Lower socio-economic status and single marital status have been indicated as risk factors for eating disorders in both genders. For example, Lindblad and colleagues (2006) found a higher proportion of single parent families and families in need of child welfare among families of male patients with anorexia nervosa compared to the general population.

Gender differences in eating attitudes and behaviors toward food among individuals with eating disorders have also been suggested. Weltzin and colleagues (2005) found that men were less likely than women to engage in typical compensatory behaviors such as vomiting and more likely to engage in activities such as excessive exercise to control their body weight. They also found that men were more likely than women to binge rather than restrict food intake. Conversely, a small-scale study of substance abuse patients in a treatment setting revealed that men and women reported similar levels of engagement in binge eating and compensatory behaviors. However, the women displayed higher

T.M. Gadalla (✉)

e-mail: tahany.gadalla@utoronto.ca

disturbed attitudes about body weight and shape compared to men (Jackson and Grilo 2002). More recently, research conducted by Gadalla (2009) examined gender differences in dieting behaviors in a nationally representative sample of Canadians with disordered eating behavior. The author found that men with disordered eating adopted less oral control and dietary restraint, were less preoccupied with body shape, and showed less desire for thinness compared to women. Furthermore, the research findings revealed no gender difference in engaging in compensatory behaviors such as vomiting.

Empirical research has also found a link between commitment to physical exercise and disordered eating attitudes and behaviors, particularly in men. Regimented physical exercise has been viewed as a predictor, risk factor and/or symptom of eating disorders (Asci et al. 2006; Woodside et al. 2004). However, research which has examined disordered eating behaviors in a community sample of men and women did not reveal gender differences in either level or intensity of physical exercise (Gadalla 2009). The temporal sequence of exercise and disordered eating behaviors, as well as the gender difference, if any, in the strength of their association have yet to be determined.

185.2 Comorbidity of Eating Disorders and Alcohol Use Disorders

During the past 20 years, the comorbidity of eating disorders and substance use disorders has emerged as a significant health issue. The American Psychological Association (2005) and the National Center on Addiction and Substance Use at Columbia University (2001) have identified the study of this comorbidity as an important research agenda. Three factors have contributed to the importance and the urgency of this issue: (1) The documented high co-occurrence rates of the two types of disorders (e.g., Corcos et al. 2001; Dansky et al. 2000; Gadalla and Piran 2007a; Krahn et al. 2005; Piran and Gadalla 2006; Piran and Robinson 2006). (2) The significant association between these comorbid disorders and medical, psychological, and social morbidity (e.g., Krahn et al. 2005; Wiederman and Pryor 1996). (3) The complicated treatment challenges associated with these comorbid disorders (Corcos et al. 2001; Dansky et al. 2000; Sinha and O'Malley 2000).

185.2.1 Research Based on Female Samples

An association between disordered eating and alcohol use disorders has been observed in samples of women drawn from treatment seeking patients, in addition to high school, college, and community populations. Clinical samples of women with eating disorders were found to have a high rate of alcohol use disorders (Wiederman and Pryor 1996). The prevalence of alcohol use disorders has been reported to be as high as 30–50% in treatment seeking samples of women with bulimia nervosa (Dansky et al. 2000). Similarly, women with alcohol use disorders have been found to have a high rate of disordered eating patterns (e.g., Grilo et al. 1995; Sinha and O'Malley 2000). In a follow-up study in which women diagnosed with either anorexia nervosa or bulimia nervosa were assessed every 6–12 months for a period of 8.6 years, and a substantial number developed alcohol-related problems during the course of the study (Franko et al. 2005).

Moreover, an association between disordered eating and alcohol consumption was also found in multiple samples drawn from high school and university students (e.g., Field et al. 2002; Neumark-Sztrainer et al. 1998). For example, when Adams and Araas (2006) examined the co-occurrence of bulimia nervosa with binge eating behaviors and high-risk alcohol behavior in a national sample of female college students, they found that students who reported purging tended to report heavier

alcohol use than those who did not. Furthermore, students who purged and drank alcohol reported more negative consequences than the non-purgers.

Few studies have examined the association between eating disorders and alcohol use disorders in nationally representative samples. Among them, Dansky and colleagues (2000) found a higher rate of alcohol dependence among women with bulimia nervosa compared with women without bulimia nervosa or with binge eating disorder. No such differences were found in the rates of alcohol abuse. In a community sample of Canadian women, 41.8% of those with a diagnosis of bulimia nervosa and 27.3% of those with sub-clinical symptoms of bulimia nervosa had drinking problems compared to 20.9% of the controls (Garfinkel et al. 1995). In a more recent study of a nationally representative sample of Canadian women, Piran and Gadalla (2006) reported significant associations between disordered eating behavior and measures of alcohol dependence and alcohol interference for women in all age groups.

185.2.2 Research Based on Male Samples

Eating disorders are much more common among women than men and have long been assumed to be found exclusively in women. Consequently, few studies have focused on eating disorders in men and even fewer have examined the association of eating disorders with alcohol use disorders in men. Most research on eating disorders in men has been based on case studies and small clinical samples without the use of appropriate control groups (Woodside et al. 2001). Men have been reported to comprise between 5% and 10% of eating disordered individuals in clinical settings (Woodside 2002) with significantly more gay and bisexual men suffering from these disorders compared to heterosexual men (Feldman and Meyer 2007). However, there is evidence to suggest that more men in the general population have eating disorders (Woodside et al. 2001) and that eating disorders in men are underdiagnosed and undertreated (Weltzin et al. 2005; Woodside et al. 2004).

A study which evaluated the relationship between alcohol dependence and eating disorders found that the lifetime rates of bulimia nervosa were found to be higher than expected in both men and women (Schuckit et al. 1996). Other findings from a small scale study of substance abuse patients in a treatment setting revealed that men and women reported similar levels of engagement in binge eating and compensatory behaviors; however, the women had higher disturbed attitudes about body weight and shape (Jackson and Grilo 2002). In a study of male patients treated for eating disorders, 37% were found to fulfill DSM-IV criteria for substance abuse (Carlat et al. 1997).

185.2.3 Research Comprised of Male and Female Samples

Gadalla and Piran (2007a) examined the above association using a nationally representative sample of 20,211 women and 16,773 men. In this study, respondents who reported being concerned about their weight during the 12 months prior to the interview, were administered the Eating Troubles module, EAT-26 developed by Garner et al. (1982). The measure used for alcohol dependence was based on the Composite International Diagnostic Interview, developed by Kessler et al. (1998). The level of alcohol interference indicated whether alcohol use interfered with the individual's normal routine, occupational/academic functioning, social activities, or relationships. The prevalence rate of disordered eating behavior for men was found to be 0.5% and that of alcohol interference 2.2% (Table 185.1). If these conditions were independent, the probability that they co-occur by chance

Table 185.1 Measures of alcohol consumption and body weight concerns in Canadian men and women, 2002 (From Gadalla and Piran 2007b. With permission)

	Men	Women
	$n = 16,773$	$n = 20,211$
Strong fear of being overweight – 12 months	7.7%	18.5%[***]
Strong fear of being overweight – lifetime	15.2%	32.3%[***]
Eating attitude test score >20	0.5%	2.8%[***]
Alcohol dependence – 12 months	3.9%	1.3%[***]
Alcohol interference – 12 months	2.2%	0.7%[***]

[***]$p < 0.0005$. The [***] indicate statistically significant difference between men and women using chi-square test

This table includes percentages of survey participants who reported having strong fear of being overweight in the 12 months prior to the interview, in their lifetime, those who scored > 20 on the EAT instrument, participants who were identified as alcohol dependent and participants whose drinking interfered with their daily activities.

Table 185.2 Rates of alcohol use in Canadian men and women in association with disordered eating behaviors (EAT-26 score ≤ 20 vs >20) (From Gadalla and Piran 2007b. With permission)

	EAT-26	Men	Women
Alcohol dependence – past 12 months	Score ≤ 20	3.8%[*]	1.3%[***]
	Score > 20	8.3%	3.8%
Alcohol interference – past 12 months	Score ≤ 20	2.2%[***]	0.6%[***]
	Score > 20	9.1%	3.0%
Sample size	Score ≤ 20	16,685	19,638
	Score > 20	88	573

This table shows the percentages of survey participants who scored > 20 versus ≤ 20 on the EAT instrument by within those who were identified as alcohol dependent

Significance levels refer to the associations between measures of alcohol use and disordered eating behavior within gender using chi-square test

[*]$p < 0.05$, [***]$p < 0.0005$

Data presented in the table indicate a strong association between disordered eating behavior and each of alcohol dependence and interference in women. For men, disordered eating behavior was strongly associated with alcohol interference and moderately associated with alcohol dependence

alone would be 0.012% (0.5% × 2.2%). However, the observed probability of the co-occurrence of eating disorders and alcohol interference was 0.048%, four times the chance probability, indicating an association between the two conditions. Similarly, the observed probability of co-occurrence of these two conditions for women was 0.085%, which was 4.4 times the probability of occurring by chance alone. All measures of alcohol use were consistently higher for women with disordered eating behavior, which was not the case for men (Table 185.2). While disordered eating behavior in women was strongly associated with alcohol dependence and alcohol interference, disordered eating behavior in men was strongly associated with alcohol interference and marginally associated with alcohol dependence.

By contrast, some studies did not find an association between eating disorders and alcohol use disorders (e.g., Dunn et al. 2002; Matthews 2004; Stock et al. 2002; Welch and Fairburn 1996). Dunn and colleagues (2002) noted that their nonclinical sample of college students who met the criteria for bulimia nervosa did not drink significantly more alcohol than non-eating disordered students. Furthermore, Stock and colleagues (2002) reported that female adolescents with restrictive eating disorders drank significantly less alcohol than matched controls. Additionally, Welch and Fairburn (1996) compared alcohol consumption in three groups of women recruited from the community,

women with bulimia nervosa, controls with other psychiatric disorders, and controls without such disorders. The authors found no difference in current alcohol consumption between bulimia nervosa cases and either control group. More recently, Matthews (2004) found no evidence of a concurrent relationship between eating disorders and alcohol use disorders in college students.

185.2.4 Review Studies

Holderness and colleagues (1994) reviewed 51 studies on eating disorders and substance use and abuse that were published between 1977 and 1991. In 24 of the studies reviewed, the percentage of individuals with bulimia nervosa who reported alcohol abuse and/or dependence ranged between 2.9% and 48.6% with a median of 22.9%. These authors also noted that among eight studies that included women with both bulimia nervosa and anorexia nervosa, the rates of alcohol abuse and/or dependence ranged between 12% and 39% with a median of 26%. More recently, Gadalla and Piran (2007b) conducted a meta-analysis of 41 studies on the co-occurrence of eating disorders and alcohol use disorders in women that were published between 1985 and 2006. Over one third of studies reviewed (15 studies) recruited their participants from the community, approximately one third (14 studies) recruited participants from educational institutions, and 29% (12 studies) recruited their participants from clinical settings (Table 185.3). The type of participants recruited for the comparison group in clinical studies also varied, with four studies recruiting controls from the community and three studies recruiting controls from general psychiatric current or previous patients. As would be expected, criteria used for eating disorder assessments were significantly associated with the type of sample used. Clinical measures were used mostly with clinical samples and behavioral measures with student samples (Fisher's exact test = 16.17, p-value = 0.001). Only four out of the 41 studies in the meta-analysis reported negative associations between eating disorders and alcohol use disorders. Two of the studies reported a negative relationship between anorexia nervosa and alcohol use disorders, with effect sizes of -0.85 and -0.49, while the remaining two studies reported negative relationships between bulimia nervosa or bulimic behavior and alcohol use disorders, with effect sizes of -0.07 and -0.92. As shown in Table 185.4, the mean effect size of overall eating disorders was 0.38 (se = 0.07) and was significantly different from zero ($p < 0.001$). A significant mean effect size was found for the relationship between alcohol use disorders and each eating disorder pattern except for anorexia nervosa. Based on Cohen's (1988) categorization of an effect size of 0.2 as small, 0.5 as moderate and 0.8 as large, the average effect size found in this meta analysis ranged from small to moderate and was largest for bulimia nervosa/bulimic behavior and alcohol use disorders.

Table 185.3 Types of samples and eating disorders assessment criteria used in the reviewed articles (From Gadalla and Piran 2007b. With permission)

Assessment of eating disorders	Type of sample			Total
	Clinical	Community	Students	
Clinical	10 (83.3%)	8 (53.3%)	1 (7.1%)	19
Psychometric	1 (8.3%)	2 (13.3%)	5 (35.7%)	8
Behavioral	1 (8.3%)	5 (33.3%)	8 (57.1%)	14
Total	12	15	14	41

This table includes a count of the number of studies used in the meta-analysis by type of sample participants and the criteria used to assess eating disorders

Fisher's exact test was used to test the association of type of participants and criteria used to assess eating disorders. Fisher's test = 16.17, p-value = 0.001, i.e. there was a significant association between the two characteristics

Table 185.4 Means, standard errors and homogeneity indices of effect size of the relationship between eating disorders and alcohol use disorders in women, by type of eating disorder (From Gadalla and Piran 2007b. With permission)

Type of eating disorder	Number of studies	Homogeneity index, Q	Between-study variability, I^2	Mean of ES (st error)
Any eating disorder	41	160.94***	75.15	0.38 (0.07)***
Bulimia nervosa/Bulimic behavior	29	132.13***	78.81	0.46 (0.10)***
Anorexia nervosa	8	22.59**	69.01	0.09 (0.14)
Purging	6	13.51*	62.98	0.41 (0.12)**
Restriction/dietary restraint	6	1.06	0.00	0.13 (0.03)***
Binge eating disorder	5	1.04	0.00	0.39 (0.14)**
Eating disorders not otherwise specified	9	12.09	33.82	0.41 (0.12)***

For articles that reported more than one measure of alcohol use disorders or eating disorders, effect sizes were derived for all measures and their mean calculated such that only one effect size per study per pattern of eating disorder was used. The overall mean (and its standard error) of all studies per type of eating disorder is shown in the above table

Mean effect sizes were transformed to z-values to test whether they were significantly different from zero. Except for anorexia nervosa, the mean effects for all types of disordered eating were significantly different from zero
* $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$
The Q statistic measures the homogeneity of effect sizes across studies. Higher values of Q indicate lack of homogeneity among study results
The I^2 index is an estimate of the percentage of total variability in effect sizes that is due to between-studies variability rather than sampling errors within studies. The table shows significant heterogeneity among studies in the relationships between AUD and each of any ED, BN/bulimic behavior, AN, and purging reported by different studies. On the other hand, the relationship between AUD and each of binge eating disorder and dietary restraint were the most consistent with minimal heterogeneity across studies

The authors also noted that the co-occurrence rates of different patterns of disordered eating with alcohol use disorders were generally weakest and most divergent when participants were recruited from clinical settings and strongest and most homogeneous when participants were recruited from student populations.

185.3 Proposed Mechanisms of the Relationships Between Eating Disorders and Alcohol Use Disorders

While high rates of comorbidity of eating disorders and alcohol use disorders have been well documented and observed in samples drawn from clinical settings, educational institutions and the community, the nature of this relationship is still unclear. Several hypotheses have been proposed, each with supportive as well as contradictory research findings.

185.3.1 The Addictive Personality Hypothesis

The addictive personality hypothesis is based on the belief that certain individuals are predisposed to become addicted to one or more substances (Brisman and Siegel 1984). Supporters of this hypothesis stress the clinical and behavioral similarities between eating disorders, especially bulimia nervosa and binge eating, and alcohol use disorders. Two suppositions are at the heart of this hypothesis: (1) eating disorders can be characterized as an addiction and (2) individuals who are vulnerable to these two addictions share certain personality traits that can be used to identify them. Neither assumption is universally accepted (Wolfe and Maisto 2000).

It has been suggested that both bulimia nervosa and alcohol use disorders involve similar brain systems and share elements of preoccupation, loss of control (Gold et al. 2003), impulsivity (Fichter et al. 1994; Wiederman and Pryor 1996), and compulsivity (e.g., Franko et al. 2005). For example, bulimic women have been described as having symptoms of impulse control, which may explain the elevated alcohol use in this population (e.g., Fichter et al. 1994; Wiederman and Pryor 1996). It is not clear, however, whether binge eating carries other addiction criteria, such as physical dependence and tolerance. Research by Keel et al. (2001) found that purging in the absence of binging in normal-weight individuals may be related more to substance use than previously believed. Findings presented by Franko and colleagues (2005) found alcohol use to be more closely related to purging than binging and concluded that both vomiting and alcohol use represent a compulsive dimension of psychopathology.

Research studies documenting higher prevalence of borderline personality disorders in individuals with both eating disorders and substance use disorders compared with individuals with eating disorders alone (e.g., Grilo et al. 1995) provide supporting evidence to the addictive personality hypothesis. However, with the overlap between diagnostic criteria for borderline personality disorder and those for bulimia nervosa and substance abuse, these high prevalence rates could be the result of the diagnostic instruments utilized (Wolfe and Maisto 2000).

185.3.2 The Developmental Hypothesis

Vulnerability to adolescent stressors has also been used to explain the observed high co-occurrence of eating disorders and alcohol use disorders. Some researchers have emphasized the role of dysregulation in the co-occurrence of disordered eating patterns and substance use (e.g., Stewart et al. 2000). This view proposes that regulatory challenges may be expressed through engagement in different disordered eating and drug consumption behaviors. For example, some adolescents may engage in experimenting in drugs as well as disordered eating behavior to conform to social and culture pressures (Wolfe and Maisto 2000).

Several studies have reported associations between the use of problem weight loss methods, such as diet pills and vomiting and alcohol use in adolescents (e.g., French et al. 1997; Neumark-Sztainer et al. 1998; Keel et al. 1998). For example, French and colleagues (1997) found alcohol use to predict purging and binge eating among white adolescent females but not black females. In another study of adolescent boys, Keel and colleagues (1998) did not find a difference in alcohol use between boys with disordered eating and those without disordered eating. More recently, alcohol use was found to predict the use of laxatives and vomiting in white females and black males in a large sample of middle school students (Garry et al. 2003). Garry and colleagues (2003) also found that female students consistently reported use of all weight loss methods more frequently than male students. The dysregulation hypothesis could be evaluated further by examining associations between disordered eating behavior and other forms of behavioral dysregulation, such as risky sexual behavior, in addition to drinking behavior (Stewart et al. 2000).

185.3.3 The Family History Hypothesis

A familial relationship has been suggested as a contributor to the observed high co-occurrence rates of eating disorders and alcohol use disorders. This hypothesis is based on evidence of genetic links to both types of disorders. However, the mechanisms underlying this hypothesis have not been adequately described (Wolfe and Maisto 2000) and the findings of a number of studies have disputed it.

Research evidence in support of a common genetic predisposition to both eating disorders and alcohol use disorders include higher rates of eating disorders in adult children of alcoholics (e.g., Jonas and Gold 1988) and high rates of family history of alcohol abuse in bulimic patients (Bulik 1987). On the other hand, no relationship was found between parental alcohol use disorders and eating disorder symptomatology (Mintz et al. 1995), nor between prevalence of eating disorders and having an alcohol-dependent relative (Meyer 1997; Schuckit et al. 1996). Finally, in a large scale female twin study, Kendler and colleagues (1995) found the genetic factors for alcohol use disorders to be unrelated to the genetic factors of alcohol use disorders.

185.3.4 The Food Deprivation Hypothesis

Dietary restraint has been suggested as a mediating mechanism in explaining the relationship between body weight and shape preoccupation and adverse patterns of alcohol drinking, especially patterns of binge drinking (Stewart et al. 2000). Dietary restraint may result in intake disinhibition leading to both eating and drinking binges. Similarly, alcohol drinking restraint, motivated by the need to avoid high caloric intake, may also result in drinking binges (Stewart et al. 2000).

Stewart and colleagues (2000) found dietary restraint to be strongly associated with measures of binge drinking, quantity of alcohol consumed and excessive drinking in female university undergraduates. The authors concluded that chronic dieting was related to heavy drinking patterns. Kleiner and colleagues (2004) examined the relationship between body mass index and alcohol use in a sample of weight management female patients and found obese patients to have lower rates of alcohol use than women in the general population. Additionally, as body mass index increased, alcohol consumption decreased and it was found that body mass index increased during supervised abstinence. The authors concluded that overeating may compete with alcohol for brain reward sites and result in reduced alcohol intake and dependence rates and that alcohol may replace existing food reward pathways.

However, some controversial evidence counters the argument for the food deprivation hypothesis. Research by Bulik and Brinded (1993) reported that bulimics and controls failed to increase their alcohol consumption following a 19-h food deprivation period. It is not known, however, whether a longer food deprivation period would result in an increase in alcohol consumption.

185.3.5 The Negative Affective Hypothesis

Negative feelings and emotional instability have also been offered as explanations of the relationship between eating and substance use disorders, including alcohol (Benjamin and Wulfert 2005). This hypothesis stipulates that some individuals use both food and alcohol to self medicate when they feel distressed or anxious.

In a longitudinal study of patients with anorexia nervosa or bulimia nervosa, poor psychosocial functioning and a history of substance use were found to predict prospective onset of alcohol use disorders (Franko et al. 2005). Franko and colleagues (2005) also found depression to predict alcohol use disorders in women with anorexia nervosa. Additionally, in a sample of female relatives of alcoholics, women with lifetime bulimia nervosa and alcohol dependence were more likely than women with either disorder alone to have major depression (Duncan et al. 2006).

In a community-based study of correlates of binge eating disorders in men and women (Grucza et al. 2007), the authors reported a significantly higher prevalence of depression and probable alcohol

use disorder in persons with binge eating disorder compared with those without binge eating disorders. Further, in a nationally representative sample of Canadians, having disordered eating behavior was associated with significantly higher odds of major depression for both genders (Gadalla and Piran, 2009). Gadalla and Piran (2009) found that the initially significant association between disordered eating behavior and alcohol dependence became nonsignificant when depression was controlled for, while the significant association between disordered eating behavior and alcohol interference was reduced when depression was controlled for. Based on the findings of the later study, the authors suggested that depression may fully mediate the relationship between eating disorders and alcohol dependence and partially mediate their relationship with alcohol interference for both men and women.

It should be mentioned, however, that both behavioral and affective dysregulation can be related to life experiences, such as trauma (van der Kolk et al. 1996), as well as to inborn temperamental tendencies (Martin et al. 2000). Indeed trauma has been found to explain the observed relationship between binge eating and alcohol abuse (Dansky et al. 2000).

185.4   Discussion and Recommendations

Although research has generally reported high rates of co-occurrence between eating disorders and alcohol use disorders, there is great variability in the reported co-occurrence rates across studies. Methodological differences among studies make it difficult to compare findings across them. For example, studies investigating the comorbidity of eating disorders and alcohol use disorders have recruited participants from heterogeneous settings, such as, schools, clinics, and communities with large variability in the size of samples. Another factor that contributes to the variability in the reported rates is the use of a variety of instruments to measure eating disorders and a wide range of criteria to assess alcohol use disorders. Alcohol consumption is a complex behavior and measures of total number of drinks consumed may not yield the same pattern of association with eating disorders as measures of binge drinking or other measures that take into account adverse consequences to drinkers' lives (Stewart et al. 2000). In addition, women on average have lower body weight relative to men, a fact which should be taken into account when comparing patterns of alcohol consumption (Matthews 2004). Another factor that complicates the comparison of findings across studies is the use of different reference times for the diagnosis of both disorders which ranged from point-prevalence rates to lifetime occurrences. Only when researchers use common criteria for assessing both eating disorders and alcohol use disorders can meaningful comparisons between studies be made. Many studies collapse all eating disorders into one category and likewise for drug and alcohol abuse. This practice adds to the difficulty of making general inferences about the comorbidity of these disorders.

In addition, since clinical based studies are affected by sampling biases, researchers have repeatedly highlighted the role of population-based studies in assessing the extent and nature of comorbidity (Dansky et al. 2000; Welch and Fairburn 1996) as well as the importance of selecting appropriate controls in clinical studies. Clinical-based studies are affected by sampling biases especially when studying patients with multiple problems since comorbidity itself may influence individuals to seek treatment (Welch and Fairburn 1996). Moreover, these patients do not represent the entire range of symptoms present in the population.

Researchers are encouraged to continue to explore the mechanisms that could mediate this consistent pattern of co-occurrence of eating and alcohol use disorders, beyond specific mechanisms related to dietary restraint and body shape preoccupation that may lead both men and women to engage in disruptive alcohol binges. Well-designed empirical research regarding the etiological

relationship between eating disorders and alcohol use disorders is lacking (Wolfe and Maisto 2000). Most studies, to date, have used cross-sectional data, which precludes any definitive conclusions regarding the temporal sequence. Longitudinal, controlled studies are needed in order to establish the temporal sequence of the occurrence of eating disorders, alcohol use disorders, depression, anxiety, and family history of substance dependence.

Very few studies have focused on eating disorders in men and even fewer have attempted to compare men with and without eating disorders or men with eating disorders versus women with eating disorders. Evidence exists to suggest that eating disorders in men are underdiagnosed and undertreated (Weltzin et al. 2005; Woodside et al. 2004). Men may not seek treatment due to their experience of less severe symptoms or because they may not consider themselves at risk for eating disorders (Woodside et al. 2004). Other barriers to seeking treatment may include cultural biases and lack of treatment settings that are dedicated for men with eating disorders (Weltzin et al. 2005). Consequently, very little is known about eating disorders in men and its relationship with other forms of psychopathology. However, with the increasing pressure on men to be fit and to look muscular, there is supportive evidence that suggests body dissatisfaction and eating disorders in men are increasing (O'Dea and Abraham 2002). More research efforts should be directed to the study of all aspects of eating disorders in men.

185.5 Applications to Other Areas of Health and Disease

The focus of this chapter has been the comorbidity of eating disorders and alcohol use disorders. However, the empirical observations and discussion of underlying mechanisms presented here can be easily extended to the comorbidity of eating disorders and drug use disorders. Elevated rates of co-occurrence of eating disorders and drug abuse have been reported by many researchers (e.g., Carlat et al. 1997; Jackson and Grilo 2002; Piran and Robinson 2006; Welch and Fairburn 1996; Wiederman and Pryor 1996). Findings of these studies suggest that, in contrast with the consistent pattern regarding the association of eating disorders and alcohol use disorders in women and men, the findings regarding illicit drug use are markedly different between genders. For example, Gadalla and Piran (2007a) found disordered eating behavior to be associated with current illicit drug use and lifetime use of cocaine/crack, amphetamines (speed), MDMA (ecstasy) and hallucinogens, PCP, or LSD, and cannabis in a community sample of women, whereas in men, disordered eating behavior was only associated with amphetamine use. Most studies, however, tended to examine the associations between eating disorders and a restricted range of substance classes (Piran and Robinson 2006) or combine all substances in one group. Some substances may be used as appetite suppressants for the purpose of weight loss (Nappo et al. 2002) and others used for their stimulant and euphoric effects (Feldman et al. 1997). Thus, it is important that future studies examine the relationship between eating disorder patterns and each class of substances separately.

Summary Points

- Empirical research provides evidence of high comorbidity between alcohol use and all disordered eating patterns, except anorexia nervosa. This comorbidity was observed for both genders and is highest with binge eating and bulimic behavior.
- More research is needed to determine the temporal sequence of the occurrence of eating disorders and alcohol use disorders and to explain the mechanisms underlying their co-occurrence.

- Emerging research indicates that disordered eating in men is a growing concern. However, few studies included male participants and even fewer examined gender differences.
- Future research is encouraged to use longitudinal data collected from population-based samples.
- The importance of using appropriate control groups in clinical studies is highlighted.

Definitions and Explanations of Key Terms

Anorexia nervosa: Anorexia nervosa is a psychiatric diagnosis that describes an eating disorder characterized by low body weight and body image distortion with an obsessive fear of gaining weight.

Bulimia nervosa: Bulimia nervosa is an eating disorder characterized by recurrent binge eating, followed by compensatory behaviors, such as self-induced vomiting and the use of laxatives, enemas, and diuretics.

Purging: Purging refers to the act of using self-induced vomiting and the use of laxatives, enemas, or diuretics to get rid of ingested food.

Binge eating disorder: Binge eating consists of episodes of uncontrollable overeating, during which a person rapidly consumes a large amount of food.

Dietary restraint: Dietary restraint refers to behaviors that are intended to limit food intake, in an effort to manage weight. Such attitudes may include cutting food into small pieces, obsession with counting calories, etc.

Eating disorders not otherwise specified: Eating disorder not otherwise specified is described in the DSM-IV-TR as a "category [of] disorders of eating that do not meet the criteria for any specific eating disorder".

Alcohol dependence: Alcohol dependence describes the use of alcohol despite significant detrimental consequences. For a person to meet criteria for Alcohol Dependence, the person must meet three of a total of seven possible DSM-IV criteria within a 12 month period. The criteria include tolerance and withdrawal, losing control of drinking, a progression of addiction, and continuing to drink despite being aware that it is causing or psychological or physiological problem(s).

Alcohol interference: Alcohol interference refers to the interference of drinking alcohol with the person's work, study, social relationships, etc.

Key Points

- Empirical research provides evidence of high comorbidity between alcohol use and all disordered eating patterns, except anorexia nervosa. This comorbidity was observed for both genders and is highest with binge eating and bulimic behavior.
- Several hypotheses have been proposed to explain the mediating mechanisms between the two psychopathologies. By and large, these hypotheses have not been empirically tested. In addition, the temporal sequence of the occurrence of eating disorders and alcohol use disorders is not yet determined.
- Although there is evidence to suggest that disordered eating in men is a growing concern, few studies included male participants and even fewer examined gender differences.

Abbreviation

BAC   Blood alcohol concentration

186.1 The Great Disinhibitor: Alcohol, Food Cues, and Eating Behavior

Lay theories of the association of alcohol and overweight focus mainly on beer-drinking men, who are believed to be at risk of developing beer bellies, defined as "a man's fat stomach, caused by too excessive consumption of beer" (*Oxford American Dictionary*, 2nd ed., 2005, p. 146). If one inferred from this that female beer-drinkers or wine drinkers of both genders were not at risk of gaining weight from excessive alcohol consumption, one would be wrong. The active ingredient in beer which is responsible for weight gain (or any other problem) is alcohol (ethanol) and beer shares this ingredient with all other alcoholic beverages. Thus, there can be wine bellies as well as beer bellies and while women are likely to store their weight in other places, both genders are equally at risk of weight gain.

In this chapter, we focus on two different ways by which alcohol can facilitate weight gain. First, alcohol does have a direct effect on caloric intake through the calories contained in alcohol. With 7 kilocalories per gram (kcal/g), alcohol has the second highest calorie content of any macronutrient, and people rarely compensate by eating less for the extra calories they take in by drinking beer or wine with their meals. Second, alcohol impairs people's ability to regulate or control their food intake. We will present a model illustrating the various influences by which alcohol can disrupt the self-regulation of eating by boosting the impulsive processing of tempting food cues in the environment and by disrupting executive control in the short and long run. Furthermore, we will discuss the modulating role of alcohol expectancies, possible spiraling patterns with respect to the interplay of alcohol and eating, and applications to other health domains.

186.2 The Direct Route: Alcohol as Non-compensated Caloric Intake

Drinking two glasses of dry white wine (200 mL) adds 150 kcal to one's meal. This might not seem much, but the daily excess of 150 kcal would result in a weight gain of 3.5 kilogram per year (Stroebe 2008). To work off an extra 150 kcal, an adult weighing 70 kg would have to walk for 37 min or jog for 18 min. Ironically, many people seem to reverse this logic and drink a lot of alcohol and/or high caloric "energy drinks" after a sporting event. Adding alcohol to a meal would not pose a risk of weight gain, if people stayed within their daily calorie limit by proportionally reducing their calorie intake from food. However, people do not (or only very imperfectly) compensate for the additional caloric burden contained in high-caloric beverages of all sort, including alcohol (Mattes 2006; Yeomans et al. 2003). One cognitive explanation for this regulatory failure is that even individuals who closely monitor their calorie intake often do not take account of the caloric content of beverages to the same degree that they monitor the caloric content of food. Hence, they do not adjust their self-regulatory standards appropriately. A second more physiological explanation is that beverages, due to their low viscosity, are far less satiating than solid foods (Hulshof et al. 1993). Taken together, alcohol's direct influence on caloric intake is typically ignored and this effect alone can pose a serious threat to a person's weight goals.

186.3 The Indirect Route: Undermining Self-regulation

As Herman and Polivy (2004) point out, viewing eating behavior as simply regulated by bodily hunger and satiety signals is a great oversimplification. Eating behavior, at least in modern societies, is to a large extent also influenced by social norms (e.g., adherence to mealtimes, the presence of other people), the food environment (e.g., the presence of tempting food cues), and, most centrally to the present purpose, by internalized self-regulatory goals people harbor with regard to their food intake. Such self-regulatory goals are often related to matters of appearance (e.g., "I want to keep a slim figure because thin is attractive") or health ("I want to avoid eating too high-cholesterol food"). However, most psychological theories of eating regulation assume that people differ in the extent to which they regulate their weight by cognitively controlling their calorie intake. For example, Schachter's (1971) Externality Theory postulated that in contrast to normal weight individuals, who regulate their eating in response to internal cues of hunger or satiation, these cues are irrelevant to eating by obese. Their eating is triggered by external food-relevant cues such as the palatability of food or external cues in the environment, which signaled palatable food (e.g., sight or smell of food; salience of food cues).

Schachter's theory was later integrated by Herman and Polivy (1984) into their "Boundary Model of Eating," which has dominated eating research for decades. Herman and Polivy (1984) introduced the individual difference variable of "Restrained Eating" and developed the "Restraint Scale" to place people on this dimension. People vary on a continuum from unrestrained to restrained eating. At the unrestrained eating end of the continuum are normal eaters, individuals who have no weight problems and regulate their calorie intake in response to internal cues. At the restrained endpoint are restrained eaters (i.e., chronic dieters), who continuously monitor their calorie intake, trying to keep it below some regulatory standard or "diet boundary" which defines the maximum amount of calories they allow themselves to consume. As the cognitive control of calorie intake requires more cognitive resources than the automatic regulation in response to internal hunger and satiety cues, regulation can easily be disrupted by external factors, which reduce the individual's ability or motivation

to control their calorie intake. It is these restrained eaters whose eating control is likely to be deregulated by alcohol consumption.

Both externality theory and boundary model agree on the basic assumption that (a) weight is homeostatically regulated through bodily signals of hunger and satiety and that (b) for various reasons this homeostatic regulation malfunctions in individuals with weight problems or in restrained eaters. Although there can be no question that food intake and body weight are homeostatically controlled, the importance of this type of regulation for the development of overweight and obesity has increasingly been questioned (e.g., Lowe and Butryn 2007; Pinel et al. 2000). For example, Pinel and colleagues (2000) argued that people living in food-replete environments rarely experience energy deficits, but eat because of the pleasure that can be derived from food. Lowe and Butryn (2007) even suggested a distinction between *homeostatic* hunger, due to the prolonged absence of energy intake, and *hedonic* hunger, which is strongly influence by the availability and palatability of food.

Stroebe and colleagues (e.g., Stroebe 2008; Stroebe et al. 2008) incorporated the idea of hedonic eating into a goal conflict model of eating, which assumes that eating regulation of restrained eaters is dominated by a conflict between two incompatible goals, namely, the goal of maintaining or reducing their weight and the goal of enjoying palatable food. These individuals try to shield their weight control goal by suppressing thoughts about palatable food. Unfortunately (at least from the point of eating control), most of us live in food-rich environments, where palatable food is widely available and where we are surrounded by cues signaling palatable food. Such cues are likely to prime the eating enjoyment goal and to increase its cognitive accessibility. Once the goal of eating enjoyment is instigated by such palatable food cues, the goal of eating control will be inhibited, leading the individual to overeat.

The idea that eating involves relatively "primitive" hedonic influences as well as opposing higher-order processes of self-regulatory goal pursuit can also be derived from dual-process or dual-system conceptions of the mind (e.g., Hofmann et al. 2009; Strack and Deutsch 2004; Wiers et al. 2010). Specifically, these models generally assume an impulsive, association-based route to behavior determination whereby stimuli in the environment can automatically and effortlessly trigger motivational states such as cravings and desires and corresponding behavioral approach tendencies that have proven useful in the past to satisfy these cravings and desires. In contrast, long-term goal pursuit involves a series of coordinated higher-order processes of reasoning, behavioral decision making and behavior regulation (for more details, see Strack and Deutsch 2004). Importantly, the latter type of processing is typically more effortful in nature, and hence more easily disrupted than impulsive processing.

Thus, according to both the goal conflict and the dual-systems framework, the eating regulation of restrained eaters is dominated by a conflict between the reflective process of maintaining and shielding the weight control goal in the service of long-term goal pursuit and the more impulsive process that capture the hedonic short-term consequences of yielding to the temptation at hand. Whether one or the other side of this conflict wins, depends on the relative strength with which regulatory and impulsive influences impinge on final behavior determination. Figure 186.1 illustrates the competing influence of impulsive and reflective processing on caloric intake. In the following sections of this chapter, we will introduce the basic elements of the model and finally discuss the ways by which alcohol may modulate the effects of impulsive and reflective processing on eating behavior.

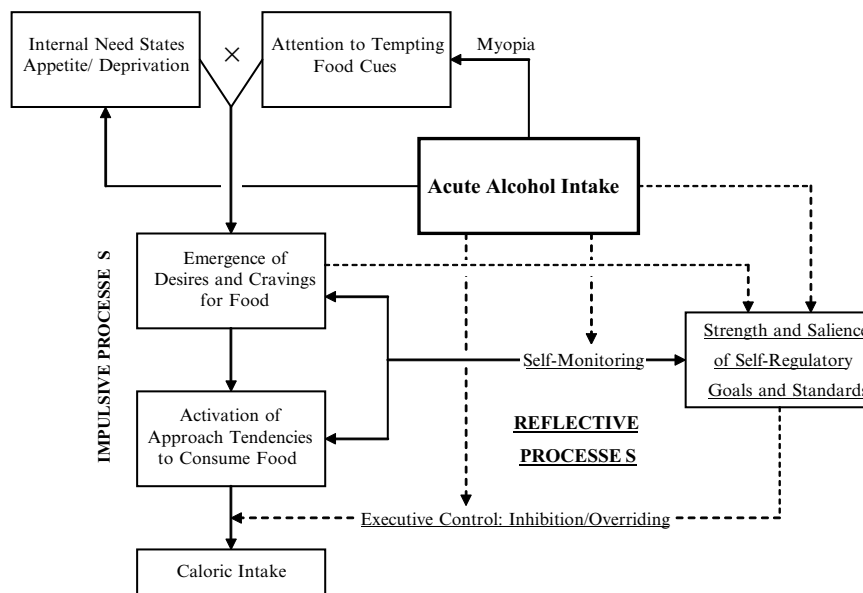
Focusing on reflective processes, Baumeister and Heatherton (1996) have identified three necessary factors for successful self-regulation: standards, self-monitoring, and the execution of control. First, self-regulatory goal standards have to be mentally represented in an accessible and consistent state during self-regulation (see Fig. 186.1). Active maintenance and shielding of self-regulatory goals from interference appears to build on working memory resources (e.g., Hofmann et al. 2008). Self-monitoring, in turn, pertains to the updated comparison of ongoing behavior with one's standards, similar to the "test" phase in feedback-loop models of self-regulation (e.g., Carver and Scheier 1981).


Fig. 186.1 A framework summarizing the key issues for possible acute alcohol effects on eating behavior as discussed in the present chapter. *Straight lines* indicate positive (facilitating) pathways. *Dotted lines* indicate negative (inhibitory) pathways. The framework holds that alcohol increases hunger and attention to salient food cues, thereby increasing the strength of cravings and desires for food. At the same time, alcohol appears to hamper reflective processing (underlined) in the service of self-regulatory goals. The figure does not show the direct link between alcohol consumption and caloric intake, indicating that alcohol in itself is a source of caloric intake that is typically not compensated for (see text)

In case discrepancies between standards and ongoing mental events are detected, an operative phase of executive control has to be set in motion if self-regulation is to be successful. Most forms of executive control can be described as either (a) the inhibition of a prepotent response (e.g., stopping an impulse to put a spoonful of mousse o chocolat into one's mouth) or (b) the overriding of a prepotent response, that is, substituting the undesired behavioral tendency with an alternative behavior (e.g., eating some healthy celery sticks instead). Self-regulation can go awry with regard to all three factors: First, people may fail to keep a clear representation of their self-regulatory goal in working memory in the first place. Second, even with intact goal-representations, they may fail to notice discrepancies between their standards and their actual thoughts or behavior. And third, even with goal representation and self-monitoring intact, people may lack sufficient self-regulatory resources (Baumeister and Heatherton 1996) or fail to recruit available resources (Muraven and Slessareva 2003) in the service of self-regulatory goal pursuit.[1]

As outlined in more detail elsewhere (Hofmann et al. 2009; Hofmann et al. 2008a), situational and dispositional boundary conditions may strongly influence people's self-regulatory success. Research on the self-regulation of eating has accumulated knowledge about conditions that disrupt the normal self-control of eating, especially for people who generally have high standards to restrain their caloric food intake (restrained eaters). Violation of dietary standards (Herman and Mack 1975)

---

[1]Note that we sketch self-regulation here as a resourceful, intentional, and conscious process of goal-pursuit. It is possible, however, that self-regulation can become habitual and automatized via repeated training (e.g., Fishbach and Shah 2006). Even though not in the focus of this chapter, such automatic forms of self-regulation may be far less susceptible to alcohol's detrimental influences on self-regulatory success described below. Common violations of self-regulatory standards suggest, however, that many individuals have not sufficiently transformed self-regulatory strategies into fully automatized routines.

temporary depletion of self-regulatory resources (Vohs and Heatherton 2000), cognitive load (Ward and Mann 2000), or tempting food stimuli (Fedoroff et al. 1997; Stroebe et al. 2008) have all been demonstrated as disinhibiting factors. As will be discussed in the next section, acute alcohol consumption is a very powerful situational disinhibitor, which appears to have a detrimental impact with regard to all the three factors of successful self-regulation identified above.

The present tug-of-war metaphor implies that the outcome of a self-regulatory conflict should not only hinge on the quality of self-regulatory goal pursuit, but also on the power of the temptation at hand. In the present framework we argue that the power of the temptation is jointly determined by the motivational need state of the organism (i.e., appetite) and the presence and features of food cues in the environment (see Fig. 186.1).[2] Exposure to palatable food stimuli triggers hedonic thoughts about the palatability of this food in restrained but not normal eaters (Papies et al. 2007) and the attention of restrained eaters becomes glued to those food stimuli (Papies et al. 2008). The hedonic quality associated with the food cue can then lead to the intrusion of cravings and desires into consciousness (Kavanagh et al. 2005). Such cravings and desires occupy attentional and working memory resources and therefore directly compete with the representation of self-regulatory goals and standards in working memory (see Fig. 186.1).

Once in the center of attention, the suppression of cravings and desires becomes difficult and can produce ironic effects such that the very thought that is supposed to be suppressed becomes even more strongly activated (Boon et al. 2002). In addition, cravings and desires are assumed to trigger the very behavioral schemas in memory that have proven to be useful in the past to fulfill the need (e.g., Strack and Deutsch 2004). Hence, tempting food cues in the environment may lead to the activation of behavioral tendencies to approach and consume the tempting object at hand (see Fig. 186.1). Whether these impulsive behavioral tendencies are enacted or not depends on whether sufficient executive control capacity can be mustered in order to inhibit or override the impulsive action tendencies.

One straightforward implication of the described role of food cues is that, all else being equal, more vivid and attractive food cues should lead to stronger desires and hence to more disinhibited behavior. For instance, work on delay of gratification suggests that resistance to temptation is more difficult when the tempting object is literally present than when it is not visible (Mischel et al. 1996). More direct evidence for this conjecture stems form a series of studies by Fedoroff, Polivy, and Herman (Fedoroff et al. 1997). Participants in the experimental group were exposed over an extended period to the sight and smell of highly attractive food. When given access to palatable food afterward, restrained eaters more likely show increased disinhibited eating.

Thus far, we have outlined a self-regulation framework that tries to understand and specify how impulsive, stimulus-triggered and reflective, goal-dependent forces clash in determining eating behavior. In the following section, we will illuminate potential mechanisms by which alcohol may affect the outcome of this struggle.

186.3.1   Alcohol's Acute Effects on Impulsive Processing Appetite and Attentional Myopia to Food Cues

There is reason to believe that alcohol may have a facilitating influence on the impulsive processing of tempting food stimuli. Specifically, alcohol may promote the strength of food cravings and desires by bolstering appetite and by enhancing attention to salient food cues (see Fig. 186.1). Indeed, one

---

[2] Because one focus of the present chapter is on external influences provided by present food cues, a second possibility not discussed further is that strong need states can also trigger from memory visual images of temptations that are not currently present, leading to similar cravings and desires as those emanating from present cues (for more details, see Kavanagh et al. 2005).

of alcohol's psychoactive effects appears to consist in a general stimulating effect on appetite (Westerterp-Platenga and Verwegen 1999). This effect is supported both by research in animals and humans although the exact physiological mechanisms by which alcohol exerts this effect are not perfectly well understood (for a review, see Yeomans et al. 2003). Accordingly, it has been found both in experimental and field studies in humans that alcohol – at least above a certain threshold – increases subjective ratings of hunger (e.g., Caton et al. 2004). As a consequence, craving and desires for tempting food cues in the environment should increase and overeating (and drinking) should become more likely.

A second acute effect by which alcohol may boost impulsive processing is attentional myopia (see Table 186.1 for key features). Originally proposed by Steele and Josephs (1990), the attentional myopia model holds that alcohol narrows the focus of attention and thoughts to the most salient stimuli in the environment. As a consequence, behavior will be disproportionally influenced by these salient cues rather to the exclusion of more distal cues. If salient cues favor the emergence of desires and cravings (e.g., rich food cues in one's environment), more disinhibited eating behavior is expected. In the food-rich environments people often find themselves in or even create themselves, this is arguably often the case. However, if the salient cues attended to favor self-controlled behavior (e.g., a dieting plan pinned on one's kitchen wall), alcohol myopia theory would even predict more self-regulated behavior.

The predictions of the attentional myopia model for alcohol consumption have been confirmed in other domains of self-regulation such as sexual risk taking (e.g., MacDonald et al. 2000). Mann and Ward (2004) applied the attentional myopia model in a study on food consumption in chronic dieters employing cognitive load (rather than alcohol) as a method to manipulate attentional capacity. Supporting the model, dieters in the low attentional capacity condition showed relatively more disinhibited eating behavior when available cues (i.e., a milkshake) promoted consumption than dieters in the high attentional capacity condition. Conversely, dieters in the low attentional capacity condition showed more restrained behavior when high-fat food contents and dieting were made salient prior to testing the milkshake as compared to the high attentional capacity group (Mann and Ward 2004). Additional measures of thought content supported the idea that attentional load induced more hedonic thoughts in the milkshake-salient condition and more dieting-related thoughts in the diet-salient condition whereas participants in the no load condition exhibited a broader range of thoughts.

In sum, alcohol's acute effects on the stimulation of appetite as well as on the narrowing of the perceptive field to the most salient cues – often consummatory in nature – may jointly contribute to an increased intrusion of food desires and cravings into consciousness. These in turn may compete with self-regulatory goals in working memory for scarce representational resources (see the negative link between cravings and self-regulatory goals in Fig. 186.1) and lead to an activation of consumption-oriented behavioral action schemas. If not held in check properly by executive control functions, overeating will become more likely.

Table 186.1 Key features of alcohol myopia

1. Alcohol myopia (Steele and Josephs 1990) refers to the tendency of alcohol to focus an individual's attention on proximal, highly salient stimuli or events in the environment to the disadvantage of more distant stimuli or events (hence the reference to myopia which is shortsightedness)

2. As a consequence, tempting stimuli (such as highly palatable food) in the environment may have a disproportionally strong influence on thought and emotion, leading to stronger cravings and desires and, ultimately, more impulsive behavior

3. However, to the degree that cues signaling control (rather than temptations) are salient, alcohol may even foster control (e.g., MacDonald et al. 2000; Mann and Ward 2004)

186.3.2   Alcohol's Acute Effects on Reflective Processing: Goal Standards, Self-Monitoring, and Executive Control

Next to alcohol's boosting influence on impulsive processes in eating (and indirect influences on the representation of self-regulatory goal standards), alcohol also appears to directly hamper reflective processing in a multitude of ways (Hull and Slone 2004). In our framework, we will focus on three main factors: representation of goal-standards, self-monitoring, and executive control capacity.

First, alcohol may impair the processes necessary to retrieve self-regulatory goal-standards into working memory and then in an active state necessary for conscious goal-pursuit. These two processes may together lead to weaker and less consistent representations of self-regulatory standards under alcohol intoxication (Baumeister et al. 1994). Some evidence indicates that alcohol, at least in higher doses, may hinder recall from long-term memory (Nelson et al. 1986). Hence, alcohol may hinder people from retrieving the very self-regulatory plans and intentions they had formed earlier. For instance, otherwise strongly represented intentions to diet may become temporarily suppressed. Also, it has been argued that successful self-regulation requires the maintenance of self-regulatory goals in working memory (Hofmann et al. 2008). Some research indicates that alcohol interferes with the maintenance function of working memory (Saults et al. 2007). Hence, self-regulatory goals may fade out of consciousness more easily under alcohol and cannot serve as well as comparison standards for self-monitoring and for mentally simulating the long-term consequences of one's conduct.

Second, there is strong evidence that alcohol negatively affects self-awareness (e.g., Hull and Bond 1986). Hence, intoxicated people may lose the ability to successfully attend to and monitor their behavior. With self-monitoring gone awry, discrepancies between the implications of an impulse to consume tempting food at hand and relevant goal standards to diet may simply go unnoticed.

Third and perhaps most central from a self-regulatory perspective, alcohol may seriously reduce people's capacity to inhibit or override prepotent impulses directed at the consumption of tempting food. That is, even though intoxicated persons may still be aware of existing conflicts between their impulses and their self-regulatory goals to some degree, they may nevertheless lack the cognitive resources for the kind of control – behavioral inhibition – that is necessary in order to stop impulsive action tendencies from becoming transformed into action or in order to resolve a conflict between two incompatible response tendencies (e.g., to eat chocolate versus celery sticks) in favor of one. This hypothesis is in line with a range of experimental studies demonstrating reduced inhibitory control after alcohol intake (e.g., Fillmore and Vogel-Sprott 1999). Most of these studies have employed the stop-signal paradigm (Logan et al. 1984) to examine the effects of alcohol on behavioral control. In a typical setup of such a task, participants have to react with quick, accurate choice responses to go-signal trials (e.g., categorizing letters via keypress). On a fraction of trials, however, a stop-signal (e.g., a brief auditory tone) accompanies a typical go-trial. In these trials, subjects are required to inhibit (i.e., suppress) the typical go-response. Inhibitory control is measured by the ability of the individual to inhibit prepotent go-responses at varying delay times with which the stop signal appears (with longer delays rendering inhibition of the go-response more difficult).

Using such a paradigm, Fillmore and Vogel-Sprott (1999) demonstrated that a moderate dose of alcohol resulting in an average BAC (blood alcohol concentration) of 73 mg/100 mL reduced the drinker's ability to inhibit behavior in response to stop-signals as compared to a placebo control group, whereas responses to go-signals were left unaffected. In other words, response inhibition seems to be much more vulnerable to the physiological effects of alcohol than response execution. Subsequent studies have shown that this effect depends on the presence of conflict between two competing action tendencies (Fillmore and Vogel-Sprott 2000). The above effect occurs when rewards are given both for acting (go-response) and for inhibition (stop-response) but disappears

when either one response is rewarded but the other is not. Taken together, these studies indicate (a) that alcohol's effects on response inhibition may be most decisive in mental tug-of-war situations in which an approach-avoidance conflict exists and (b) that alcohol is likely to tip the scales in favor of the approach reaction in such cases.

The cognitive capacities (representing standards, self-monitoring, inhibition) discussed in this section can all be subsumed among other functions under the umbrella term of executive cognitive functioning. A large body of neuropsychological data indicates that the neural substrate of executive cognitive functioning is provided by the prefrontal cortex, particularly its dorsolateral region (e.g., Giancola 2000). Hence, alcohol's acute effects on a whole range of executive cognitive functioning abilities may be explained by its detrimental effects on this brain region in particular. In fact, alcohol seems to predominantly affect the glucose metabolism in the prefrontal cortex as corroborated by neuroimaging research (e.g., Volkow et al. 1995). The prefrontal cortex is the central part of a system of neural networks that are assumed to be involved in working memory functions and in the top-down control (i.e., inhibition and overriding) of subcortical structures such as the amygdala, insulae, mesolimbic cortex and the striatum (Bechara 2005), which provide the neuroanatomical basis for stimulus-triggered affective states and impulsive action tendencies. Hence, the observation that alcohol leads to less inhibited behavior accords well with the notion that it selectively impairs the very structure that is "in a logical neuroanatomical position to intercept and inhibit these lower brain impulses" (Giancola 2000, p. 585).

186.3.3 Supporting Empirical Evidence

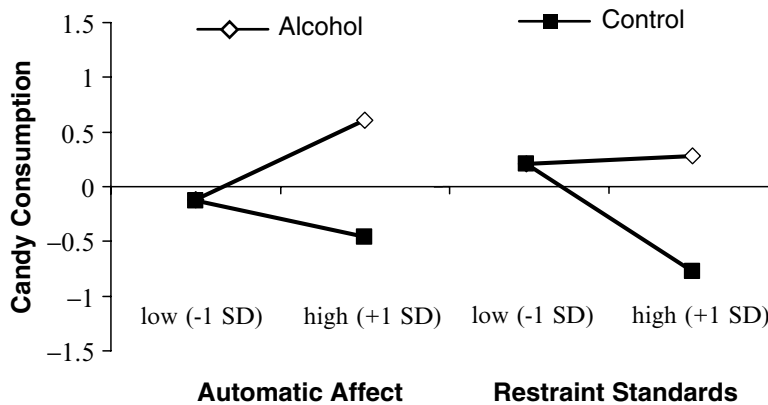
Taken together, the present framework predicts that alcohol may boost the strength of impulses (via food cravings and the activation of impulsive action tendencies) while at the same time reducing the capacity for reflective processing. In other words, alcohol should lead to an increased influence of impulsive processing and to a reduced influence of self-regulatory goal standards on eating behavior. These predictions were directly tested in a study by Hofmann and Friese (2008). At the beginning of the study, female participants completed a number of screening questionnaires including a measure of dietary restraint standards (Stunkard and Messick 1985) to assess individual differences in self-regulatory goal standards. We also assessed individual differences in impulsive affective reactions toward candy with a version of the Implicit Association Test (Greenwald et al. 1998). This task measures how quickly participants associate a given object (M&M's candies in this case) with positive versus negative affect (for more details, see Hofmann and Friese 2008). High scores on the measure indicate more positive automatic affective reactions toward the food and hence can be taken as an indicator of impulsive processing. After the assessment phase, participants engaged in two different product tests. In the first product test, they consumed a drink that either consisted of orange juice with vodka (alcohol condition) or solely orange juice (control condition). An intermediate filler task gave the alcohol dose time to unfold its impact before participants tasted and rated candy in a second product test. A first finding was that participants in the alcohol condition on average consumed significantly more candy than participants in the control condition (Hofmann and Friese 2008). More importantly, however, we also investigated the degree to which candy consumption could be predicted by impulsive influences (i.e., automatic affect) versus reflective influences (i.e., dietary restraint standards) depending on whether participants had consumed alcohol or not. As expected, candy consumption was reliably predicted by automatic affect for participants in the alcohol condition as indicated by the positive slope between automatic affect and candy consumption in Fig. 186.2 (left panel). However, candy consumption was not predicted by automatic affect in the control condition (Fig. 186.2, left panel).


Fig. 186.2 Candy consumption as a function of alcohol consumption, automatic affect toward candies, and dietary restraint standards. The y-axis represents z-transformed candy (m&m's) intake during an unobtrusive taste and rate task with higher numbers indicating more candy consumption. Automatic affect toward the candy was assessed with an Implicit Association Test (Greenwald et al. 1998) as a measure of hedonic, impulsive reactions toward the candy. Restraint standards with regard to eating were assessed with a self-report scale. As can be seen from the two graphs, the relationship between automatic affect and candy consumption was stronger (as indicated by the steeper regression slope) for participants who had consumed alcohol before the taste and rate task (such that participants with high automatic affective reactions consumed most candy). In contrast, the expected negative relationship between restraint standards and candy consumption was more pronounced in sober participants (such that participants with high restraint standards consumed least candy) (Adapted from Hofmann and Friese 2008. With permission)

Conversely, dietary restraint standards were quite ineffective in participants who had consumed alcohol as indicated by the flat line in the right panel of Fig. 186.2. Dietary restraint, however, regulated candy consumption effectively for sober participants as indicated by the negative slope in Fig. 186.2 (right panel). Viewed in combination, these results yield strong evidence for the hypothesis that alcohol consumption fosters the influence of impulses on eating behavior while at the same time reducing the behavioral impact of self-regulatory goal standards as a controlling influence.

Similar findings on the relative impact of impulsive versus reflective influences on consummatory behavior has been obtained in a number of studies using other moderators such as cognitive load (Friese et al. 2008), ego depletion (Hofmann et al. 2007), or individual differences in working memory capacity (Hofmann et al. 2008; Thush et al. 2008). The strong convergence across the alcohol-related findings and the other moderators raises the question whether there may be a common element among these moderators that is responsible for producing functionally equivalent results. We think that the underlying connecting element may lie in the impairment of two central executive cognitive functions involved in impulse control: working memory capacity and inhibitory control (Giancola 2000; Hull and Slone 2004). Without support from these executive functions, bringing behavior in line with self-regulatory goals becomes more difficult. As reflective processing wanes, impulsive processes gain weight in determining the final outcome of a self-regulatory conflict.

186.3.4 Physiological Versus Alcohol Expectancy Effects

We have argued that alcohol impairs self-regulation by boosting impulsive influences and interfering with reflective processing. One remaining issue is whether all of these effects are purely due to the physiological effects of alcohol, or whether at least parts of these effects are the result of cognitive

Table 186.2 Key features of alcohol expectancies

1. Alcohol expectancies refer to people's beliefs about the effects of alcohol on thought, feeling, and action
2. Alcohol expectancies can be positive or negative
3. Typical positive alcohol expectancies comprise the beliefs that alcohol improves mood, reduces tension, increases sociability, and boosts self-esteem and assertiveness (e.g., Hull and Slone 2004)
4. Typical negative alcohol expectancies encompass the beliefs that alcohol decreases self-control, impairs intellectual performance, increases aggressiveness, and, at least in higher doses, creates unpleasant feelings of nausea.
5. It is generally assumed that positive alcohol expectancies increase the likelihood of alcohol consumption whereas negative expectancies decrease it.
6. Next to influencing alcohol consumption, alcohol expectancies have also been shown to mediate the effects of consuming alcohol. Thus, like a self-fulfilling prophecy, individuals may tend to behave in accordance with their alcohol expectations. Interestingly, it seems already sufficient for some of these effects to occur that individuals *believe* that they have consumed alcohol regardless of whether their actual drink really contained alcohol or not (Hull and Bond 1986).

mechanisms. More specifically, it has been argued that alcohol effects may be modulated by alcohol expectancies (see Table 186.2 for key features). Alcohol expectancies refer to the cognitive expectations people hold with regard to the consequences of alcohol consumption. A first assumption in the alcohol literature is that alcohol expectancies will influence the degree of alcohol *consumption* in a given situation of interest (Hull and Slone 2004). That is, people who harbor certain positive alcohol expectancies (e.g., "Alcohol makes me more relaxed when I am stressed") will consume more alcohol if they are in a situation where these expectations are relevant (e.g., having to deliver a stressful speech) than people who do not hold these expectancies or people who hold negative expectancies (e.g., "Alcohol will make me lose my concentration"). Applied to the relationship between alcohol and eating, the degree of alcohol consumption in the presence of eating may be influenced by the type of expectancies people hold. For instance, dieters holding the negative expectancy that alcohol will impair their self-regulation should be more cautious in consuming alcohol than dieters who do not hold that expectation and these kinds of negative expectancies may aid the self-regulation of eating as far as the consumption of alcohol is concerned. On the other hand, some individuals may primarily harbor positive alcohol expectancies and these may then have detrimental effects on dietary control. For instance, individuals may believe that alcohol helps them to deal with negative affect such as the frustration of having to refrain from so many tasty foods they would otherwise like to eat or feelings of guilt upon violation of dietary schedules. As discussed in more detail below, such positive expectancies may stimulate alcohol consumption in the presence of tempting food cues and ultimately lead to violations of standards and even to patterns of spiraling distress (Baumeister et al. 1994).

A second assumption concerning the role of alcohol expectancies is that alcohol expectancies can modulate the very *effects* of alcohol on behavior (Hull and Slone 2004). These expectancy effects may even be independent of the pharmacological effects of alcohol. That is, individuals may behave in accordance with their expectations whenever they believe that they have consumed alcohol, regardless of whether they actually received an alcoholic drink or a placebo (Hull and Bond 1986). For instance, it is plausible that individuals who expect alcohol to disinhibit their behavior in turn act more disinhibited than individuals who do not hold these expectations, all else being equal. This is because alcohol expectations may bias ongoing information processing systematically such that the expected behavioral outcome becomes more likely. Whether physiological and expectancy effects are additive or whether they interact is still an issue of ongoing debate (Hull and Bond 1986). There is, however, some indication that alcohol's physiological effects on the impairment of control tend to be stronger among those expecting detrimental effects on control (Fillmore et al. 1998), although negative expectancies may also sometimes lead to increased efforts at compensating the expected

impairments (Fillmore and Blackburn 2002). Possibly, whether such negative expectancies lead to decreased versus increased efforts at self-regulation following alcohol consumption may depend on how strongly people are motivated to summon an extra amount of willpower to counteract the expected effects. If control motivation is low, negative alcohol expectancies may lead to a pattern of acquiescence (Baumeister and Heatherton 1996) by which people actively give in to the temptation at hand (in the sense of the what-the-hell effect). If control motivation is high, however, negative expectancies may trigger increased efforts at self-regulation, similar to compensatory effects obtained with regard to other risk-situations such as ego depletion (Muraven and Slessareva 2003). Interestingly then, whereas negative alcohol expectancies about alcohol's disinhibiting influence may help people to resist consuming alcohol in the first place, once people are led to consume alcohol (though a lapse of self-control or social pressure) the same expectancies may be hard to counteract and amplify the physiological effect.

186.4 Alcohol's Long-term Effects on Executive Functioning

Next to alcohol's acute effects, there is mounting evidence that chronic alcohol consumption may have negative long-term effects on self-regulatory capacity (Volkow et al. 2004; Wiers et al. 2007). Specifically, chronic alcohol use may lead to frontal lobe dysfunctions as indicated by neurophysiological studies documenting decreased frontal lobe glucose utilization and blood flow in alcoholism (for a review, see Moselhy et al. 2001). These neuropathological changes may underlie the performance deficits in alcoholics as compared to nonalcoholics on a large range of executive cognitive functioning (Moselhy et al. 2001). Alcohol's long-term deleterious effects may be particularly consequential during adolescence, a sensitive period of brain maturation that is fraught with both opportunities as well as risks for the development of self-regulatory capacities (Steinberg 2005). In other words, chronic alcohol use during adolescence may slow down or even disrupt the development of the very functions needed for adult self-regulatory competencies. Early alcohol use and its negative effects on self-regulatory ability may be one reason underlying the co-occurrence of alcohol abuse and eating disorders, characterized by impulsive eating such as bulimia nervosa, binge eating disorder, and obesity (e.g., Grilo et al. 2002).

186.5 The Dynamic Interplay of Alcohol Consumption and Eating: Patterns of Snowballing

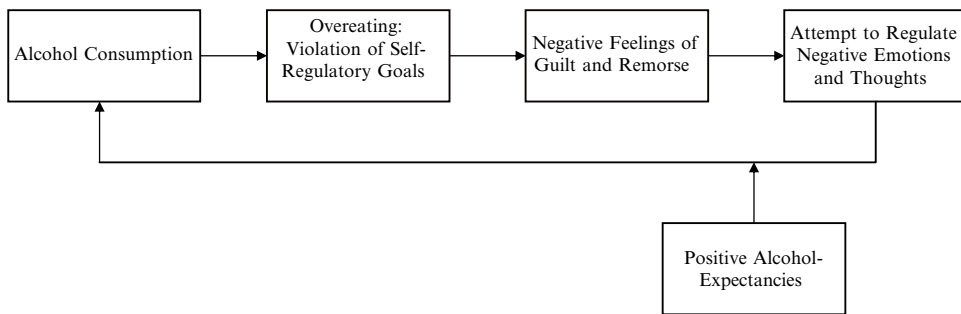
Thus far, we have examined the impact of alcohol as a predictor/moderator on eating behavior as an outcome in a linear fashion. As typical for the psychology of self-regulation, reality is often more complex. Specifically, adopting a feedback-loop perspective on self-regulation (Carver and Scheier 1981), self-regulatory outcomes may often serve as inputs for new self-regulatory loops and so forth. In this section, we want to specifically highlight one such dynamical pattern that may help to explain why the combination of alcohol use and eating behavior may sometimes "snowball," leading to a vicious circle of self-regulatory failure (Baumeister et al. 1994). An example of a potential snowballing pattern is illustrated in Fig. 186.3. As outlined above, acute alcohol intoxication may lead to disinhibited eating by boosting cravings and desires with regard to tempting food as well as by weakening resistance to these urges (Hofmann and Friese 2008). Failure to meet one's dietary standards may in turn trigger emotional distress (especially feelings of guilt or remorse) as soon as the person


Fig. 186.3 A vicious cycle of alcohol consumption and overeating. The figure illustrates a possible "snow-balling" pattern of self-regulatory failure whereby alcohol consumption is both a cause of overeating (i.e., alcohol leading to disinhibited eating) as well as a consequence of overeating (i.e., alcohol as a means to cope with negative emotions due to overeating)

starts to self-monitor and reflect upon these failures. These negative emotional states, coupled with positive alcohol expectancies about its soothing effects, may lead the person into a new drinking episode in an attempt to cope with the negative feelings and thoughts (Baumeister et al. 1994), whereby the whole cycle may start all over again. Although clearly speculative, such dysfunctional patterns of misregulation may underlie the development of pathological forms of eating and account in part for the above-mentioned comorbidity between alcohol abuse and eating disorders. Once alcohol use enters the scene of eating disorders, it may be best understood as an integral part (i.e., both cause and effect) in an often vicious cycle of self-regulatory failure.

186.6 Conclusion: Alcohol and Eating

As this chapter has shown, alcohol can be considered a great threat to the self-regulation of eating behavior. What makes alcohol a particularly dangerous threat is the fact that, as we have tried to show, alcohol is akin to an enemy that uses several different weapons at once. To recapitulate, these include the direct caloric impact of alcohol as a beverage not typically compensated for, boosting effects on impulsive processing which may lead to increased craving for tempting food, and detrimental effects on the self-regulatory mechanisms involved in inhibiting and overriding prepotent but unwanted action impulses (see also summary points). Even though the attack is a broad one, all of these direct and multiple indirect effects ultimately appear to converge toward the same target: enhanced caloric intake. Alcohol thus really seems to earn the title chosen for the present chapter. However, at least two qualifications need to be emphasized. First, alcohol's effects seem to emerge mainly if there is a cognitive conflict in the first place (Fillmore and Vogel-Sprott 2000). Only if the hedonic, short-term prospects clash with highly valued long-term goals such as weight control or health concerns is alcohol likely to enter the ring as a decisive force. For this reason, restrained eaters are particularly at risk to experience alcohol's negative consequences on self-regulatory goal pursuit. Second, these effects may be modulated by alcohol expectancies such that people who expect alcohol to have a disinhibiting effect on their eating behavior may have a good reason for abstaining from alcohol consumption, but, once alcohol is consumed may be at special risk for what-the-hell types of effects (unless an extra surplus of willpower is summoned to counteract these expectancy effects).

186.7 Application to Other Areas of Health

The present framework can also be applied to other areas dealing with the self-regulation of health behavior (Hofmann, Friese et al. 2008; Wiers et al. in press). Most centrally, alcohol may act as a disinhibiting influence on other appetitive domains such as sexual behavior and drinking itself by boosting impulsive processes and impairing reflective processing. In other domains of health behavior where impulsive influences may be less salient (e.g., the use of sunscreen, for instance), alcohol may still impact reflective processing and lead to more careless behavior because people may fail to represent and act in accordance with their long-term health goals and standards. However, to the degree that attention can be directed toward salient cues signaling control (Mann and Ward 2004) or to the degree that self-regulatory behavior can be delegated to more automatic and habitual routines, the great disinhibitor may loose some of its disruptive power on the self-regulation of human behavior.

Summary Points

- Eating in humans can be regarded as self-regulatory behavior by which individuals often strive to attain certain self-regulatory goals such as weight control or healthy food intake
- Eating as self-regulation typically involves a fragile conflict between self-regulatory goals and impulsive, appetitive influences on eating behavior the latter of which are driven by the interplay of internal need states and external food cues in the environment
- The outcome of such self-regulatory conflicts can be strongly influenced by situational boundary conditions such as alcohol consumption.
- Alcohol has multiple short-term effects on eating behavior. These comprise direct and indirect effects.
- Direct short-term effects are given by the caloric load of alcohol itself are typically not compensated for.
- Indirect short-term effects involve (a) an increase in appetite and (b) detrimental short-term effects on self-regulation as given by a weaker representation of goal standards, reduced self-monitoring, and reduced executive control.
- These effects have a physiological basis but are also modulated by alcohol expectancy effects.
- Alcohol also has long-term effects on cognitive functioning which may further undermine the self-control of eating behavior. These chronic effects may partly account for the observed comorbidity between alcohol abuse and impulsive eating disorders.
- Alcohol use may be an integral part of dysfunctional self-regulatory loops whereby alcohol promotes overeating and overeating in turn promotes alcohol consumption. Such "snowballing" patterns may be a second factor accounting for the comorbidity between alcohol abuse and eating disorders.

Definition of Key Terms

Self-regulation: An individual's attempt to behave in accordance with his or her self-regulatory goal standards (e.g., dietary standards).
Self-monitoring: A comparison of actual behavior with one's self-regulatory goal standards. Discrepancies between the two indicate that further self-regulation is necessary.

> **Behavioral inhibition:** Higher-order mental control process by which a prepotent action tendency is stopped.
>
> **Alcohol myopia:** Narrowing of attention to most salient cues in the stimulus environment due to alcohol consumption.
>
> **Alcohol expectancies:** People's beliefs about the positive or negative effects of alcohol on thought, feeling, and action.

Chapter 187
Brain Atrophy in Alcoholics

E. González-Reimers and F. Santolaria-Fernández

Abbreviations

AMPA	Alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
BMI	Body mass index
cAMP	Cyclic adenosine monophosphate
CREB	cAMP responsive element binding-protein
CT	Computerized tomography
DNA	Desoxiribonucleic acid
DEXA	Dual-energy x-ray absorptiometry
EEG	Electroencephalogram
GABA	Gamma-amino-butyric acid
HT	Hydroxytryptamine
MDA	Malondialdehyde
MRI	Magnetic resonance
NF-κB	Nuclear factor kappa B
NADP	Nicotinamide adenine dinucleotide phosphate
NADH	Reduced nicotinamide adenine dinucleotide
NMDA	N-methyl-D-aspartate
TNF	Tumor necrosis factor

187.1 Introduction

Ethanol exerts deleterious effects on the brain, both acutely and chronically. Acute alcohol intake affects brain function in a dose-dependent manner, so that at lower doses of ethanol induces euphoria and altered mood, in greater amounts it impairs speech and motor function, whereas higher doses affect respiratory and cardiovascular functions and may result in death. These risks are also present in binge drinkers; in addition, these alcoholics also develop organic brain damage and cognitive dysfunction. In fact, with time, chronic alcohol consumption leads to dependence and frank addiction,

Ofra s/n 38320, La Laguna, Tenerife, Canary Islands, Spain
e-mail: egonrey@ull.es

whereas progressive cognitive dysfunction and brain atrophy also ensue, even with moderate amounts of ethanol consumption. Although not the only neurological alteration suffered by the chronic alcoholic patient, brain atrophy is frequently observed; it often affects relatively young people, and severely impairs mood, memory, judgement and other cognitive skills, so that it constitutes a major challenge for patients, physicians and society. This chapter focuses on some of the factors involved in the pathogenesis of brain atrophy, especially those related with altered nutrition in the wide sense of the term.

187.2 The Clinical Problem

Drinking patterns differ across countries and also within countries, according to age, sex, social class and lifestyle. In rural areas, excessive drinkers, mainly consumers of wine, develop cirrhosis after many years of regular consumption. At the other end of the spectrum, socially ostracised, homeless, undernourished alcoholics, usually living in an urban environment, are more prone to develop vitamin deficiency and Wernicke–Korsakoff syndrome. Another group of drinkers is constituted by binge drinkers, more frequently found among young people living in urban areas; sometimes binge periods coexist with heavy smoking and consumption of illicit drugs. Therefore, the neurocognitive alterations usually found in alcoholics are heavily influenced by lifestyle, drinking pattern, and coexistence of liver disease and/or other neurotoxic factors, making it difficult to discern if the observed effects are due to ethanol itself, to liver dysfunction, coexisting malnutrition, or depend more heavily on the effects of other drugs, such as tobacco or illicit drugs. In addition, different educational levels – roughly associated with drinking patterns – and previous behavioural disorders, which in many alcoholics act as contributing factors to alcohol dependence, complicate the scenario. It has been reported that more than 80% of those adolescents with alcohol abuse or dependence also showed another psychopathology (Thatcher and Clark 2005). Moreover, genetic predisposition, and the ability of ethanol to modulate the activity of at least 58 genes involved in neuronal activities (38 down-regulated, 15 up-regulated, 5 up-/down-regulated), potentially subjected to polymorphism (Wang et al. 2009), further complicates our understanding and knowledge of the mechanisms, which underlie brain alterations in alcoholics (Table 187.1).

Central nervous system affectation in chronic alcoholics includes brain atrophy, with variable degrees of cognitive dysfunction; the Wernicke–Korsakoff syndrome, related to thiamine deficiency, and cerebellar cortical degeneration, leading to dysmetria and ataxia, but also playing a role in cognitive impairment. Although pellagroid dermatitis is sometimes observed in malnourished alcoholics, ataxia and dementia due to vitamin B3 deficiency is uncommon. Other syndromes, such as Marchiafava–Bignami syndrome, or acute pontine myelinolysis, are less frequently encountered, but should be considered in the clinical evaluation of alcoholic patients with impaired mood and/or judgement, obtundation, stupor or frank coma, with or without variable symptoms related to cerebellar dysfunction. In addition, alcoholics show reduced cerebral blood flow (Christie et al. 2008), and are at increased risk of stroke and cerebral trauma. Furthermore, neurological effects of acute ethanol intoxication and of ethanol withdrawal, and the less frequently described ethanol- and tobacco-related amblyopia, complete the clinical syndromes derived from affectation of the central nervous system in the alcoholics. Thus, the spectrum of ethanol-induced brain alterations is wide, and the underlying mechanisms are incompletely understood, especially taking into account that the pathogenesis of central nervous system dysfunction may differ according to the nature and intensity of exposure, i.e., acute alcohol intoxication, chronic alcohol consumption and binge-drinking. Other factors, such as malnutrition or liver failure or, possibly, even the type of alcoholic beverage, may

Table 187.1 Key points of brain atrophy

Anatomoclinical forms of chronic brain damage	Brain cortical and subcortical atrophy
	Cerebellar degeneration
	Toxic amblyopia
	Pellagra
	Wernicke–Korsakoff encephalopathy
	Marchiafava–Bignami disease
	Central pontine myelinolysis
	Increased prevalence of stroke and cerebral trauma
Clinical features of brain atrophy	May vary from subtle alterations (Impaired verbal problem solving, abstracting abilities, visual–spatial performance, verbal memory and the ability to adapt problem-solving strategies to changing requirements) to frank dementia
	Mostly reversible with prolonged ethanol withdrawal
Underlying anatomic lesions	Neuronal death
	White matter alterations (demyelination and axonal death)
Proposed mechanisms	Direct effect of ethanol
	Cytokine (especially TNF-α) mediated neuroinflammation.
	Oxidative damage (disbalance between antioxidants and prooxidants)
	Thiamine deficiency
	Protein deficiency and malnutrition
	Excitotoxicity
	Coexisting liver disease

contribute. Importantly, the risk of dementia is increased in binge-drinkers (Jarvenpaa et al. 2005), as well as the risk of developing chronic alcoholism.

In any case, brain dysfunction is frequently observed in alcoholics admitted to general care services due to organic problems. Despite some discrepancies regarding its true prevalence, cognitive dysfunction, at least in its mildest forms, has been documented in more than 50% of alcoholic patients. Although verbal reasoning and verbal learning skills are relatively preserved, verbal problem solving, abstracting abilities, visual–spatial performance, verbal memory and the ability to adapt problem-solving strategies to changing requirements become more or less severely impaired. In a study of 100 alcoholics who had been sober for at least 21 days before inclusion in the analysis, cognitive efficiency (assessed by a battery of tests including perceptual motor skills, visuospatial processing, learning and verbal and non-verbal problem solving) was significantly impaired compared with 80 controls (Nixon et al. 1995). In that study, alcoholics also showed more depression, anxiety and symptoms related to childhood behavioural disorders, attention deficit disorders and conduct disorders, than controls, but the cognitive impairment could not be attributed to the coexisting behavioural dysfunction. Thus, although some conditions during childhood, such as conduct disorders, stress, anxiety and depression, or attention-deficit/hyperactivity disorders may predispose to ethanol abuse in later years, cognitive impairment takes place without the necessity of any other predisposing situation. Classically, cognitive impairment was attributed to frontal lobe lesions and their associated connections with other cortical and subcortical regions, but in recent years it has been shown that alcohol-mediated brain damage affects many other parts of the central nervous system, including hippocampus, corpus callosum (alterations in attention and executive functions have been related to subtle alterations in corpus callosum, Pfefferbaum et al. 2006), and pathways connecting the cerebellum and other parts of the central nervous system, such as cerebellothalamocortical and cerebelloponto cerebellar pathways.

187.3 Neuropathology

Ethanol provokes generalized brain shrinkage (Fig. 187.1), largely due to loss of cerebral white matter, but also to a reduction in the cortical grey matter, especially observable with magnetic resonance (MRI) or computerized tomography (CT).

Regarding white matter, the maximum atrophy has been observed in the prefrontal white matter (Kril et al. 1997), corpus callosum (Pfefferbaum et al. 2006) and cerebellum (Fitzpatrick et al. 2008). In general, the degree of brain atrophy has been related with the intensity of ethanol consumption. Ding et al. (2004) observed a relation between the amount of ethanol ingested and the area of the fluid-filled spaces in the brain. Harper showed an increase in the pericerebral space in men drinking more than eight drinks per day (Harper 2009). In the study by Kubota et al. (2001) of 1,432 non-alcoholic individuals, moderate alcohol consumption (less than 50 g/day) did not seem to affect brain volume; however, in the Framingham study Paul et al. (2008) did find a relation between any amount of ethanol consumption and brain atrophy. White matter regions in the frontal lobe were those mostly affected in alcoholics, especially among patients with Wernicke's encephalopathy, but also showing a relation with ethanol intake, estimated as maximum daily ethanol consumption (Kril et al. 1997). In a study on 43 alcoholics we found a significant ($p = 0.007$) relationship between the duration of alcohol intake and the bifrontal index, suggesting a relationship between ventricular dilatation and ethanol consumption (Fig. 187.2). Also, a relation was found between cortical atrophy assessed by CT and duration of ethanol consumption (rho = 0.37, $p = 0.014$). However, no relation was found between the total life-long amount consumed (expressed as kilogram ethanol/kilogram body weight) and the presence of brain atrophy.

Changes in white matter probably include both alterations in myelination and axonal integrity (Harper 2009), and it is possible that a synergist effect between ethanol consumption and thiamine deficiency also exists. These changes are reversible, at least in part, after ethanol withdrawal. Therefore, in alcoholic brain damage, there may be two components, one reversible and one permanent. In the latter, neuronal death would provoke axonal degeneration and white matter shrinkage, whereas structural alterations of myelin would be reversible after alcohol abstinence. Bartsch et al. (2007), in a study of 15 patients who completed abstinence, showed a significant brain volumetric gain, whereas no changes were observed among 10 controls. Changes in abstinent alcoholics were more marked in the superior vermis, perimesencephalic infratentorial and supratentorial periventricular borders, and

frontomesial and frontoorbital edges, and are not explainable only on the basis of simple rehydratation. These changes were accompanied by regain in cerebral choline, suggesting recovery from white matter damage potentially consistent with astrocyte regrowth and remyelination. Also, an increase in frontomesial N-acetylaspartate was observed. Cerebellar choline was significantly related with brain volume recovery, and frontomesial N-acetyl aspartate increase showed a significant correlation with improvement in attention and concentration, although not with other neuropsychological tests (auditory verbal learning test, standard progressive matrices, vocabulary test). In another study also performed with MRI and an automated three-dimensional method (boundary shift integral), the most rapid volume recovery was observed among those with the greatest baseline brain shrinkage and drinking severity. The study was performed with 18 alcoholics, and, in the first month of abstinence, tissue gain was apparent around the third, fourth and lateral ventricles, cerebellum, pons, hippocampi and the boundaries of frontal, parietal and superior temporal lobes. This study also showed a rapid reversal of volume gain to baseline levels even with consumption of relatively small amounts of ethanol (five drinks per day during 9 days) in reincident patients (Gazdzinski et al. 2005). These data strongly support the direct effect of ethanol on brain alterations and stresses the benefits of ethanol withdrawal, confirming early reports, which showed that even short-term (1 month) abstinence increases cortical grey matter volume, whereas long-term abstinence (1 year) leads to shrinkage of the enlarged ventricles. Working memory, visual spatial abilities and motor abilities also improve (Crews and Nixon 2009).

Frontal cortical grey matter is also affected, with neuronal loss and dendritic shrinkage, which are reversible after abstinence (Harper 2009). Indeed, as early as 2 days after intragastric administration of large amounts of ethanol to rats, neuronal death is already observed in several areas of the brain, accompanied by reduced hippocampal neurogenesis. Changes are more pronounced in adolescent rats and in those genetically predisposed (Crews and Nixon 2009). Detailed autopsy studies have revealed that neuronal loss was found in the superior frontal association cortex, while no loss was observed in the motor cortex. Loss of neurons was also observed in the hypothalamus, affecting the supraoptic and paraventricular nuclei, especially among those who consumed more than 100 g ethanol/day (Harding et al. 1996). Together with increased neuronal death, it is possible that ethanol also inhibits neuronal regeneration, reducing the survival of progenitor neuronal cells and also blunting the maturation and growth of the dendritic arbor of these cells (Crews and Nixon 2009).

Cerebellum alterations are also widespread among the alcoholics, especially among heavy drinkers during 10 or more years (Andersen 2004). Prevalence studies of cerebellar degeneration among alcoholics yield variable results depending upon the criteria employed (autopsy, radiological (MRI/CT scan) or clinical data), but may be estimated to be around 25–30%. In a series of 36 alcoholics with brain atrophy attended at our hospitalization unit, cerebellar atrophy affected 33% (García-Valdecasas-Campelo et al. 2007). Cerebellar affectation is characterized by shrinkage of the anterior superior cerebellar vermis and loss of Purkinje cells in the vermis and lateral lobes of cerebellum. These alterations cause ataxia and instability. Although some data suggest that ethanol alone does not cause cerebellar damage but only when coexisting with thiamine deficiency, experimental evidence does support that ethanol treatment and withdrawal reduces the number of Purkinje cells (Andersen 2004). In addition, white matter atrophy, particularly affecting the vermis, has also been described in chronic alcoholics. Cerebellar alterations in alcoholics may not only affect motor functions, but may also be related to cognitive and emotional disturbances – the so-called cerebellar cognitive affective syndrome (Fitzpatrick et al. 2008). These manifestations depend on the disruption of the cerebellocerebral circuitry, which connects the cerebellum and cerebral associative and paralimbic areas. The disruption of this circuitry provokes deficits in executive functioning and visuospatial skills, language alterations and disturbed personality and affective behaviour, all of which may add to the alterations due to direct frontal lobe affectation observed in the alcoholics. Cerebellar atrophy may also recover with abstinence (Cardenas et al. 2007).

187.4 Pathogenesis

187.4.1 Inflammation and Oxidative Damage

Detailed studies using a binge drinker rat model suggest that neuronal death occurs during ethanol intoxication, and not during withdrawal periods (Crews and Nixon 2009). Ethanol-induced brain damage may be related to oxidative stress derived from proinflammatory enzymes activated during ethanol intoxication. Inflammation not only causes neuronal death, but also inhibits regeneration. Transcription factors, such as cyclic adenosine monophosphate (cAMP) responsive element binding-protein (CREB), regulate the transcription of pro-survival factors, protecting neurons from excito-toxicity and apoptosis (Mantamadiotis et al. 2002).On the other hand, nuclear factor kappa B (NF-κB) is involved in proinflammatory and immune responses, is activated by cytokines, oxidative stress and glutamate, and promotes transcription of genes involved in the synthesis of proinflammatory cytokines such as tumor necrosis factor (TNF)-α. Ethanol has been associated with an increase in DNA binding to NFkB and a decrease in DNA binding to CREB, at least in hippocampal entorhinal cortex slice cultures (Zou and Crews 2005). By this way it is possible to explain the increase of reduced nicotinamide adenine dinucleotide phosphate oxidase (NADPH-oxidase) and other enzymes involved in the production of reactive oxygen species and the increase of oxidative damage mediated by ethanol. In this regard, there is the possibility that oxidative damage mediate brain atrophy (Nordmann 1994). In addition, several studies point out that flavanoids and other antioxidants exert protective effects in patients with Alzheimer's disease and there are even some reports suggesting that ingestion of wine in moderate amounts may protect against dementia, an effect that could be related to antioxidants present in wine.

Neuroinflammation may be related to neuronal degeneration. Microglial and asctrocyte responses to various brain insults include release of highly toxic products, such as reactive oxygen species, nitric

oxide, excitatory amino acids, cytokines and complement components, which cause neurodegeneration. Increased proinflammatory cytokines and chemokines expression suggest the presence of a brain proinflammatory status in several models of chronic brain damage. Experimental data have shown that an acute ethanol load cause lipid peroxidation in several areas of the brain (Uysal et al. 1989). Several studies suggest that antioxidants protect the brain from binge ethanol-induced damage and also tend to reverse ethanol-induced inhibition of neurogenesis (Crews et al. 2006). All these data, together with the well-known effect of TNF-α enhancing oxidative stress, strongly suggest a major role of this cytokine in neurodegeneration. Indeed, it is possible that part of increased lipid peroxidation is mediated by pro-inflammatory cytokines (Crews et al. 2006). In alcoholic subjects and experimental animals, increased intestinal permeability leads to a continuous exposure of Kupffer cells to intestinal antigens; these cells become activated and secrete pro-inflammatory cytokines, TNF-α being the most abundant of these. Increased TNF-α enters the brain; there, its increase lasts longer than in other tissues and exerts neurotoxic effects, including demyelination and neurodegeneration. The different behaviour of TNF-α after alcohol exposure, with rapid decrease in liver and serum, but persistence in brain, could be important in binge drinkers, with progressive neurodegeneration (Crews et al. 2006). TNF-α potentiates glutamate excitoxity, linked to excessive glutamate activation of N-methyl-D-aspartate (NMDA) receptor, since it reduces glial glutamate transporter activity and thus may also play a role in neurodegeneration (Zou and Crews 2005). Increased glutamate is related to an increase in the desire to consume ethanol. Therefore, increased TNF-α would be not only related to brain damage, but also to alcohol dependence. In accordance with these statements, in a study on 34 alcoholics we found significant relationships between TNF-α values (in percentiles) and several indices of cortical atrophy, such as bifrontal index, Evan's index and Huckmann's digit (Fig. 187.3).

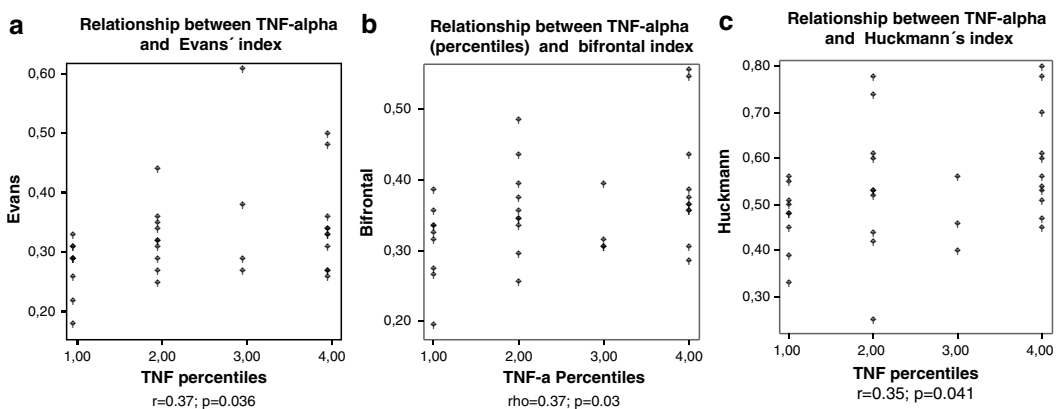
In acutely intoxicated rats (5 g/kg ethanol, intraperitoneally), raised liver and brain malondialdehyde (MDA) levels were observed, reaching maximum differences with respect to controls 4 h after ethanol injection (Uysal et al. 1989), a result which lends support to the hypothesis of oxidative damage as a major pathogenic mechanism in ethanol-related brain damage. However, rats subjected to chronic ethanol ingestion (5 g/kg in saline for 6 weeks, although details on how rats ingested ethanol and the amount consumed are not provided) did not show changes in brain MDA or glutathione, despite an increase in both liver MDA and glutathione levels.


Fig. 187.3 Relationships between ventricular dilatation and Tumor necrosis factor (TNF)-alpha. Relationship between TNF-alpha (in percentiles) and several parameters related with ventricular dilatation (a = Evans' index; b = bifrontal index; c = Huckmann's digit). In the three panels it is evident that more intense degrees of ventricular dilatation are observed among those patients with higher TNF-alpha percentiles

187.4.2 Trace Elements

In close relation with oxidative damage, some trace elements could play a role in brain atrophy of alcoholics. Theoretically, some of them, such as zinc, copper, manganese and selenium, are involved in the antioxidant systems, so that their deficiency could explain some of the alterations observed. Chronic alcoholics show low serum zinc and selenium levels, and some controversy exists regarding copper. However, the relation of changes in trace elements with brain damage has been scarcely explored. There are several studies dealing with the relation between brain atrophy and copper levels. Squitti et al. (2002) found a relation between serum copper and brain atrophy in patients with Alzheimer's disease, so that levels over 1.02 mg/dl discriminated individuals with Alzheimer's disease from controls, with a sensitivity of 60% and a specificity of 95%. Toxicity of copper was probably related to the induction of peroxidation, but treatment with d-penicilamine, despite showing a lowering effect on lipid peroxidation, did not alter cognitive decline. On the other hand, in patients with Wilson disease, midbrain atrophy shows a correlation with neurological symptoms, both in probable relation with copper toxicity (Strecker et al. 2006). We also analysed the relationship between serum copper and brain atrophy, but our (preliminary) results do not support the existence of a relationship between copper and brain atrophy in alcoholics.

Increased iron has been related with early edema and, later, brain atrophy, after intracerebral bleeding, a process which can be reversed by deferoxamine. Indeed, after bleeding, once haemoglobin is degraded, iron concentration increases severalfold (Hua et al. 2007), and is capable of causing edema and brain damage by oxidative stress. Maschke et al. (2005) failed to find any relation between vermal atrophy and dentate iron concentrations – assessed by MRI – in alcoholics, but in a study of 29 alcoholics we found that serum ferritin is significantly higher among those with cerebellar atrophy (Fig. 187.4). No differences, however, were observed with serum iron. Thus, ferritin being an acute phase reactant, the possibility exists that the difference is more in relation with inflammation than with a direct effect of iron storage.

In Alzheimer's disease, as well as in alcoholic brain damage, controversy also exists regarding the role of zinc (Menzano and Carlen 1994). Low zinc may be involved in neuronal apoptosis, and in an increase in NMDA-gated neurotoxicity (Peters et al. 1987). It is hypothesized that low zinc levels may

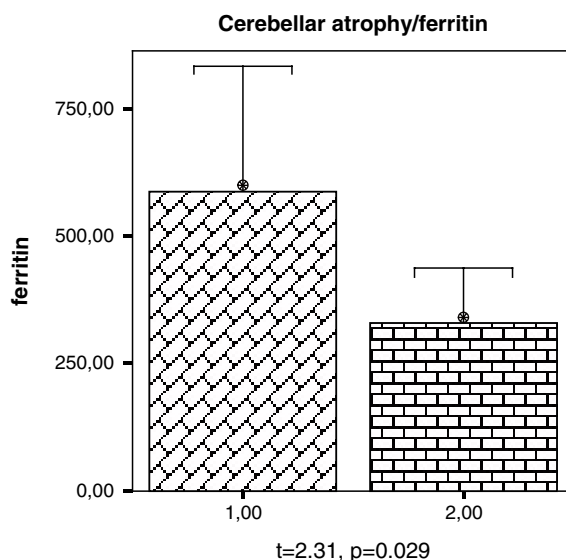
Fig. 187.4 Relationship between serum ferritin and cerebellar atrophy. Relationship between serum ferritin and cerebellar atrophy. Patients (12) with cerebellar atrophy (1, *left bar*) showed higher ferritin levels (in ng/ml) than those (17 patients) without cerebellar atrophy (2, *right bar*)


Fig. 187.5 Relationship between serum zinc and Evans'index. *Direct* relationship between serum zinc and Evans'index. Although the number of cases is small, this result does not support a role of low zinc in brain atrophy

Relationship between serum zinc and Evan´s index

rho=0.64; p=0.002
account for chronic alcoholic brain damage as well as alcohol withdrawal seizures, and a possible link between low zinc levels and hypercortisolism, as well as between hypercortisolism and brain dysfunction has been postulated (Menzano and Carlen 1994). However, this link is still merely hypothetical, and some results are inconsistent. For instance, we found a direct relationship between Evan's index and serum zinc (Fig. 187.5), a result that directly contrasts with the hypothesis linking brain atrophy to low zinc levels. We also failed to find any relation between cortisol levels and brain atrophy.

Selenium is another important element in the antioxidant system, since it is a cofactor of the glutathione-peroxidase system. It has been also shown that selenium is a necessary cofactor for normal brain development. Moreover, selenium depletion is associated with decreased activity of selenium-dependent enzymes and enhanced neuronal loss in animal models (Schweizer et al. 2004). Although low serum selenium levels have been repeatedly reported in alcoholics, the role of selenium deficiency in alcohol-related brain atrophy is largely speculative and results are not consistent. For instance, in a study of 21 alcoholics, serum selenium was directly related with bifrontal index (i.e., the more selenium, the more intense atrophy, Fig. 187.6), a result which does not support any role of low selenium on brain atrophy.

187.4.3 Vitamins

Deficiency of several vitamins, such as ascorbic acid, vitamin A, and vitamin E (due to antioxidant capabilities); cyanocobalamin, vitamin B6 and folic acid (by their relation with hyperhomocystein-aemia), and thiamine (as an etiologic factor of the Wernicke–Korsakoff encephalopathy) may be involved in the pathogenesis of brain atrophy in alcoholics.

As the above-mentioned trace elements, vitamin E may also protect against lipid peroxidation. Chronic ethanol feeding results in increased vitamin E demand by the liver (Nordmann 1994). Although the role of vitamin E in the central nervous system is uncertain, it has been shown that

rho = 0.44; p = 0.048
vitamin E supplementation may decrease ethanol-induced lipid peroxidation in rat cerebellum (Nordmann 1994).

A condition that must be considered in the study of brain disturbance in alcoholics is the Wernicke–Korsakoff syndrome, due to thiamine deficiency, which may also appear in nonalcoholics with protracted vomiting and/or different degrees of malnutrition. Typically, the clinical picture improves with thiamine supplementation. However, in many alcoholics – reaching as much as 80% of those affected by Wernicke's encephalopathy – Korsakoff psychosis ensues (Fitzpatrick et al. 2008). This is characterized by anterograde amnesia, cognitive impairment and confabulation, reduced affect, visuospatial alteration and also altered problem-solving capacity. Mammilary bodies and the dorsomedial nucleus of the thalamus are well-described anatomic targets of this entity, although others also describe neuronal loss in the anterior thalamic nuclei (Harding et al. 2000). In alcoholics, thiamine deficiency may result from inadequate intake, impaired absorption, reduced liver storage, and decreased transformation of thiamine in its active form. Thiamine deficiency may act synergistically with ethanol in the pathophysiology of cognitive impairment in alcoholics (Sechi and Serra 2007). Several mechanisms may be involved, such as reduction of thiamine-dependent enzyme activity, alteration of mitochondrial function and impaired oxidative metabolism, all leading to neuronal death. Decreased transketolase, alpha-ketoglutarate dehydrogenase and pyruvate dehydrogenase are observed in autopsy samples of cerebellar vermis of alcoholic patients with Wernicke–Korsakoff. Although a genetic predisposition has been sought for Wernicke–Korsakoff enecephalopathy, results are not conclusive (Guerrini et al. 2009).

On the other hand, many alcoholics with thiamine deficiency show brain atrophy, but the degree of atrophy is similar to that of patients with normal thiamine levels. As in alcoholics without any superimposed disease, atrophy of corpus callosum is also observed in relation with Wernicke's encephalopathy, but only in those cases related to ethanol abuse (Lee et al. 2005). Therefore, probably, there is a synergistic effect of thiamin deficiency and ethanol intake on brain alterations, at least regarding white matter shrinkage. In addition, several observations support a role of thiamine deficiency in cerebellar shrinkage, although the precise mechanism remains elusive. In this sense, the supplementation of staple foods like bread (and, eventually, beverages such as beer) with thiamine is a recommended practice (Harper 2009).

Brain atrophy has been put in relation with hiperhomocysteinaemia, especially at the hippocampus, in a study of 52 alcoholics who showed high levels of homocysteine (reaching 27 μmol/l in female alcoholics), low levels of folate and B6, but normal B12 levels (Bleich et al. 2003). This result is consistent with observations performed on otherwise healthy elderly subjects and in cases of dementia. Possibly, oxidative damage is the underlying mechanism, although low vitamin B12 levels are associated with brain atrophy (Vogiatzoglou et al. 2008) and more rapid cognitive decline. However, the precise pathogenic mechanisms, as well as the role of vitamin B12 in brain atrophy of alcoholics are largely unknown.

187.4.4 Nutritional Status: Protein–Calorie Malnutrition and Obesity

Protein–calorie malnutrition is a well-recognized alteration in alcoholics: indeed, not only muscle wasting, but frank malnutrition is a widespread finding in several studies dealing with alcohol-related pathologies. Although commonly associated to other nutritional deficiencies, several studies performed in growing children and individuals with eating disorders (Nogal et al. 2008) have described alterations in the myelinization process, ventricular dilatation and increased width of cortical sulci with cerebral atrophy in protein calorie malnutrition. In addition, prolonged malnutrition frequently precedes cerebellar alterations. In a study of 36 chronic alcoholics not affected by Wernicke–Korsakoff encephalopathy and 12 patients with Wernicke's encephalopathy it was found that malnutrition was associated with a sixfold increase in the risk of cerebellar atrophy. Cerebellar atrophy was present in 10 out of 12 undernourished alcoholics not affected by Wernicke's encephalopathy, but also in 11 out of 24 well-nourished alcoholic patients (Nicolas et al. 2000). These results also suggest that factors other than malnutrition are involved in cerebellar shrinkage in alcoholics. Indeed, ethanol consumption was also directly related to cerebellar shrinkage using stepwise regression analysis, in accordance with a previous study of the same group, performed on 40 well-nourished alcoholics, who showed a greater degree of brain shrinkage with age than controls, accompanied by functional derangement. Both morphological and functional alterations were correlated with the lifetime amount of ethanol consumed (Nicolas et al. 1997).

However, in 42 non-selected alcoholics, several nutritional parameters, especially those related to muscular assessment, such as brachial perimeter and handgrip strength, were also related to brain atrophy (Fig. 187.7a–c). Moreover, total lean mass was lower among alcoholics with frontal atrophy (not quantified, but assessed by a neuroradiologist), as well as trunk lean mass and limb lean mass. Interestingly, no relation was found between body mass index (BMI) and brain atrophy, or between fat parameters and brain atrophy. In this regard, obesity may also lead to brain atrophy and altered cognitive function. In a cross-sectional study on 114 individuals aged 40–66 years, brain atrophy was independently related both with age ($\beta = -0.39$) and BMI ($\beta = -0.22$; Ward et al. 2005). The association between increased BMI, brain atrophy and deranged cognitive performance has been confirmed in further studies, even in healthy adults, although the possibility exists than brain atrophy in these individuals is related to other risk factors, such as hyperhomocysteinaemia, dyslipemia, hypertension or diabetes.

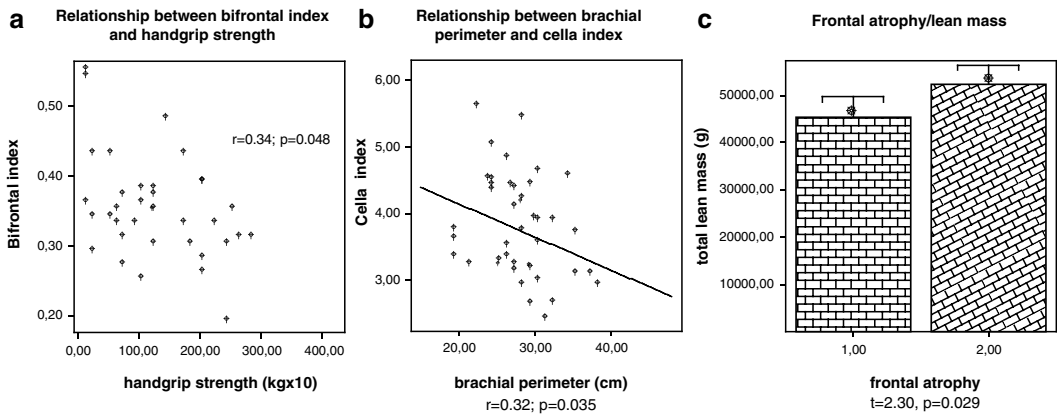
Malnutrition in alcoholics has many causes, but, undoubtedly, poor nutritional intake is an important one (Santolaria et al. 2000). Irregular feeding is frequently observed in heavy alcoholics who have lost familial and wider social links. Classifying a series of patients in three groups according to eating habits, we found that cortical atrophy, estimated by measuring the width of cortical sulci, was more intense among those with poor eating habits (Fig. 187.8). Although it is likely that those with poor nutritional intake not only had protein calorie malnutrition, but also vitamin and micronutrient deficiency, this result stresses the importance of adequate nutrition in the alcoholic population at risk of brain atrophy (García-Valdecasas-Campelo et al. 2007).


Fig. 187.7 Relationships between nutritional parameters and brain atrophy. Relationships between nutritional parameters and brain atrophy (*panel a* = relationship between handgrip strength and bifrontal index; *panel b* = relationship between cella index and brachial perimeter; *panel c* = relationship between the presence (1) or not (2) of frontal atrophy assessed by a neuroradiologist and total lean mass (assessed by dual energy x-ray absorptiometry)

187.4.5 Liver Disease

Impaired liver function may also be associated with brain atrophy. In a classic neuropathological study on autopsies of 25 alcoholics and 44 controls, Harper and Krill (1985) found that the pericerebral space was 8.3% ± 3.3% in controls, but 16.2% ± 4.4% in alcoholics with liver disease, even greater than in alcoholics with Wernicke's encephalopathy. Amodio et al. (2003) found that several indices of brain atrophy were altered in 68 alcoholics, some of them of non-alcoholic etiology; indeed, atrophy was independent of alcoholic etiology, but was related only to age and to psychometric

Fig. 187.9 Relationships

and liver cirrhosis. Cirrhotics
(*left bar*, 17 cases) show less
ventricular dilatation than
non-cirrhotics (*right bar*,
30 cases). This result speak
against a possible relation
between liver failure and
brain atrophy
impairment and EEG changes, confirming previous studies. In this regard, Bernthal et al. (1987), studying 49 non-alcoholic cirrhotics, found that some of them showed brain atrophy, but others had brain edema, and that these changes were related to altered psychometric tests; Tarter et al. (1986) found a significant inverse relationship between serum albumin and bifrontal index (r = −0.32, $p <$ 0.05), and serum albumin and third ventricle (r = −0.30, $p < 0.05$) in 42 patients affected by nonalcoholic chronic liver diseases. Although high ammonia has been hypothesized to play a role in these alterations, no relation was found between brain atrophy indices and blood ammonia. It is possible that other factors, such as nutritional status, vitamin deficiency, or oxidative damage, may also account for these results. In this regard, in 17 alcoholic cirrhotics and 30 non-cirrhotic alcoholics (all heavy drinkers), we found that non-cirrhotic alcoholics showed more dilated ventricles than cirrhotics (Fig. 187.9) despite similar age. Moreover, a direct relationship was observed between cella index and bilirubin (r = 0.39, $p = 0.008$), and an inverse one between cella index and prothrombin activity (r = −0.32, $p = 0.03$), suggesting again that ventricular dilatation is more intense among those with preserved liver function, so that, in our experience, liver dysfunction is not related to brain atrophy.

187.4.6 Biochemical Changes and Altered Neurotransmission

It is hypothesized that alcohol-induced brain damage is attributable to two main mechanisms. The first is direct neurotoxicity mediated by ethanol, possibly by disturbances in the excitatory neurotransmission system. In addition, as commented before, thiamine deficiency may play an additive role, and this would be the second mechanim. There are marked differences in the alterations observed in neurotransmitter systems in binge drinkers and in chronic alcoholics (Ward et al. 2009). Glutamate, an excitatory neurotransmitter involved in learning and its modulation of consolidation and recall, is found to be raised in the nucleus accumbens in a binge-drinking experimental model in rats, but not in chronic alcoholics during alcohol consumption. Moreover, the amount of released glutamate depends on rat strain. Meléndez et al. (2005) showed an increase in extracellular glutamate in the nucleus accumbens, which was related to decreased uptake 24 h after a seven-day period

of intraperitoneal administration of 1 g /kg ethanol. Glutamate acts by binding to several receptors, including NMDA, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and metabotropic glutamate receptor. It seems that in chronic alcohol exposure NMDA receptors are inhibited. However, as early as 3–5 h after detoxification there are changes in NMDA receptor sensitivity and an increase in glutamate release, which may be related to behavioural disturbances and alcohol craving (Ward et al. 2009).

Dopamine is involved in the mesolimbic reward pathway, and ethanol ingestion increases dopaminergic transmission and the firing rate of dopaminergic neurons. Chronic alcoholics need larger amounts of ethanol to evoke dopamine release to maintain the pleasurable effects of ethanol intake. These mechanisms are dramatically altered during ethanol withdrawal, leading to dysphoria and malaise. In addition, activation of D1 dopamine receptors, through phosphorilation of intermediate elements of the intracellular signal cascade, may affect glutamate activation of NMDA receptor, overriding the alcohol-induced inhibition of NMDA. Importantly, excessive activation of NMDA receptors is a major cause of neuronal cell death (Ward et al. 2009), probably by oxidative damage.

Ethanol modulates serotonin release in various areas of the central nervous system, especially through receptor 5HT-3, with different effects if exposure is acute or chronic. Serotonin release is involved in several aspects of alcohol-seeking, alcohol addiction and alcohol intoxication (Rodd et al. 2007), since it affects mood and cognitive performance. Serotonin levels depend on the levels of its precursor tryptophan, which competes with other large neutral amino acids for transport into the brain. For this reason, mental performance may be related to the ratio tryptophan/large neutral amino acids, which decreases after ethanol consumption. However, the possible effects of the altered metabolism of serotonin on brain shrinkage and neuronal death, as well as those of γ-aminobutyric acid (GABA), the main inhibitory neurotransmitter, also modulated by ethanol, are not known.

The opioid system is also influenced by ethanol. In a binge-drinking model in newborn rats (2.5 g/kg ethanol by nasogastric tube during days 2–6 of life) increased apoptosis of beta endorphin-secreting neurons (Sarkar et al. 2007) was observed, via activation of transforming growth factor beta-1 linked apoptotic signalling.

It is possible that neurotransmitters are also involved in the recovery of brain damage after abstinence. Alcohol withdrawal may lead to regeneration of the atrophic brain, with a nearly total functional recovery after prolonged abstinence. This is associated with ultrastructural changes including growth of both white and grey matter. As early as one day after stopping a binge-drinking period, proliferating microglia is observed in cortical and non-cortical brain regions (Crews and Nixon 2009). This first burst of cell proliferation is followed by the identification of immature neurons, peaking around 14 days of abstinence, located in certain areas, such as dentate gyrus. Although precise mechanisms are unknown, it is possible that glutamate-activated trophic NMDA receptors lead to increased CREB transcription, resulting in cell growth.

187.5 Conclusions

In summary, brain atrophy is a well-described entity in the alcoholic population, which may severely impair cognitive functions. Ethanol itself may cause brain atrophy through several mechanisms involving both accelerated neuronal death and blunted regeneration; probably, the principal mediator of these alterations is ethanol-induced neuroinflammation, which leads to cytokine activation and oxidative damage. Undoubtedly, coexisting alteration in vitamins, hormones micronutrients, as well as poor nutritional status, may all contribute to diffuse brain damage. It is also likely that thiamine deficiency, common in the alcoholics, also plays a synergistic role. Finally, some data, obtained by

other authors, also suggest a role of ethanol-associated liver disease on brain damage. In any case, our knowledge about this entity is still fragmentary and incomplete, and considerable research is needed for the efficient control of this complication.

187.6 Applications to Other Areas of Health and Disease

The abuse of ethanol, either in the form of excessive chronic consumption, or as binge drinking, is widespread, especially among adolescents and young adults. Even with appropriate nourishment, both forms of alcoholism may cause neurocognitive impairment and organic brain damage. Therefore, this problem is of paramount importance for the entire society, since it confers a risk of dementia to a significant proportion of young people, in addition to the many other disturbances caused by ethanol excess. Since withdrawal is associated with a marked improvement of neurocognitive damage, urgent social measures to limit excessive ethanol consumption are needed, especially directed at young people.

Equally important for the entire society is the Wernicke–Korsakoff syndrome, due to thiamine deficiency. Supplementation of basic foods, such as bread, or even alcoholic beverages, such as beer, with thiamine is a safe practice, already implemented in several countries.

Brain alterations in alcoholics also constitute another example of the rapidly expanding field of cytokine-related organ damage. This is linked to oxidative damage, and considerable research is still needed to precisely define the mechanisms involved, the potential therapeutic role of antioxidants, and the relation between altered cytokine release and neurotransmitter modulation and excitotoxicity.

The bulk of evidence indicate that severe protein deficiency may alter maturation and central nervous system function. As commented before, some alcoholics with intense addiction usually suffer loss of social and family links, and, literally forget about eating, a fact which strongly contributes to impaired nutrition. Brain atrophy in alcoholics is related with protein undernutrition. It is important to deepen our knowledge about the mechanism connecting cognitive impairment and protein deficiency, since this may help a wide proportion of people threatened by hunger in the developing world.

Summary Points

- Chronic brain damage associated to excessive ethanol consumption include cortical and subcortical atrophy, cerebellar degeneration, toxic amblyopia, pellagra, Wernicke–Korsakoff encephalopathy, Marchiafava–Bignami disease, central pontine myelinolysis and increased prevalence of stroke and cerebral trauma.
- Clinical features of brain atrophy may vary from subtle alterations (impaired verbal problem solving, abstracting abilities, visual-spatial performance, verbal memory, and the ability to adapt problem-solving strategies to changing requirements) to frank dementia. They are mostly reversible with prolonged ethanol withdrawal.
- Underlying anatomic lesions include neuronal death and white matter alterations (demyelination and axonal death)
- Pathogenesis of brain atrophy is complex and partially understood, but several mechanisms undoubtedly play a role, including: direct effect of ethanol metabolism, cytokine (especially TNF-α)-mediated neuroinflammation, oxidative damage (disbalance between antioxidants and prooxidants), thiamine deficiency, protein deficiency, excitotoxicity, and, perhaps, hyperammoniaemia related to coexisting liver disease.
- Recovery may be achieved with prolonged ethanol withdrawal and adequate nutrition

Definitions and Explanations

Wernicke–Korsakoff encephalopathy: Common complication observed in alcoholics, related to thiamine deficiency. Lethargy, disorientation and stupor may be accompanied by ophthalmoplegia and ataxia. Organic symptoms may improve with thiamine supplementation, but in some cases, confabulation, hallucinations, anterograde amnesia and intellectual impairment may ensue (Korsakoff's dementia).

Central pontine myelinolysis: Uncommon, usually fatal, complication of alcoholics, of unknown pathogenesis, characterized by demyelination and necrosis of pons and other areas of the brain leading to spastic quadriplegia, pseudobulbar palsy, and coma. Lesions and clinical picture are similar to those observed after rapid correction of profound hyponatremia.

Marchiafava–Bignami disease: An uncommon disorder which affects corpus callosum, leading to demyelination and necrosis. Initially described in Italian consumers of red wine, it also affects people worldwide, including malnourished nonalcoholics. There are three clinical forms (acute, subacute and chronic). Clinical picture ranges from convulsions and coma to mild dementia and progressive neurological deterioration.

Tobacco- and Alcohol-related amblyopia: Scotomas (blind spots) and decreased visual acuity within the central portion of the visual field, which affects undernourished alcoholic smokers, presumably caused by alcohol-mediated optic neuropathy, possibly associated with deficiency of thiamine and other micronutrients. It improves with proper diet, but may lead to permanent loss of vision if untreated.

Proinflammatory Cytokines: Molecules with pleiotropic effects, mainly involved in the inflammatory response, produced by many cells but especially by macrophages and cells involved in the immune response. Macrophages and immune cells secrete cytokines usually in response to antigens, and they generally act as signaling molecules, inducing synthesis and/or secretion of other inflammatory mediators.

Oxidative damage: Alteration of different molecules (especially DNA, lipids) of the cells by reaction with highly reactive compounds, mainly related to oxygen metabolism, including superoxide anion, hydroxyl anion, and hydrogen peroxide (powerful triggers of cytokine secretion). DNA alterations disrupt cellular metabolism and may be carcinogenic, and membrane lipid peroxidation causes cell death.

Antioxidants: Substances and/or enzymatic pathways that transform highly reactive oxidant species into less dangerous ones. Clinically important antioxidant systems which become altered in the alcoholic include glutathione peroxidase, superoxide dismutase and catalase. Several vitamins (A, C, E), and micronutrients also exert antioxidant activity.

Excitotoxicity: Mechanism of neuronal cell death, due to intense and prolonged activation of excitatory neurotransmitter (glutamate) receptors which generate increased influx of cations such as calcium and sodium, which in turn alter intracellular homeostasis and enzymatic pathways, ultimately leading to oxidative damage and cell death.

Tolerance: It is said that a subject is tolerant to alcohol when he needs progressively larger doses to achieve the same effects Tolerance leads to **physical dependence**, which is a state in which the patient needs ethanol to feel well, so that negative physical symptoms of withdrawal result from abrupt discontinuation or dosage reduction. Physical dependence is different from **addiction**, which refers only to the compulsive psychological necessity to consume a certain drug.

Dopamine neurotransmitter: Neurotransmitters are substances released into the synaptic cleft during neuronal stimulation. Dopamine acts in the mesolimbic system and plays a role in ethanol reward. During chronic consumption larger amounts of alcohol are required to evoke dopamine response (Tolerance), whereas in abstinence, rapid fall in dopamine release causes dysphoria (dependence).

Chapter 188
Alcohol Consumption in Predementia and Dementia Syndromes

Francesco Panza, Vincenza Frisardi, Patrick G. Kehoe, Cristiano Capurso, Alessia D'Introno, Anna M. Colacicco, Gianluigi Vendemiale, Antonio Capurso, and Vincenzo Solfrizzi

Abbreviations

AD	Alzheimer's disease
APOE	Apolipoprotein E
ARCD	Age-related cognitive decline
βA	Amyloid beta
CAD	Coronary artery disease
CASI	Cognitive abilities screening instrument
CVD	Cerebrovascular disease
MCI	Mild cognitive impairment
MUFA	Monounsaturated fatty acids
PUFA	Polyunsaturated fatty acids
SFA	Saturated fatty acids
VaD	Vascular dementia
WML	White matter lesions

188.1 Introduction

188.1.1 Current Epidemiology of Dementia and Predementia Syndromes

Since population aging has become a worldwide phenomenon, the burden of age-related neurode-generative diseases, particularly dementia, is expected to increase dramatically in both developed and developing nations. The deterministic boundaries of perceived normal cognitive aging are not clearly defined while the clinical categorisation of predementia and dementia syndromes remain, at present, a work in progress. Dementia is a syndrome defined by impairments in memory and other cognitive functions that are severe enough to cause significantly reduced performance from a previous level of social and occupational functioning. Dementia is estimated to affect approximately 6% of the people aged 65 years and older, with the prevalence increasing exponentially with age, rising

Table 188.1 Key features of dementia syndromes

1. Dementia is a syndrome definite by impairments in memory and other cognitive functions that are severe enough to cause significant decline from a previous level of social and occupational functioning
2. AD is the most common dementia and primary neurodegenerative disorder in the elderly, gradually leading to a complete psychological and physical dependency and finally to death within 1–2 decades
3. The diagnosis of AD is essentially a clinical one, and it is based on a typical clinical picture and findings, with a set of clinical criteria often used in research
4. Cognitive function declines over time, and the diagnosis of AD can be considered when the patient has impairments in memory and at least in one other cognitive function (executive dysfunction, agnosia, aphasia, apraxia), severe enough to cause impairment in social or occupational functioning
5. In advanced AD, common symptoms include also confusion, behavioural and gait disturbances, and the patients are increasingly dependent on others in activities of daily living
6. Another common form of dementia is VaD, its clinical presentation varies greatly depending on the causes and location of cerebral damage
7. Large-vessel disease leads commonly to multiple cortical infarcts and a multifocal cortical dementia syndrome
8. Small-vessel disease, usually resulting from hypertension and diabetes, causes periventricular white matter ischemia and lacunar strokes characterized clinically by subcortical dementia with frontal lobe deficits, executive dysfunction, slow information processing, impaired memory, inattention, depressive mood changes, slowing of motor function, Parkinsonian features, small-step gait, urinary disturbances and pseudobulbar palsy
9. The characteristic neuropsychological profile of VaD is believed to include frequently early impairment of attention and executive control function, with slowing of motor performance and information processing, while episodic memory is relatively spared compared to that in AD

This table lists the key facts of dementia syndromes including clinical pictures and criteria of Alzheimer's disease (AD) and vascular dementia (VaD), the most common dementia syndromes

to between 40% and 70% at the age of 95 years and above (Qiu et al. 2007). In Westernised countries, the most common forms of dementia are Alzheimer's disease (AD) and vascular dementia (VaD), with respective frequencies of 70% and 15% of all dementias (Whitehouse et al. 1997) (Table 188.1). Therefore, AD is the most common dementia and primary neurodegenerative disorder in the elderly that gradually leads to a complete psychological and physical dependency on others and finally to death within 1–2 decades. In the present chapter, we will use the term "predementia syndrome" to identify all conditions with age-related (non-pathological) deficits in cognitive function reported in the literature, including a mild stage of cognitive impairment based on a model of normality and the presence of pathological conditions considered predictive or early stages of dementia (Panza et al. 2005) (Table 188.2). Such predementia syndromes have been defined for AD and VaD, but have not yet been operationalized for other specific forms of dementia. Therefore, the term "predementia syndromes" includes different conditions and among these predementia syndromes, mild cognitive impairment (MCI) is, at present, the most widely used term to indicate nondemented aged persons with no significant disability and a mild memory or cognitive impairment that cannot be explained by any recognisable medical or psychiatric condition (Petersen et al. 1999; Winblad et al. 2004) (Table 188.2).

There is now ample evidence that MCI is often a pathology-based condition with a high rate of progression to AD (Petersen et al. 1999). Therefore, MCI has been classed as the predementia syndrome for AD (Panza et al. 2005). Recently, a number of subtypes of MCI have been proposed, intended to reflect the heterogeneity of different types of dementia (Table 188.2). In fact, the recent subclassification of MCI according to its cognitive features (including dysexecutive MCI and amnestic-MCI (aMCI) or aMCI and non-amnestic MCI (naMCI); single or multiple domain aMCI or naMCI) and clinical presentation (MCI with parkinsonism or cerebrovascular disease), or likely aetiology (MCI-AD, vascular MCI, or MCI-Lewy Body Disease) all represent an attempt to exert some control over this heterogeneity (Panza et al. 2010). Recently, a critical review was undertaken

Table 188.2   Key features of predementia syndromes

1. The term "predementia syndromes" identifies all conditions with age-related deficits in cognitive function reported in the literature, including a mild stage of cognitive impairment based on a normality model and pathological conditions considered predictive or early stages of dementia

2. Among predementia syndromes, MCI is, at present, the most widely used term to indicate non-demented aged persons with a mild memory or cognitive impairment that cannot be accounted for any recognized medical or psychiatric condition

3. The general criteria for MCI include (a) memory complaint, (b) objective memory disorder, (c) absence of other cognitive disorders or repercussions on daily life, (d) normal general cognitive function, (e) absence of dementia

4. MCI definitions can be broadly classified as amnestic (aMCI) and nonamnestic (naMCI)

5. There is now ample evidence that MCI is often a pathology-based condition with a high rate of progression to AD, and aMCI, with a central role for memory disorder and with relative preservation of other cognitive domains, was identified as the predementia syndrome for AD

6. aMCI can be subdivided into a single-domain subtype with a pronounced memory deficit or a multiple-domain subtype that includes memory impairment along with some impairment in other cognitive domains such as language, executive function, and visuospatial skills

7. The other major MCI subtype is naMCI, which similarly can be subdivided into single and multiple domain subtypes

This table lists the key facts of predementia syndromes including diagnostic criteria and clinical classification of mild cognitive impairment (MCI), the most common predementia syndrome

to try to define a new consensus on MCI, and a modification of Petersen's original criteria (Petersen et al. 1999) was proposed during the conference in Montreal (Winblad et al. 2004). Subsequently, the European Consortium on Alzheimer's Disease (EADC) (http://eadc.alzheimer-europe.org/introduction.html) working group on MCI proposed a novel diagnostic procedure with different stages, combining neuropsychological evaluation and family interview to detect MCI at the earliest possible stage (Portet et al. 2006).

The clinical presentation of VaD varies greatly depending on the causes and location of cerebral damage (Roman 2002). Large-vessel disease leads commonly to multiple cortical infarcts and a multifocal cortical dementia syndrome, whereas small-vessel disease, usually resulting from hypertension and diabetes, causes periventricular white matter ischemia and lacunar strokes characterized clinically by subcortical dementia with frontal lobe deficits, executive dysfunction, slow information processing, impaired memory, inattention, depressive mood changes, slowing of motor function, Parkinsonian features, small-step gait, urinary disturbances, and pseudobulbar palsy (Roman and Royall 1999). Recently, the term vascular cognitive disorder (VCD) has been proposed by Sachdev (Sachdev 1999) and it would become the global diagnostic category for cognitive impairment of vascular origin (Roman et al. 2004). VCD would include the group of syndromes and diseases characterized by cognitive impairment resulting from a cerebrovascular etiology. The main categories of VCD are vascular cognitive impairment (VCI) [i.e., vascular cognitive impairment no dementia (vascular CIND), and vascular MCI], VaD, and mixed AD plus cerebrovascular disease (CVD) previously termed "mixed dementia" (Sachdev 1999; Roman et al. 2004). Dementia is defined as executive control deficit producing loss of function for instrumental activities of daily living, while mixed AD plus CVD is defined as preexisting AD worsened by stroke (equivalent to prestroke dementia). Finally, VCI is a term referred to all forms of mild to severe cognitive impairment associated with CVD, including vascular CIND and vascular MCI, e.g., predementia syndromes with a presumed primary vascular basis. VCI is considered a premonitory phase of VaD, although VCI not always proceeds to VaD (Sachdev 1999; Roman et al. 2004). The characteristic neuropsychological profile of VCI is believed to include frequently early impairment of attention and executive control function, with slowing of motor performance and information processing, while episodic memory is relatively spared compared to that in AD (Erkinjuntti et al. 2000) (Table 188.1).

188.1.2 Lifestyle Changes and Prevention of Dementia and Predementia Syndromes

At present, there is no curative treatment for dementia and AD, nor is there a therapeutical approach to prevent the conversion of MCI to dementia. In previous years, extensive research has increased our knowledge of the aetiology of AD, other dementing disorders, and predementia syndromes, and several hypotheses have emerged from both laboratory and epidemiological research. Epidemiological evidence in particular supported the hypothesis that modifiable vascular and lifestyle-related factors are associated with the development of dementia and predementia syndromes in later life, opening new potential avenues for the prevention of these diseases (Panza et al. 2009a).

Given the lack of effective pharmacotherapies to treat dementia, lifestyle changes may offer alternative or supplementary treatment options for predementia syndromes, i.e., MCI or age-related cognitive decline (ARCD). Evidence from population-based longitudinal epidemiologic studies suggests that moderate exercise and physical activity are associated with a lower risk of dementia (Panza et al. 2009a). Among lifestyle- and vascular-related factors, the impact of diet, Mediterranean diet in particular, has also been the subject of recent interest (Panza et al. 2009a) while regular moderate consumption of alcohol (≤24 g/day) have been reported to prevent coronary artery disease (CAD) and to reduce the risk of ischaemic and haemorrhagic stroke (Panza et al. 2009a).

There is also much evidence existing and emerging, from population-based longitudinal cohort studies predominantly but also from some case-control studies, which suggest that alcohol consumption, particularly red wine within limits and/or of certain types, decreases risk of cognitive impairment or decline, predementia, and dementia syndromes. This is despite chronic alcohol abuse causing progressive neurodegenerative disease (Panza et al. 2009a) (Table 188.3). However, some of the variability in these studies may be due to cross-sectional designs used, restrictions by age or sex, or incomplete ascertainment (Panza et al. 2009a). It is especially important to examine data for men and women separately when alcohol consumption is a predictor variable, because gender-based consumption levels

Table 188.3 Key features of alcohol

1. An alcohol is any organic compound in which a hydroxyl group (–OH) is bound to a carbon atom of an alkyl or substituted alkyl group
2. Generally, the word alcohol refers to ethanol, the type of alcohol found in alcoholic beverages
3. Ethanol is a colourless, volatile liquid with a mild odour, which can be obtained by the fermentation of sugars
4. Ethanol in alcoholic beverages has been consumed by humans since prehistoric times for a variety of hygienic, dietary, medicinal, religious, and recreational reasons
5. The short-term effects of alcohol on the human body can take several forms. Alcohol, specifically ethanol, is a potent CNS depressant, with a range of side effects. The consumption of large doses of ethanol causes drunkenness (intoxication), which may lead to a hangover as its effects wear off. The amount and circumstances of consumption play a large part in determining the extent of intoxication
6. The long-term effects of alcohol in excessive quantities are capable of damaging nearly every organ and system in the body. Regularly consumption of alcohol is correlated with an increased risk of developing alcoholism, cardiovascular disease, malabsorption, chronic pancreatitis, alcoholic liver disease, and cancer. Damage to the CNS and peripheral nervous system can occur from sustained alcohol consumption
7. Research has found a correlation between light to moderate consumption of alcohol, one to two alcoholic beverages per day, and reduced risk of heart disease as well as other health benefits, including reduction in all-cause mortality and decreasing risk of dementia, including AD. However, at present, due to poor study design and methodology, the literature is inconclusive on whether moderate alcohol consumptions increases the risk of dementia or decreases it

This table lists the key features of alcohol including definition, short- and long-term health effects, and current research findings on the health effects of light to moderate consumption of alcohol

CNS central nervous system, *AD* Alzheimer's disease

are very different. In virtually every study which included both sexes, women consumed alcohol less frequently and in smaller amounts than men. Moreover, education, smoking, or the widely recognized AD genetic risk factor apolipoprotein E (*APOE*) ε4 allele often modified the association between alcohol drinking and cognitive impairment or decline. Indeed reported association between less years of education and predementia and dementia syndromes is supported by the majority of studies, although few studies have investigated lifestyle factors as a possible covariant with education (Panza et al. 2009a). Socioeconomic and educational factors, which contribute to drinking behaviour in different populations and countries, might influence the strength of association of alcohol and cognitive impairment or decline. Furthermore, the *APOE* ε4 allele, which has variable prevalence in different geographic locations (Panza et al. 1999) could be a possible effect modifier for the associations between alcohol/vascular risk factors and dementia syndromes (Panza et al. 2009a).

An alternative growing body of evidence suggests that chronic cigarette smoking is associated with abnormalities in brain morphology, cerebral blood flow, increased oxidative stress, and with increased risk of stroke, and these factors could confound and counteract possible cognitive benefits afforded by low to moderate alcohol consumption among smokers (Panza et al. 2009a). However, smoking and alcohol use are related; there are more heavy drinkers who smoke, which may produce a possible multiplicative risk effect for cognitive impairment or decline. Of note, drinking inversely correlates with increased age while risk for cognitive impairment occurs most often at extremely old age long after the peak drinking years of youth (Panza et al. 2009a). It is possible that over time, possibly influenced by cognitive decline, alcohol consumption will change, and therefore long-term follow-up studies are needed to clarify the outcomes of these changes. Furthermore, aspects of when and how drinking is measured and how these measurements relate to when and how cognitive decline is measured are important sources of variability that need to be borne in mind in these studies.

In this chapter, we have summarized the findings of the studies of alcohol consumption in cognitive impairment or decline, predementia, and dementia syndromes. We have reviewed clinical and epidemiological studies from the international literature, including both cross-sectional and longitudinal studies that involved subjects aged 60 years and above and where description of the diagnostic criteria for predementia or dementia syndromes has been attempted. Special attention was paid to the possible mechanisms behind reported associations of alcohol drinking with cognitive impairment or decline, predementia, and dementia syndromes.

188.2 Alcohol Consumption and Cognitive Functions in Older Age

188.2.1 Regular Alcohol Consumption and Cognitive Functions in Older Age

Several studies have assessed regular alcohol consumption and cognitive function among older adults, but with inconsistent results (Goodwin et al. 1987; Herbert et al. 1993; Christian et al 1995; Hendrie et al. 1996; Launer et al. 1996; Dent et al. 1997; Dufouil et al. 1997; Broe et al. 1998; Edelstein et al. 1998; Elias et al. 1999; Carmelli et al. 1999; Elwood et al. 1999; Leibovici et al. 1999; Dufouil et al. 2000; Cervilla et al. 2000a,b; Galanis et al. 2000; Bond et al. 2001, 2005; Zuccalà et al. 2001; Schinka et al. 2002; Verhaegen et al. 2003; Zhou et al. 2003; Stampfer et al. 2005; Lindeman et al. 2005; Ganguli et al. 2005; Reid et al. 2006; Ngandu et al. 2007; McGuire et al. 2007) (Tables 188.4 and 188.5). Early studies involving relatively small samples of young to middle-aged male social drinkers supported the notion that drinking at any level was associated with poorer performance on cognitive tests (Panza et al. 2009a). However, other studies corroborated these results

Table 188.4 Principal cross-sectional studies on the relationship between alcohol consumption and cognitive impairment in older subjects

References	Setting and study design	Subjects	Methods	Results and conclusions
Cross-sectional studies				
Goodwin et al. (1987)	Cross-sectional, population-based	270 men and women aged 65–89 years	Cognitive abilities assessed with a 30-item mental status questionnaire, abstract thinking measured with the HCT, and WMS. Emotional status measured by a 92-item self-rating checklist, and social interaction evaluated with a revised form of the Interview Schedule for Social Interaction. Alcohol consumption assessed during a 3-day period and questionnaires about present and past alcohol intake	Present or past alcohol intake was not associated with decreased cognitive, psychological, or social status
Hendrie et al. (1996)	Cross-sectional, population-based	2,040 participants aged 65 and older from a community-dwelling sample of black Americans	Community Screening Interview for Dementia, delayed recall of the EBMT, and ADL.; evaluation of alcohol consumption	Also after potential confounders were included, there was a small but significant dose effect of drinking for the drinkers, with subjects in the heaviest drinking category scoring poorest in cognitive tests and daily functioning. The scores of abstainers were worse than those of subjects in the lightest drinking category
Dufouil et al. (1997)	Cross-sectional, population-based	574 men and 815 women, aged 59–71 years	MMSE, TMT-B, WAIS -Revised, BVRT, Benton Facial Recognition Test, Paced Auditory Serial Addition Test, Auditory Verbal Learning Test, RPM, Word Fluency Test, and Finger Tapping Test; evaluation of alcohol intake and smoking habits	In men, no significant relation between alcohol consumption and cognitive scores was found. In contrast, among women, with a range of daily alcohol consumption between zero and approximately four drinks, an overall positive linear association between cognitive scores and alcohol consumption was found, also after adjustment for age, income, education, and depressive symptomatology
Carmelli et al. (1997)	Cross-sectional, population-based	589 male participants aged 59–69 years	MMSE, DSST, and BVRT. Evaluation of alcohol intake, smoking habits, and APOE genotyping	After adjustment for age, education and CVD, smoking was significantly associated with poor cognitive function in current smokers compared with never smokers, whereas light drinking (one or fewer drinks per day) showed a protective effect compared with abstainers. Stratification by APOE ε4 indicated that the protective effect of light drinking was stronger and the harmful effect of smoking was weaker among APOE ε4 carriers than among noncarriers

Elwood et al. (1999)	Cross-sectional, population-based	1,870 men aged 55–69 years	CAMCOG and MMSE, AH4 evaluating verbal and mathematical reasoning, and CRT. Evaluation of alcohol intake and smoking habits.	Light and moderate drinking showed no association with cognitive functions. Cigarette smoking showed no association, but there is evidence that the more able smokers quitted and become ex-smokers
Bond et al. (2001)	Cross-sectional and longitudinal, population-based (8 years)	1,836 participants aged 65 and older	CASI, CRT, and NART. Evaluation of alcohol intake and cigarette smoking habits	Lower cognitive test scores were observed for men who were either abstainers or in the heavy drinking group. For women, a linear relationship between alcohol consumption and cognitive performance was seen on two of the four measures of cognitive functioning, suggesting a possible positive relationship between light to moderate drinking and cognitive performance
Zuccalà et al. (2001)	Cross-sectional, multicenter pharmacoepidemiology survey	15,807 hospitalized patients, mean age 70.9 years	Hodkinson Abbreviated Mental Test score, and evaluation of alcohol intake	Adjusting for potential confounders, alcohol consumption was associated with decreased probability of cognitive impairment, a daily alcohol consumption of less than 40 g for women and 80 g or less for men might be associated with a decreased probability of cognitive impairment
Schinka et al. (2002)	Cross-sectional, population-based	395 participants aged 60–84 years	Neuropsychological battery that provided measures of general cognitive ability, executive function, memory, evaluation of alcohol intake and cigarette smoking habits	No evidence for a beneficial J-curve or threshold effect for drinking was found, but did not reveal any detrimental effect. No detrimental effect of smoking was found in any analysis; nor was there any evidence of an interaction between alcohol and cigarette use on any cognitive measure
Zhou et al. (2003)	Cross-sectional, population-based	3,012 participants aged 60 years old and older	MMSE and ADL, evaluation of alcohol intake, and smoking habits	Alcohol drinking was associated with cognitive impairment, and in all people who drink every day, there was a significantly increased risk of cognitive impairment. Smoking was also related to cognitive impairment, and current smoking was associated with a significantly increased risk of cognitive impairment
Lindeman et al. (2005)	Cross-sectional, population-based	883 participants aged 65 years old and older	MMSE, WAIS - Revised, Digits Forward, Fuld Object-Memory Evaluation, CDT, and two Color TMT; evaluation of alcohol intake	Older participants who ingested alcohol had significantly better test scores than did the abstainers on seven of nine cognitive function tests after adjusting for differences in sex, ethnicity, age, and years of education

Table 188.4 (continued)

References	Setting and study design	Subjects	Methods	Results and conclusions
Cross-sectional studies				
Reid et al. (2006)	Cross-sectional, population-based	760 men aged 65–89 years	TMT-B, DSST, FAS Test, and Hopkins Verbal Learning test, and evaluation of alcohol use	Current light to moderate drinking (i.e., 7 or fewer drinks per week), as compared to never and former drinkers, and the number of years drinking at this level are both associated with better cognitive performance in older males

This table lists the principal findings of cross-sectional clinical and epidemiological studies on the relationship between alcohol consumption and cognitive impairment in older subjects, including setting, study design, and cognitive assessment used

HCT Halstead Category Test, *WMS* Wechsler Memory Scale, *EBMT* East Boston Memory Test, *ADL* Activities of Daily Living, *MMSE* Mini-mental State Examination, *TMT* Trail Making Test, *WAIS* Wechsler Adult Intelligence Scale, *BVRT* Benton Visual Retention Test, *RPM* Raven Progressive Matrices, *DSST* Digit Symbol Substitution Test, *APOE* Apolipoprotein E, *CAMCOG* Cambridge Cognitive Examination, *CRT* Choice Reaction Time, *CASI* Cognitive Abilities Screening Instrument, *NART* National Adult Reading Test, *CVD* Cerebrovascular Disease, *CDT* Clock Drawing Test

Table 188.5 Principal longitudinal studies on the relationship between alcohol consumption and cognitive decline in older subjects

References	Setting and study design	Subjects	Methods	Results and conclusions
Longitudinal studies				
Herbert et al. (1993)	Longitudinal, population-based (3 years)	1,201 subjects aged 65 years and older	Structured performance tests of immediate memory, digit span (from WAIS), and orientation; diagnosis of AD; evaluation of alcohol intake and smoking habits	Change in only one of the 3 cognitive tests (digit span) was significantly associated with one alcohol category (15 ml per day), and no dose-response relation was observed
Christian et al. (1995)	Retrospective cohort and co-twin-control study	4,739 twins born between 1917 and 1927	Two self-reported drinking histories (1970s and 1980s) and a telephone mental status interview (1990 and 1991)	No evidence was found to indicate an association between moderate long-term alcohol intake and lower cognitive scores in aging individuals. There was a suggestion of a small protective effect of past moderate alcohol intake on cognitive function with aging
Launer et al. (1996)	Cross-sectional and longitudinal, population-based (3 years)	489 men aged 69–89 years	MMSE, evaluation of alcohol intake and smoking habits	After adjustment for age, education, and smoking status, men with CVD/diabetes and low-to-moderate alcohol intake had a significantly lower risk for poor cognitive function than abstainers. Alcohol intake was not associated with cognitive decline
Dent et al. (1997)	Longitudinal, random sample of veterans of the second world war (9 years)	209 men, mean age: 64.3 years	WAIS, WMS, BVRT, RPM, Rey Auditory Verbal Learning Test, Controlled Oral Word Association Test, Boston Naming Test, NART, CRT, and HCT evaluation of alcohol intake and noncontrast computed tomography	Persistent lifelong consumption of alcohol and the level of intake seemed not to have any impact on cognitive performance among men in old age
Broe et al. (1998)	Longitudinal, population-based (3 years)	327 subjects, aged 75 years and older	MMSE, Reid Memory Test, tests of verbal fluency, subsets of the Boston Naming Test and similarities; CDT; and copied drawings of a cube, coils, and interlocking infinity loops; diagnosis of dementia and AD; evaluation of physical exercise, alcohol and smoking use	There were few significant associations between health habits and cognitive performance and these were not found consistently across cognitive measures

Longitudinal studies				
Edelstein et al. (1998)	Longitudinal, population-based (13–18 years)	511 men and women aged 40–80 years	MMSE, TMT-B, Category Fluency, BFSRT, and BVRT, evaluation of alcohol intake and smoking habits	Moderate alcohol consumption and cigarette smoking patterns, reported 13–18 years and 3–7 years previously were weakly and inconsistently associated with subsequent cognitive function
Elias et al. (1999)	Cross-sectional and longitudinal, population-based (24 years)	1,786 subjects, aged 55–88 years	Eight cognitive tests of verbal memory, learning, visual organization and memory, attention, abstract reasoning, and concept formation; evaluation of weekly alcohol intake	Women who drank moderately (2–4 drinks/day) showed superior performance in many cognitive domains relative to abstainers. For men, superior performance was found within the range of 4–8 drinks/day, although fewer significant relations were observed. These results were confirmed by prospective analyses of 24-year drinking history
Leibovici et al. (1999)	Longitudinal, population-based (3 years)	833 subjects over 60 years	A computerized neuropsychometric examination assessed attention, primary and secondary memory, implicit memory, visuospatial ability, and language. Diagnosis of AD and evaluation of alcohol and tobacco consumption were also performed	Wine consumption was associated with an increased risk of decline over time in attention and in secondary memory. Smoking was associated with a decreased risk for decline over time in attentional and visuospatial functioning. No clear combined effect of smoking and drinking was found, even though smoking was found to increase the risk of decline in language performance when adjusted on wine consumption
Dufouil et al. (2000)	Longitudinal, population-based (4 years)	1,389 subjects, aged 59–71 years	MMSE, evaluation of alcohol consumption, APOE genotyping, and smoking habits	Alcohol consumption was associated with a decreased risk of cognitive decline in individuals without the APOE ε4 allele, whereas moderate drinking increased the risk of decline in APOE ε4 allele carriers. Also, lifetime smoking was a risk factor for cognitive decline in individuals without the APOE ε4 allele. The data also suggested a slight protective effect of smoking in APOE ε4 allele carriers
Cervilla et al. (2000a)	Longitudinal, population-based (1 year)	889 subjects, aged 65 or older	Cognitive impairment assessed at baseline and 1 year later using the organic brain syndrome (OBS) cognitive impairment scale from the short CARE structured assessment, evaluation of alcohol intake and smoking habits	No association between alcohol consumption and onset of cognitive impairment was found. Persistent cigarette smoking into late-life increased the risk for cognitive impairment

Cervilla et al. (2000b)	Longitudinal, population-based (9–12 years)	1,083 subjects, aged 65–74 years	MMSE, evaluation of alcohol intake and smoking habits	Older subjects who were abstinent before the age of 60 had poorer cognitive outcome than did those who drank mildly or moderately
Galanis et al. (2000)	Longitudinal, population-based (18 years)	3,556 men of Japanese ancestry, aged 71–93 years	CASI, and evaluation of alcohol intake	Positive association between a history of moderate alcohol consumption and cognitive performance in the elderly, as men who had consumed up to one drink a day during middle age were later found to have significantly better cognitive test results than nondrinkers
Verhaegen et al. (2003)	Cross-sectional and longitudinal, population-based (4 years)	516 subjects aged 70 years and older	Cognitive by unit-weighted consisted of four intellectual abilities (perceptual speed, episodic memory, fluency, and knowledge), each assessed by composites of two tests, evaluation of alcohol consumption and smoking behaviour	Cross-sectionally, better cognitive performances have been observed with higher levels of alcohol drinking, while alcohol was not associated with 4-year declines in cognition
Stampfer et al. (2005)	Cross-sectional and longitudinal, population-based (2 years)	12,480 subjects aged 70–81 years	Telephone Interview for Cognitive Status, EBMT, TICS 10-word list, a test of verbal fluency, and the digit span backward test. Evaluation of alcohol consumption and APOE genotype	After multivariate adjustment, moderate drinkers had better mean cognitive scores than nondrinkers. For cognitive decline, on test of general cognition, the relative risk of a substantial decline in performance over a 2-year period was 0.85 among moderate drinkers, as compared with nondrinkers. There were no significant differences in risks according to the beverage and no interaction with the APOE genotype
Bond et al. (2005)	Cross-sectional and longitudinal, population-based (8 years)	1,836 participants aged 65 and older	CASI, evaluation of alcohol intake and cigarette smoking habits	Alcohol consumers had higher scores (less cognitive decline) on cognition, measured by the CASI over an 8-year follow-up period, than abstainers. There were no significant gender differences in the absolute scores on CASI, and the rate of change over time did not vary
Ganguli et al. (2005)	Longitudinal, population-based (7 years)	1,681 individuals aged 65 years or older	Neuropsychological test panel of the CERAD, and among these tests: MMSE and TMT. Evaluation of alcohol intake and smoking habits	This cohort showed a consistent pattern of better baseline scores and lesser decline over time in individuals who consumed alcohol minimally or moderately, compared to those who reported no drinking at baseline

Longitudinal studies				
Ngandu et al. (2007)	Longitudinal, population-based (21 years)	1,341 participants aged 65–79 years	MMSE, and neuropsychological tests evaluating episodic memory, semantic memory, psychomotor speed, executive function, prospective memory, and subjective memory. Evaluation of alcohol intake, smoking habits, and APOE genotyping	The nondrinkers both at midlife and later had a poorer cognitive performance than drinkers, especially in the domains related to fluid intelligence, i.e., executive function, psychomotor speed, as well as episodic memory, whereas the other cognitive functions showed little association with alcohol drinking. No interactions between APOE ε4 and alcohol or sex and alcohol were found.
McGuire et al. (2007)	Cross-sectional, population-based	2,716 subjects, aged 70 years and older	Adapted Telephone Interview for Cognitive Status, and evaluation of alcohol intake	For older adults with a level of cognitive functioning within normal ranges, moderate amounts of alcohol, an average of one drink or less daily, was protective for women, but not men

This table lists the principal findings of longitudinal clinical and epidemiological studies on the relationship between alcohol consumption and cognitive impairment in older subjects, including setting, study design, and cognitive assessment used. *WAIS* Wechsler Adult Intelligence Scale, *AD* Alzheimer's disease, *MMSE* Mini-Mental State Examination, *WMS* Wechsler Memory Scale, *BVRT* Benton Visual Retention Test, *RPM* Raven Progressive Matrices, *CRT* Choice Reaction Time, *HCT* Halstead Category Test, *CDT* Clock Drawing Test, *BFSRT* Buschke-Fuld Selective Reminding Test, *APOE* Apolipoprotein E, *CASI* Cognitive Abilities Screening Instrument, *CERAD* Consortium to Establish a Registry for Alzheimer Disease, *TMT* Trail Making Test, *EBMT* East Boston Memory Test

for a subsample of women whose drinking patterns were similar to their male counterparts (Panza et al. 2009a). Subsequent research with male and female college students and elderly men led to the conclusion that no significant negative relation exists between social drinking and level of cognitive functioning, although elevated alcohol consumption among young female social drinkers were related to better performance on many cognitive tests (Panza et al. 2009a).

More recent studies involving older subjects have indicated that a U- or J-shaped curve may best describe the relation between the level of alcohol consumption and cognitive performance (Goodwin et al. 1987; Christian et al. 1995; Hendrie et al. 1996; Launer et al. 1996). In general, light to moderate drinkers of alcohol performed at a higher cognitive level than either abstainers or heavy drinkers (Goodwin et al. 1987; Hendrie et al. 1996), although there were some notable exceptions (Goodwin et al. 1987; Launer et al. 1996). One study in particular, that involved older African American adults found that consumption of up to 5–6 g of alcohol per day (1/2 drinks) was correlated with better cognitive performance than abstainers (Hendrie et al. 1996). On the other hand, in one report, statistical adjustment for age, income, education, and gender rendered the findings non-significant (Goodwin et al. 1987). In another study, the protective effects of moderate alcohol consumption (odds ratio OR (95% confidence interval (CI)) = 0.3 (0.2–0.7) for less than one drink and 0.2 (0.1–0.4) for 1–2 drinks per day) were limited only to those participants who exhibited clinical conditions associated with atherosclerosis (Launer et al. 1996). However, as discussed above, significant variability in different countries on the level of alcohol content in drinks as well as in the criteria used in different articles to define terms such as light, moderate, and heavy drinking make the interpretation of findings difficult (Panza et al. 2009a).

Lower levels of alcohol intake have proportionally greater effects in the elderly, due to their reduced lean body mass and lower percentage of body weight made up of water. In fact, in several cross-sectional studies, moderate drinking, from up to 1 drink per day (up to 14 g of alcohol) to 4 drinks per day (52 g of alcohol), as compared with nondrinking has been associated with a better performance in many cognitive domains (Elias et al. 1999; Carmelli et al. 1999; Bond et al. 2001, 2003). In fact, in the Framingham Heart Study, the association between alcohol consumption and cognitive performance was analyzed separately for men and women, since the researchers anticipated a different gender-based alcohol-cognition relationship (Elias et al. 1999). Test performance of moderate male drinkers (>2 and <4 drinks per day) were significantly better than abstainers on logical memory delayed recall, whereas heavy (>4 and <8 drinks per day) drinkers performed better on logical memory delayed recall, attention and concentration (AC) composite score, and total composite score. Female drinkers showed superior performance compared to abstainers on more cognitive tests than male drinkers. Light female drinkers (1–2 drinks per day) performed better on logical memory delayed recall, on the learning and memory (LM) composite and the total composite, whereas moderate female drinkers scored significantly better than abstainers on delayed memory, word fluency, similarities, and the AC, LM, and total composite (Elias et al. 1999). Moreover, the Kame project, a study that used data from 1,836 cognitively intact elderly Japanese American men and women aged 65 and older, found that up to 26 g of alcohol per day for women was associated with higher Cognitive Abilities Screening Instrument (CASI) scores (Bond et al. 2001). In a recent cross-cultural comparison of Japanese and non-Hispanic White American older adults, the Kame project found that current consumption of alcohol (13–26 g of alcohol, 1–2 drinks per day), compared to abstinence or past alcohol consumption, was more strongly associated with higher CASI scores for women than men (Bond et al. 2003).

Furthermore, in cross-sectional studies, both better (Dufouil et al. 2000; Schinka et al. 2002; Lindeman et al. 2005; Reid et al. 2006) and poorer (Yoshitake et al. 1995) cognitive performances in association with higher levels of alcohol drinking have been observed (Table 188.4). In particular, the issue of sex differences in the relation of alcohol consumption and cognitive performance was

addressed by Dufouil and colleagues (2000) using data from the Epidemiology of Vascular Aging (EVA) study. This study included 574 men and 815 women, aged 59–71 years. No association between drinking and cognition was found for the male participants; while for the female participants, moderate alcohol consumption was associated with better performance on seven of the cognitive tests and an overall composite score (Dufouil et al. 2000). In fact, the OR for higher cognitive performance (i.e., the top 10% of the distribution of summary scores from the neuropsychological battery) was 2.5 (95% CI = 1.1–5.7) for women who usually consumed 2 or more drinks per day in comparison with nondrinkers. At the same time, some studies have found no associations between alcohol drinking and several cognitive functions (Elwood et al. 1999, Schinka et al. 2002). Elwood and colleagues did not find any significant association between alcohol consumption and cognitive function amongst 1,870 men aged 55–69 years from the Caerphilly Study, though ex-drinkers had markedly lower test scores than either current drinkers or men who had never drunk alcohol (Elwood et al, 1999).

The studies that have assessed changes in cognition prospectively have had contradictory results (Herbert et al. 1993; Christian et al. 1995; Launer et al. 1996; Dent et al. 1997; Broe et al. 1998; Leibovici et al. 1999; Dufouil et al. 2000; Cervilla et al. 2000a,b; Galanis et al. 2000; Verhaegen et al. 2003; Stampfer et al. 2005; Bond et al. 2004, 2005; Ganguli et al. 2005; Ngandu et al. 2007; McGuire et al. 2007) (Table 188.5). Drinkers in general have been proposed to have a greater decrease in global cognitive function (Dufouil et al. 2000) and attention (Leibovici et al. 1999) as compared with nondrinkers, but moderate drinkers (about one drink or less than 15 ml of alcohol per day) to have less decline in general cognition (relative risk (95% CI) = 0.77 (0.67–0.88)) (Stampfer et al. 2005) or psychomotor speed (Herbert et al. 1993) than nondrinkers. Further, some studies showed no association at all (Launer et al. 1996; Broe et al. 1998; Cervilla et al. 2000a,b; Verhaegen et al. 2003). However, in the Gospel Oak project, there was a non-significant association in the direction of a protective effect against onset of cognitive impairment for moderate drinkers (1–30 units per week, with 1 unit equivalent to a glass of wine or a single measure of spirits) compared with nondrinkers and heavy drinkers (30 units and over per week) (Cervilla et al. 2000a). Amongst longitudinal studies, Launer and colleagues showed in the Zutphen Elderly Study that men with cardiovascular disease or diabetes and light to moderate alcohol intake had a significantly lower risk of poor cognitive function compared to abstainers obtaining effects of large magnitude (OR (95% CI) = 0.3 (0.2–0.7) for less than one drink and 0.2 (0.1–0.4) for 1–2 drinks per day), but alcohol intake was not associated with cognitive decline in a 3-year follow-up (Launer et al. 1996). Finally, in a representative elderly cohort over an average follow-up of 7 years, a pattern of light to moderate drinking (from drinking once a month or less to drinking daily and weekly), compared to not drinking, was associated with lesser average decline in cognitive domains over the same period. In particular, the seemingly beneficial effects of alcohol intake against cognitive decline appeared concentrated in the areas of executive functions (OR (95% CI) = 0.20 (0.05–0.85) for light drinking and 0.05 (0.01–0.45) for moderate drinking), and general mental status (OR (95% CI) = 0.30 (0.14–0.65) for light drinking and 0.08 (0.02–0.28) for moderate drinking) (Ganguli et al. 2005). The results of this study were also consistent with those of the EVA Study, which found that alcohol intake was associated with a lower risk of cognitive deterioration among subjects without an *APOE* ε4 allele, but a higher risk in *APOE* ε4 carriers. In fact, compared with nondrinkers, non-ε4 carriers who reported drinking 2 drinks or more per day had a 50% decreased risk of cognitive deterioration (Dufouil et al. 2000).

The associations between current cognitive performance and alcohol drinking 5–24 years earlier have also been studied, with conflicting results. The global cognitive function may be poorer amongst both alcoholics and past drinkers as compared with nondrinkers or moderate drinkers (Christian et al. 1995) whilst being better among moderate drinkers and poorer among heavy drinkers as compared with nondrinkers (Galanis et al. 2000). Furthermore, although there were some gender

differences in observed associations, data from 1,469 relatively well-educated, noninstitutionalized subjects from Rancho Bernardo, California offered no compelling evidence that social drinking caused or prevented impaired cognitive function 13–18 years later (Edelstein et al. 1998). The large number of comparisons and inconsistent results suggest that the few statistically significant findings may be false positives. In the Framingham Heart Study, the mean levels of alcohol consumption over 24 years prior to neuropsychological testing in relation to cognitive performance was examined (Elias et al. 1999). For men, increasing alcohol consumption was associated with better performance only for logical memory delayed recall. For women, however, all measures, with the exception of similarities, were associated with better performance as consumption level increased (Elias et al. 1999). Moreover, in the cognitive sub-study of the Medical Research Council (MRC) Treatment Trial of Hypertension in Older Adults, involving a cohort of 1,083 older subjects that was followed-up for 9–12 years, those who were abstinent before the age of 60 had poorer cognitive outcomes than did those who drank lowly or moderately (Cervilla et al. 2000b). More recently, the Cardiovascular Risk Factors Aging and Dementia (CAIDE) Study investigated the relationship between midlife alcohol drinking and late-life cognitive functions (average follow-up period of 21 years) as well as between late-life alcohol drinking and late-life cognitive functions (Ngandu et al. 2007). In the CAIDE Study, at both midlife and late life examinations, the nondrinkers had a poorer cognitive performance than drinkers, especially in the domains related to fluid intelligence, i.e., executive function, psychomotor speed, as well as episodic memory, whereas the other cognitive functions showed little association. The late-life frequent drinkers had a better performance than the infrequent drinkers in episodic and prospective memory, whereas the midlife frequent and infrequent drinkers did not differ from each other in any of the cognitive domains. Further, no interactions between *APOE* ε4 allele and alcohol or sex and alcohol were found (Ngandu et al. 2007). On the other hand, in other longitudinal studies, a significant association between alcohol drinking and several cognitive measures has been proposed especially among women (Elias et al. 1999; McGuire et al. 2007). Smoking or *APOE* ε4 allele often modified the association between alcohol drinking and cognitive functions. However, studies on the interaction between smoking and alcohol consumption have yielded inconclusive results (Leibovici et al. 1999; Schinka et al. 2002; Ngandu et al. 2007). The role of alcohol in cognition might be modified by the presence of the *APOE* ε4 allele (Carmelli et al. 1999; Dufouil et al. 2000), but the patterns of interaction suggested have seen different results (Stampfer et al. 2005; Ngandu et al. 2007). Some studies investigating the effect of different types of alcohol on the cognitive function found no beverage-specific differences (Christian et al. 1995; Stampfer et al. 2005; Ngandu et al. 2007).

188.3   Alcohol Consumption, MCI, and Dementia

Alcohol consumption is also one of the possible determinants of clinical dementia (Hebert et al. 1992; Yoshitake et al. 1995; Broe et al. 1998; Orgogozo et al. 1997; Lemeshow et al. 1998; Kivipelto et al. 2001; Ruitenberg et al. 2002; Lindsay et al. 2002; Huang et al. 2002; Truelsen et al. 2002; Mukamal et al. 2003; Luchsinger et al. 2004; Larrieu et al. 2004; Järvenpää et al. 2005; Simons et al. 2006; Deng et al. 2006; Mehlig et al. 2008; Fujishima and Kiyohara 2002; McCallum et al. 2007; Leibovici et al. 2002) (Table 188.6). Epidemiological studies have recently reported an association between wine consumption and the incidence of AD. Red wine in particular was investigated in the Personnes Agees QUID (PAQUID) study, in which the relative risk for dementia and AD among 318 subjects who drank three or four glasses of wine each day in comparison with 971 total abstainers were 0.21 and 0.25, respectively. Among the 922 older subjects who drank no more than one or two

Table 188.6 Principal studies on the relationships among alcohol consumption and dementia, vascular dementia, Alzheimer's disease, and mild cognitive impairment

References	Setting and study design	Subjects	Methods	Results and conclusions
Hébert et al. (1993)	Longitudinal, population-based (3 years)	1,201 subjects aged 65 years and older	Structured performance tests of immediate memory, digit span (from WAIS), and orientation; diagnosis of AD; evaluation of alcohol intake and smoking habits	After adjustment for age, sex, and education, the estimated OR of AD was 0.7 (95% CI 0.3–1.4) for ever smokers compared with never smokers. For 40 pack-years of smoking, the OR of AD was 0.8 (95% CI 0.6–1.1). Consumption of 30 ml of alcohol per day was associated with an OR of 1.1 (95% CI 0.8–1.5). These findings suggested that recent mild-to-moderate consumption of alcohol is not substantially related to incidence of AD and that smoking does not increase risk of the disease
Yoshitake et al. (1995)	Longitudinal, population-based (7 years)	828 subjects aged 65 and older	Diagnosis of dementia, AD, and VaD; evaluation of alcohol consumption	Multivariate analysis showed that age, systolic blood pressure, drinking habits, and prior stroke episodes were significant independent precursors of VaD
Orgogozo et al. (1997)	Longitudinal, population-based (3 years)	3,777 subjects aged 65 and older	Diagnosis of dementia and AD; evaluation of alcohol intake	In the 318 moderate drinkers, as compared to the 971 nondrinkers, and after adjusting for possible confounders, the OR were respectively 0.19 for incident dementia and 0.28 for AD. Among the 922 mild drinkers respect to the abstainers the relative risk for AD was reduced significantly
Broe et al. (1998)	Longitudinal, population-based (3 years)	327 subjects, aged 75 years and older	MMSE, Reid memory test, tests of verbal fluency, subsets of the Boston naming test and similarities; CDT, and copied drawings of a cube, coils, and interlocking infinity loops; diagnosis of dementia and AD; evaluation of physical exercise, alcohol and smoking use	No associations were found with dementia or AD
Leibovici et al. (1999)	Longitudinal, population-based (3 years)	833 subjects over 60 years	A computerized neuropsychometric examination assessed attention, primary and secondary memory, implicit memory, visuospatial ability, and language. Diagnosis of AD and evaluation of alcohol and tobacco consumption were also performed	While moderate wine consumption was found to be associated with a fourfold diminishing of the risk of AD, this effect was found to disappear when institutionalization was taken into account. No protective effect for AD was found for smoking

Study	Design	Sample	Outcomes	Results
Kivipelto et al. (2001)	Longitudinal, population-based (3 years)	3,777 subjects aged 65 years and older	Diagnosis of dementia and AD; evaluation of alcohol intake	In the 318 moderate drinkers, as compared to the 971 nondrinkers, and after adjusting for possible confounders, the odds ratios were respectively 0.19 for incident dementia and 0.28 for AD. Among the 922 mild drinkers respect to the abstainers, the relative risk for AD was reduced significantly
DeCarli et al. (2001)	Cross-sectional and longitudinal, population-based (25 years)	369 individual twins, aged 67–81 years	Diagnosis of MCI, evaluation of alcohol intake, and APOE genotyping	Alcohol consumption was slightly protective against the risk of MCI, in the fourth examination of this cohort
Ruitenberg et al. (2002)	Longitudinal, population-based study (6 years)	5,395 subjects aged 55 years and older	Diagnosis of AD, VaD, or other dementia; evaluation of alcohol intake, and APOE genotyping	Light to moderate drinking (1–3 drinks per day) was significantly associated with a lower risk of any dementia and VaD. No evidence that the relation between alcohol and dementia varied by type of alcoholic beverage was found
Lindsay et al. (2002)	Longitudinal, population-based study (5 years)	6,434 subjects, aged 65 years and older	Diagnosis of incident AD, evaluation of alcohol intake, smoking habits, and APOE genotyping	APOE ε4 allele was associated with increased risks of incident AD, while regular wine consumption was associated with reduced risks. Smoking was not related to the risk of AD
Huang et al. (2002)	Longitudinal, population-based study (6 years)	402 subjects, aged 75 years and older	Diagnosis of incident dementia and AD and alcohol drinking	Light to moderate alcohol consumption was associated with a decreased incidence of dementia and AD
Truelsen et al. (2002)	Nested case-control of a longitudinal, population-based study (15 years)	83 demented patients and 1,626 nondemented subjects as controls, aged 65 years and older	MMSE and diagnosis of dementia, and alcohol intake assessed 15 years before	Average weekly total alcohol intake had no significant effect on risk of dementia. Monthly and weekly intake of wine was significantly associated with a lower risk of dementia. For beer and spirits, only a monthly intake of beer was significantly associated with an increased risk of dementia. The effect of alcohol on risk of dementia did not differ between men and women
Mukamal et al. (2003)	Nested case-control of a longitudinal, population-based study (6 years)	373 cases with incident dementia and 373 controls	Diagnosis of incident dementia (AD and VaD), average alcohol consumption, and magnetic resonance imaging findings	Compared with abstention, consumption of 1–6 drinks weekly is associated with a lower risk of incident dementia among older adults. A trend toward greater odds of dementia associated with heavier alcohol consumption was most apparent among men and participants with an APOE ε4 allele, with similar relationships of alcohol use with AD and VaD

(continued)

Table 188.6 (continued)

References	Setting and study design	Subjects	Methods	Results and conclusions
Luchsinger et al. (2004)	Longitudinal, population-based study (4 years)	908 subjects aged 65 years and older	Diagnosis of incident dementia (AD and dementia associated with stroke) and alcohol intake	After adjusting for age, sex, APOE ε4 status, education, and other alcoholic beverages, only intake of up to three daily servings of wine was associated with a lower risk of AD. Stratified analyses by the APOE-epsilon 4 allele revealed that the association between wine consumption and lower risk of AD was confined to subjects without the APOE ε4 allele
Larrieu et al. (2004)	Longitudinal, population-based study (8 years)	2,950 subjects, aged 65 years and older	Diagnosis of incident dementia and AD, and wine consumption	Even after adjustment on age, sex and education, moderate drinkers had a decreased RR of developing a dementia in the subsequent 8 years compared to nondrinkers with a RR of 0.56. Results on AD were quite similar, with a RR of 0.53 among moderate drinkers
Anttila et al. (2004)	Longitudinal, population-based study (23 years)	1,464 men and women aged 65–79 years	Diagnosis of incident dementia and MCI, and subjects classified as those who never drank alcohol, those who drank "infrequently" (less than once a month), and those who drank "frequently" (several times a month)	Alcohol drinking in middle age showed a U shaped relation with risk of MCI in old age. Only the carriers of APOE ε4 had an increased risk of dementia with increasing alcohol consumption
Espeland et al. (2005)	Longitudinal, population-based study (4.2 years)	4,451 community-dwelling women aged 65–79 years	Diagnosis of incident MCI and dementia, and annual modified MMSE. Subjects classified as abstainers, <1 drink/day, and >1 drink/day	Moderate alcohol intake was associated with an approximately 50% reduced risk of combined probable dementia and/or MCI. Significant decline in global cognition was less common among women who reported alcohol intake at baseline, also after adjustment for both demographic/social and clinical factors
Järvenpää et al. (2005)	Longitudinal, population-based study (25 years)	554 twins, aged 65 years or older at the time of dementia assessment	Diagnosis of incident dementia, evaluation of alcohol consumption, and binge drinking (i.e., alcohol exceeding the amount of 5 bottles of beer or a bottle of wine on 1 occasion at least once per month)	Midlife reports of binge drinking or passing out as a result of excessive alcohol intake at least twice during the previous year were risk factors for dementia later in life
Simons et al. (2006)	Longitudinal, population-based study (16 years)	2,805 subjects, aged 60 years and older	Diagnosis of incident dementia, and evaluation of alcohol intake	Moderate alcohol intake seemed to offer substantial protection against the onset of dementia

	Study design (duration)	Sample	Diagnosis/assessment	Findings
Deng et al. (2006)	Longitudinal, population-based study (2 years)	3,286 subjects, aged 60 years and older	Diagnosis of incident dementia, AD, and VaD and evaluation of alcohol intake	Light to moderate drinkers had a lower risk of dementia than nondrinkers, but a non-significant increased risk was observed in heavy drinkers
Solfrizzi et al. (2007)	Longitudinal, population-based study (3.5 years)	1,445 men and women aged 65–84 years	Diagnosis of incident MCI and progression from MCI to dementia; subjects classified as abstainers, 0–1 drink/day, 1–2 drink/day, and >2 drinks/day	In patients with MCI up to 1 drink/day of alcohol or wine may decrease the rate of progression to dementia. No significant associations were found between any levels of drinking and the incidence of MCI in noncognitively impaired individuals vs. abstainers
Mehlig et al. (2008)	Longitudinal, population-based study (34 years)	1,462 women aged 38–60 years	Diagnosis of dementia; evaluation of alcohol intake and smoking habits	Wine was protective for dementia, and the association was strongest among women who consumed wine only. In contrast, consumption of spirits at baseline was associated with slightly increased risk of dementia

This table lists the principal findings of longitudinal clinical and epidemiological studies on the relationships among alcohol consumption and dementia, VaD, AD, and MCI, including setting, study design, and cognitive assessment used

WAIS Wechsler Adult Intelligence Scale, *AD* Alzheimer's Disease, *OR* Odds Ratio, *95% CI:* 95% Confidence Interval, *MMSE* Mini-Mental State Examination, *CDT* Clock Drawing Test, *VaD* Vascular Dementia, *MCI* Mild Cognitive Impairment, *APOE* Apolipoprotein E, *RR* Relative Risk

glasses of wine each day compared to the abstainers the relative risk for AD was reduced significantly (0.55) (Orgogozo et al. 1997). This protective effect remained significant after further post hoc analyses were conducted (Lemeshow et al. 1998). Furthermore, these cross-sectional findings were confirmed in the subsequent 8-year follow-up of the PAQUID study, where among 2,950 initially nondemented subjects, moderate drinkers had a decreased relative risk of developing dementia (relative risk = 0.56) compared to nondrinkers (Lemeshow et al. 1998).

These results were consistent with the findings from some cohort studies (Ruitenberg et al. 2002; Lindsay et al. 2002; Huang et al. 2002; Deng et al. 2006, 98–100, 107), but not others (Hebert et al. 1992; Yoshitake et al. 1995; Broe et al. 1998; Fujishima and Kiyohara 2002; Kivipelto et al. 2001). The relationship between alcohol consumption and risk of dementia (AD, VaD, or other dementia) was also examined in the Rotterdam Study. The findings of this study, with an average follow-up of 6 years, suggested that light to moderate alcohol consumption (1–3 drinks per day) is associated with a reduced risk of dementia in individuals aged 55 years or older (hazard ratio (HR) (95% confidence interval) (CI) = 0.58 (0.38–0.90)); this effect seems to be unchanged by the source of alcohol (Ruitenberg et al. 2002). No association was found in women, whereas a lower risk was found for men drinking 1–3 drinks per day (HR (95% CI) = 0.58 (0.40–0.74)). A modification effect was found when the *APOE* ε4 allele was taken into consideration; the risk was lower among drinkers with an *APOE* ε4 allele, whereas it was less clear for drinkers without the *APOE* ε4 allele (Ruitenberg et al. 2002). This topic was also investigated in the Kungsholmen Project, a community-based dementia-free cohort (n = 402) followed for almost 6 years. Light to moderate alcohol consumption (as defined by them to be 1–21 drinks per week in men, 1–14 drinks per week in women) was associated with a decreased incidence of dementia (relative risk (95% CI) = 0.5 (0.3–0.7)) and AD (relative risk (RR) (95% CI) = 0.5 (0.3–0.7)) (Huang et al. 2002). In the Canadian Study of Health and Aging (CSHA), on 4,615 cognitively normal older subjects reassessed 5 years later, wine consumption (at least weekly consumption) was associated among other factors with a reduced risk of AD (OR (95% CI) = 0.49 (0.28–0.88)) (Lindsay et al. 2002). Finally, in China, light to moderate drinkers (1–21 drinks per week in men, 1–14 drinks per week in women) had a lower risk of dementia (OR (95% CI) = 0.52 (0.32–0.85)) than nondrinkers, but non-significant evidence towards elevated risk in heavy drinkers (OR (95% CI) = 1.45 (0.43–4.89)). A greater reduction of risk was observed for men (OR = 0.37) than for women (OR = 0.76) (Deng et al. 2006). Moreover, the effect of light to moderate drinking seemed most prominent for AD (OR (95% CI) = 0.63 (0.55–0.72)) than for VaD (OR (95% CI) = 0.31 (0.19–0.51)) or other dementia (OR (95% CI) = 0.45 (0.12–1.69)) (Deng et al. 2006).

In a nested case–control study on 373 cases with incident dementia and 373 controls who were selected from 5,888 adults aged 65 years and older, and participated in the CHS, the adjusted OR for dementia among whose weekly alcohol consumption was less than 1 drink was 0.65, compared with abstention; was 0.46 and 0.69 compared with 1–6 drinks and with 7–13 drinks, respectively, and was 1.22 when compared with 14 or more drinks (Mukamal et al. 2003). A trend toward greater odds for dementia associated with heavier alcohol consumption was most apparent among men and participants bearing an *APOE* ε4 allele, with similar relationships of alcohol use with AD and VaD (Mukamal et al. 2003). In the Copenhagen City Heart Study which rated alcohol consumption in a different manner to many other studies, the risk of developing dementia was significantly lower among monthly wine drinkers (HR (95% CI) = 0.43 (0.23–0.82)), in weekly wine drinkers (HR (95% CI) = 0.33 (0.23–0.82)) and, but not significantly, in daily drinkers. An increased risk for beer and for spirits was found in monthly, weekly, and daily drinkers, but not significantly. No difference was found between men and women. No association was found between any number of drinks (less than 1, 1–7, 8–14, 15–21, 22, or more) of alcohol consumed per week and the risk of dementia (Truelsen et al. 2002). The findings from the CHS were consistent with the PAQUID Study (Orgogozo et al. 1997) and the Rotterdam Study (Ruitenberg et al. 2002), but suggested a higher risk of dementia

with consumption greater than 2 drinks per day. Surprisingly, the Rotterdam Study found that the lower risk of dementia associated with alcohol use was more consistent among individuals with an *APOE* ε4 allele (Ruitenberg et al. 2002), but no significant interaction was detected. In the Washington Heights Inwood-Columbia Aging Project, with 908 subjects aged 65 years and older, the number of drinks per week was collected at baseline and subjects were classified as nondrinkers, light drinkers (less than 1 drink per month to 6 drinks a week), moderate drinkers (1–3 drinks a day), and heavy drinkers (more than 3 drinks a day). The light and moderate drinking categories were combined because of the low number of moderate drinkers. A significantly lower risk of AD was found in light to moderate wine drinkers in elderly individuals without the *APOE* ε4 allele (HR = 0.44, p = 0.004). No modification effect by sex was found (Luchsinger et al. 2004).

Some other population-based, prospective studies, with longer follow-up periods studied the effects of different patterns of alcohol intake on dementia (Järvenpää et al. 2005; Simons et al. 2006; Mehlig et al. 2008). In fact, in the Finnish Twin Cohort Study with a follow-up period of 25 years, reports of midlife binge drinking (i.e., alcohol exceeding the amount of five bottles of beer or a bottle of wine on one occasion at least once per month) or losing consciousness due to excessive alcohol intake at least twice during the previous year were risk factors for dementia later in life (RR (95% CI) = 3.2 (1.2–8.6)) (Järvenpää et al. 2005). A longitudinal cohort study conducted in Dubbo (Australia) on 2,805 subjects aged 60 years and older, initially free of cognitive impairment and followed for 16 years, confirmed as a modest intake of alcohol seemed to offer substantial protection against the onset of dementia, showing larger effect for 15–28 units per week (HR (95% CI); 0.40 (0.21–0.79) (Simons et al. 2006; McCallum et al. 2007). Finally, in the Prospective Population Study of Women in Goteborg, Sweden, in a 34-year follow-up, wine was protective for dementia (current drinking vs former or never drinking) (HR (95% CI) = 0.6 (0.4–0.8)), and the association was strongest among women who consumed wine only (HR (95% CI) = 0.3 (0.1–0.8)). In contrast, consumption of spirits at baseline was associated with slightly increased risk of dementia (HR (95% CI) = 1.5 (1.0–2.2)) (Mehlig et al. 2008).

For predementia syndromes, in a group of 369 nondemented, community-dwelling older men who participated in the National Heart, Lung, and Blood Institute (NHLBI) Twin Study, alcohol consumption was found to be slightly protective (relative risk (95% CI) = 0.93 (0.88–0.99)), but if individuals with CVD were excluded from the analysis this association disappeared (DeCarli et al. 2001). Recently, the impact of alcohol consumption on the incidence of MCI was evaluated in 1,445 cognitively normal individuals and on its progression to dementia in 121 patients with MCI, aged 65–84 years, participating in the Italian Longitudinal Study on Aging (ILSA), a large, population-based, prospective study with a sample of 5,632 subjects 65–84 years old with a 3.5-year follow-up. Patients with MCI who consumed up to 1 drink per day of alcohol had a reduction in the rate of progression to dementia in comparison with patients with MCI who never consumed alcohol (HR (95% CI) = 0.15 (0.03–0.78)). Overall, patients with MCI who consumed less than 1 drink per day of wine compared to nondrinkers had a decrease in the rate of progression to dementia of about 85% (HR (95% CI) = 0.15 (0.03–0.77)). Moderate intake of alcohol deriving from wine, in drinks controlled for the intake of alcohol deriving from other sources across a number of levels, was also associated with a significantly lower rate of progression to dementia. No significant associations were found between any levels of drinking and the incidence of MCI in non-cognitively impaired individuals versus abstainers (Solfrizzi et al. 2007) (Fig. 188.1).

To the best of our knowledge, only two other studies have examined the effect of alcohol consumption on risk for the incidence of MCI (Anttila et al. 2004; Espeland et al. 2005). After an average follow-up of 23 years, nondrinkers (OR (95% CI) = 2.15 (1.01–4.59)) and frequent drinkers (OR (95% CI) = 2.57 (1.19–5.52)) were both more than twice as likely to have MCI in old age as occasional drinkers (Anttila et al. 2004). However, the *APOE* genotype seemed to modify the relationship, such
Fig. 188.1 Multivariate hazard ratios of incident mild cognitive impairment (MCI) among noncognitively impaired subjects and progression to dementia among patients with MCI. The Italian Longitudinal Study on Aging (ILSA). This figure shows the multivariate hazard ratios of incident MCI among noncognitively impaired subjects (Model 1) and progression to dementia among patients with MCI (Model 2) who drank <1 alcoholic drinks/day (circle with solid line) or one to two alcoholic drinks/day (square with solid line) or >2 alcoholic drinks/day (rhomb with solid line) versus abstainers (from Solfrizzi et al. Neurology. 2007;68:1790–89, with permission)

that the risk of old age dementia increased with increasing midlife alcohol consumption only among carriers of the *APOE* ε4 allele (Anttila et al. 2004). In the ILSA sample, we failed to confirm these findings, but we note that the alcohol consumption reported was a midlife determination (Solfrizzi et al. 2007). Probably, a follow-up period longer than 3.5 years would have revealed that moderate alcohol consumption might influence the incidence of MCI. On the other hand, our findings are consistent with those obtained in the Women's Health Initiative Memory Study with a 4.2 year-follow-up, which found that moderate alcohol intake (≥1 drink per day) was associated with an approximately 50% reduced risk of combined probable dementia and MCI (OR (95% CI) = 0.4 (0.28–0.99)) (Espeland et al. 2005). However, after adjusting for demographic and socioeconomic factors and baseline Modified Mini Mental State Examination (3MSE), the significance disappeared (Espeland et al. 2005). Currently, ours is the first study in which alcohol consumption was associated with the rate of progression of MCI to dementia, in fact, up to 1 drink/day of alcohol or wine may decrease the rate of progression to dementia in patients with MCI (Solfrizzi et al. 2007).

Very recently, a systematic review with meta-analysis was carried out to investigate any relationship between incident cognitive decline or dementia in the elderly and alcohol consumption between 1995 and March 2006 that only included data on subjects aged ≥65 from longitudinal studies (Peters et al. 2008). The quality of the studies included in this meta-analysis was assessed using standard criteria that measured key factors including appropriate design, recruitment, analysis, and provision of suitable information relating to key aspects of the study (Peters et al. 2008). Outcomes measured were very variably defined ranging from dementia alone or as well as various subtypes (mainly AD and VaD) or of subtypes of dementia (AD and VaD) alone or in combination (Peters et al. 2008). Eleven studies assessed cognitive decline or predementia syndromes (Peters et al. 2008). Studies with inadequate definition of the outcomes of interest were also excluded. Meta-analyses suggested that, at least in epidemiological studies, light to moderate alcohol use was associated with a 38% reduced risk of unspecified incident dementia (Fig. 188.2). Also in the studies included in this meta-analysis, there was no close agreement as to what might be considered an "appropriate" level of

alcohol consumption particularly since the classification of light to moderate drinking varied widely. Possible benefit against dementia was shown for a variety of definitions including more than 1 drink per day, for weekly or monthly wine consumption; for 250–500 ml (usually wine); for more than 3 drinks per day and from 1 to 28 units per week (Peters et al. 2008). For effects on AD risk, light to moderate alcohol was associated with a significantly reduced risk of 32%, defining optimal amounts as weekly consumption of wine, 1–6 or more than 2 drinks per week, or more than 3 drinks/250–500 ml per day (usually wine), or where studied by gender, 1–3 per day in males (Peters et al. 2008). Although the point estimates were also in a similar direction for VaD and cognitive decline (0.82 and 0.89, respectively), the results were not statistically significant (Peters et al. 2008) (Fig. 188.3). With regard to effects on cognitive function, results for what could be considered "optimal" or non-deleterious consumption were mixed regarding the amount consumed per month or per day, in subjects with cardiovascular disease or diabetes where results ranged from 1–2 drinks per week, while for VaD patients 1–3 drinks per day in males appeared to be beneficial (Peters et al. 2008). Finally, another very recent meta-analysis included 15 prospective studies (follow-ups ranged from 2 to 8 years), with samples including 14,646 participants evaluated for AD, 10,225 participants evaluated

for VaD, and 11,875 followed for any type of dementia (Anstey et al. 2009). This meta-analysis indicated that light to moderate alcohol intake was associated with a 25–28% reduction in risk of AD, VaD, and any dementia compared with alcohol abstinence in older adults. Heavy drinking was not associated with increased risk of dementia in the present study (Anstey et al. 2009).

188.4 Alcohol and Cognitive Disorders: Possible Mechanisms

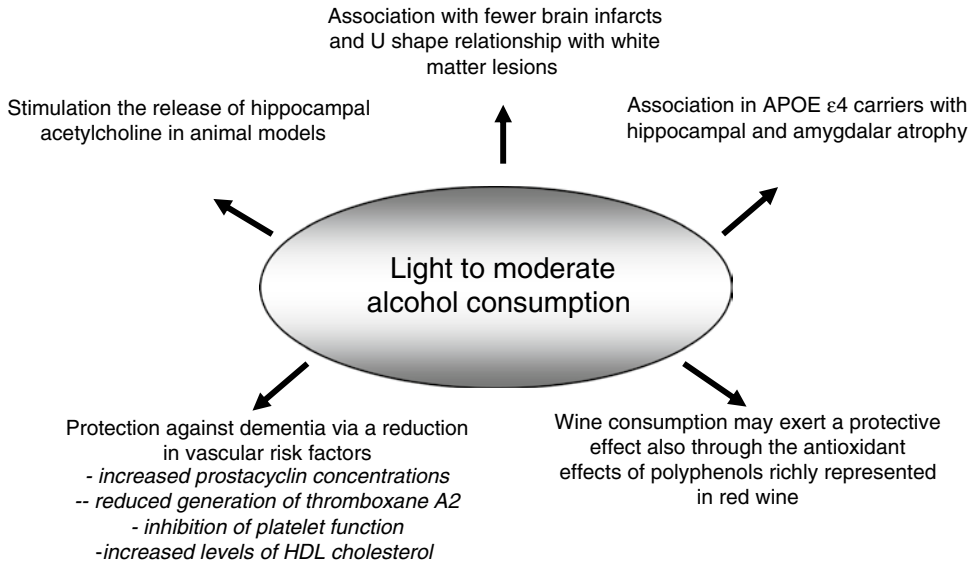
The mechanism by which light alcohol intake could be protective against cognitive decline impairment or decline in older age or against predementia and dementia syndromes is, at present, unclear (Fig. 188.4). The association between alcohol drinking and cognitive function could have different explanations in relation to cognitive domains explored. White matter lesions (WMLs), for example, would play a neuropathological role, given that alcohol drinking influenced measures of psychomotor speed, episodic memory, and executive function (Panza et al. 2009a). In fact, alcohol drinking has been associated with fewer brain infarcts and was shown to have a U-shape relationship with the prevalence of WMLs (Panza et al. 2009a). Furthermore, WMLs and infarcts, in turn, may reflect a vascular mechanism responsible for the observed association between alcohol and cognitive functions (Panza et al. 2009a). Different mechanisms may underlie the observed adverse effects of heavy


Fig. 188.4 Synopsis of the mechanism by which light to moderate alcohol intake could be protective against cognitive impairment or decline in older age or against predementia and dementia syndromes. This figure lists various possible mechanisms of light to moderate alcohol consumption linked to their neuroprotective properties against cognitive decline including modulation of cerebrovascular disease (e.g., white matter lesions), stimulation of the release of hippocampal acetylcholine in animal models, association with hippocampal and amygdalar atrophy, reduction in vascular risk factors or through the antioxidant effects of polyphenols richly represented in red wine

drinking and the potential beneficial effects of light to moderate drinking, and may also partly explain why deficits are reported in certain functions (e.g., delayed recall), whereas benefits are seen in others (e.g., learning) (Panza et al. 2009a). Indeed, higher doses of alcohol may affect cognitive functioning through increased release of acetylcholine from the hippocampus (Fadda and Rossetti 1998), which is an important neurotransmitter in memory and attention (Panza et al. 2009a). In contrast, evidence from animal studies indicated that low doses of alcohol may stimulate the release of hippocampal acetylcholine (Stancampiano et al. 2004). Finally, moderate alcohol consumption was associated with lower rates of cardiovascular disease and reduced cardiovascular risk factors (Naimi et al. 2005), which may serve to protect brain vasculature and prevent subclinical strokes, resulting in better preservation of cognitive performance (Panza et al. 2009a).

Alcohol consumption might protect from unspecified dementia by effects on the cerebral vasculature, supporting the observation that light to moderate alcohol intake might be protective against ischemic stroke (Palomaki and Kaste 1993). Moreover, light to moderate alcohol use is associated with a lower prevalence of MRI-defined WMLs and subclinical infarcts (den Heijer et al. 2004), although MRI abnormalities, HDL cholesterol levels, and fibrinogen levels only marginally influenced the association of alcohol consumption and dementia in the CHS (Panza et al. 2009a). The suggested protection against CVD resulting from light to moderate alcohol consumption may explain the perceived protection alcohol offers against VaD. In the Rotterdam study, the protective effect of alcohol consumption was found mainly for VaD, and the authors suggested that moderate alcohol intake might protect against dementia via a reduction in vascular risk factors (Panza et al. 2009a). In fact, moderate doses of alcohol may alter blood clotting mechanisms though increase of prostacyclin concentrations and reduction of thromboxane A2 generation and thus may inhibit platelet function (Panza et al. 2009a). Moderate alcohol consumption may also contribute to increased plasma levels of endogenous tissue-type plasminogen activator (tPA), a serine protease that regulates intravascular

fibrinolysis, and fibrinolytic activity while decreasing plasma fibrinogen levels (Panza et al. 2009a). It is also known that alcohol is associated with increased levels of HDL cholesterol, its subfractions HDL2 and HDL3, and its associated apolipoproteins A-I and A-II (Panza et al. 2009a). The association with HDL cholesterol is deemed to account for up to a half of the reduction in coronary events associated with moderate alcohol consumption (Panza et al. 2009a).

While the aforementioned factors could affect the risk of unspecified dementia and, probably, of VaD, other experimental and clinical findings may partly explain the suggested protection against AD provided by light to moderate alcohol consumption. Small amounts of alcohol have been reported to be associated with a lower prevalence of vascular brain findings and, in *APOE* ε4 carriers, with hippocampal and amygdalar atrophy, as assessed by MRI (den Heijer et al. 2004). Experimental studies found that ethanol initially increases hippocampal acetylcholine release, which could conceivably improve memory performance (Panza et al. 2009a).

Processes that originate, modulate, or precipitate the deposition of amyloid beta (βA) in the brain, such as oxidative stress, rather than vascular processes, may better explain the development of AD, and the vascular effects of the alcohol in alcoholic beverages may not be enough to explain the protective effects of the moderate intake of alcohol from dementia. The previously mentioned contribution of alcohol to increased plasma levels of endogenous tPA (Panza et al. 2009a) could promote Aβ removal since tPA is responsible for the formation of plasmin which is suggested to be an Aβ degrading enzyme (Miners et al. 2008). Wine consumption may exert a protective effect, either through alcohol intake itself, or through the antioxidant effects of polyphenols richly represented in red wine, or through both (Panza et al. 2009a). Although there have been some effects associated with alcohol-free red wine (Panza et al. 2009a), the constituents of red wine also have potentially beneficial vascular effects (139, 140) including, enhanced endothelial nitric oxide release (141), and reduced atherosclerosis in *APOE*-deficient mice (Waddington et al. 2004; Panza et al. 2009a). Red wine polyphenols are a complex mixture of flavonoids (mainly anthocyanins and flavan-3-ols) and non-flavonoids (such as resveratrol and gallic acid). Flavan-3-ols are the most abundant, with oligomeric and polymeric procyanidins (condensed tannins) often representing 25–50% of the total phenolic constituents (Waterhouse 2002). A recent study identified procyanidins as the principal vasoactive polyphenols in red wine and showed that they are present at higher concentrations in wines from areas of Southwestern France and Sardinia, where traditional production methods ensure that these compounds are efficiently extracted during vinification (Corder et al. 2006). Given the link between VaD, vascular risk, and the increasing body of evidence suggesting that AD may be influenced by vascular factors (Panza et al. 2009a), it may be concluded that the vascular protection associated to wine consumption decreases the risk of incident dementia/AD. In fact, in the 5-year follow-up PAQUID cohort, a significant inverse association between flavonoid intake and the risk of dementia was found (Commenges et al. 2000). It has been also suggested that the antioxidant properties of the flavonoids in wine may help prevent the oxidative damage implicated in dementia. Furthermore, oxidative stress is also likely to develop in the brain, contributing to neuronal death by various mechanisms such as formation of βA peptide, DNA damage, and abnormal tau protein (Panza et al. 2009a). The presence in wine of non-alcoholic components, such as particular antioxidants, could explain a differential effect of wine on dementia since liquor which does not seem to have as strong an effect has been shown to have less antioxidant activity than wine (Panza et al. 2009a). Nonetheless, in some studies on the neuroprotective role of moderate alcohol consumption, the most typically consumed alcohol types were beer and spirits (Panza et al. 2009a).

It is also possible that moderate lifestyles in general, which obviously vary according to different cultural environments, protect from cognitive impairment. Thus, it may not be the direct effect of alcohol or specific substances in alcoholic drinks that provide the protection, but moderate alcohol drinking may be an indicator of a complex set of favourable social and lifestyle factors. A protective

effect of alcohol on cognitive function in moderate drinkers may reflect a relatively poor health status among abstainers or because cognitive status influences alcohol consumption and overall health status (Panza et al. 2009a). The Mediterranean diet may serve as an interesting model for further studies of the association between alcohol and cognitive functioning, given the suggested role of many components of this diet (monounsaturated fatty acids (MUFA), polyunsaturated fatty acids (PUFA), and red wine) (Panza et al. 2009a) in different degrees of cognitive impairment. Indeed, the typical dietary pattern of Mediterranean diet is characterized by high intake of vegetables, fruits and nuts, legumes, cereals, fish, and MUFA with relatively low intake of meat, and dairy products, and moderate consumption of alcohol. Recently, in a community-based study involving 2,258 nondemented individuals in New York, adherence to a traditional Mediterranean diet was associated with a significant reduction in risk for AD (Scarmeas et al. 2006). However, in this study, the median daily intake of MUFA to saturated fatty acids (SFA) ratio for individual food categories by Mediterranean diet score tertiles was <1 and in overall about 2.5 times lower than the same value calculated from other studies on Mediterranean diet. This is notable given that a high MUFA to SFA ratio is one of the most important characteristics of the Mediterranean dietary pattern. Moreover, given the suggested role of different components of Mediterranean diet, it could be possible that alcohol influences the metabolism of PUFA and that this interaction could explain the role of both alcohol and PUFA in dementia and AD. Alcohol is a potent modulator of fatty acid metabolism and is known to influence the fatty acid profiles of different organs (Panza et al. 2009a). In animal studies, chronic alcohol exposure has been shown to decrease long-chain PUFA concentrations, especially docosahexaenoic acid and arachidonic acid in liver and brain tissues, depending on dosage and length of alcohol exposure (Panza et al. 2009a). In this context, the suggested neuroprotective role of light to moderate alcohol consumption may be a marker for a more complex dietary pattern or group of metabolic interactions. Further studies with dietary patterns more similar to the original Mediterranean model are needed to help dissect and confirm the aspects that contribute to the protective role offered by this diet against cognitive decline and dementia.

188.5 Applications to Other Areas of Health and Disease

As discussed, the beneficial effects of regular consumption of moderate levels of alcohol (≤24 g/day) have been demonstrated in the prevention of CAD and consistently show associations with reduced risk of ischemic and hemorrhagic stroke (Panza et al. 2009a). The definition of moderate drinking is very variable (ranging from 5 to 60 g of alcohol per day) depending on the study population and the assessment tools used (Panza et al. 2009a). The definition of moderate drinking used in the 2005 USDA Dietary Guidelines suggests consumption to be no more than 1 drink per day for women and no more than 2 drinks per day for men (U.S. Department of Health and Human Services and U.S. Department of Agriculture 2005). Heavy drinking is considered consuming an average of at least 2 drinks per day for men and at least 1 drink per day for women (U.S. Department of Health and Human Services and U.S. Department of Agriculture 2005). For light drinking, there is no standard definition but is presumably less than moderate drinking. Binge drinking is a pattern of alcohol consumption that achieves blood alcohol concentration to ≥0.08%; usually corresponds to >4 drinks on a single occasion for men or >3 drinks for women within 2 h (Panza et al. 2009a). However, definitions are not standardized in the literature and are not agreed on by all researchers (Panza et al. 2009a). In the United States, a standard alcoholic drink is more specifically defined as 12 ounces of regular beer, five ounces of wine, 1.5 ounces of 80 proof distilled spirits or liquor (gin, rum, vodka, whiskey), 17.74 ml of alcohol or 14 g of alcohol (Panza et al. 2009a). Thus, at the extreme, 2 drinks a day would be up to approximately 30 g of alcohol.

In particular, for cardiovascular conditions, reduction in both incidence of clinical CAD and severity of angiographically documented CAD has been documented with moderate alcohol drinking (Panza et al. 2009a). The benefit was consistently shown with various types of alcoholic drinks and drinking patterns (Panza et al. 2009a). Until large, prospective, randomized trials are available, which may be very difficult to undertake in practical terms, the preponderance of data that suggest that consumption of 1–2 drinks in men and 1 in women will be beneficial to the cardiovascular system (Panza et al. 2009a). Furthermore, heavy drinking is associated with increased hemorrhagic stroke risk, and there is some consensus about this relation in relevant reports (Klatsky 2005). The antithrombotic actions of alcohol might also result in increased hemorrhagic stroke risk at moderate drinking levels, but reports differ about whether lighter drinking increases hemorrhagic stroke risk or is unrelated (Panza et al. 2009a). The alcohol–hemorrhagic stroke relation seems similar for subarachnoid and intracerebral hemorrhage (Klatsky 2005). Reports are less concordant about alcohol–ischemic stroke interactions, but several analyses suggest a U-shaped or J-shaped distributions when the amount of drinking is plotted against ischemic stroke risk (Klatsky 2005). A meta-analysis performed on 35 studies on this topic revealed that heavy alcohol consumption increases the relative risk of stroke while light to moderate alcohol consumption may be protective against total and ischemic stroke (Reynolds et al. 2003). Nonetheless, the Cardiovascular Health Study (CHS) confirmed that association of alcohol use and risk of ischemic stroke was a U-shaped distribution, with modestly lower risk among consumers of 1–6 drinks per week, but even moderate alcohol intake may be associated with an increased risk of ischemic stroke among *APOE* ε4-carrier older adults (Mukamal et al. 2005a). Finally, in the Health Professionals Follow-up Study, a prospective analysis of more than 38,000 men who were free of known cardiovascular disease, alcohol consumption appeared to be associated with a higher risk for ischemic stroke among those who consumed more than 2 drinks per day (Mukamal et al. 2005b). However, alcohol was apparently not associated with risk at lower levels of intake. A pattern of intake characterized by moderate use 3–4 days per week appeared to be associated with the lowest risk. Red wine consumption was inversely associated with ischemic stroke risk, an association that was significantly different from the comparable associations of other beverages. These findings may also offer support for stroke reduction where to gain cardiovascular benefits people should avoid consuming more than 2 drinks daily (Mukamal et al. 2005b).

Regular, moderate wine consumption is often associated with reduced morbidity and mortality from and to a variety of chronic diseases in which inflammation is a root cause (Walzem 2008). Wine comes in a wide variety of styles that contain different ethanol and polyphenol contents. Controversy remains as to whether the alcohol or polyphenols contribute more to the health benefits of regular moderate wine consumption. The overall effect of wine consumption on health depends upon the total amounts consumed, the style and possibly the pattern of consumption (Walzem 2008). The apparent effect of wine consumption may be modified by other aspects of diet, for example, those consuming various levels of alcohol may also consume differential volumes of fruit, vegetable, and whole grain, and as such phytochemical intake and benefit may vary, particularly if wine may serve as a primary dietary source of phytochemical (Walzem 2008).

188.6 Conclusions

Drugs currently used in the symptomatic treatment of cognitive impairment and dementia unfortunately have a very limited therapeutic value, particularly on the management of psychiatric and behavioural symptoms. This is a constant reminder of the necessity to seek new therapeutic options to slow down the progression of predementia and dementia syndromes.

In the past few years, vascular and lifestyle-related factors for predementia and dementia syndromes have been an area of intensive research. At present, cumulative evidence has suggested that vascular risk factors may be important in the development of MCI, dementia, and AD (Panza et al. 2009a). Light to moderate alcohol drinking has been proposed as a protective factor against MCI and dementia in several longitudinal studies, but contrasting findings also exist and deriving overall conclusions from these studies has many limitations. Many of these studies were limited to cross-sectional design, restriction by age or sex, or incomplete ascertainment. Moreover, outcomes measured, the range of beverages that are available, drinking patterns and how they are categorised as well as follow-up periods studied and possible interactions with other lifestyle-related (i.e., smoking) or genetic-related (i.e., *APOE* genotype) factors are all sources of great variability. Indeed, the body of evidence examined in this chapter and the recent meta-analyses cited (Peters et al. 2008; Anstey et al. 2009) of all research published within the last 10 years suggested that light to moderate alcohol use may be associated with a reduced risk of unspecified incident dementia and AD, while for VaD, cognitive decline, and predementia syndromes the current evidence is only suggestive of a protective effect. Thus, at present, the most commonly used outcome measures for these kinds of studies appear to be unspecified dementia and AD, where prevalence and diagnostic classifications make the studies more practical compared with the small number of studies reporting VaD and other subtypes of cognitive decline. These are more difficult to classify, which is often further complicated by the relatively high vascular factor contribution to AD cases. On the other hand, the cardiovascular mechanisms that related to the suggested protective effects of alcohol may have an even greater effect on VaD (Table 188.7).

For the different types of beverages that exist, several studies have suggested that light to moderate wine consumption may be protective against dementia and cognitive decline but not total alcohol intake, beer, or spirits, although this is not conclusive (Panza et al. 2009a). In this context, it would be desirable to differentiate types of wine (e.g., red, white, rosé), but this information is not currently available. The failure to detect differences between types of beverages in some studies might be a consequence of differential gender interactions, although these analyses were adjusted for gender. Other issues are that some geographical regions typically consume specific types of alcoholic beverage (e.g., beer and spirits in Northern Europe), although observed associations and benefits offered by specific types of beverages were inconclusive. In general, wine-only drinkers may tend to consume wine less often than those who also drink other kinds of alcohol. In this way, wine-only drinkers could be viewed as the ones who consume the moderate quantities of ethanol beneficial for health, while the others may consume larger quantities; negative consequences of ethanol may outweigh the positive effects of healthy ingredients. Of course, measurement of alcohol consumption

Table 188.7 Key points of clinical and epidemiological studies on the relationships among alcohol consumption and dementia and predementia syndromes

A. Among lifestyle-related factors, low to moderate alcohol drinking has been proposed as a protective factor against the development of age-related changes of cognitive function, predementia syndromes, and cognitive decline of degenerative (Alzheimer's disease, AD) or vascular origin (vascular dementia, VaD) in several longitudinal studies, but contrasting findings also exist

B. Light to moderate alcohol use may be associated with a reduced risk of unspecified incident dementia and AD, while for VaD, cognitive decline, and predementia syndromes the current evidence is only suggestive of a protective effect

C. Epidemiological evidence suggested that the protective effects of alcohol are more likely with wine consumption and the absence of an apolipoprotein E (APOE) e4 allele. At present, there is no indication that light to moderate alcohol drinking would be harmful to cognition and dementia, and it is not possible to define a specific beneficial level of alcohol intake

This table lists the principal features of clinical and epidemiological studies on the relationships among alcohol consumption and dementia (AD and VaD) and predementia syndromes

must consider both volume consumed and the alcohol content of drinks, which is very variable in everyday living and in previous research, and this will remain an important consideration in considering previous research and planning future studies.

Whether the present divergent findings can be explained by the drinking patterns has not been extensively investigated, and studies with long follow-up periods are few (Panza et al. 2009a). It is possible that over time, and perhaps in association with cognitive decline, alcohol consumption patterns will change, and, therefore, long-term follow-up studies are needed to clarify the issue. Furthermore, with respect to the measurement of alcohol intake, in addition to the volume and alcohol content issue mentioned, the amount of detail collected on patterns of consumption varies widely in some studies which often range from data on recent consumption to some assessing historial patterns of consumption or lifetime abstinence/change in consumption. This may be particularly pertinent in the elderly as people may reduce consumption as they age, although not all studies agree with this (Panza et al. 2009a), however, it also contains hazards associated with recall bias. It may be that the prevalence of binge drinking has only increased recently, especially for women, but it is surprising that so few studies assessed this in their participants (Panza et al. 2009a). Therefore, the impact of alcohol drinking on cognitive functions might be somewhat different at different time points in individual's lives. Nonetheless, the current balance of evidence suggests that alcohol consumption in old age substantially agrees with that of midlife consumption in relation to cognitive decline (Panza et al. 2009a). At present, there is no evidence indicating whether starting to drink at a later age would be beneficial against predementia or dementia syndromes.

Furthermore, smoking may be a significant confounder of alcohol effects and thus both may not only individually affect dementia and cognitive decline, but each may also modify the effects of the other. In fact, there were several studies focused on alcohol and cognitive impairment or decline, in which there was no evidence of an interaction between alcohol and smoking on cognitive measures, with a few notable exceptions (Panza et al. 2009a). The overall findings from three Canadian data sets suggested that smoking may reduce the risk of dementia among drinkers (Tyas et al. 2000) while another recent study reported that these interactions were significant only for wine and smoking, suggesting that ingredients other than ethanol in wine may be protective against the adverse effects of smoking or of course it could suggest that there is higher consumption of wine amongst smokers compared with nonsmokers (Mehlig et al. 2008). Further analysis of this interaction, particularly in longitudinal studies and within genetic risk groups, is needed to determine whether this interaction can be replicated.

Finally, genetic susceptibility seems to modify the effect of alcohol on risk of dementia and predementia syndromes, with some, but not all studies suggesting that the *APOE* ε4 carrier status acting as a possible effect modifier for these associations (Panza et al. 2009a). Nonetheless, the protective effects of light to moderate alcohol consumption against dementia and cognitive decline are more likely in the absence of an *APOE* ε4 allele (Panza et al. 2009a). The effect of the *APOE* ε4 allele on dementia is suggested to attenuate with increasing age, which might partly explain the conflicting results concerning effect modification in studies on elderly cohorts (65 years and older) (Panza et al. 2009a). Very recently, in the CAIDE study, after an average follow-up of 21 years, there was a statistically significant multiplicative (*p*-values: infrequent drinking = 0.04, frequent drinking = 0.03) and additive interaction (infrequent drinking: relative excess risk from interaction (RERI) = 1.97, $p < 0.001$, frequent drinking: RERI = 2.95, $p < 0.001$) between the *APOE* ε4 carrier status and alcohol drinking for dementia risk (Kivipelto et al. 2008). One possible explanation could be that people with the ε4 allele have less effective neural repair mechanisms (Panza et al. 2009a), and thus they would be more susceptible to the deleterious effects of alcohol. It is also possible that it is a particular drinking pattern (i.e., binge drinking) which together with *APOE* ε4 carrier status forms a hazardous combination in some populations (Panza et al. 2009a). However, what has yet to be investigated as a possible additional variable is whether any additional genetic variants, such as genes encoding enzymes involved in alcohol metabolism, may also be involved.

Ultimately, since intervention studies are unlikely to be performed in this area, perhaps the most useful evidence comes from overview of epidemiological studies which still have a number of limitations. At present, there doesn't appear to indication that light to moderate alcohol drinking would be harmful to cognition and dementia. However, it is not possible to define a specific beneficial level of alcohol intake in relation to what might be beneficial to cognitive function and dementia. Acknowledging the well-known harmful effects related to heavy consumption of alcohol and the lack of long-term follow-up studies or randomized controlled trials, it would be premature to recommend whether some alcohol consumption, even to abstainers would be helpful in preventing cognitive decline or predementia syndromes or even delaying the onset of dementia. Possibly, at present, in moderate to heavy alcohol drinkers, experiencing memory difficulty, or with suggested diagnoses of MCI or early AD, among management options, given the challenge in achieving total abstinence, allowing some light to moderate drinking (rather than encouraging which may convey confusing health messages), provided there are no other contraindications to suggest otherwise may at the very least not contribute significant additional harm (Panza et al. 2009a).

Summary Points

- An increasing body of epidemiological evidence suggests that light to moderate alcohol consumption could offer some benefit for some health outcomes including cognitive function and heart disease.
- In particular, light to moderate alcohol drinking has been proposed, although not universally, as a protective factor against the development of age-related changes of cognitive function including predementia syndromes, and cognitive decline of degenerative (Alzheimer's disease, AD) or vascular origin (vascular dementia, VaD) in several longitudinal studies.
- Different outcome measures, types of beverages, measurement of drinking patterns, or follow-up periods, or possible interactions with other lifestyle-related (e.g., smoking) or genetic factors (e.g., *APOE* or other genes) are current sources of great variability where there need to be efforts to refine.
- Light to moderate alcohol consumption may be associated with a reduced risk of unspecified incident dementia and AD, while it may also be a benefit for less studied VaD, cognitive decline, and predementia syndromes.
- Reported protective effects from alcohol consumption seem to be most likely attributed to the consumption of wine and in people not having *APOE* e4 alleles. However, at present, there is no indication whether light to moderate alcohol drinking would be harmful to cognition and dementia, and it is not possible to define a specific beneficial level of alcohol intake.

Key Terms and Definitions

Alcohol: Any organic compound where a hydroxyl group (−OH) is bound to a carbon atom of an alkyl or substituted alkyl group. Generally, the word alcohol refers to ethanol, the type of alcohol found in alcoholic beverages. Ethanol is a colourless, volatile liquid with a mild odour which can be obtained by the fermentation of sugars.
Dementia: It is a syndrome defined by impairments in memory and other cognitive functions that are severe enough to cause significant impairment and decline from a previous level of social and occupational functioning.

Predementia syndrome: This term identifies all conditions with age-related deficits in cognitive function, including a mild stage of cognitive impairment based on a model of normality or also due to pathological conditions considered predictive or early stages of dementia.

Mild cognitive impairment (MCI): It is a clinical label that includes non-demented aged persons with memory impairment that is more pronounced than what would be expected normal for that age but not severe enough as to cause significant disability.

Age-related cognitive decline (ARCD): It is defined as an objectively identified decline in cognitive functioning consequent to the aging process that is within normal limits given the person's age, not as pronounced as for MCI, but for which there are no defined diagnostic criteria, and scant usage in epidemiological studies.

SD   Sweet disliking
SL   Sweet liking
GABA   γ-Aminobutyric acid
FH+   Positive family history of alcoholism
FH–   Negative family history of alcoholism
PMS   Premenstrual syndrome

189.1 Introduction

We all like sweets from the moment we are born. Mother Nature designed us this way because sweet taste is an indicator of highly caloric carbohydrate foods that are necessary for us to survive at early age. Mother's milk is very sweet, if anyone remembers. We perceive sweet taste as calming, soothing, and comforting. Reaction to the sweet taste is our basic pleasure, the yardstick by which we measure all our positive experiences. That is why even in our language the word "sweet" is synonymous with anything good. We call our loved ones *sweethearts* and *sweeties*, our favorite music is *sweet music*, and, even in business, we are trying to make *sweet deals* with our partners.

Our response to the sweet taste is closely associated with our overall ability to experience all natural pleasures. Therefore, any changes in our hedonic response to sweets may reflect changes in functional activity of the brain reward system. For example, preference for stronger sweet taste and craving for sweets was consistently reported in individuals suffering from anxiety, depression, and dysphoria. Furthermore, our knowledge of the soothing effect associated with eating sweet foods that we acquired in infancy can provide us a serious disservice in our adult life: some of us continue to use sweet foods as a tranquilizer which, in some cases, leads to the development of binge eating behavior and obesity.

The key role in regulation of our pleasurable response to sweet taste is played by endogenous opioid peptides (e.g., endorphins and enkephalins) that have similar physiological effects to exogenous opiate drugs such as morphine and heroine. These endogenous peptides as well as their multiple

receptor subtypes (e.g., μ, β, κ) are found in various networks throughout the brain, but particularly within the regions involved in emotional regulation, responses to pain and stress, endocrine regulation, and food intake.

Despite the importance of sweet taste and its association with emotional health, the literature about this subject is scarce. In this chapter I will attempt to systematize the existing knowledge regarding physiological mechanisms underpinning hedonic response to sweets and the links between distortions of sweet taste and various psychiatric conditions with an emphasis on alcoholism.

189.2 Hedonic Response to Sweet Taste

The gustatory system is primarily devoted to a quality check of food, while simultaneously detecting nutrients and avoiding toxic substances. Sweet is one of the five primary taste qualities (along with bitter, sour, salty, and umami). Sweet-tasting foods and beverages are highly preferred by plant-eating animals including humans, presumably because sweetness reflects the presence of caloric sugars.

Liking sweet tastes is strongly influenced by inborn (innate) factors and positive hedonic (pleasurable) responses to sweet taste can be detected in human infants during the first minutes after birth (Steiner et al. 2001). Hedonic response to sweet taste is believed to be a stable heritable trait that reflects qualitative differences in taste perception rather than more cognitive reactions based on associations between the taste and attitudes toward, or social acceptability of, liking sweet foods (Looy and Weingarten 1991). The role of genetic factors in perception of sweet taste and preference for sweet foods can be illustrated by the results of a recent study of 473 twin pairs, which showed that approximately half of the variation in liking for sweet solution and liking and use-frequency of sweet foods (49–53%) was explained by genetic factors, whereas the rest of the variation was due to the environmental factors unique to each twin individual (Keskitalo et al. 2007).

189.2.1 Sweet-liking/Sweet-disliking Phenotypes

It is important to note that although all humans have an innate preference for the sweet taste, the magnitude of hedonic response to sweet taste as well as avidity to consume sweet foods significantly varies across individuals. Such differences may be noted in infancy (Steiner et al. 2001) and persist as children become young adults (Desor and Beauchamp 1987). Two major stable patterns of hedonic response to sweet taste have been described in the literature (Thompson et al. 1976). With Type I response (often referred to as *sweet disliking*), subjects prefer progressively higher concentrations of sucrose solution up to the middle range of concentration, followed by a breakpoint after which preference declines with increased concentration. The Type II response (also referred to as *sweet liking*) is characterized by continuous increase with eventual leveling off in liking of progressively more concentrated sucrose solutions (Fig. 189.1). Similar patterns have been described in animals as well (Sinclair et al. 1992), which may indicate that these patterns can be a characteristic of all mammals.

189.2.2 Factors Influencing Hedonic Response to Sweet Taste

Although perception of sweet taste appears to be a fairly stable trait, there are some factors that are known to be associated with variability of hedonic response to the sweet taste.
Fig. 189.1 Types of hedonic response to sweet taste in animals and humans. Although both animals and humans have an innate preference for sweet-tasting substances, the magnitude of hedonic response to sweet taste as well as avidity to consume sweet foods significantly varies across individuals. Two major stable patterns of hedonic response to sweet taste have been described in the literature. With Type I response (often referred to as *sweet disliking*, *SD*), subjects prefer progressively higher concentrations of sucrose solution up to the middle range of concentration, followed by a breakpoint after which preference declines with increased concentration. The Type II response (also referred to as *sweet liking*, *SL*) is characterized by continuous increase with eventual leveling off in liking of progressively more concentrated sucrose solutions. These two patterns of hedonic response to sweet taste are believed to be associated with activity of the brain opiate system that to a large extent is regulated by genetic factors. Sweet liking is believed to be associated with suppression of the opioidergic transmission in the brain

Ethnic background: Ethnic origins have been shown to have an impact on the hedonic response to sweet taste. For example, Americans of African descent were shown to prefer stronger sweet taste than Americans of European descent (Bacon et al. 1994).

Age: The degree of preferred sweetness also may vary with age. Children tend to prefer sweeter solutions compared to adults (De Graaf and Zandstra 1999). Younger people also consume more sugar than do older people (Drewnowski 1997).

Gender-related factors: Sex differences may also influence hedonic response to sweet taste, with women being more sensitive to the mood-altering effect associated with eating sweet-tasting foods and reporting stronger cravings for sweet-tasting foods (Kampov-Polevoy et al. 2006). It is of interest that the sex differences in hedonic response to and craving for sweets can be seen only in adult individuals, while no such difference was noted in infants (Beauchamp and Moran 1982). These findings may indicate that sex hormones may play a significant role in the development of sweet preferences as was initially suggested by Wade and Zucker (1969). The other indications that sex hormones can modulate a perception of and craving for the sweet taste come from studies that showed a fluctuation of sweet cravings and consumption of sweet foods (but not other types of foods) throughout the menstrual cycle (Bowen and Grunberg 1990).

In summary, a pleasurable response to the sweet taste is an innate reaction and the level of positive emotional response to sweet taste, as well as consumption of sweets, are influenced to a large degree by genetic factors. There are two major patterns of the hedonic response to sweet taste – sweet disliking and sweet liking. Of the factors identified to date that influence hedonic response to sweet taste, gender seems the most influential with women being more sensitive to mood-altering effect of sweet-tasting foods and more likely to crave and eat sweets in response to emotional stress.

189.3 189.3 Physiological Mechanisms Underpinning Hedonic Response to Sweet Taste

The mechanisms regulating hedonic response to sweet taste are complex, and detailed discussions of these complexities are beyond the scope of this chapter. Here, a brief overview of the two major categories of mechanisms of response to sweet taste is presented: the peripheral mechanisms, responsible for the perception of sweet taste, and the central mechanisms, responsible for emotional response for sweets.

189.3.1 Peripheral Mechanisms/Role of the Taste Receptors

The initial event of perception of sweet taste occurs in taste receptor cells, which are clustered in the taste buds in taste papillae on the tongue surface. The perception of sweetness intensity is related to the number of papillae that varies widely among people. These variations may be due to alleles in genes that develop and maintain sensory cells. To date, three sweet-taste receptors have been identified in both mice and humans, which are regulated by polymorphisms of sweet-receptor genes (*TAS1R1, TAS1R2, TAS1R*3). Polymorphisms of these genes have a large effect on the intake of sweet-tasting substances in both animals and humans (Liao and Schultz 2003).

189.3.2 Central Mechanisms/Role of the Brain Reward System

Hedonic responses to sweet taste may be modulated not only by peripheral mechanisms, but also by the brain reward system that regulates perception of all naturally occurring pleasures. This system was first described by Olds and Milner (1954) who observed that when electrodes were placed in certain areas of the brain, rats would actively self-stimulate these areas often to the exclusion of other activities including eating. The brain reward system is located in the mesolimbic part of the brain and involves complex interrelationships of at least four important neurochemical pathways (i.e., serotonergic, opioidergic, GABAergic, and dopaminergic), with a pleasurable response associated with increased dopamine accumulation in the nucleus accumbens. Without the normal functionality of the brain reward system, an individual will experience a so called reward-deficiency syndrome that includes hypohedonia (diminished ability to experience pleasure) and inability to cope with stress. Individuals with the reward-deficiency syndrome are likely to seek substances and/or behaviors that will overcome this hypohedonic state by activating the brain reward system. These substances and behaviors include alcohol, opiates, psychostimulants, nicotine, carbohydrates, cannabinoids, gambling, sex, and indulgence in any excessive pleasure or thrill-seeking behaviors, such as video gaming, etc. (for review, see Comings and Blum 2000).

Sweet-tasting substances (both caloric and noncaloric sweeteners) stimulate sweet-taste receptors on the surface of the tongue, which, in turn, results in activation of the μ-opioid receptors on GABA interneurons (projection neurons that interact with dopamine neurons) in the ventral tegmental area, to cause a disinhibition of dopamine cell firing in the nucleus accumbens that is subjectively perceived as pleasure (Lemon et al. 2004). Microdialysis studies show a robust rise in extracellular accumbens dopamine levels following exposure to sweet tastes. Recently, Pecina and Berridge (2005) have shown that the perception of pleasantness of sweet taste in rats is strongly influenced by

μ-opioid receptor activation in a single cubic millimeter site localized in the rostrodorsal quarter of the medial shell of the nucleus accumbens, an observation indicating very tight neuroanatomical localization of the hedonic response to sweet taste. According to DiChiara and North (1992), opioid pathways in the brain reward system are associated with feelings of satiety, sedation, rest, and "bliss." In this regard, it is important to note that sweet preference and hedonic response to sweet taste seem to be associated with activity of the brain opioid pathways. Animal studies showed that stimulation of these pathways with morphine shifts the sweet preference/aversion curve left toward preference for weaker sweet taste (Calcagnetti and Reid 1983), while its blockade shifts sweet preference toward more concentrated sweet solutions (Leventhal et al. 1995). Therefore, the sweet-liking phenotype, described earlier in this chapter may be associated with inhibition of the opioidergic pathways in the brain reward system and can be a potential marker of the reward-deficiency syndrome.

Knowledge of physiological mechanisms underpinning hedonic response to sweet taste leads to several hypotheses that may have important practical implications:

1. Considering that eating of sweet-tasting foods is associated with stimulation of the opioidergic pathways in the brain, one would expect that consumption of sweets will exert an effect similar to those of opiate agonists (e.g., morphine) – produce a positive affective state, reduce emotional stress, and cause analgesia. On the other hand, chronic consumption of sweet-tasting foods may lead to the development of elements of physical dependence such as increased consumption of sweets, loss of control over eating sweets, as well as development of symptoms similar to symptoms of opiate withdrawal when consumption of sweet-tasting foods is discontinued.
2. Considering the ability of sweet-tasting foods to produce positive emotional states and reduce emotional stress, one would also expect that people will eat sweets to self-medicate the negative mood states such as anxiety, fatigue, and/or depression.
3. Considering that preference for stronger sweet taste (sweet liking) is associated with blockade of opioidergic pathways that play an important role in regulation of the activity of the brain reward system, it is logical to hypothesize that the sweet-liking phenotype may serve as a marker for the reward-deficiency syndrome. If this hypothesis is correct, we would expect the sweet-liking phenotype to be associated with the negative affect and with the inclination to self-medicate this affective state with sweet-tasting foods, alcohol, and drugs of addiction.

The following sections seek support for the above-mentioned hypotheses in the available literature.

189.4 Effects of Ingestion of Sweet Foods

The effects of ingestion of sweet tasting food are summarized in Table 189.1.

Table 189.1 Effects associated with eating of sweet-tasting foods

Effects of acute intake	Effects of chronic intake
Feeling of well-being, sedation, and relaxation Reduction of emotional stress and alleviation of negative mood states	Development of symptoms that are similar to symptoms of physical dependence: 1. Enhanced intake of sweet-tasting foods 2. Abrupt discontinuation of eating sweets after a period of daily intake of sweet-tasting foods may lead to symptoms similar to symptoms of opiate withdrawal
Analgesia	Development of tolerance to analgesic effect of opiate drugs

189.4.1 Effect of Acute Ingestion of Sweet-Tasting Substances

189.4.1.1 Effect of Sweet Taste on Mood

As stated earlier, positive emotional reactions to sweet taste can be detected in humans within the first few minutes after birth. Intraoral sucrose administration has been shown to induce rapid and sustained calming effects in crying newborns (for review, see Bhattachrjee and Mathur 2005). Similar mood-altering effects of sweet-tasting foods have been noted in adults as well. For example, eating of sweet food improves an experimentally induced negative mood state in healthy adults (Macht and Mueller 2007), with the effect being more pronounced in women than in men. Furthermore, college students reported that the magnitude of their craving for sweet carbohydrate foods correlates with the severity of the negative mood states such as anxiety, fatigue, and/or depression (Christensen and Pettijohn 2001). Therefore, positive mood effects of sweet-tasting foods may contribute to the habit of eating sweets as a coping mechanism against stress.

189.4.1.2 Effect of Sweet Taste on Perception of Pain

There is a large body of evidence indicating that consumption of sweet-tasting foods may produce significant analgesia in both animals and humans. For example, acute exposure to sweet (e.g., sucrose) solutions was shown to produce analgesia sufficient to conduct minor surgical procedures in human infants. A similar effect was demonstrated in prepubertal children as well as in adult females but not in adult males. The brain opioidergic pathways seem to play an important role in sweet-induced analgesia because such analgesia may be reversed by the opiate antagonist naloxone (for review, see Bhattachrjee and Mathur 2005).

189.4.2 Effect of Chronic Ingestion of Sweet-tasting Foods: Do We Become Dependent on Sweetness?

Although acute consumption of sweet foods may cause marked opiate-mediated analgesia, chronic exposure to sweets attenuates morphine-induced analgesia, which indicates the development of tolerance to opiates. Furthermore, animal studies demonstrate that chronic exposure to sweet-tasting foods may lead to the development of symptoms similar to those seen in individuals with substance dependence. For example, rats maintained on a diet of chronic intermittent access to a sucrose solution and chow tend to increase their sugar intake (Avena et al. 2006) and show behavioral and neurochemical changes similar, albeit smaller in magnitude, to rats dependent on opiates (Rada et al. 2005; Colantuoni et al. 2002).

There is emerging evidence showing that chronic exposure to sweet foods may cause long-term changes in preference for and consumption of sweet foods in humans, at least in children. For example, infants fed with sugar solutions prefer stronger sweet taste and like sweet foods later in life more than children who have not been fed with sweet water as infants (Beauchamp and Moran 1982). Children who were routinely fed sugar water during infancy preferred significantly higher levels of sucrose when compared to those who were rarely or minimally exposed (Pepino and Mennella 2005). In adults, immediate but short-lived reduction in sweet preference can be noticed after ingestion of the sweet solution (Cabanac and Duclaux 1970). However, this effect was noted only in individuals with sweet-disliking phenotype but not in sweet-liking individuals (Looy et al. 1992; Looy and Weingarten 1992).

189.4.3 Acute Effect of Noncaloric Sweeteners

It is important to emphasize that the effects sweet foods have on the brain reward system are associated with the oral stimulations of sweet-taste receptors rather than with the chemical composition or caloric value of ingested food. This hypothesis is supported by the elegant animal experiments using a sham-feeding procedure, when the food, after being eaten, did not enter the stomach but rather was removed from the gastrointestinal tract, thus eliminating any postabsorptive effect of consumed foods (Hajnal et al. 2004). This study provided a clear indication that concentration-dependent increase in dopamine levels in the rat nucleus accumbens depends on the taste but not on the composition of the studied foods. These findings may also explain why the noncaloric sweetener saccharine increases beta-endorphin levels in rat cerebrospinal fluid and plasma of the same magnitude as natural sugars (Yamamoto et al. 2000).

In summary, oral sucrose administration has been shown to produce positive emotional responses, to alleviate negative mood states, and to produce marked analgesia. These phenomena have been reported in both animals and humans, with women being more sensitive to these effects than men. Such effects are more likely to be associated with the sweet taste than with the chemical composition or caloric value of ingested food. Chronic consumption of sweet-tasting substances may lead to a condition similar to physical dependence to opiates with symptoms including elevated sugar consumption, increased tolerance to morphine, and signs of opiate withdrawal.

189.5 Sweet Taste and Mood Disorders

The literature provides consistent evidence showing that negative mood states are associated with the preference for stronger sweet taste, craving for sweet foods, and excessive consumption of sweet-tasting foods. For example, a study of healthy children shows significant correlation between sweet preference and depressive symptoms (Mennella et al. 2008). It is also believed that some people use sweet-tasting foods to self-medicate their negative emotional state.

Healthy individuals: In the study of healthy college students, Christensen and Pettijohn (2001) have shown that 90% of females and 55% of males identified themselves as cravers for sweet carbohydrate foods. In this sample, the magnitude of carbohydrate cravings significantly correlated with the experience of negative mood states such as anxiety, fatigue, and/or depression.

Patients with depression: In a clinical population, depressed individuals were shown to have a greater craving for and consumption of sweet carbohydrate foods than non-depressed controls (Christensen and Somers 1996; Wurtman 1988). Furthermore, the magnitude of the preference for sweet foods in depressed patients positively correlated with the level of depression (Fernstrom et al. 1987).

The association between depressed mood and sweet craving/consumption is most evident in patients with seasonal affective disorder, a condition characterized by recurrent depressive episodes that typically begin to appear in the fall and remit in the spring. These patients report strong cravings for sweet foods that are consistently associated with the depressive episodes (Rosenthal et al. 1984). Moreover, patients with seasonal affective disorder report that indulging in their craving significantly reduces negative mood (Leibenluft et al. 1993).

Patients with premenstrual syndrome (PMS): The other illustration of a link between negative affect and craving for sweets is PMS. It is commonly known that food cravings and mood tend to fluctuate throughout the menstrual cycle. In comparison to other phases of the menstrual cycle, during the luteal phase (10 days preceding menses), women report increased craving and consumption of sweet carbohydrate foods, which can double in comparison with postmenstrual period (Bowen

and Grunberg 1990). This phenomenon is especially pronounced in women with PMS when the depressed mood positively correlates with craving for sweet foods (Both-Orthman et al. 1988). Women also reported an improvement in mood following consumption of the carbohydrate-rich meal (Wurtman et al. 1989).

In summary, sweet preference and craving for sweet-tasting foods positively correlates with severity of the negative mood states (e.g., anxiety, depression) in both healthy individuals and patients with clinical depression. Consumption of sweets alleviates negative mood states and can be used for self-medication.

189.6 Hedonic Response to Sweet Taste and Excessive Alcohol Intake

189.6.1 Animal Studies

189.6.1.1 Association Between Consumption of Sweet-tasting Solutions and Alcohol Intake

During the last three decades, evidence indicating a close positive association between hedonic response to sweet taste, avidity to consume sweet-tasting foods, and excessive alcohol intake in both animals and humans has accumulated. The first evidence connecting consumption of sweets with alcohol intake came from animal studies. In 1978, Ramirez and Sprott reported that C57BL mice, known for their high voluntary alcohol intake, consume much larger quantities of saccharin solution than do DBA/2J mice that are known for their relatively low alcohol intake. A similar association (*correlation coefficient* = 0.7) between voluntary consumption of a 0.1% saccharin solution and subsequent voluntary consumption of 15% alcohol solution was demonstrated in randomly bred Wistar rats (for review, see Kampov-Polevoy et al. 1999).

Later studies showed that association between consumption of sweet solutions and alcohol intake may have a genetic origin. For example, Belknap et al. (1993) showed a high genetic correlation (*correlation coefficient* = 0.77) between saccharin and alcohol intake in 15 inbred mouse strains. A similar correlation between sucrose consumption and alcohol intake can be seen in the F2 generation of crosses between alcohol-preferring C57BL/6ByJ and alcohol-avoiding 129/J strains of mice. Further analysis showed that intakes of sucrose and ethanol are influenced by a few genes and that the "genetically determined component of these correlations was stronger than the component related to environmental factors" (Bachmanov et al. 1996). Similar results have been demonstrated in rats genetically selected for their high/low alcohol intake (Overstreet et al. 1997).

189.6.1.2 Saccharin-induced Polydipsia and Excessive Alcohol Intake

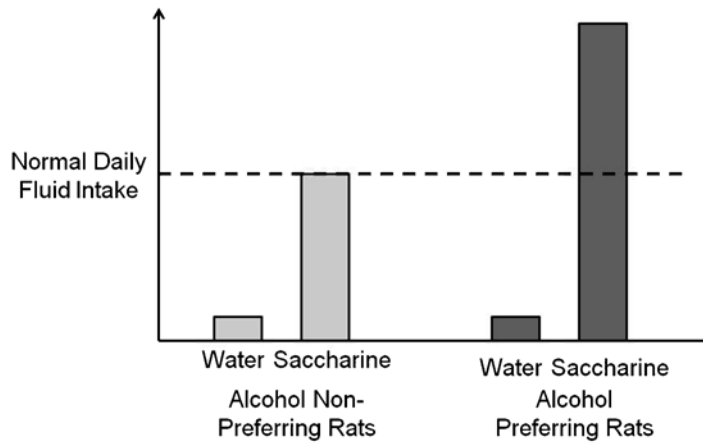
One of the interesting characteristics of intake of sweetened solutions by alcohol-preferring rats is their tendency to consume these solutions far beyond the limit of normal daily fluid intake. This tendency was initially reported in randomly bred rats (Kampov-Polevoy et al. 1990), when it was noted that, although all studied rats had a high preference for 0.1% saccharin solution, some of them (40%) consumed saccharin solution on average 32% over the limit of their normal daily fluid intake, a condition we described as saccharin-induced polydipsia. Subsequently, these polydipsic rats consumed almost 10 times as much alcohol during the first week of an alcohol/water choice experiment as rats that consumed saccharin solution within the limits of their normal daily fluid intake.


Fig. 189.2 Association between consumption of sweet-tasting substances and alcohol intake in rats. The figure illustrates the results of the study of consumption of sweet 0.1% saccharine solution in a free choice with water by rats genetically selected for excessive voluntary alcohol consumption and rats genetically selected to reject alcohol. The diagram shows that both strains of rats have similar high preference for saccharine solution that exceeds 90%. However, alcohol-nonpreferring rats, that are known to be sweet dislikers, consume sweet solution within the limits of normal daily fluid intake, when alcohol preferring rats who are known to be sweet likers, may double and in some cases quadruple their DFI when sweet solution is available. These findings are consistent with the results of clinical studies showing that sweet-liking individuals have an elevated risk to both alcohol-use disorders and bulimia nervosa that manifests itself by loss of control over food intake. Furthermore, comorbidity between substance-use disorders and bulimia is reported to be as high as 50%

Saccharine-induced polydipsia is especially apparent in rats genetically selected for alcohol preference. For example, high alcohol drinking rats exhibited a 370% increase in daily fluid intake when 0.1% saccharin solution was available along with water, whereas low-alcohol-drinking animals consumed saccharin within their normal daily fluid intake (Overstreet et al. 1997) (Fig. 189.2). Saccharin-induced polydipsia was shown to be a reliable predictor of subsequent alcohol intake, with a correlation coefficient of up to 0.9 between these two variables in P rats (Kampov-Polevoy et al. 1995), which makes this trait one of the best predictors of alcohol intake in rodents.

The dramatic increase in daily fluid intake in the presence of saccharin exhibited by alcohol-preferring rats may be an animal analogue of the clinical phenomenon known as *loss of control*. In the clinical situation, loss of control refers to the behavior in which a rewarding substance is taken in larger amounts or over longer periods of time than is intended. Interestingly, the link between loss of control over the consumption of sweets and the excessive alcohol intake was noted in humans as well. For example, overall comorbidity between eating disorders (e.g., bulimia nervosa that manifests itself by loss of control over food intake in general and sweet foods in particular) and alcohol abuse/dependence was reported to be as high as 50% (Dansky et al. 2000).

189.6.1.3 Preference for the Strong Sweet Taste and Alcohol Intake

In 1992, Sinclair et al. reported that rats with a genetically determined predisposition to high alcohol consumption preferred more concentrated sweet solutions compared to alcohol-avoiding rats. In this study, alcohol-preferring rats, as well as alcohol-nonpreferring rats, were tested by being given a free choice between tap water and an ascending series of saccharin concentrations, starting at 2 mg/L and doubling the concentration every day until a final level of 4096 mg/L was reached.

This experiment showed that, when rats were exposed to up to the 64 mg/L saccharin solution, their preference for it was generally the same in all animal groups. However, when exposed to more concentrated saccharin solutions, alcohol-nonpreferring rats generally had a lower preference ratio, compared to alcohol-preferring rats. The relevance of these findings to human alcoholism was later tested by evaluating the sweet preferences of alcoholics and nonalcoholic control subjects, as described in the following section.

189.6.2 Human Studies

189.6.2.1 Association Between the Sweet-liking Phenotype and Alcohol Intake

There is growing evidence linking the sweet-liking phenotype (preference for stronger sweet taste) and genetic risk for alcoholism. Our own study of healthy college students (Kampov-Polevoy et al. 2003a) indicates that sweet liking is more prevalent in children of alcoholic parents who are known to have four to nine times greater risk of becoming an alcoholic than children of nonalcoholic parents. Similar findings have been reported in the samples of alcoholics, addicts, and control (non-addicted) subjects (Kampov-Polevoy et al. 2003b). Thus, these and similar studies support the hypothesis that the sweet-liking phenotype is associated with the genetic risk of alcoholism.

However, unlike animal studies, in humans, the sweet-liking phenotype by itself seems to be insufficient to predict a diagnosis of alcohol dependence in clinical samples. As can be seen in the
Fig. 189.3 Preference for five sucrose concentrations in male alcoholics with (FH +) and without (FH-) family history of alcoholism. This diagram presents a distribution of preferred sugar solutions in the sample of male patients with alcohol dependence ($n = 48$). The diagram shows approximately equal representation of sweet likers (patients preferring highest offered [0.83 M] sugar solution) and sweet dislikers (patients preferring lower sucrose solutions) in the sample. Sweet liking seems to be associated with the genetic risk of alcoholism and, therefore, is more prevalent among the children of alcoholic parents ($n = 20$) than among children of nonalcoholics ($n = 28$). Therefore, the sweet-liking phenotype may be considered as a potential marker for the familial form of alcoholism

Fig. 189.3, in a sample of alcoholic patients there is a similar representation of sweet-liking and sweet-disliking individuals, which indicates that sweet-liking status is linked not to diagnosis of alcoholism but to genetic risk for this disease evaluated on the basis of family history.

So now, the question is whether the sweet-liking phenotype has any practical value for prediction of the actual risk for having alcohol-use disorders in any given individual. The studies conducted during the last decade show that such prediction can be made if sweet liking is combined with another factor – personality trait called novelty seeking. Novelty seeking has been consistently associated with deviance proneness, disregard of social norms as well as with early onset of alcohol drinking and excessive alcohol drinking (Finn et al. 2000). In their recent report, Grucza et al. (2006) demonstrated that novelty seeking modulates the level of the alcoholism risk in high-risk families with high novelty seeking magnifying this risk and low novelty seeking acting as a protective factor. On the other hand, in the low-risk families, there was no effect of novelty seeking on the prevalence of alcohol-use disorders. These findings are consistent with our own data indicating that, in clinical populations, the estimated odds of being an alcoholic, on average, increase by 11% as NS score increases by 1 point in sweet-liking but not in sweet-disliking subjects (Kampov-Polevoy et al. 2004) (Fig. 189.4). Combination of preferred sucrose concentration and novelty-seeking score was shown to predict alcoholic vs. nonalcoholic group status at 65% sensitivity and 94% specificity, with correct classification in 85% of subjects (Kampov-Polevoy et al. 1998). Our most recent study (unpublished data) of 158 healthy college students demonstrated that individuals with a sweet-liking phenotype and high novelty seeking had a 27-fold increase in likelihood for having alcohol-related problems compared to sweet-disliking individuals with low novelty seeking.

In summary, there is growing evidence showing the hedonic response to sweet taste and the avidity to consume sweet-tasting foods is closely associated with the level of alcohol consumption in both animals and humans. This phenomenon, which, to a large extent, is based on genetic mechanisms,
Fig. 189.4 Interaction between sweet-liking/sweet-disliking phenotypes and novelty seeking in prediction of alcoholic status of an individual. Both the sweet-liking and high novelty-seeking phenotypes are frequent findings in patients with alcohol-use disorders. However, neither of these traits separately can accurately predict an individual's risk for alcoholism. Sweet liking is associated with elevated sensitivity to the rewarding effect of alcohol and family history of alcoholism, but sweet liking alone has not been linked to excessive drinking. On the other hand, novelty seeking was shown to be closely associated with early onset of drinking, frequency and severity of drinking episodes, and disregard of societal norms. The diagram illustrates interaction of two independent factors, novelty seeking and sweet-liking phenotype, in the prediction of the alcoholism risk. One can see a dramatic increase of the risk of being an alcoholic in sweet likers with high novelty-seeking scores. At the same time in sweet-disliking individuals who are less sensitive to the rewarding effect of alcohol, excessive alcohol drinking associated with high novelty seeking does not lead to the development of alcohol-use disorders

was first described in laboratory animals where consumption of sweet saccharin solution can be considered as the most accurate predictor of the voluntary alcohol consumption of any given animal. In humans, the relation between response to sweet taste and alcohol intake is more complex. While genetic risk of alcoholism estimated on the basis of family history of alcoholism was shown to be associated with hedonic response to sweet taste, sweet response by itself is not sufficient to predict the risk of alcohol-related problems. Such prediction can only be made using a combination of hedonic response to sweet taste that reflects activity of the brain reward system and novelty seeking – a personality trait that is consistently associated with deviance proneness and excessive drinking.

189.7 Application to Other Areas of Health and Disease

As discussed above, the pleasure associated with consumption of sweet-tasting foods is one of our fundamental pleasures. Stimulation of the sweet-taste receptors in the oral cavity leads to the release of β-endorphins in the brain that have an effect similar to those of opiate agonists, such as morphine, that cause analgesia as well as feelings of well-being, sedation, and "bliss." Individuals with hypofunction of the brain opiate system have a diminished ability to experience pleasure, including pleasure associated with eating sweets. That leads to the preference for stronger sweet taste (i.e., sweet liking), which may be considered to be a marker of the activity of the brain opiate system.

The link between hypofunction of the brain opiate system, diminished ability to experience pleasure, and perception of sweet taste may explain the positive association between distortions of the sweet taste and negative mood states such as depression and anxiety that has been noted in both clinical populations and healthy individuals. Considering that a mentioned dysfunction of the brain opiate system may at least partially be determined by genetic mechanisms (for review see Gianoulakis 2004), testing hedonic response to the sweet taste may be an important instrument for evaluation of genetic predisposition to these disorders although further investigations are needed.

Furthermore, individuals with the hypofunction of the brain opiate system and reward-deficiency syndrome are likely to seek substances and/or behaviors that will overcome this hypohedonic state by activating the brain reward system. The most natural choice in this situation is the one we all learned in infancy – when in distress, we need to eat something sweet. At first it was sweet mother's milk or sugar water that calmed the baby down. Later in life, a candy served the same purpose. Eating sweets leads to the instant release of β-endorphins in the brain that has an effect of the internal tranquilizer. As adults, women, who are more sensitive to the mood-altering effect of sweets (Kampov-Polevoy et al. 2006), are more likely to eat sweets to cope with negative emotions and stress, which may explain a higher prevalence of bulimia nervosa noted in women compared to men (Antczak and Brininger 2008). It should be also mentioned that women diagnosed with bulimia nervosa are likely to be sweet likers (Franko et al. 1994), which may indicate that sweet-liking status and the associated dysfunction of the brain opiate system may predispose women to this disorder.

On the other hand, men, who are less sensitive to the positive mood-altering effect of sweets, may choose alcohol to cope with negative emotional states. This behavior is more likely to be observed in sweet-liking men who are more sensitive to the rewarding effect of alcohol. Furthermore, combination of sweet liking, indicative of sensitivity to the positive emotional effect of alcohol, with high novelty seeking that facilitates drinking behavior and disregard of societal norms, produces high risk for developing alcohol-related problems and alcohol-use disorders.

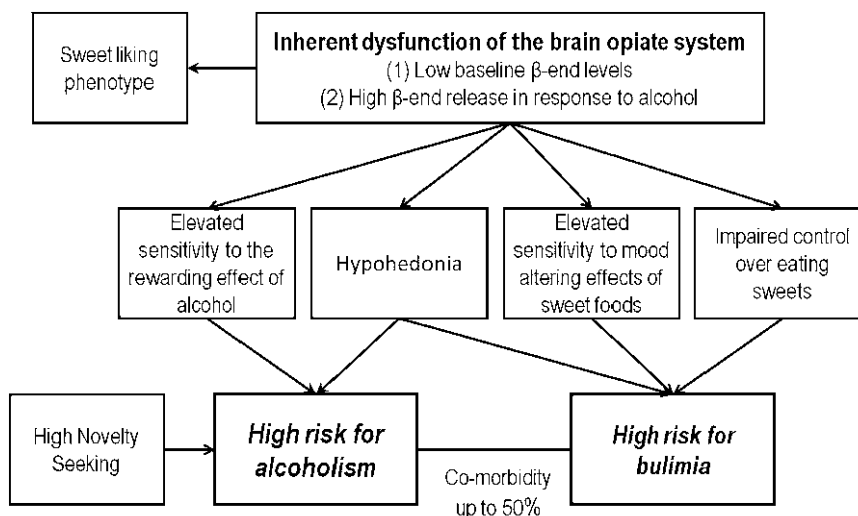
A conceptual model that illustrates a link between hedonic response to sweet taste, affective disorders, alcohol-use disorders, and bulimia are presented in Fig. 189.5.


Fig. 189.5 The following diagram may help to conceptualize material presented in this chapter. The brain opioidergic pathways play an important role in mediation of hedonic responses to sweet taste. Inhibition of these pathways caused by either genetic factors (e.g., in children of alcoholics) or by opioid receptor blockers (e.g., naloxone) shifts the preference toward stronger sweet taste. Therefore, preference for stronger sweet taste (sweet liking) may be an indicator of the dysfunction of the brain opioidergic pathways. These pathways play an important role in functioning of the brain reward system and their inhibition may lead to diminished ability to experience pleasures and elevated sensitivity to rewarding effects of sweet-tasting foods and alcohol. As a result, sweet-liking individuals, both animals and humans, are prone to use and abuse sweet foods and alcohol to self-medicate their negative emotional state and to cope with emotional stress. Sweet-liking women seem to be more sensitive to mood-altering effects of sweet foods and use these foods for coping with negative affect. This elevated sensitivity in combination with impaired control over eating sweets may explain higher prevalence of bulimia nervosa in women compared to men. Sweet-liking men, who are less sensitive to the mood-altering effect of sweet-tasting foods, are more likely to use alcohol for self-medication of negative affect. High novelty seeking that facilitates frequent episodes of excessive drinking significantly increases the risk of alcohol-use disorders in sweet-liking men. The high comorbidity between alcohol-use disorders and bulimia nervosa also supports the hypothesis that these disorders may have similar mechanisms

Summary

- A pleasurable response to sweet taste is an innate reaction. The level of positive emotional response to sweet taste, as well as consumption of sweets, is influenced to a large degree by genetic factors.
- There are two major patterns of the hedonic response to sweet taste – sweet disliking and sweet liking.
- Oral sucrose administration produces positive emotional responses, alleviates negative mood states, and produces marked analgesia in both animals and humans, with women being more sensitive to these effects than men. Such effects are more likely to be associated with sweet taste than with chemical composition or caloric value of ingested food.
- Chronic consumption of sweet-tasting substances may lead to a condition similar to physical dependence to opiates with symptoms including elevated sugar consumption, increased tolerance to morphine, and signs of opiate withdrawal when access to sweets is discontinued.
- Sweet preference and craving for sweet-tasting foods positively correlates with severity of the negative mood states (e.g., anxiety, depression) in both healthy individuals and patients with clinical

depression. Consumption of sweets leads to alleviation of the negative mood states and can be used for self-medication.

- Hedonic response to sweet taste and the avidity to consume sweet-tasting foods are closely associated with the level of alcohol consumption in both animals and humans. In animal experiments, consumption of sweet saccharin solution can be considered as the most accurate predictor of the voluntary alcohol consumption of any given animal.
- In humans, the association between response to the sweet taste and alcohol intake is more complex than in animals. While the genetic risk of alcoholism estimated on the basis of family history of alcoholism was shown to be linked with hedonic response to sweet taste, sweet response by itself is not sufficient to predict the risk of alcohol-related problems. Such prediction can be made only using a combination of hedonic response to sweet taste that reflects activity of the brain reward system and novelty seeking – a personality trait that is consistently associated with excessive drinking.

It is important to keep in mind that:

- Sweet likers are more sensitive to mood-altering and analgesic effects of sweets than sweet dislikers.
- Women are more sensitive to these effects than men.
- Children are more sensitive to these effects than adults.

Terminology List

Sweet disliking: Describes a pattern of sweet preference that is characterized by continuous increase, with eventual leveling off in liking of progressively more concentrated sweet solutions.

Sweet liking: Describes a pattern of sweet preference that is characterized by preference to progressively higher concentrations of sucrose solution up to the middle range of concentration, followed by a breakpoint after which preference declines with increased concentration.

GABA: γ-Aminobutyric acid is the main inhibitory neurotransmitter in the mammalian central nervous system.

Polydipsia: Excessive or abnormal fluid consumption.

Hypohedonia: Diminished ability to experience pleasure.

Chapter 190
Anxiety and Self Medication with Alcohol

Carmen C. Moran and Anthony J. Saliba

Abbreviations

GAD   Generalised anxiety disorder
PANAS   Positive affect negative affect schedule

190.1 Introduction

People drink alcohol for many reasons and in many contexts. The reasons for drinking can be categorised in several ways, including physiological and familial perspectives, and can be influenced by various factors, including social pressure and marketing of the product. Estimates of drinkers in the population are extremely variable, in one study alone ranging from 92% to 6%, but the variation included differences across countries, gender, and other sample characteristics (Gmel et al. 2006). The variability associated with estimates may be at least somewhat related to the difficulty in defining a 'drinker'; is someone who consumes a few glasses per year at social functions such as weddings to be included for instance? In many countries over half the population are drinkers, at least some of the time (Breslow and Graubard 2008; Gmel et al. 2006). In a US-wide study of over 20,000 drinkers, 26% of men and 20% of women admitted to drinking daily (Breslow and Graubard 2008).

Early research sought to establish a relationship between alcohol consumption and the reduction of negative emotions. However, not all drinking is problematic nor related to psychopathology. There is a vast literature on problem drinking, addiction, and the threats to well-being that overconsumption poses for the drinker and for others. Several journals are dedicated to this problem. This chapter does not review that literature; rather, this chapter examines the research on drinking motives, which focuses on nonclinical samples and reasons for drinking potentially independent of alcohol addiction or dependence. The presumption behind this approach is that 'drinking motives are the most proximate factor that precedes alcohol use' (Kuntsche et al. 2007, p. 76). Such information can, in turn, help inform health providers about circumstances when nonclinical aspects of alcohol consumption may or may not be problematic, such as moderate consumption to self-manage sub-clinical levels of anxiety.

190.2 Anxiety

One of the major factors that affects drinking motives is anxiety. While there is concern about giving too much emphasis to mood reduction as a prime reason for drinking (Hussong et al. 2008; Wilson et al. 1989), current research shows that anxiety level is an important influence when included with other variables in research on consumption. Table 190.1 presents the key features of anxiety and its relationship to drinking motives.

Anxiety has many lay and formal definitions. Even in the research literature it is not consistently defined or measured. In part this is due to the different ways people experience anxiety and in part due to the different words used to describe the feelings associated with anxiety. Various terms are used apparently interchangeably with anxiety, including some that are associated with specific disorders, such as 'phobia' and 'panic', with passing states, such as 'apprehensiveness' and 'fear', or with longer term emotional states such as 'angst'. In some cases anxiety is seen as part of a temperamental disposition, in others as a reaction to events. In the latter case, the term anxiety may be used in the same way as 'stress'.

Symptoms of anxiety vary across individuals, but there are some commonly reported ones: high levels of apprehension and worry, restlessness, muscle tension, and sometimes other physical symptoms such as accelerated heart rate and difficulty getting to sleep (Andrews et al. 2003; Menzies and Moran 1994). When symptoms become excessive, prolonged, and very distressing, they may result in a clinical diagnosis such as generalised anxiety disorder (GAD). When accompanied by specific beliefs, fears, or behavioural avoidance, then the conditions of agoraphobia or social phobia may be diagnosed. There are many other anxiety disorders with some overlap in symptomatology and diagnostic criteria (American Psychiatric Association 1994; Andrews and Slade 2002). The prevalence of anxiety and anxiety disorders is high, especially when compared with mood and behavioural disorders (e.g., see Fig. 190.1). Despite the variety of anxiety and related disorders, a common picture of anxiety is one of worry, tension, and internal physical discomfort, with an overarching negative emotional state.

The precise nature of anxiety is important in the study of motives for drinking. It is generally accepted that anxiety is accompanied by negative affect but unlike depressive states, anxiety is not associated with an absence of positive affect. Thus, an anxious person may have a range of emotions,

Table 190.1 Key features of anxiety

1. Anxiety is an unpleasant subjective *state*, which can also be related to a personality *trait*, that is, be part of an enduring characteristic of a person
2. Anxiety can be characterised by cognitive, emotional, physiological, and behavioural symptoms. People vary in the extent to which they experience anxiety in these domains
3. Anxiety is related to reactions associated with the fight-or-flight (and freeze) response. Current research examines anxiety reactions across numerous biopsychosocial systems
4. Anxiety is sometimes differentiated from fear, with fear having a more objective cause than anxiety. That is, fear is considered to be about a threat that most people would recognise. Anxiety is more subjective.
5. Estimates on the prevalence of anxiety is difficult, because people can use different terms to explain the feelings associated with anxiety, such as 'stressed', 'fearful', 'jittery'. Anxiety can also be passing. Surveys usually focus on the prevalence of anxiety disorders
6. Anxiety *disorders* are characterised by *very* high levels of anxiety, usually prolonged, and accompanied by varying physical and behavioural patterns depending on the disorder. For example, these patterns can include avoidance, compulsive repetitive behaviours, and hyperactivity, which in turn relate to disorders such as phobia, obsessive–compulsive disorder, and post-stress disorders
7. Survey estimates put the 12 month prevalence of anxiety *disorders* at 14% (Australian Bureau of Statistics 2008). This means that within a 1-year period, 14 people in 100 reported having anxiety disorder

This table lists the key features of anxiety, and the basic distinction between the feelings of being anxious and an anxiety disorder

Fig. 190.1 Prevalence of anxiety, affective, and substance use disorders in Australia. Prevalence data show the percentage of people affected by anxiety, affective (mood) and substance use disorders in a 12-month period. These data were collected as part of large nationwide survey on health (Data from Australian Bureau of Statistics 2008. With permission)
both positive and negative, and alcohol consumption may vary depending on the prevailing emotional state, that is, whether it is positive or negative. Consumption will also vary according to whether an individual has a tendency to use alcohol to cope. In recent times *individual differences in anxiety* and *using alcohol to cope* have been researched using one of two main frameworks: (a) the Self Medication Model and (b) the Drinking Motives Model. The Self-Medication Model focuses mainly on negative affective states, whereas the Drinking Motives Model considers the reasons for drinking in terms of both positive and negative effects.

190.3 Self-medication Model

The Self-medication model (also known as the Self-Medication Hypothesis) relates to the consumption of alcohol in order to deal with negative emotions that cannot be addressed in other ways or through other resources (Khantzian 2003). The Self-Medication Model overlaps somewhat with the Drinking Motives Model described below. However, research using the Self-Medication Model is more focused on clinical disorders and is less likely to look at positive emotions as a reason for drinking.

Individuals high in arousability have been shown to exhibit higher levels of anxiety (Hicks et al. 1992). Self medication with alcohol may be more frequent in those who are physiologically reactive under stress. Using 'normal' college students, Colder examined reasons for drinking, alcohol use, concurrent or recent stressors and physiological reactivity in an experimental context (Colder 2001). The coping motive (as a measure of self-medication) was related to stressful life events and to emotional reactivity measured physiologically through respiration bellows, electrocardiograph, and skin conductance. In this study, the coping motive was not related to trait[1] negative affect (measured with PANAS items such as 'scared' and 'distressed'). These results suggest that the construct *drinking to cope* is more likely to be associated with being physiologically sensitive to stress. It could be proposed that those whose physiological reactions are less elevated by stressful events are less likely to regard drinking as a way of coping with their reactions, and thus less likely to use alcohol for self-medication.

---

[1] According to trait theory in Psychology, traits are relatively stable over time and although differ amongst individuals, are not influenced by external factors nearly as much as are 'states'.

Much of the work on the Self-Medication Model looks at depression rather than anxiety. For example, Suh et al. (2008) report that the tendency to self medicate with alcohol was associated with lower depression scores. The low depression scores were not a consequence of drinking at the time of measurement. Because the low depression was also associated with high repression scores, Suh suggested that participants were denying their depression (i.e., they were repressing their depression). It is not clear from other aspects of the results whether this was in fact the case. Indeed, it is possible that the self-medication worked, at least in terms of the target symptoms.

Because self-medication research overlaps with that of the drinking motives research, further relevant research is discussed below under the motives model, and occasionally the terms coping motive and self-medication are used interchangeably.

190.4 The Drinking Motives Model

In the Drinking Motives Model three motives are frequently discussed: the enhancement motive, the social motive, and the coping motive (Cooper et al. 1992). Enhancement motives are measured by items such as 'because it [drinking alcohol] makes you feel good'. Social motives are measured by items such as 'it makes social gatherings more enjoyable'. Coping motives are measured by items such as 'to forget your worries'. A fourth motive, the conformity motive, is sometimes included.

The relationship between drinking motives and type of affect is summarised in Fig. 190.2. The underlying assumption is that people can drink to increase positive affect or drink to reduce negative affect. The focus of the motive may be internal or external. The internal–positive affect combination provides the *enhancement* motive, which is drinking to feel good about oneself. Increasing positive affect can also be external in focus, such as drinking to enjoy a party more, and this is the *social* motive. Decreasing negative affect can be internal in focus, and this is captured in the *coping* motive and the desire to be rid of anxiety and other negative feelings. Finally decreasing negative affect can be external in focus and this relates to the *conformity* motive and the desire to reduce isolation and rejection.

Benefit gained:

	Internally	Externally
Increase positive affect	*Enhancement motive*	*Social motive*
Decrease negative affect	*Coping motive*	*Conformity motive*

Direction of Change

Fig. 190.2 Representation of the Drinking Motives Model. The Drinking Motives Model as represented in this figure is adapted by the authors from Cooper's motives questionnaire (Cooper et al. ; Cooper 1994), which in turn has been examined in other research. This figure shows how the motives for drinking are differentially focussed on either increasing or decreasing negative affect (or feelings) and on gains that are internal or external

190.5 Drinking Motives and Consumption Patterns: Initial Results

In early research, each of the three main drinking motives was associated with alcohol consumption frequency, but in different ways. The coping motive was associated with more frequent drinking and potential abuse and dysfunction, whereas the enhancement motive was associated with frequent and heavy drinking but not alcohol abuse. The social motive was mainly associated with increased drinking in social situations (Cooper et al. 1992). In a later study on adolescent drinking and overuse, a conformity motive was added to the questionnaire to capture issues related to adolescent peer pressure to drink (Cooper 1994). The results resembled those of the 1992 study in that the coping motive was associated with high use and 'drinking problems', whereas the enhancement motive was associated with high frequency and quantity but not 'drinking problems'. The social and conformity motives were not strong predictors of quantity consumed or problem drinking, but subsequent research has examined social motives as they relate to social anxiety and extended information on this aspect of drinking. This research is discussed under the heading of social anxiety below.

190.6 Anxiety and the Coping Motive

The coping motive is especially relevant in the context of anxiety and can be defined as drinking to cope with emotional discomfort or distress, in other words to deal with anxiety. The coping motive is usually hypothesised to be the best predictor (within the motives model) of problem drinking. While taste is a strong motive for drinking alcohol, in data from our ongoing research we note that drinking to reduce anxiety is also very frequently reported as a reason for drinking, for different types of alcohol beverages (see Fig. 190.3). High anxiety on its own, however, is not a predictor of
Fig. 190.3 Motives for drinking by type of beverage. In terms of the Drinking Motives Model discussed in this chapter, 'feeling good' parallels enhancement motive, 'more outgoing' parallels the social motive, 'reducing anxiety' parallels the coping motive, and 'peer pressure' parallels the conformity motive. In this data, 'taste' is the most strongly cited reason for drinking alcohol, but other motives are also salient, particularly the desire to relax, which could be related to the other motives, for example to the coping, enhancement and social motives. The patterns of motives are relatively consistent across different beverage types, except for the premixed drinks (Data are authors' own)

increased alcohol consumption. Research has shown that motives and drinking behaviours interact with type of mood or emotional state.

In order to evaluate this claim, it is necessary to differentiate between coping motives for alleviating depressed mood and those for alleviating anxious mood, rather than just looking at drinking 'to feel better'. Participants high on anxiety coping motives are more likely to drink when anxious, whereas those high on depression coping motives are more likely to drink when depressed (Grant et al. 2009). This pattern suggests that high anxiety alone is not responsible for increased alcohol consumption, but does predict an increase in consumption for those already with a tendency to drink to cope with anxiety. Thus, 'anxiety-drinkers' do not necessarily drink when depressed, but do when anxious. Other people high in anxiety do not drink to cope, and thus do not necessarily increase their drinking when anxious. In a similar vein, Martens et al. reported that individuals high in negative affect (measured on the PANAS, which includes items such as afraid, nervous) and coping drinking motives were at greater risk for alcohol-related problems (Martens et al. 2008)

Personality interacts with both anxiety and having a high coping motive. Individuals drinking because of a coping motive are also higher on measures of neuroticism and anxiety sensitivity (perceiving anxiety symptoms as highly aversive; Goldstein and Flett 2009). High generalised anxiety is more likely to be associated with the coping motive when mediated by a high expectation that alcohol reduces anxiety. These variables, high anxiety, coping motive, and high expectancy have been shown to combine to predict high consumption. Goldsmith and colleagues sampled undergraduate students, and those who formed a hazardous drinking subgroup that were more likely to have positive expectations about alcohol's beneficial effects on tension and worry (Goldsmith et al. 2009). The coping motive is defined as drinking in order to reduce anxiety; research supports the pattern that those high on coping motive are also likely to be higher on anxiety, perceive anxiety symptoms as more aversive, and be more likely to expect alcohol to relieve their anxiety.

190.7 Social Anxiety and the Coping Motive

Social anxiety tends to be related more to the coping motive than the social motive for drinking. Social anxiety refers to anxiety that occurs in social situations, usually where a person feels they are being evaluated. It can be related to specific situations, such as parties or public speaking, or it may be more generalised. It could be expected that the social motive would be especially relevant to this group. The general rubric of social anxiety is different to the personality trait of introversion (the two are sometimes considered one and the same); however, individuals with social anxiety are often higher in introversion (Janowsky et al. 2000). The current authors have several unpublished datasets that suggest a link between introversion and alcohol consumption, presumably driven by a coping motive – allowing them to overcome the anxiety associated with tasks they find difficult under normal circumstances yet are expected to do as part of modern-day life.

Drinking is also mediated by *self-image*, a construct which includes assessing one's self-worth according to others' approval (Moeller and Crocker 2009). Being highly concerned with self-image, however, also generates high levels of anxiety. Self-image factors may indirectly determine drinking levels when those who score high on self-image goals see high alcohol use as an *expected* behaviour within their peer group and their high anxiety about self image then makes them more likely to drink to reduce that anxiety. Self-image goals have been shown to be associated with both coping motives and with higher heavy episodic drinking in University undergraduates (Moeller and Crocker 2009). Moeller and Crocker did not measure social motives, as they were particularly interested in drinking to cope with anxiety.

The impact of others' opinions on one's behaviour does not always indicate problems of self-image or anxiety, as other people sometimes provide useful information about social norms (the descriptive social norm, as distinct from the injunctive social norm). Lee and colleagues found that when combined with a high social motive for drinking, friends' approval (the injunctive norm) could lead to risky drinking in social situations (Lee et al. 2007). They did not measure anxiety and its relationship to need for approval.

Social anxiety is an inconsistent predictor of drinking in the absence of other mediating variables and has been related to both increased and decreased consumption (Ham and Hope 2005; Ham et al. 2005). Lewis et al. (2008) offer a complex mediation model that suggests this may be the case because social anxiety is not directly related to alcohol problems, except when socially anxious subjects are also high on the coping or conformity motives. High socially anxious subjects have been shown to have both higher consumption in social situations and greater expectancies that the alcohol will reduce their social anxiety (Tran et al. 2004). On the other hand, socially anxious subjects did not differ from others when drinking in positive affect situations (Tran et al. 2004). Social anxiety, therefore, relates more strongly to the coping motive, that is, reducing anxiety, than to the social motive which is more about increasing enjoyment.

Nevertheless, social motives have been reported as more relevant predictors of alcohol misuse than coping motives in some social contexts, for example in a sample of younger adolescents aged 13–16 (Bradiza et al. 1999). Misuse in this context was assessed by a mix of frequency and amount consumed, which is suggestive of frequent binge drinking. Frequent binge drinking, although intermittent and thus 'passing', can be associated with other behaviours that have more enduring negative consequences (e.g., as a result of inappropriate sexual activity and drink-driving).

Some researchers combine motives, for example, the desire to feel good in social situations is interpreted as a coping motive as well as a social motive. Some questionnaires may specifically address this, such as *The Alcohol Expectancies for Social Evaluative Situations Scale* (Bruch 1992), which measures coping motives in terms of social motives. Socially anxious people have an attentional bias to social threat that may prompt increased consumption to cope with that threat. That is, self-medication with alcohol may be also prompted by perceptual factors in social contexts (Carrigan et al. 2004). Generalising this to the treatment of problem drinking, therapists need to consider not just social anxiety levels but perceptual factors operating in social contexts.

190.8 In Vivo Research

Most of the work on drinking motives is done in the context of the three or four motives proposed by Cooper and relies on survey methodologies. As an alternative to the survey method, Swendsen and colleagues asked participants to respond to questions generated on a handheld computer three times a day across 30 days (Swendsen et al. 2000). The questions assessed current mood: active, peppy, happy, relaxed, quiet, bored, sad, or nervous. The participants also entered information on their drinking either as they drank or just prior to drinking. Information from the Beck Depression Inventory, State-Trait Anxiety Inventory and demographic questions were also collected. Although the study was framed in terms of the Self-Medication Model, the results resemble those framed in the coping model framework because they addressed interactions between positive and negative affective states and drinking. Nervousness was the only negative state to be associated with increased alcohol consumption. Being happy was associated with increased alcohol consumption as well, which supports the drinking model's assumption that drinking is not always motivated by a need to manage negative affect.

Swendsen's study suggests using alcohol to cope worked because it was associated with a subsequent reduction in anxiety. As already noted in other research, in this study the effect was more marked for those higher in anxiety than depression: People high on anxiety were more 'rewarded' by drinking than those high on depression. People seem to be well aware of this differential effect themselves and are more likely to drink to cope when anxious but not when depressed (Hussong et al. 2005). Whether such rewards are beneficial or harmful to the individual over time will depend on other factors including the presence of specific anxiety disorders and comorbidity factors (Robinson et al. 2009). The physiological and behavioural consequences of alcohol consumption are also important considerations.

190.9 Measurement of Alcohol Intake

Within research using the survey method, consumption is most often measured in terms of self-reported frequency, such as number of days per month, and quantity, such as number of drinks in a sitting. The amount of alcohol is not always clearly specified in terms of standard measures of alcohol or 'standard drinks'. Survey participants often estimate the amount in terms of number of drinks. Consumption may be reported as separate constructs of frequency, quantity, and problem-related drinking behaviours, but treated as a global measure such as 'increased consumption' or 'problem drinking'. Self-reported drinking may be influenced by socially desirable response patterns; these can be powerful enough in some individuals to cause an underestimation of consumption by as much as 33% (Davis et al. 2010). It is not possible to make a simple linear adjustment to responses since individual differences impact on response bias in a complex way.

Differences in patterns of drinking may be more informative than individual analyses on frequency, quantity and problems. For example, low frequency but high consumption is indicative of binge drinking, which may then be associated with problems as a result of drinking. O'Connor and Colder (2005) demonstrated five classifications of alcohol usage patterns in a sample of college students, which they then differentially related to the personality variables 'sensitivity to reward' and 'sensitivity to punishment'. Sensitivity to reward was a significant predictor of the usage patterns of binge drinking and problem drinking. Behavioural problems were more associated with binge drinking for female subjects. That is, if they engaged in binge drinking they were more likely to have subsequent problems, which include social consequences. Relating the personality variables to the Drinking Motives Model, O'Connor and Colder found that sensitivity to reward was significantly correlated with all drinking motives, whereas sensitivity to punishment was more strongly correlated to the coping motive and the conformity motive. Thus sensitivity to reward was associated with binge and problematic drinking, and furthermore, the relationship was mediated by the coping, social and enhancement motives for drinking but not the conformity motive. This study suggests that consumption is related more to a desire to feel better in oneself, rather than appear better to others.

190.10 Anxiety Disorders and Alcohol Consumption

The relationship between alcohol use and anxiety is bi-directional: people drink when anxious (self-medication, high coping motive) but drinking can lead to higher anxiety and in some cases generalised anxiety or panic disorder (Brady et al. 2007). With other anxiety disorders, especially social phobia and agoraphobia, the symptoms cause the person to self-medicate with alcohol which may or may not prove problematic over time (Brady et al. 2007; Kushner et al. 1990; Page and Andrews

1996). Alcohol increases anxiety in some disorders, but decreases it in others. In cases where there is one broad diagnosis such as agoraphobia, self-medication for anxiety levels may depend on other comorbidity factors such as panic attacks. As Brady and colleagues point out, unravelling the relationship is complicated by co-existing diagnoses and alcohol reactions (Brady et al. 2007). From a health perspective, the individual's anxiety as well as any problematic drinking would need to be addressed in terms of bi-directional effects. The literature shows a long history of self-medication with alcohol (thus supporting the relevance of the coping motive) although other terms were used in the very early literature. Conger (1956) for example, who highlighted the impact of the anxiolytic properties of alcohol, framed alcohol use in the context of learning theory rather than a motives model.

The moderate consumption of alcohol to control subclinical levels of anxiety *may* be an acceptable practice (though further research is required). What is clearer is that alcohol consumption to control *clinical* levels of anxiety that remain otherwise untreated is unwise.

190.11 Gender Differences

Gender is a potentially important individual difference in coping with alcohol because of the way alcohol is differentially used and metabolised by males and females. However, it is not possible to provide a consistent picture of gender differences in the context of drinking motives. Whereas there are some known patterns of gender differences in alcohol consumption, for example, males drink more, on average (Gmel et al. 2006), the results as they relate to anxiety, self-medication, and the coping motive are not clear. In specific anxiety disorders, such as agoraphobia or social phobia, there is a long-held clinical impression that males are more likely to self-medicate with alcohol (Moran and Andrews 1985). On the other hand, women report higher levels of arousability and are more likely to present with anxiety disorders (Saliba et al. 1998).

Whereas there is a demonstrated relationship between high alcohol consumption and anxiety reduction for males, alcohol may increase anxiety in women in social contexts (Wilson et al. 1989). However, when Wilson and colleagues tested a female sample they found alcohol elevated mood, but the effect was found in the placebo group as well suggesting a strong expectancy effect operating in their study. They did not report on alcohol use outside the laboratory setting other than to state that preexisting expectations about alcohol were not related to their results (Wilson et al. 1989). In our dataset ($N = 1,229$) we have found some small but statistically significant gender differences. This information is presented in Table 190.2, which shows that men score higher on items related to social and enhancement motives. Of special relevance to this chapter, we found no significant gender differences for drinking to cope with anxiety.

Men utilise health services much less frequently than women, are less likely to arrange regular check-ups and are also less likely to have symptoms checked for fear of wasting the health professional's time (Australian Institute for Health and Welfare 2001; O'Brien et al. 2005). Unsurprisingly therefore, the incidence of a range of diseases is higher in males than females (Saliba 2008). Although speculative, it may be that males are more in need of self-medication practices due to an unwillingness to seek help.

Using an adolescent sample, Hussong and colleagues were unable to find any consistent patterns of self-medication with alcohol and variables such as mood and conduct problems, and decided that the gender differences did not deserve further examination in their results (Hussong et al. 2008). This seems to be the pattern in several studies, where the differences are not sufficiently consistent, if they exist at all, to be able to draw broad conclusions. A whole of modelling approach, where multivariate analyses incorporates the influence of age, situation, personality, arousability and other variables, as well as gender, is required to determine the influence of gender on self-medication with alcohol.

Table 190.2 Motives for drinking alcohol by gender

| Motives[a] | Means (s.e.m.)[b] | | p |
	Female	Male	
Enhancement (makes me feel good)	3.19 (.048)	3.34 (.056)	.036
Social (makes me more outgoing)	2.49 (.046)	2.69 (.055)	.004
Coping (reduces my level of anxiety)	2.83 (.049)	2.80 (.056)	.681
Conformity (most of my friends drink it)	2.36 (.051)	2.47 (.059)	.129

[a]Motives are based on 'reasons for drinking' rather than the Cooper (1992) scale referred to in text

[b]Standard error of the mean

Gender differences are inconsistent in the literature on drinking motives. In our large Australian sample ($N = 1,229$) men scored significantly higher on a five-point scale for social and enhancement motives than women (albeit with small differences) but there were no significant gender differences for drinking to cope with anxiety or conforming to friends' behaviour (Data are the authors' own)

In the motives and self-medication literature, therefore, there is no *consistent* evidence that males are more likely to score higher on self-medication or on the coping motive, or show a differential relationship between motive and consumption when compared with females. This lack of consistent gender difference may relate to the age group of several samples, the nonclinical nature of the samples used, or changes to gender differences in drinking behaviours in recent years.

190.12 Other Factors Related to Anxiety, Motives and Self-medication

One of the major limitations in the motives and self-medication literature is the reliance on either student or clinical samples. While the importance of problem drinking in these groups is unequivocal, there is also a need for information on the everyday drinker who is older and not presenting at clinics, and the extent to which drinking to alleviate 'everyday' anxiety poses a health risk. In addition, there is little or no emphasis on the type of beverage consumed. For example, there is no information in this body of research on motives for drinking wine and whether the effects differ from those for drinking spirits. Our currently unpublished data suggest there are differences across beverages, particularly with consumers of mixed drinks (see Fig. 190.3). In light of this and recent research demonstrating a health benefit for wine, over and above alcohol (Lindberg and Ezra 2008), it would seem to be important to examine motives for drinking across individual beverages.

The recent media discussion on the putative health benefits of wine has added to the list of possible motives for drinking that are not covered in the 'Drinking Motives Model'. The literature is sparse on information about how many people believe wine is healthy. Figure 190.4 offers some data in this regard, showing that approximately 26% believe wine to be healthy, with the remainder undecided or disagreeing. Saliba and Moran (2010) found that those who perceive wine as healthy consume more frequently in terms of daily patterns, without consuming more volume of wine across time (see Fig. 190.5). There is also some initial evidence in this data to support the idea that those who drink wine to reduce anxiety are also more likely to believe it is healthy for them ($r = .237, p < .0001$).

Fig. 190.4 Percentage of people who consider wine to be healthy. Over 26% of a large Australian telephone survey (*N* = 1229) agree or strongly agree that wine is healthy A large proportion did not agree. The question did not ask whether wine was unhealthy, so disagreement does not indicate a belief that wine is specifically unhealthy (Data are authors' own)

Fig. 190.5 Frequency and Volume of Consumption by level of belief that wine is healthy. This figure shows that those who strongly agree that wine is healthy drink more frequently (*bottom line*) but tend to drink the same or less overall (*top line*). Thus a belief that wine is healthy does not appear to predispose to overuse (Data are authors' own)

This effect is more evident in older adults. In light of the widespread information about the putative health affordance of wine, it is timely to extend the research on drinking motives to include other information on beliefs and motives for drinking specific types of alcohol.

190.13 Applications to Other Areas of Health and Disease

In Western counties, large percentages of people drink alcohol at least some of the time and anxiety reduction can be a proximal motive for drinking. For the health provider, the challenge is to determine when this is problematic. The coping motive framework helps predict when well-being or health is threatened rather than enhanced, but a multivariate approach is needed, for example incorporating personality and situational variables. Research suggests that the coping motive is likely to be associated with higher consumption and potential problematic drinking, in high anxious individuals. The social motive is more likely to be associated with binge-drinking, which may be age related, but there are no clear predictions for longer term problems due to drinking per se, although there can be major negative consequences as a result of alcohol-induced risk behaviours. The enhancement motive has been shown to have inconsistent relationships with level of alcohol use. These patterns can vary depending on samples. In most cases, current work is based on adolescent or young college students.

The motives model has application to other areas of consumption and well-being. It provides a useful pathway to consider the broader set of variables that impinge on consumption and over-consumption of food, alcohol, and other drugs. The motives model is now being applied to marijuana use (Lee et al. 2009; Zvolensky et al. 2009). There is a clear need to reduce smoking, and psychological therapies examine patients' motives for smoking across a broad biopsychosocial perspective (Lujic et al. 2005). Using the motives framework can provide additional information on reasons for smoking, without being in competition with well-established theoretical perspectives (Piko et al. 2007). However, as the motives model suggests, behaviour is not driven only by a desire to reduce negative affect, whether anxiety or depression, but is also driven by a desire to increase positive affect. Personality traits and situational factors influence the import of particular motives. As a result, health and disease behaviours can be driven by motives as outlined in the motives model above, but a multivariate approach will be most fruitful in understating the drivers of healthy and unhealthy behaviours.

Summary Points

- Large proportions of people drink alcohol and some drink often. Not all alcohol consumption is problematic. A broad base of information on motives for drinking contributes to the differentiation between problem and nonproblem drinking.
- Anxiety is a commonly cited reason for drinking, with an underlying assumption that alcohol will help alleviate anxiety symptoms.
- The relationship between anxiety and alcohol consumption can be researched using either the Self-Medication Model or the Drinking Motives Model. The Self-Medication Model focuses mainly on negative affective states, whereas the Drinking Motives Model considers the reasons for drinking in terms of both positive and negative affect.
- The Self-Medication Model treats consumption of alcohol as a means to deal with negative emotions that cannot be addressed in other ways or through other resources (Khantzian 2003).

- In the Drinking Motives Model three to four motives are frequently discussed: the enhancement motive, the social motive, the coping motive and the conformity motive (Cooper et al. 1992; Cooper 1994). The enhancement motive is measured by items such as 'because it [drinking alcohol] makes you feel good'. The social motive is measured by items such as 'it makes social gatherings more enjoyable'. The coping motive is measured by items such as 'to forget your worries'. The conformity motive is measured by a desire to fit in with others expectations.
- The coping motive is the best predictor (within the motives model) of problem drinking. Research suggests that the coping motive is likely to be associated with higher consumption and potential problematic drinking, in high anxious individuals. High anxiety on its own, however, is not a predictor of increased alcohol consumption. Motives and drinking behaviours interact with type of mood or emotional state, as well as expectations about the effects of alcohol.
- Social anxiety refers to anxiety that occurs in social situations, usually where a person feels they are being evaluated. Social anxiety is associated with an increase in the coping motive rather than the social motive for drinking.
- The social motive is more likely to be situationally determined and associated with binge drinking, which may be age related. The enhancement motive has been shown to have inconsistent relationships with level of alcohol use. The conformity motive is not a strong predictor in general circumstances. These patterns can vary depending on samples.
- The relationship between alcohol use and anxiety is bi-directional: people drink when anxious (self-medication, high coping motive) but drinking can lead to higher anxiety and in some cases can be associated with the onset of an anxiety disorder.
- Clinical interventions for problem drinking cannot target anxiety alone because the state itself does not predict problem drinking; rather incorporating a motives model with knowledge of anxiety level provides a better predictor.
- The recent media discussion on the putative health benefits of wine has added to the list of possible motives for drinking that are not covered in the Drinking Motives Model. Other motives may also be relevant to drinking behaviours.
- The motives model has application to other areas of consumption and well-being. It provides a useful pathway to consider the broader set of variables that impinge on consumption and overconsumption of food, alcohol and drugs.

Definitions and Explanations of Key Terms

Anxiety: A state characterised by high levels of apprehension and worry, restlessness, muscle tension, and sometimes other physical symptoms such as accelerated heart rate and difficulty getting to sleep. When it becomes chronic or is associated with extreme distress or behavioural problems it becomes an anxiety disorder.

Social anxiety: Anxiety that occurs in social situations, usually where a person feels they are being evaluated.

Positive affect: A pleasant emotional state or feeling, characterised by positive labels such as happiness, calm, or a sense of well-being.

Negative affect: An unpleasant emotional state or feeling, characterised by negative labels such as anxiety, depression, or distress.

Self-medication: Ingestion of substances based on experience rather than formal professional advice, in order to achieve a beneficial effect, usually a change in sense of well-being.

The Drinking Motives Model: Model to explain drinking based on special goals related to management of positive and negative affect.

Quality of Life

Chapter 191
Developmental Aspects of Health Related Quality of Life (HRQL) in Food Related Chronic Disease: The Example of Food Allergy

Audrey DunnGalvin and Jonathan O'B. Hourihane

Abbreviations

HRQL	Health Related Quality of Life
FAQLQ	Food Allergy Quality of Life Questionnaire
PF	Parent Form
FAIM	Food Allergy Independent Measure
OIT	Oral Immunotherapy

191.1 Introduction

In recent decades our understanding of human health has changed. In the 1970s, older biomedical definitions of health, based on 'an absence of disease', were justly criticized as reductionist and limited in scope and clinical researchers began defining health as a dynamic, multifactor, biopsychosocial phenomenon that influences physical, psychological and social functioning (Engle 1977). Recognition of the importance of these influences on health and disease is consistent with evolving conceptions of mind and body and represents a significant change in medicine and the life sciences. Recent developments include the idea that emotional processes such as stress moderate activity in nearly all systems of the body and can directly influence the pathophysiology of disease. Discovery of these and other relationships between behaviour and health has changed the way health and disease are understood. The biopsychosocial perspective has also changed how health and disease are measured. It is now recognised that it is essential to include outcome measures that reflect the patient perspective for evidence-based decision making in clinical practice. Outcomes research has been key in altering the culture of clinical practice and health care research by changing how we assess the end results of health-care services, including clinical and therapeutic interventions, evaluation and health policy. Further, the promotion of evidence-based practice has increased the demand for outcome data. Health related quality of life measures provide a powerful means of measuring outcomes, enabling service providers in the clinical field to audit 'outcome' information for particular populations, thereby altering and improving resources and programmes, and prioritizing needs.

Health Related Quality of Life (HRQL) is a multidimensional construct, which evaluates physical, psychological and social components that may be impacted by a disease or medical condition, from the patient perspective. There are two major types of HRQL instruments, generic and disease-specific. Generic HRQL instruments are not specific to any particular disease and are therefore useful for comparing HRQL across different conditions, whereas disease-specific questionnaires focus on issues pertinent to one disease. However, generic instruments are necessarily more 'general' and therefore less sensitive to the particular problems associated with a particular condition. Disease-specific HRQL questionnaires which provide an in-depth picture of the day to day concerns of patients are an increasingly important outcome measure particularly in the context of chronic diseases. They are also able to capture small changes in HRQL that may occur as a result of clinical or therapeutic treatment.

However, there are important questions that must be answered before HRQL measures can reach their full potential in research, practice and policy. These questions include: what are the correlates of HRQL (e.g. anxiety, compliance, risk perception, coping behaviours) and how may they impact on perception of health and health reporting? Which variables are causally related to HRQL status, and which variables are the effects of HRQL status?

Since HRQL depends on the subjective perception of a disease, what are the underlying neurobiological mechanisms, and are these unidirectional or bidirectional?

Such questions have relevance for the interpretation and usefulness of HRQL measures in clinical practice (e.g. treatment choices for certain patient groups and individual patients), health policy (e.g. the allocation of health-care funds), the development of psycho-educational interventions (the precise targeting of information) and research (the causal direction of factors related to HRQL). We know that physiological measures often correlate poorly with functional capacity and well-being (Guyatt 1985) and patients with the same clinical criteria often have dramatically different responses, which depend on the subjective perception of disease impact. Such perception may be impacted by gender, for example, resulting in different health-reporting rates between sexes (DunnGalvin et al. 2006, 2008).

Some researchers in the field have attempted to develop causal pathway models to explain the direction of factors related to health related quality of life. Wilson and Cleary (1995) proposed that there is an unidirectional relationship between several kinds of outcomes, for example, biological and physiologic phenomena give rise to symptoms (and treatment side effects), which in turn have effects on functioning domains (such as physical, social and role functioning). The constellation of these effects leads to general health perceptions and, ultimately, an individual's concept of his/her overall HRQL. All of the above are also influenced by innate characteristics and environmental factors. Ferrans et al. (2005) modified the Wilson and Cleary model to make it simpler and have added more complete explanations for the components of the model. Sousa and Kwok (2005) used structural equation modelling to examine the relationship between the components of the original model. They conclude that the model fits the data (derived from patients with HIV) reasonably well but suggested that links be added between symptoms and general health perceptions and symptoms and HRQOL. The correlations for these links, however, were modest to low.

The previous models briefly allude to the possibility that the flow of the model may not be strictly unidirectional but do not provide data on this important consideration. If the flow is bidirectional for some of the components, this has profound implications in terms of interpretation and application of HRQL results. Furthermore the models have been developed from adult patients, and developmental considerations have not been taken into account (DunnGalvin et al. 2009a–d).

The evolution of the biopsychosocial perspective on health and health related quality of life has also coincided with a growing recognition of the multidimensionality and complexity of causation, including how environmental, social, psychological and biological systems interact to influence

health and developmental outcomes. Thelen and Smith (1994:127) suggest that 'the boundaries between what is innate and what is acquired become so blurred as to be at the very least uninteresting compared to the powerful questions of developmental process'.

A developmental trajectory or pathway may be understood as a lifelong process of developmental integration that involves complex interactions between biological and environmental factors that influence the phenotypic expression of physiology, psychology and behaviour (Halfon and Hochstein 2002). They may also delineate critical or sensitive transition points in development when physiological or environmental variables associated with a particular disease may have a relatively greater impact and/or interact with already existing normative demands and changes in socialization (Halfon and Hochstein 2002). Because children are rapidly changing and developing in response to these biopsychosocial influences, the developmental process plays an important role in shaping and determining their health and health related quality of life.

Research on the perception of health related quality of life – and its impact in terms of behaviour – may be particularly relevant in the context of chronic disease in childhood, as children not only have to meet their age-related developmental tasks, but they also have to manage their disease, which leads to a heightened risk of maladaptation (DunnGalvin et al. 2009a–d). A chronic condition may affect and/or interact with already existing normative demands and changes in socialization (Schmidt. 2003). Thus, although most children follow normative developmental pathways and encounter predictable transition points, disease-specific pathways may be embedded within these trajectories and influence the phenotypic expression of physiology, psychology and behaviour (Halfon and Hochstein 2002). Adaptational processes of children and adolescents with chronic conditions are of utmost importance because of their long-term consequences. Children with any chronic condition have twice the risk of developing mental health disorders of healthy children, even without an accompanying physical disability (Schmidt 2003).

In this chapter we review literature on the impact of food allergy on HRQL of children, teens and their parents. Biological hypersensitivity to environmental stimuli is a central feature of food allergy entailing a need for constant vigilance about, and avoidance of, certain foods (Table 191.1).

We begin with a brief overview of prevalence, mechanisms and clinical symptoms of food allergy. We then examine literature on the impact of food allergy on the perceived health related quality of life of children, teens and parents. Next, we present research on developmental differences in perception of the impact of food allergy and the behaviours or coping strategies children evolve in order to deal with this impact. We then draw on selected neurobiological literature in allergic diseases, in addition to some of the key psychobiological theories in current work on threat perception in health, to argue for a broader understanding of HRQL. This review also aims to provide a scientific basis for

Table 191.1 Key facts of food allergies

- *A food allergy* is an adverse immune response to a food protein and the food protein triggering the allergic response is termed a food *allergen*.
- Food allergy is distinct from other adverse responses to food, such as food intolerance, pharmacologic reactions and toxin-mediated reactions.
- Six to eight percent of children under the age of three, and nearly 4% of adults, have food allergies and prevalence is rising.
- Food allergies cause roughly 30,000 emergency room visits and 100–200 deaths per year in the USA.
- The most common food allergies in adults are shellfish, peanuts, tree nuts, fish and eggs, and the most common food allergies in children are milk, eggs, peanuts and tree nuts.
- Treatment consists of avoidance diets, in which the allergic person avoids all forms of the food to which they are allergic. For people who are very sensitive, this may include touching or inhaling the problematic food.
- Those diagnosed with a food allergy may carry an autoinjector of epinephrine such as an EpiPen or Twinject.

the development of appropriate models linking symptoms, functioning, development, underlying physiological mechanisms and HRQOL.

191.2 Prevalence, Mechanisms and Clinical Manifestations of Food Allergy

Atopy may be defined as a genetically and environmentally determined predisposition to clinically expressed disorders, including allergic rhinitis, atopic dermatitis or eczema, food allergy and allergic asthma, regulated through immune phenomena in which many cells (i.e. mast cells, eosinophils and T-lymphoctytes) and associated cytokines, chemokines and neuropeptides play a role.

Food allergy is growing in prevalence, and increasing rates of diagnosis means that many more parents and children must learn to live and cope with food allergy. Food allergy affects approximately 6–8% of young children and 3–4% of young adults in the UK, USA and Europe (Sampson 2005).

Allergy, particularly to peanuts, is the most common cause of anaphylaxis outside hospital yet there are other common food causes such as shellfish, fish, milk, soy, wheat and eggs (Sampson 2005). These foods may not only cause fatal or near-fatal reactions, but also tend to induce persistent sensitivity in most patients, in contrast to other foods such as milk, eggs and soybeans, which are frequently associated with milder reactions and are usually outgrown.

The life-threatening nature of anaphylaxis makes prevention the cornerstone of therapy (Hourihane et al. 1998a). Avoidance of the responsible food allergen and emergency management in the form of injectable epinephrine (Epipen or Anapen), in case food allergen is accidentally ingested, is the only reliable therapy offered to those living with food allergy. Anticipatory guidance measures form the cornerstone of advice, including reading food ingredient labels, concern for cross-contamination, vigilance in a variety of social activities and immediate access to the Epipen. However, avoidance is complicated by the fact that peanuts, nuts and soy can be found in many foods (e.g. breads, muffins, pastries, biscuits, cereals, soups, ice creams, seasoning, sauces) and in different forms as an emulsifier or thickening agent.

Food allergy occurs when the body's immune system mounts an exaggerated response against the offending food, which acts as an allergen. It is a type of hypersensitivity reaction. It can be either:

- A type I, IgE-mediated reaction: this is the usual cause of food allergy. After initial sensitisation, the release of mediators such as histamine are triggered each time a person is exposed to the food. It is these mediators that cause symptoms.
- A delayed, type IV-mediated reaction: these reactions are mediated mainly by T-cells. They typically affect the gastrointestinal tract or skin, for example, exacerbation of eczema in children after milk ingestion.

The European Academy of Allergy and Clinical Immunology has proposed a revised nomenclature for allergic and related reactions (Johansson et al. 2004). According to this proposal, adverse reactions to food should be termed 'food hypersensitivity'. The term food allergy should be used when immunological mechanisms have been demonstrated, and includes both IgE- and non-IgE-mediated reactions. All other reactions, which have sometimes been referred to as 'food intolerance', should be termed non-allergic food hypersensitivity (Fig. 191.1).

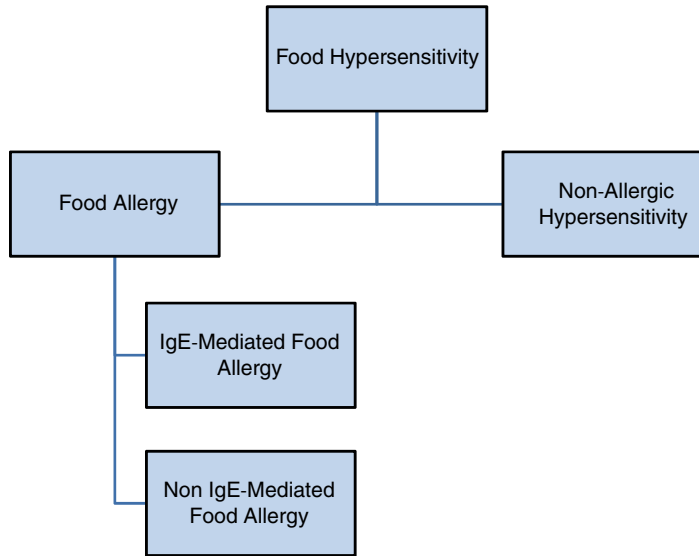
In an IgE-mediated reaction, symptoms involving the oropharynx and gastrointestinal tract may occur within minutes of ingesting a food allergen. Itching and swelling of the lips, tongue and soft palate as well as nausea, abdominal pain, vomiting and diarrhoea have all been demonstrated secondary to food allergy (Sicherer 2002). Anaphylaxis refers to a sudden, severe, potentially fatal, systemic allergic reaction that can involve skin, respiratory tract, gastrointestinal tract and cardiovascular system. The most dangerous symptoms include breathing difficulties and a drop in blood


Fig. 191.1 Nomenclature proposed by the European Academy of Allergology and Clinical Immunology. Flow chart with terms describing adverse reactions to foods (Adapted from Johansson et al. 2004)

pressure, or shock, which are potentially fatal. Symptoms of anaphylaxis may develop within seconds or a few hours after ingestion of a food allergen, with the vast majority of reactions developing in the first hour. Symptoms can include swelling (especially lips, tongue or throat), difficulty in breathing, abdominal cramps, vomiting, diarrhoea, circulatory collapse, coma and death. Typical allergy medications such as antihistamines work too slowly and cannot reverse the effects of chemical mediators. Adrenaline or epinephrine, therefore is the treatment of choice and must be administered by injection promptly (Hourihane 1998b; Sicherer 2002).

A growing number of families must live and cope with food allergy on a day-to-day basis, however, the socio-emotional impact of food allergy on children and families has been little researched until recently (DeBlok 2009; DunnGalvin et al. 2007, 2008). The majority of research in food allergy has been bio-medical in orientation, focusing on issues such as the molecular structure of allergens, or methods of diagnosis. In the last 5 years, there has been a growing interest in the development of questionnaires to measure the impact of food allergy on health related quality of life (DeBlok et al. 2007). These studies have provided an insight into the everyday burden of living with food allergy.

191.3 The Impact of Food Allergy on Health Related Quality of Life (HRQL)

Early studies used generic HRQL questionnaires, in particular the Child Health Questionnaire (Landgraf et al. 1999) to investigate the impact of food allergy on perceived health related quality of life (DunnGalvin et al. 2008, 2010).

191.3.1 Research Using Generic HRQL Measures

The first study on HRQL was carried out by Primeau and colleagues (2000), who studied a sample of 301 patients and evaluated the quality of life and family relations of children and adults with

peanut allergy, and compared the results to that of children and adults with rheumatological disease (CRD). It was shown that the parents with food allergic children had difficulties in many areas. Remarkably, the authors found that families with peanut allergic children experience significantly more disruption in their familial and social interactions/activities than families with a child with CRD and suggested that this may be due to the constant risk of sudden death in the peanut allergy group leading to greater parent restriction of activities. There was also evidence that the educational and emotional support needs of families with food allergy are not being met (Sicherer 2002). The authors found that the effect of manufacturers labelling their product with 'May contain traces of nut' gave rise to parents' frustration and limited food choices. In addition, parents have the responsibility of ensuring their children do not ingest peanuts or food containing traces of peanuts which may be difficult in the context of modern food preparative techniques.

Sicherer et al. (2001) measured parental perception of physical and psychological functioning of families living with food allergy. The authors randomly selected 400 members of the food and anaphylaxis network, with families of children age 5–18 years old and had 253 responses. Results indicated that peanut allergy impacted significantly on general health, parental distress and family activities. Those with two or more food allergies scored significantly lower, depending on how many foods they were avoiding. There was also evidence to suggest that the educational and emotional support needs of these families are not being met.

Bollinger et al. (2006), in a survey of 87 parents in the USA, found that over half had made significant changes to their social activities to accommodate their child's food allergy, avoiding birthday parties, soccer games and school field trips. Forty-one percent of the parents surveyed said their child's allergy had a significant impact on their own stress levels. The authors conclude that studies are needed about how stress and avoiding activities might affect the psychological and social development of children with food allergies.

Avery et al. (2003) assessed the effect of peanut allergy on the quality of life in children aged 7–12 years and contrasted this with experiences of children with insulin-dependant diabetes mellitus (IDDM). Their results indicated that children with IDDM have similar problems as children with peanut allergy. These include food choices, social restriction, issues relating to school, the carrying and use of a syringe and the chronic nature of the condition. Results showed that children with peanut allergy had poorer quality of life and are more anxious concerning accidental ingestion of peanut than children with diabetes are of having a hypoglycaemic reaction. Gender differences have also been noted (Marklund et al. 2004), with girls reporting lower HRQL.

191.3.2 HRQL Research Using Disease-Specific Measures

The first validated HRQL food allergy specific measure, the Food Allergy Quality of Life–Parental Burden (FAQL-PB) questionnaire (Cohen et al. 2004) measures the parental burden associated with having a child with food allergy. Scores in the food-allergic cohort were significantly lower for general health perception, parental distress and worry, and interruptions and limitations in usual family activities, than in healthy controls. Scales were also lower in subjects with multiple food allergies.

More recently, several measures have been developed to assess quality of life in children and teens, under the aegis of EuroPrevall, an EU project which aims to improve quality of life for parents, children, teenagers and adults with food allergy (DeBlok et al. 2007; DunnGalvin et al. 2008, 2010). EuroPrevall is a multidisciplinary integrated project (IP) involving 17 European member-states. Of the 63 partners, there are 15 clinical organisations and six small–medium sized enterprises (SMEs) as well as the leading allergy research organisations in Europe. Since the project began in 2005, new partners have also joined from New Zealand, Australia, Russia, India, Ghana and China. Three food

allergy specific questionnaires have been developed and published under the auspices of EuroPrevall (DunnGalvin 2008, 2010; Flokstra DeBlok et al. 2008, 2009a, b). These are Food Allergy Quality of Life Questionnaire – Parent Form (parent-administered for children aged 0–12 years), and the Food Allergy Quality of Life Questionnaire – Child/Teen/Adult Form (self-administered for children and teens aged 8–17 years and adults aged 18 +)

The FAQLQ-PF, -CTF and AF were developed and validated in five stages: (1) item generation using focus groups with children, teens, and parents' expert opinion and literature review; (2) item reduction, using clinical impact and factor analysis; (3) the evaluation of internal and test-retest reliability and construct validity; (4) cross-cultural and content validity examined by administering the questionnaire in a US sample (FAQLQ-PF, only); and (5) longitudinal validity examined by administering the questionnaire over three time points pre/post food challenge.

Key Points of the Food Allergy Quality of Life Questionnaire: Parent Form (FAQLQ-PF)

Developed using gold standard quantitative and qualitative methodology
Three age groups:

- 0–3 years – 14 items
- 4–6 years – 26 items 1 Form
- 7–12 years – 30 items

Three subscale scores (*emotional impact; food anxiety; social and dietary limitations*) calculated as the mean of each scale. The total score is calculated as the mean of the three subscales.
Supplementary sections:

- clinical child variables
- parental concern for their child's emotional and physical health
- stress levels experienced by parents and family
- impact on child and family activities
- expectation of outcome following accidental ingestion of allergen
- satisfaction with clinical therapy, intervention, information, etc.

Very high reliability and validity (cross-sectional, cross-cultural, longitudinal).
Validated in seven languages, to date.

The development and validation studies found a severe impact of food allergy on HRQL in relation to psychosocial aspects of children's and teen's everyday lives. For example, in the initial focus groups put in place to generate items for the FAQLQ-PF, parents suggested that the anxiety associated with the risk of a potential reaction has more profound effects on emotional and social aspects of a child's everyday life, than clinical reactivity induced by food intake. The importance of a subscale assessing this aspect of anxiety was subsequently confirmed using clinical impact and factor analytic methodologies (DunnGalvin et al. 2008–2010). Children were also found to be 'generally anxious', that is, the anxiety associated with food often 'generalised' to non-food situations (DunnGalvin & Hourihane, 2009,a,b,c). In addition, multivariate analysis showed an interaction between sex and age group for impact of general emotional impact on HRQL scale, in effect, parents of boys reported higher mean total scores up to the age of 6 years; parents of girls reported higher mean scores in the 6–12 years age group, particularly in the subscales 'general emotional impact' and 'food anxiety'; whereas boys had higher scores in the 'social and dietary limitations' subscale at all ages. Example of items associated with each subscale may be seen in Table 191.2.

Table 191.2 Examples of items and content in the three subscales of the *Food Allergy Quality of Life Questionnaire – Parent Form* (FAQLQ-PF) (Reprinted from DunnGalvin et al. 2008)

Emotional Impact: Items concern psychological phenomena such as feeling different from other children, frustration, control and generalised anxiety stemming from food allergy: *My child feels different from other children because of food allergy.*

Food Anxiety: Items concern anxiety relating to food: *My child is afraid to try new foods because of food allergy.*

Social and Dietary Limitations: Items concern everyday dietary and social restrictions: *My child's ability to take part in pre-school events involving food (class parties, treats, lunchtime) is limited by food allergy.*

Three factors (emotional impact, food anxiety, social and dietary limitations) emerged following exploratory and confirmatory factor analysis in the development and validation of the Food Allergy Quality of Life Questionnaire – Parent Form (FAQLQ-PF)

Fig. 191.2 Flowchart showing study design and FAQLQ-PF scores at three time points (baseline, 2 months, 6 months) for children aged 0–12 years undergoing diagnostic food challenges. Although significant differences were found between positive and negative groups on all subscales and total score at 6 months (F (2,59) = 6.221, $p < 0.003$), HRQL improved significantly post challenge time points (all $p < .05$) for *both* positive and negative groups. Higher scores indicate greater impact of food allergy on HRQL (Reprinted from Hourihane and DunnGalvin 2009)

We evaluated longitudinal validity by administering the FAQLQ-PF to parents of children 0–12 years before the child underwent a clinically indicated food challenge, and at 2 months and 6 months post food challenge (DunnGalvin et al. 2010; Hourihane et al. 2009). In total, 82 children underwent a challenge (42 positive, 40 negative). Although significant differences were found between positive and negative groups on all subscales and total score at 6 months (F (2,59) = 6.221, $p < 0.003$), interestingly we found that HRQL improved significantly post challenge time points (all $p < .05$) for *both* positive and negative groups (Fig. 191.2). A possible explanation for improvement in the 'positive' groups (long suspected but never documented) concerns the impact of uncertainty on perception of HRQL. This also suggests that a food challenge (open or double blind) may be valuable, not only as an essential diagnostic tool, but as a therapeutic one. In effect, by providing a sense of certainty, a food challenge may have a positive impact on HRQL, irrespective of outcome. Other published research on uncertainty in chronic disease strengthens this argument (e.g. Mullins et al. 2007).

Table 191.3 Odds ratios for likelihood of volunteering to take part in IT study calculated according to level of expectation of adverse outcomes following accidental ingestion by their child (FAIM): 1 = Group B, consent to immunotherapy (DunnGalvin et al. in press)

FAIM: Expectation of Adverse Outcomes (1)	Odds Ratio (95% CI)	*p*-Value
Adjusted Effects[a]		
What chance do you think your child has of accidentally ingesting the food to which they are allergic? (>3.5)	3.421 (1.811–6.267)	.03
What chance do you think your child has of having a severe reaction if food is accidentally ingested? (>3.5)	3.945 (1.965–5.105)	.001
What chance do you think your child has of dying from their food allergy following ingestion in the future? (>3.5)	4.263 (2.351–7.613)	.005
What chance do you think your child has of effectively treating them or receiving effective treatment from others (including Epipen administration) if they accidentally ingest a food to which they are allergic? (>3.5)	3.267 (1.905–5.344)	.01
FAIM total score (>3.5)	6.753 (3.451–9.728)	.002

[a]Adjusted for age, sex, experience of anaphylaxis, experienced symptoms, socio-economic variables

Parents who perceive that their child is at high risk of dying from food allergy are more likely to enrol their child in an investigational trial in which the child will be given peanut immunotherapy (OR 6.75; CI 3.45–9.73). This perceived level of threat may be an important factor motivating parents to consent to their children taking part in investigational therapies in a 'controlled' environment

A recent study (DunnGalvin et al. 2009d) examined specific psychological factors, related to HRQL, that may impact on parents' decisions to take part in clinical studies. Parents of food allergic children were offered investigational oral immunotherapy (OIT) in the regular outpatient clinic. Forty parents (Group A) declined, and 25 parents (Group B) agreed to take part. Both groups completed the Food Allergy Quality of Life – Parent Form (FAQLQ-PF).

Our results show that parents who perceive that their child is at high risk of dying from food allergy (Table 191.3) are more likely to enrol their child in an investigational trial in which the child will be given peanut immunotherapy (OR 6.75; CI 3.45–9.73). This is in spite of the fact that the experimental therapy is intensive and has attendant adverse risks including induction of anaphylaxis, compared to the routine clinical practice. The association was independent of the severity of symptoms, experience of anaphylaxis and perception of the impact of food allergy on HRQL. Socio-economic status was not a significant factor.

These findings may be explained, in part, by parental concern to avoid potentially life-threatening consequences of accidental ingestion in the often 'uncontrolled' environment of their child's everyday life. This perceived level of threat may be an important factor motivating parents to consent to their children taking part in investigational therapies in a 'controlled' environment, even though this involves a protocol in which reactions are more likely than if not in the trial. These findings concur with Zupanic et al. (1997), who found that determinants of parental authorisation for involvement of newborn infants in clinical trials included perceptions of risk and benefit to the child.

191.4 Living and Coping with the Impact of Food Allergy

The way in which children and adolescents perceive and cope with chronic health conditions is considered as an increasingly important predictor of health and psychological well-being in clinical and psychosocial research (Schmidt et al. 2003). In medical and health psychology, efforts have increasingly been made to assess coping of children and adolescents with chronic conditions. Coping has

not only been shown to be related to patient HRQL, but mediates health behaviour as well as health-care utilisation (Feeney 2000).

Although quantitative studies provide consistent, replicable results that can be compared across populations, there are also inherent complexities in studying the experience of living with a disease in the dynamic, interactional process within the family. Life transitions provide a naturalistic research opportunity to investigate adaptability to stress and the link to health outcomes and health related quality of life.

Thus, there is an increasing recognition of the need to qualitatively explore patients' experiences, of what it is like to live with a chronic condition in order to better understand the decisions people make about coping and managing their condition. The personal meaning of having a particular disease 'is strongly related to the patient's self-care and to the degree of psychological and social adaptation to the disease' (Kyngas and Hentinen 1995:734) and compliance with medical direction is thus determined in part by the person's individual perception of the condition and its management.

A recent study (DunnGalvin et al. 2008, 2009) represented a first attempt to provide an integrated developmental framework to explain the onset, development and maintenance of food allergy related cognitions, emotions and behaviour. Sixty-two children/teenagers aged 6–15 years took part in 15 age appropriate focus groups, 52% of whom were female. Parents were also interviewed. All children were physician diagnosed with IgE-mediated food allergy and had been issued with an anapen/epipen. Through qualitative enquiry, a framework for evaluating children with food allergy was developed. Developmentally appropriate techniques such as vignettes (where children could comment on characters in the third person) and activity books were designed to stimulate discussion, maintain interest and minimize threat to the child's self-esteem.

Analyses of the data encompassed precipitating events (stressful events in children's lives caused by food allergy related factors), psychological impact (cognitive appraisal and emotional effects) and behavioural consequences or coping strategies. Open coding (the first step in analysis) in qualitative grounded theory (Charmaz 2000) may be seen as a descriptive 'still' of all the meaning in the data. For example, children discussed growing up and living with food allergy, about feeling different, about low awareness in their social worlds, about their fears and uncertainties in relation to experiencing an allergic reaction, food safety and socialising in many different contexts (eating out, going to the cinema, being with friends, meeting new people). The transcript data was organised into multiple codes and then into categories. Axial coding (the next step in analysis) links codes with distinct

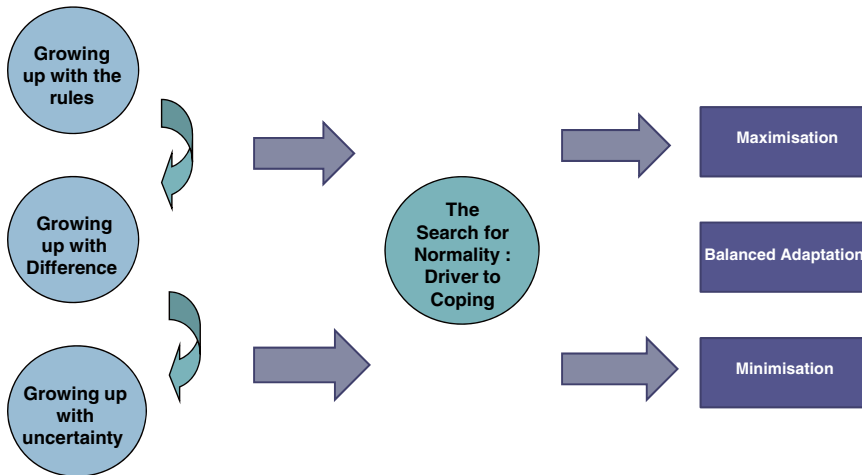
Fig. 191.3 Flowchart showing analytic method in grounded theory. Open coding in grounded theory attempts to fracture the data in order to extract as much information as possible. The transcript data was organised into multiple codes and then into categories. Axial coding links codes with distinct categories structure (experience) with process (what happens as a result) while, at the same time, attempting to retain as much meaningful information as possible. Selective coding results in a theoretical model (DunnGalvin and Hourihane 2009)


Fig. 191.4 The basic model of structure and process: experience and behaviour. The experience of living with food allergy, 'living with the rules', 'living with difference' and 'living with uncertainty' leads children to cope by means of minimisation, maximisation and balanced adaptation, in the search for normality (DunnGalvin and Hourihane 2009)

categories to form a substantive theory of action, while, at the same time, attempting to faithfully represent the dynamic interrelationships of the children's experience. The analytic method is illustrated in Fig. 191.3.

Our findings indicated that experience and coping in food allergy is more than simply a strategy, it is a cumulative history of interactive processes (age, gender and disease specific) that are embedded in a child's developmental organization.

We can conceptualise food allergy as a central 'lens' in children's lives through which they interpret experiences. When children and teens are confronted with a stressful event, such as a birthday party, a novel situation, an allergic reaction or making new friends, the way in which they appraise the event and its attendant emotional impact are viewed through this lens. The basic model is illustrated in Fig. 191.4.

How this lens is constructed and its psychological impact (uncertainty, anxiety, confusion, difference) on individual children is modified by age, gender, context, prior experience, attitudes of parents, attitudes of peers and levels of general awareness. In most children under the age of 8 years, there is a certainty of parental and adult knowledge and a consequent sense of control of events relating to food allergy. However, an important transition point occurs when children learn or feel that parents (and therefore children themselves) cannot conclusively prevent an allergic reaction, after which we see a change in cognitions, emotions and behaviour, and coping strategies become more differentiated.

191.5 Living with Uncertainty Is a Central Theme in the Experience of Food Allergy

To provide an example, *living with uncertainty* (DunnGalvin et al. 2008a, b; 2009a–d) is an important concept that affects children's sense of control, beliefs about risk, level of vigilance and confidence in safety. Young children have an illusory perception of control because of parent protection. However, we see the roots of uncertainty in even very young children who are aware of parent anxiety and speak about

the possibility of a reaction occurring at any time, 'because you never know what might happen'. However, always being aware and alert to the possibility of danger is a heavy burden for children in their everyday lives. Becky (age 10) explains 'because food is always around it is hard to forget about it' and Matt (age 11) says '…I can't just eat something like my friends … or be with people without thinking about what they are eating'. Being constantly vigilant also affects children's enjoyment of social events 'well … it means you can never relax at a party and just enjoy it' (Kevin, age 11).

Anxiety appears to be particularly strong in children aged 9–12 years. Even when carefully following the rules, children often cannot pinpoint why a reaction occurred. Older children and teens emphasise the uncertainty of living with food allergy and the consequent feeling of a loss of control: 'sometimes you can't find the cause [of a reaction] … it just happens, you know … not knowing makes you worried and unsure of yourself … what can you do' (Fran, age 15); 'people have died … and sometimes they don't even know why … even toothpaste has been blamed' (Patrick, age 14). Low general awareness also contributes to uncertainty. Adolescents have a full understanding and realisation of uncertainty in their everyday lives. For example, Grace (age 13) captured the feelings of many teens when she describes why she feels anxious: 'when I get up in the morning I can't be sure I won't have a reaction that day'.

A growing awareness of uncertainty impinges on children's beliefs and subsequent coping strategies. Although being vigilant allows children to feel some form of control over uncertainty, this is undermined because of low understanding and awareness in restaurants, shops, activity camps, schools, peers, etc., in the general population and difficulties in the interpretation of labels on foods. Although their roots may be discerned in children in the youngest age group, by adolescence, children's coping strategies become more defined, in some cases more rigid, and an expanding social world gives further impetus to the search for normality. *Normality* has multiple meanings depending on the particular developmental trajectory of the child in question. The search for normality becomes clearer when we turn to the coping strategies children use to manage food allergy. For some, normality may mean assurance that they are safe at all times and are accepted and understood by particular friends, for others it

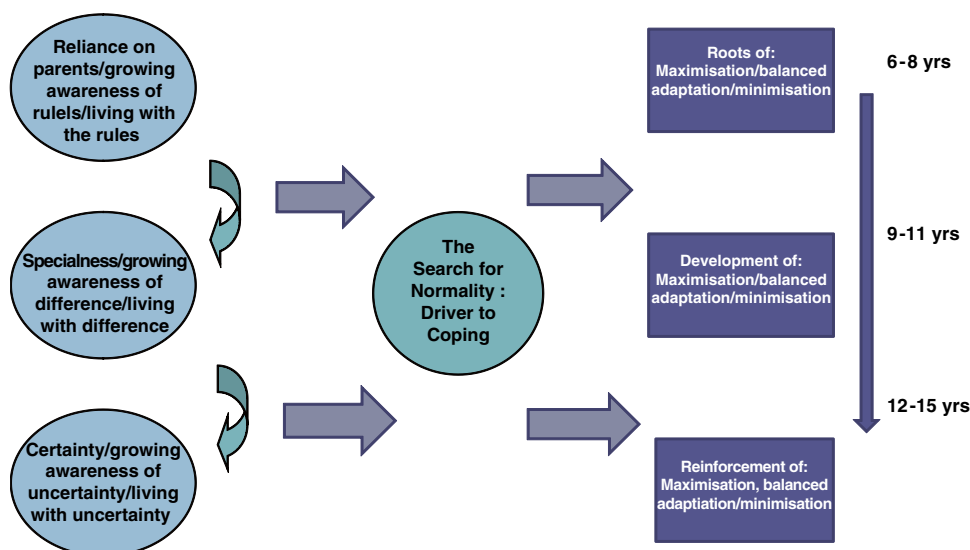

Fig. 191.5 The developmental pathway model. Following axial coding, developmental differences were examined based on the Fig. 191.4 above, in order to describe a conceptual theory of the studied phenomenon: growing up, living and coping with food allergy (DunnGalvin et al. 2009)

means being able to interact freely and being accepted as normal 'in the real world', and for some it means finding a balance between the two. The developmental model is shown in Fig. 191.5.

Coping strategies were found to lie on a maximisation/avoidance to minimisation/risk continuum. They may be emotion focused or problem focused, often they are both. Some are actions, interactions or cognitions. Their defining quality is that they are used in clusters by particular children. *Maximisation* involves placing food allergy at the centre of your life, *minimisation* involves rejecting food allergy as an important part of your life and *balanced adaptation* involves balancing safety with integration. Emotional, cognitive and behavioural strategies are associated with each of these axial categories.

Anxious children tended to use avoidant strategies to cope with living with food allergy. Many clinicians assume that these strategies are necessary and adaptive, if they are proportionate. However, we found that high levels of anxiety, vigilance and generalised avoidance of situations and people not directly related to food consumption are associated with maladaptive avoidant strategies. A surprising finding was that anxious children and teens are not necessarily those who experience the most or recent reactions. For example, many of the children who described themselves as anxious or worried about food allergy could not remember ever having had a serious reaction.

Minimising strategies are also maladaptive in that children who use them also engage in risky behaviour, such as deliberately eating an allergic food. Children are told by clinicians and parents that being allergic to a certain food means that they can never have 'even a taste' of that allergen, any food containing the allergen or any food that may have come into contact with the allergen. Because of the difficulty for clinicians and scientists in determining risk thresholds, children must live by this rule. There were, however, important developmental differences. For example, it was noticeable that younger children described deliberately eating an allergic food in their homes or when parents were present at a social occasion, out of curiosity to experience what peers can eat without difficulties. By 'eating just a little bit' and seeing how they react, children in the middle age group appear to be trying to determine their own risk thresholds: 'you'd have a small bit now and then and see what happens' (Johnny, age 11). It may also be a way for children to exert control over uncertain conditions. Older children, and particularly teens, appeared deliberately eating an allergic food as a means of coping in a social situation in order to cope with feelings of difference. This risk behaviour developmental process is illustrated in Fig. 191.6.

Parents and children share many of the same broad-based experiences, concerns and anxieties, and use many of the same coping strategies as emerged from focus groups with children and teens. Parents struggle with how to support children's independence while controlling their own anxiety and genuine fears of increased risk. Parents respond to conditions in individual ways in a search for normality by maximization, minimization and balanced adaptation, clusters of coping strategies that were also found in children.

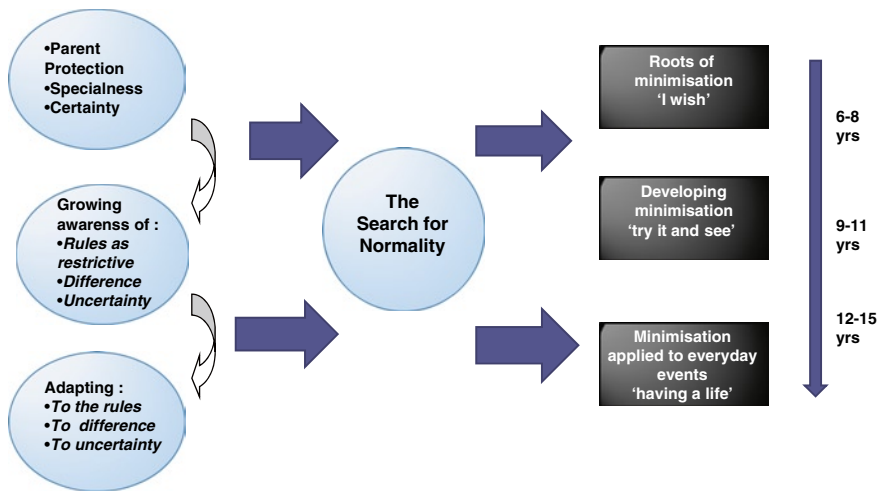
Our findings of high levels of anxiety in a food allergic sample of children and parents are supported by epidemiological research. In child/adolescent populations with allergic diseases in general, up to one third may meet criteria for co-morbid anxiety disorders (Bender Berz et al. 2005). In adult populations with asthma, the estimated rate of panic disorder ranges from 6.5% to 24% (Katon 2004). Studies have also documented associations between anxiety disorders and allergy (Kovalenko et al. 2001). Patients attending allergy clinics reported higher levels of depression compared to the general population. A birth cohort study in Finland (Timonen 2003) revealed that at epidemiological levels, skin prick test positive females exhibited up to a 1.8-fold greater risk of developing lifetime depression when compared with skin prick test negative subjects. In addition, the corresponding risk increased up to 2.7-fold among females, who had a positive skin prick test together with self-reported allergic symptoms. Maternal atopy alone almost doubled the risk of lifetime depression in female probands when compared with families in which no maternal atopy existed. In contrast, parental atopy did not predict any type of depression in male probands.


Fig. 191.6 The developmental pathway model applied to the evolution of risk behaviour. Because they were diagnosed when infants, young children feel that they are 'the same' as other children, and parents help them to feel normal and protected in their everyday lives. They therefore have an illusory perception of control and certainty. As children become more aware of the rules as restrictive, together with a growing awareness of difference and uncertainty, the search for normality becomes stronger and children evolve strategies in order to cope. Although their roots may be discerned in children in the youngest age group, by adolescence, children coping strategies become more defined, and in some cases more rigid, and an expanding social world gives further impetus to the search for normality (DunnGalvin and Hourihane 2009)

191.6 Underlying Mechanisms Related to Perception of HRQL: Physiological and Psychological Responsiveness

Research (animal and human) shows how the environment (including the prenatal environment) can change our anatomy, brain and central nervous system. Neuroendocrine sensitisation effects following exposure to maternal stress during the first year of life have been reported in 4.5-year-olds (e.g. Essex et al. 2002). A recent study undertaken in a sample of 10-year-old children from the Avon Longitudinal Study of Parents and Children (ALSPAC) has demonstrated for the first time a significant link between prenatal anxiety, particularly in late pregnancy, and individual differences in salivary cortisol (O'Connor et al. 2003). A relatively small study has also identified a link between maternal anxiety and salivary cortisol in children at 5 years of age. Children whose mothers exhibited higher levels of morning cortisol during pregnancy, and more fear of bearing a disabled child, showed higher levels of salivary cortisol (Gutteling et al. 2005). The same group showed similar associations in another sample of children at 4–6 years of age (Gutteling et al. 2004). Clearly, further studies are required to fully understand the relationship between PS/anxiety during pregnancy and HPA function in human children and adults.

Neuroendocrine changes have also been associated with social adaptation in pre-school children (Gunnar et al. 2003). In understanding childhood influences on health and health perception, this neuroendocrine window provides an opportunity to examine these person-environment responses. Assessing cortisol activity in response to starting pre-school, Gunnar and colleagues emphasise that it is neuroendocrine *adaptability* that is important rather than simply the level of response. Providing evidence for the context-specific HPA activation during childhood experiences, it appears that it is the repeated triggering of the stress response rather than neuroendocrine activation itself which may be problematic for shy children, as they perceive threat to a greater number of everyday events (Watamura et al. 2004).

For most children who become allergic or asthmatic, the polarization of their immune system into an atopic phenotype probably occurs during early childhood. The establishment of the Th1/Th2 balance during early childhood and the final tuning at the important middle childhood years (Sampson 2005) implies that children may be especially vulnerable to environmental and lifestyle stressors affecting this balance. This period coincides with the transition point discussed earlier, when children begin to experience uncertainty. Chronic diseases that are characterised by dysregulation of inflammation, such as food allergy, are particularly susceptible to modulation by stress and emotion.

Prenatal, perinatal and early life events (e.g. stress in mothers) appear to be crucial in programming the infant's immune system, independent of genetic susceptibility. Maternal genetics related to oxidative stress genes may influence the child's atopic risk beginning in utero. Sustained cortisol secretion can affect Th1/Th2 differentiation both in the foetus and in the newborn infant, and is able to increase susceptibility to allergic diseases (von Hertzen 2002). Wright and colleagues (2004a) found that higher caregiver stress in the first 6 months after birth was associated with increases in the children's allergen-specific proliferative response (a marker of the allergic immune response), higher total IgE levels and increased production of TNF-α and reduced IFN-γ in a birth cohort of children predisposed to allergic disease. This risk is thought to be mediated by the effects of stress on neuro-immunoregulation, which in turn modulates hypersensitivity responses. A dysfunctional neuroendo-crine-immune interface associated with abnormalities of the 'systemic anti-inflammatory feedback' and/or 'hyperactivity' of the local pro-inflammatory factors may play a role in the pathogenesis of atopic/allergic diseases and later co-morbid anxiety disorders.

Chronic stress may induce a state of hyporesponsiveness of the HPA axis, whereby cortisol secretion is attenuated leading to increased secretion of inflammatory cytokines typically counter-regulated by cortisol. While the ability to activate an increase in cortisol in response to some stimuli in early life may be adaptive, prolonged exposure to stress may change the cortisol response if examined at a later developmental stage (Wright et al. 2004b).

Sex differences have also been noted. Different patterns of cytokine responses between males and females have been suggested as contributing in part to gender-specific differences in the self-reporting rates and perception of HRQL in food allergy, discussed earlier. We already know that components of stress and the stress response differ between men and women. The tend-and-befriend response, mediated by oxytocin and endogenous opioids, may be more applicable to women than the fight-or-flight response, which was based largely on studies of men. Even within the flight-or-flight response pattern there are sex-based differences. The HPA axis interacts with the reproductive function, such as menstruation. Further, the *nature* of stressors may also influence sex differences in immune reactivity to stress (Kang et al. 1997) involving a complex interaction between biology and environment. For example, there are gender differences in the *types* of stressors to which an individual is likely to be exposed. The complexity of these sex- and gender-based interactions may explain the more adverse effects of food allergy on female over male general emotional well-being, discussed earlier.

As discussed, a number of studies have examined the impact that the activity of the stress system may have on immune activation and symptoms in humans. A state of stress-induced HPA hyporesponsiveness has also been demonstrated in research participants with chronic inflammatory disorders. Wamboldt et al. (2003) found an attenuated cortisol response among adolescents with positive skin test reactivity to an allergic disease compared with those with skin test positivity alone or nonatopic individuals. It appears that chronic stress may induce a state of hyporesponsiveness of the HPA axis, whereby cortisol secretion is attenuated leading to increased secretion of inflammatory cytokines typically counter-regulated by cortisol.

Some studies have considered whether immune activation and the *experience* of having an atopic disease, particularly during childhood, influence the responsiveness of the HPA axis. The extant literature indicates that both physiological and psychological stressors activate similar neural circuitry, acting as two different routes to a bidirectional communication network between the brain

and the immune system (Maier and Watkins 1998). During an immune response, the brain and the immune system communicate with each other in order to maintain homeostasis. Two major pathways, the HPA-axis and the SNS are involved in this bidirectional interaction (Elenkov et al. 2000). Consistent with this model, neural circuitry underlying stress and emotions can regulate inflammation (Black 2002) and peripheral inflammatory mediators can influence mood and cognitive function (Wichers and Maes 2003).

The advent of cognitive neuroscience and functional neuroimaging has brought unprecedented new opportunities to study the neurobiology of these processes. Rosencrantz and colleagues (2005) examined the neural circuitry underlying the interaction between emotion and asthma symptom exacerbation, using fMRI during antigen challenge to examine regional brain activation in adults with mild allergic asthma. They demonstrated an association between activity in the anterior cingulated cortex (ACC) and insula to asthma-relevant emotional stimuli (e.g. wheeze) compared with valence-neutral stimuli and markers of inflammation in participants exposed to an antigen. The activation accounted for > 40% of the variance in peripheral markers. These brain regions may be hyperresponsive to disease-specific emotional and afferent physiological signals, which may contribute to the dysregulation of peripheral processes, such as inflammation (McAfoose and Baune 2009). The authors suggest that reciprocal modulation may occur between peripheral factors regulating inflammation and central neural circuitry underlying emotion and stress reactivity.

This is an area of research which has the potential to provide answers to questions relating to the complex interaction between physiology and psychology in the developmental pathways of allergic diseases in males and females (DunnGalvin et al. 2006), and may have preventative and therapeutic implications in terms of both immune and anxiety disorders (DunnGalvin et al. 2009c).

191.7 Cognitive Emotional Sensitisation

The theory of *cognitive emotional sensitisation* (Brosschot 2002) may further elucidate explanatory mechanisms for findings in the biopsychosocial impact of food allergy. This theory is based on the notion of *cognitive bias*, one of the best-documented cognitive phenomena in experimental psychopathology.

The simplest form of plasticity in nervous systems is that repeated stimulation may lead to habituation (decreased response) or sensitization (increased response). Sensitization has been widely observed across the phylogenetic scale, and may be present at multiple levels in the organism: at the cellular, psychological and interpersonal level (see Brosschot 2002). Generally, sensitisation is caused by an increased efficiency in the synapse due to repeated use, in particular following irregular and extreme stimulation. It constitutes a feed-forward mechanism, helping the individual to react more efficiently in situations with increased probability of harm (Ursin and Eriksen 2001; Overmier 2002). Brosschot (2002) used the metaphor of an unfolding scanner or antenna, directing its dish towards the source of potentially threatening information and amplifying it. The level of background arousal is very important: high levels of arousal result in the stimulus repetition inducing sensitization, even though repetition of that same stimulus under conditions of low arousal would lead to habituation (see Overmier 2002).

Cognitive emotional sensitisation is therefore a higher form of sensitisation, involving cognitive bias. Much research has shown that anxious persons have a cognitive processing priority for information that is related to their fears. The emotional Stroop results show that this multilevel sensitization could develop for many different types of concern-related information. For example, in relation to pain, Crombez (1998) emphasises two important determinants that pertain to our findings: *novel* pain produces a large disruption in a primary task, as does the temporal *unpredictability* of an aversive

noxious stimulus. In an attempt to find an explanation for the lack of consistency across some attentional bias studies, Crombez also emphasizes the importance of anxiety in the manifestation of cognitive bias, and suggests analysing more precisely what *type* of information is *really* threatening for what *type* of patient, whether, as discussed earlier, this is a threat to safety or to self-concept.

Emotional arousal tends to bring to awareness of one's predominant cognitive bias and potentially triggers one's most salient behavioural programmes. Anxiety in itself, unrelated to relevant health threat, may activate neural networks in children with food allergy because these networks are easily activated by *any* stimulus that induces limbic activity (Ursin 2001). Thus, children need not have actually, or recently, experienced an allergic reaction in order to feel anxious. The type of threat, in addition to emotional arousal, is also very important; for example, if a child perceives that revealing that he/she is food allergic will have an impact on his/her ability to fit in with peers, this may result in risky behaviour rather than avoidant behaviour.

Finally, each time anxiety is felt and the networks are triggered, arousal probably helps to further strengthen the associations in this network. Emotional arousal at the time of experiencing a stimulus (internal as well as interaction with environment) is thought to be critical in influencing memory strength for this stimulus and therefore consolidation of the strong fear network and its sensitization (Brosschot 2002). The amygdala modulates the establishment of memory traces in other brain regions (e.g. the hippocampus; see McCaugh 2004). Although much research attributes a specialised role for harm avoidance to the amygdala circuits (see review LeDoux and Phelps 2000), and for reward processing to the nucleus accumbens (DiChiara et al. 2004), these structures support a number of additional functions, such as associative learning and attention filtering which cut across both appetitive and aversive processing. Associative learning is affected by the way in which feedback is processed, that is, the representation of the value of the outcome that becomes linked through learning to the stimuli options (Ernst et al. 2003). The learning itself may be fully developed by middle to late childhood and behaviour expressed as highly trained (and probably neurally pre-activated), easily triggered behavioural patterns or, at the neural level, sensitized motor programs, coupled to the corresponding highly activated cognitive (and emotional) network (Brosschot 2002; Ursin and Eriksen 2001).Finally, increasing coordination and integration of the mostly physiological regulatory systems (e.g. information processing) over the course of development means that by the time children reach their teens, self-perception, emotional reactions and cognitive appraisal mechanisms have become relatively stable and consistent. Therefore, perception of HRQL and attendant behaviours may develop and depend on many factors, such as the amount and type of subjective threat, parental risk perception, peer and general attitudes to the disease, social environment, sex, age of development and culture (including gender).

191.8 Applications to Other Areas of Health and Disease

In this chapter, using food allergy as an example, we reviewed relevant literature to argue for a broader evaluation of HRQL in order to provide a framework for the construction of appropriate models linking symptoms, functioning, development, underlying physiological mechanisms and HRQOL in chronic disease involving food in children.

The research presented here implies that studies in health related quality of life that take account of biobehavioural developmental subsystems are likely to be more informative than those restricted to physiological or psychological domains alone. Developing functional systems interact, react with and program one another. For example, early life origins research has delineated mechanisms linking psychological stress, personality and emotion to neuro-immunoregulation as well as

increased risk of atopy. Furthermore, it appears that immune activation and the *experience* of having an allergic disease, particularly during childhood, influences the responsiveness of the HPA axis.

The implications of this developing field of research are enormous with applications extending to include the effect of social experience on learning and on health outcomes. Social and physiological adaptation is required in order to cope with transitional life experiences, whether these are due to early maternal separation in the form of childcare, starting school, the experience of competition or a particular disease.

A chronic condition may affect and/or interact with normative developmental pathways and risk of maladaptive outcomes may follow transition points that are particular to a specific disease. Disease-specific pathways may be embedded within developmental trajectories and predict phenotypic expression of physiology, psychology and behaviour. A simple illustration of this dual pathway is shown in Fig. 191.7.

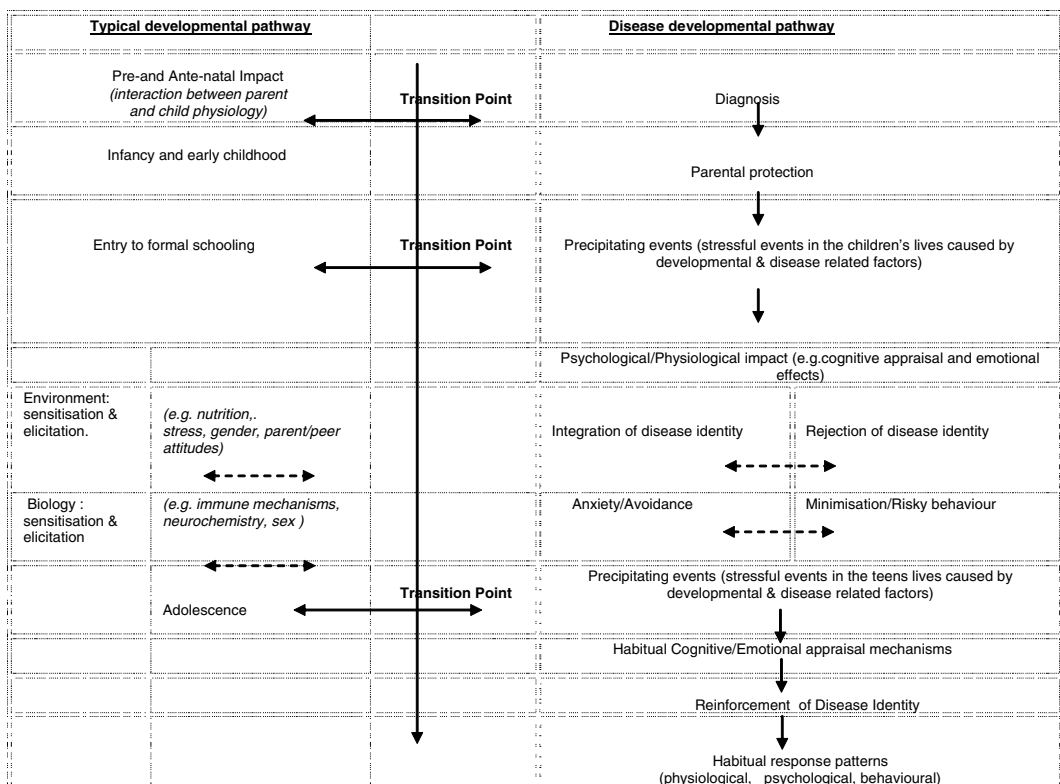
Findings may also be applicable to other chronic diseases involving diet such as diabetes and celiac. Diabetes, like food allergy, is a 'hidden' disease, largely unsymptomatic but characterised by sudden and unpredictable symptomatic events. In a series of focus groups with children aged 6–12 with diabetes (submitted), we found many of the same transition points (e.g. balancing safety with the need to 'belong'); however, there were also differences. In addition to a growing awareness of 'uncertainty' in


Fig. 191.7 Developmental framework model illustrating the integration of food allergy-specific pathway within the normal trajectory. A chronic condition may affect and/or interact with normative developmental pathways and risk of maladaptive outcomes may follow transition points that are particular to a specific disease. Disease-specific pathways may be embedded within developmental trajectories and predict phenotypic expression of physiology, psychology and behaviour (Dunn Galvin and Hourihane in press)

managing diabetes, there was a growing awareness of 'embarrassment' and a public attitude of 'blame' toward the diabetic adolescent. This awareness resulted in concealment and risky behaviour in some cases. Research in diabetes shows that adolescence, when responsibility for self-care is largely transferred from parent to child, is consistently associated with a decline in metabolic control (e.g. Hoey et al. 1999). While the decline is partly attributed to physiological changes the main cause is a substantial decline in levels of self-care (e.g. Morris et al. 1997). Anxiety and depression associated with uncertainty has also been noted in childhood diabetes (Mullins et al. 2007). Further, the need to address uncertainty in the context of its differing gender impact may also be discerned from research into other 'hidden' diseases. Austin et al. (2000), in a 4-year study on adjustment in epilepsy, found that girls evolved more behaviour problems from pre- to post-adolescence. In addition, they found that children were very worried about the possibility and unpredictable nature of seizures.

191.9 Conclusion

An integrated developmental perspective provides a powerful place to illuminate our understanding of individual differences in the expression and impact of chronic diseases. For example, research into the behavioural significance of the different trajectories of biopsychosocial maturation can aid in the development of psychoneurobiological models that may ultimately predict health-related quality of life outcomes.

A HRQL research infrastructure that has sufficient scope (both breadth and depth) will still fail in its goal if the knowledge is not linked across levels and domains. Four elements are essential to success in integration. The first is the development of a coherent conceptual framework within which the connections make sense. The second involves a cross-disciplinary research project in order to address key issues of linkage between developmental processes and outcomes at different levels. The third element relates to the need for innovative quantitative and qualitative methodologies which can be used to tease out the relative contribution of biopsychosocial factors to HRQL. The last relates to the need for longitudinal birth cohort studies.

A broader understanding of HRQL will ultimately lead to the promotion of earlier, more effective preventive strategies and interventions focused on maximizing optimal health development and quality of life.

Summary Points

- Outcomes research has been key in altering the culture of clinical practice and health care research by changing how we assess the end results of health care services.
- Health Related Quality of Life (HRQL) is a multi-dimensional construct, which evaluates physical, psychological, and social components, from the patient perspective.
- There are important questions that must be answered before HRQL measures can reach their full potential in research, practice and policy.
- Disease- specific pathways may be embedded within normal developmental trajectories and predict phenotypic expression of physiology, psychology and behaviour.
- The immune system in concert with psychological factors, such as stress, may play a role in the development of abnormal immune and allergic responses. In turn, immune activation and the experience of having an atopic disease, particularly during childhood, may influence the responsiveness of the HPA axis.

- Appropriate pathway models must be developed to incorporate broader aspects linked to HRQL and to incorporate developmental biopsychosocial trajectories.
- An integrated developmental perspective may promote increased understanding of individual differences in the expression and impact of many chronic diseases, with applications extending to include the effect of social experience on learning and on health outcomes.
- A broader understanding of HRQL may lead to the promotion of earlier, more effective preventive strategies and interventions focused on maximizing optimal health development and quality of life.

Key Terms

Health related quality of life: A multidimensional construct, which evaluates physical, psychological and social components that may be impacted by a disease or medical condition, from the patient perspective.

Reliability: The consistency of a measurement, or the degree to which an instrument measures the same way each time it is used under the same condition with the same subjects.

Validity: There are several forms of validity, but in essence, validity refers to the ability of a measure to capture the construct of interest (e.g. health related quality of life) in a meaningful and effective manner.

Developmental trajectory: A lifelong process of developmental integration that involves complex interactions between biological and environmental factors that influence the phenotypic expression of physiology, psychology and behaviour.

Sensitive transition point: Period in development when physiological or environmental variables associated with a particular disease may have a relatively greater impact and/or interact with already existing normative demands and changes in socialization.

Coping/adaptation: How individuals mobilize, guide, manage, energise and direct behaviour, emotion or orientation, or how they fail to do so, under stressful conditions, such those associated with a chronic disease.

Sensitisation/cognitive emotional sensitisation: Sensitisation is caused by an increased efficiency in the synapse due to repeated use, in particular following irregular and extreme stimulation. Cognitive emotional sensitisation is a higher form of sensitisation, involving cognitive bias.

192.1 Introduction

The number of older people is growing rapidly worldwide and looks set to continue to increase further in the future. For example by 2025, one-tenth of the world's population will be aged 65 or older and Asia will see the proportion of its elderly population almost double, from about 6% in 2000 to 10% in 2025. In absolute terms, this represents a stark increase in just 25 years from about 216 millions to about 480 million older people. This has created a need for additional knowledge of age-related changes relevant to nutrition, which has importance in the treatment and prevention of disease, and in maintaining good health and quality of life (QoL) in an ageing population. It is well recognized that with advancing age, there is a high incidence of chronic diseases, and evidence points to the importance of nutrition in the development, susceptibility and outcome of these diseases. There is no doubt that good nutrition contributes to the health and well-being of elderly people and to their ability to recover from illness (Fig. 192.1).

192.2 Age-Related Physiological and Pathological Changes Relevant to Nutrition

Ageing in man may be accompanied by changes, which may impair the search for food and its subsequent intake, but such changes are complex and difficult to document. Anorexia and weight loss are common and important clinical problems in the elderly; and the causes are multifactorial. There is a growing recognition that age-related physiological anorexia may predispose to protein-energy undernutrition (PEU), in the elderly particularly in the presence of other 'pathological' factors associated with ageing; such as social, psychological, physical and medical factors, the majority of which are responsive to treatment.

192.2.1 Physiological Changes

192.2.1.1 Hormonal Changes

The potential mechanisms of physiological anorexia of ageing are however, poorly understood but they are the focus of recent research. Current evidence suggests that a combination of reduced sensory perception within the gastrointestinal tract, a decline in opioid modulation of feeding, particularly in older women, and an increase in the satiating effects of Cholecystokinin (CCK) contribute to this anorexia. For example, CCK, the best characterized of the gastrointestinal hormones is known

to play a role in the control of food intake. There is evidence that sensitivity to the satiating effects of CCK increases with age. The combination of increased circulating CCK concentrations and enhanced sensitivity to the satiating effects of CCK in older people suggests that CCK may be a significant contributor to the anorexia of ageing.

With age, the time taken for the emptying of the stomach after large volumes of food is altered, this affects satiation. This may explain why older adults feel a greater satiating effect after an average meal compared to younger ones. Other hormones (leptin), neurotransmitters (opioids & nitric oxide) and protein (cytokines) may also have a role to play in anorexia and weight loss of ageing.

192.2.1.2 Gastrointestinal Tract

Objective changes in smell and taste have been observed, which may directly decrease food intake or alter the type of foods, which are selected. With ageing, there may be a progressive loss in a number of taste buds per papilla on the tongue. The remaining taste buds, which detect primarily bitter or sour tastes, show a relative increase with ageing. In addition, the ability to identify foods while blindfolded decreases with advancing age. This is a common perceived problem among elderly individuals who complain of loss of both taste and smell. Impaired appetite is often associated with reduction in taste and smell, which occur in up to 50% of elderly people. Taste thresholds are higher among institutionalized than in healthy elderly men and the use of drugs, particularly antihypertensive medication, appears to be a contributing factor. There are some documented gastrointestinal changes in the elderly, which could affect their food intake. For example changes in peristaltic activity of the oesophagus, which may result in delay of oesophageal emptying. Absorption of some nutrients, in particular vitamin B_{12} may be impaired because of mild ageing-related achlorhyria, but the evidence here is incomplete. Some researchers have reported widespread nutritional deficiencies associated with bacterial contamination of the small bowel. Others have reported a significant improvement in nutritional status in elderly patients after treatment of bacterial contamination with antibiotics. Stronger evidence point to no association between bacterial colonization of the bowel and nutritional status. The most likely interpretation of these apparently conflicting reports is that bacterial contamination of an anatomically normal small bowel in the elderly is the result rather than the cause of malnutrition. The mechanisms through which malnutrition might cause bacterial growth are not fully understood but there is evidence that the activity of several enzyme systems involved in bactericidal processes may be reduced in malnutrition.

192.2.1.3 Body Mass and Composition

Changes in body composition seen with ageing includes a decrease in lean body mass and an increase in body fat. Decreased physical activity accounts for the increased body fat and this may lead to decreased energy or calorie intake with ageing. These changes in body composition including those in fat distribution may be associated with changes in various physiological functions that affect metabolism, nutrient intake, physical activity and risk for chronic disease.

192.2.1.4 Energy Requirement

To date, the scientific evidence about energy requirement in the elderly is often incomplete and highly variable. The reasons for this include: paucity and variability of data on energy intake and

requirements; and most important of all, diversity of physical activity patterns in the elderly population. In a series of studies, elderly subjects from the USA consumed on average more energy than subjects in European studies, however the USA trials included less people compared to the European studies. The DHSS longitudinal study, which examined energy intake in 365 elderly people in 1967/1968 and 5 years later found that the average energy intake had fallen from 2,235 to 2,151 kcal per day for men and from 1,711 to 1,636 kcal per day for women. A similar trend for energy intakes to fall with age over 5 years was observed in a study of 269 elderly people in Gothenberg, Sweden.

192.2.2 Energy Expenditure

192.2.2.1 Basal Metabolic Rate (BMR)

BMR reflects the energy requirements for maintenance of the intracellular environment and the mechanical processes such as respiration and cardiac function that sustain the body at rest. It usually accounts for between 60% and 75% of total energy expenditure. The FAO/WHO/UNU Expert Consultation (1985), used equations to predict BMR. These equations may be less appropriate for the elderly populations, especially older men because of small numbers in the study, since more data have been collected which allowed a more precise estimate of current energy requirement in the elderly. BMR increases with body size, particularly with lean body mass and this explains why it is higher in men than women; and 10–20% less in old people because of reduced muscle mass and increased fat mass with ageing.

192.2.2.2 Physical Activity

In most working populations, physical activity accounts for 10–35% of total energy expenditure. The energy expenditure of different activities depend on the amount of work being carried out, the weight of the individual and the efficiency with which that work is carried out. In general, ageing is associated with a reduction in efficiency, which may make standard tasks like walking expend up to 20% more energy in older people. This reduced efficiency may be one reason why older individuals slow down. It may be contributing to negative energy balance, weight loss and undernutrition in some settings.

192.2.2.3 Thermogenesis

The term Thermogenesis encompasses a wide variety of phenomena which include energy expenditure and heat generation associated with feeding, body temperature maintenance and thermogenic response to various specific stimuli such as smoking, caffeine, and drugs. thermogenesis has also been postulated to play a part in the regulation of body weight. This field of research is complex in humans, and the theory is derived mainly from animal models. In the elderly, resting circulating catecholamine concentrations are elevated, and the responsiveness to catecholamines may decline with age, as is the case in experimental animals. Thermic response to meal ingestion in human appears to be influenced by age, physical activity and body composition. It is possible that the fall in the capacity for thermogenesis with age may explain the increased risk of hypothermia in the elderly. However, in most cases of hypothermia there is a precipitating physical cause such as stroke, which may or may not have a direct effect on thermogenesis.

192.2.2.4 Protein Requirement

There is almost a consensus regarding the current recommendation for protein intake of free living healthy elderly, which is between 0.75–0.8 g/kg. Total protein contained in lean body mass falls with age and protein synthesis, turnover, and breakdown all decrease with advancing age. Based on series of studies and literature review in 1980, Munro and Young stated that progressive loss of protein is a major feature of ageing throughout adult life. This appears to affect some tissues, notably muscle, more than others. There is no direct evidence to suggest that this erosion of tissue protein is due to lack of adequate amounts of protein in the average diet. Ill health, trauma, sepsis and immobilization may upset the equilibrium between protein synthesis and degradation. A group of researchers studied the dietary protein requirements of elderly men and women aged 56–80 years using short-term nitrogen balance techniques and calculations recommended by the 1985 Joint FAO/WHO/UNU Expert consultation. They have also recalculated nitrogen-balance data from three previous protein requirement studies in elderly people. From the current and retrospective data they reported that a safe protein intake for elderly adults would be 1.0–1.25 g/kg/day.

192.2.2.5 Vitamins

Because of low food intake and increased incidence of physical diseases, which may interfere with intake, absorption, metabolism and utilization, vitamin deficiency is more likely in the elderly compared to the young. Intake of most vitamins is reduced in smokers and alcoholics are more likely to suffer from folate and thiamine deficiency. Up to 50% of elderly in the surveyed populations ingests vitamin supplements even though there is no documented benefit from this practise when the diet is adequate. Some studies showed that multivitamin supplement on elderly patients produced significant clinical benefits. However, most other studies, which examined vitamin supplementation often, showed no consistent statistically significant difference between supplement and placebo administration. Two large surveys of vitamin status in elderly people within the past 12 years have improved knowledge of this subject: The Boston Nutritional Status Survey and the Survey in Europe on Nutrition and the Elderly. Current evidence including the SENECA and the Boston surveys on vitamin requirements of elderly people with reference to the National Research Council recommended dietary allowances (RDA) is that "there are data to indicate that the 1989 RDAs are too low for the elderly population (i.e., ≥51 years) for riboflavin, vitamin B_6, vitamin D and vitamin B_{12} – at least for certain groups of elderly people. The present RDAs for elderly people appear to be appropriate for thiamin, vitamin C and folate, but are probably too high for vitamin A. There are not enough data to make judgement on the appropriateness of the RDAs, or safe and adequate intakes for elderly people for vitamin K, niacin, biotin and pantothenic acid".

192.2.2.6 B-group Vitamins and Homocysteine

B vitamins including folate and vitamins B_2, B_6, and B_{12}, are major determinants of homocysteine metabolism and plasma tHcy concentration and hyperhomocysteinaemia is associated with cardiovascular, mental and bone health. The National Diet and Nutrition Survey of older people in the UK reported low biochemical status of one or more micronutrients in 40% of the older population, including B vitamins. Although several case-control and prospective cohort studies showed associations between modest elevation of plasma total homocysteine and cardiovascular disease, including stroke, only recently that sufficient evidence has mounted to suggest that the association is independent

and may be dose related. Several observations suggest that homocysteine have a role in the development of vascular diseases. For example, homocysteine may promote the oxidation of low-density lipoprotein cholesterol, vascular smooth muscle cell proliferation, platelet and coagulation factors activation and endothelial dysfunction. The prevalence of hyperhomocysteinaemia in the general population is between 5% and 10%. However, rates may be as high as 30% to 40% in the elderly population. Homocysteine may therefore, represent an important and potentially modifiable risk factor for cardiovascular diseases in the elderly. Causes of moderate hyperhomocysteinaemia which are all more common in the elderly include nutritional deficiencies of folic and B-group vitamins (B_{12}, B_6 and B_2), renal impairment, hypothyroidism, malignancies (acute lymphoblastic leukaemia, carcinoma of the breast, ovary and pancreas), medications/toxins (folate antagonists such as methotrexate, phenytoin, carbamazepine and vitamin B6 antagonists such as theophylline, azarabine, oestrogen-containing oral contraceptives, cigarette smoking), severe psoriasis, genetic defects in homocysteine metabolism and ageing per se. In a prospective study of 2,127 men and 2,639 women aged 65–67 years in 1992–1993 from Hordaland County, Norway, 162 men and 97 women died during a median 4.1 years of follow-up. The association between mortality and plasma total homocysteine (tHcy), distributed by quintiles with use of those with a concentration < 9.0 μmol/L as the referent group, was highly significant for both nonvascular and cardiovascular causes of death. An increase in tHcy of 5 μmol/L was associated with a 49% increase in all-cause mortality, a 50% increase in cardiovascular mortality, a 26% increase in cancer mortality and a 104% increase in noncancer, noncardiovascular mortality. Thus, plasma tHcy was a strong predictor of both cardiovascular and noncardiovascular mortality. A number of recently completed randomized trials on B vitamin homocysteine lowering and risk of stroke do not provide clear evidence of any beneficial effect, although in one trial fewer patients assigned to active treatment than to placebo had a stroke. There are many ongoing prospective, controlled intervention trials using folate, vitamin B_{12} and vitamin B_6 as homocysteine-lowering agents, the results of which (plus future metanalyses) may provide important information as to whether these vitamins can be protective against cardiovascular diseases including stroke. However, even if homocysteine-lowering therapies prove to be effective it still does not clear up whether the beneficial effect can be ascribed to a reduction in homocysteine or to an independent effect of the B-vitamins themselves.

A recent cross-sectional study from Scotland in the UK tested the association between cognitive performance and plasma vitamin B_{12}, folate and homocysteine in community-dwelling elderly. The authors used several cognitive tests in 2 cohorts, one aged 63 years and the other aged 78 years. They reported that concentrations of folate and B_{12} were positively associated with cognitive ability after controlling for childhood IQ. Cognitive function was inversely related to plasma homocysteine concentrations. A new hypothesis of the link between high levels of homocysteine and depressed mood is emerging. A plausible explanation for the association is that high homocysteine levels cause cerebrovascular disease and neurotransmitter deficiency, which cause depression of mood. Interventional studies would be needed to test this hypothesis.

192.2.2.7 Antioxidants

There are many theories on the ageing process. One important theory is that accumulation of oxygen-free radicals over the years leads to cumulative damage to cellular structure and function and consequently physical changes of ageing. Since then, there has been much interest in the role of antioxidants on the ageing processes.

There are several reasons why consumption of fruit and vegetables merits special attention. Besides contributing to non-starch polysaccharides, they are rich sources of vitamins and minerals

such as carotene, vitamins A, E, C and potassium. Several of these micronutrients have antioxidant properties and they may have a role in protecting against oxidative free radicals, which may be involved in the mechanism of atherosclerotic injury and ageing. Evidence is also accumulating to show that free radical damage may be important in other diseases such Parkinson's disease, Alzheimer's disease, chronic inflammatory disease and cancer and that some of diseases (cardiovascular and cancer) may be prevented or delayed to some extent by dietary changes such as reduction in fat intake and increased consumption of fruits, grains and vegetables.

192.2.2.8 Trace Elements

Knowledge of the exact role and dietary requirements for some of the following minerals (Cobalt, Copper, Chromium, Flouride, Iodine, Manganese, Molybdenum and Selenium) is incomplete for three reasons: they have only recently been found to be essential; dietary deficiencies of many are unknown; and the utilization of one may be affected by the amount of other elements present. However, for some there are recommended dietary intakes, which may be adequate and safe, but their optimum intakes are unknown.

192.3 Pathological Changes

192.3.1 Medical and Social Factors

Risk factors for undernutrition amongst elderly people in the community includes: isolation with an inability to go out shopping, loss of spouse, depression and bereavement, decreased mobility, dementia, anorexia due to disease especially cancer, medications, poor dentition, alcoholism and most important of all acute illness. In institutions, lack of supervision and assistance at mealtimes may be an important factor resulting in poor food intake (Table 192.1).

   Because old people are disproportionately isolated, on low income or disabled, socio-economic factors and disease are likely to have more influence on their nutritional status than age alone.

Table 192.1 Factors associated with poor nutritional status in older people in community and home care settings

Poor eye sight and hearing problems
Joint problems and hand tremors
Isolation
Inability to go out shopping and poor income
Depression and bereavement
Poor cognitive and physical functioning
Nausea, and vomiting
Poor appetite
Anorexia due to disease especially cancer, medications
Poor dentition and chewing problems
Acute illness
In institutions,
lack of supervision and assistance at mealtimes may be an important factor resulting in poor food intake

192.3.2 Cognitive Function

Cognitive decline and dementia are common in old age. For example, one in five of hospitalized older people has cognitive impairment at any one time, whereas dementia affects one in 20 people over the age of 65 and one in five over the age of 80. The central nervous system requires constant supply of glucose, and adequate brain function and maintenance depends on almost all essential nutrients. For example, B-group vitamins (folate and vitamin B_6 and B_{12}) deficiency or congenital defects in the enzymes associated with these pathways has been found to be associated with severe impairment of brain function. Although severe deficiencies and congenital defects are rare, milder subclinical vitamin deficiencies are not uncommon in the elderly. Many recent experimental and epidemiological studies have shown associations between loss of cognitive function or dementia and inadequate B-group vitamin status in older people. A recent study has found graded association between elevated plasma homocysteine, an indicator of inadequate B-group vitamins and cognitive impairment in healthy elderly community dwellers. A recent Cochrane review examined the effects of folic acid supplementation, with or without vitamin B_{12}, on elderly healthy or demented people, in preventing cognitive impairment or retarding its progress. The small number of studies which have been reviewed provide no consistent evidence either way that folic acid, with or without vitamin B_{12}, has a beneficial effect on cognitive function of unselected healthy or cognitively impaired older people. In a preliminary study, folic acid was associated with improvement in the response of people with Alzheimer's disease to cholinesterase inhibitors. In another, long-term use appeared to improve the cognitive function of healthy older people with high homocysteine levels. More studies are needed on this important issue. A growing body of evidence also supports the notion that oxidation and inflammation are part of the mechanisms responsible for cognitive decline and progression to dementia in older people. Recent research found that the use of vitamin E supplements, but not vitamin C supplements, may be related to modest cognitive benefits in older women. Supplementation with Vitamin E has also been found to lead to significant delay in the progression of dementia.

Macronutrients such as carbohydrates may have a role on cognitive function. A study of 11 men and 11 women aged 61–79 years consumed either 300-ml drink containing 774 KJ as pure protein, carbohydrate, or fat or a nonenergy placebo on four separate mornings after an overnight fast. Energy intake from protein, carbohydrate, or fat was found to enhance memory independently of elevations in blood glucose.

The extent of the relationship between inadequate nutrients status and loss of cognitive function in older people remains unclear. Advances in the understanding of this complex relationship may depend on the outcome of longitudinal prospective nutritional intervention studies starting prior to the onset of neurocognitive decline.

192.3.3 Depression and Well-being

The relationship between nutrition and older people psychiatry has received little attention. Recent research on the role of micronutrients in psychiatric disorders in older adults has revealed that low folic acid/vitamin B12 has been found to be associated with depression in older persons. For example, the Rotterdam study has reported a relationship between hyperhomocyteinaemia, vitamin B12 and folate deficiency and depressive disorders. Quality of life has also recently become a clinically relevant outcome measure when evaluating new treatment strategies in patient's population, particularly an older one. Studies have shown a close relationship between undernutrition and poor quality of life in some populations such as institutionalized older people and cancer patients. A study
Fig. 192.2 The effect of supplements on the number (%) of patients with no depression (No), mild depression (M), and severe depression (S), over 6 months compared to placebo

published recently has shown that oral nutritional supplementation of hospitalized acutely ill older patients led to a statistically significant benefit on depressive symptoms. Improvement in depressive symptoms also coincided with increase in red-cell folate and plasma vitamin B12 concentrations (Fig. 192.2). There is also some evidence, which suggests that a low intake of fish and/or n-3 PUFA is associated with depressed mood. Recently completed randomized controlled intervention trials found no effect of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) supplementati on mental well-being in the general older population studied.

192.4 Nutritional Status and Quality of Life in Older People

With advancing age both undernutrition and chronic diseases become more common [1]. There is evidence linking protein-energy undernutrition or its markers with clinical outcomes in acute and non-acute care settings. Poor nutrition leads to ill health and ill health to poor nutrition, so identifying priorities for managements still remain a challenge. A recent review of the literature on nutrition and older people psychiatry reported that although this issue has received little attention, there has been recent research on the role of micronutrients in psychiatric disorders in older adults. Studies have also shown a close relationship between undernutrition and poor quality of life in some populations such as institutionalized older people and cancer patients. Quality of life is a subjective multidimensional measure reflecting functional status, emotional and social well-being as well as general health. It has recently become a clinically relevant outcome measure when evaluating new treatment strategies in patient's population particularly older ones (Table 192.2).

Studies on assessment of the efficacy of nutritional support on older patient's outcomes hitherto have been limited to open ones. A metaanalysis of trials of protein and energy supplementation in older people reported that data were limited by the poor quality of most included trials. Future trials should have sufficient power, proper concealed allocation and blinding of treatment and should focus on outcome measures of relevance to patients such as improvement in function and quality of life.

Table 192.2 Key features of quality of life

- Health is defined by a state of complete physical, mental and social well-being and not only absence of disease
- Health-related quality of life scores often attempt to measure the psychological, physical and social effects of an illness and it is response to treatment
- Quality of life is therefore a subjective multidimensional measure reflecting functional status, emotional and social well-being as well as general health
- Quality of life has recently become a clinically relevant outcome measure when evaluating newtreatment strategies in patient's population particularly older ones

Despite growing evidence that nutritional support improves outcome in older people, there is however lack of good-quality data of the effects of nutritional support on quality of life measures in older people.

192.4.1 Assessment of Quality of Life

Health is defined by a state of complete physical, mental and social well-being and not only absence of disease. Health-related quality of life scores often attempt to measure the psychological, physical and social effects of an illness and it is response to treatment. This latter point is important because in this day and age, efficacy of treatment is not only judged on safety and ability to improve clinical outcomes but also on acceptability to patients and cost-effectiveness. Outcome measures which encompass quality of life measure such as the SF 36 are therefore very important especially in older people (Table 192.3). A large number of generic and disease-specific quality of life measures have been developed and some have been validated mainly for cancer in palliative care.

192.4.2 Undernutrition and Quality of Life

A prospective study of 579 randomly selected home-living older people has found that lower self-perceived health had the highest power to predict risk of malnutrition, with increased number of depression symptoms and higher age as second and third predictors.

A very recent systematic review examined the relationship between health-related quality of life and nutritional status of the patient. The authors reviewed studies that relate health-related quality of life to nutritional status and examined the tools (questionnaires) that they were to use to investigate this relationship. A critical review of published studies was carried out via an investigation of the following databases: MEDLINE (via PubMed), EMBASE, The Cochrane Library, Cumulative Index to Nursing and Allied Health Literature (CINAHL), Institute for Scientific Information (ISI) Web of Science, Latin American and Caribbean Health Sciences Literature (LILACS), Spanish Health Sciences Bibliographic Index (IBECS). The search was carried out from the earliest date possible until July 2007.The medical subject heading terms used were 'quality of life', 'nutritional status' and 'questionnaires'. The articles had to contain at least one questionnaire that evaluated quality of life. Twenty-eight documents fulfilling the inclusion criteria were accepted, although none of them used a specific questionnaire to evaluate HRQoL related to nutritional status. However, some of them used a combination of generic questionnaires with the intention of evaluating the same. Only three studies selectively addressed the relationship between nutritional status and quality of life, this evaluation being performed not by means of specific questionnaires but by statistical analysis of data obtained via validated

Table 192.3 Key features of SF-36 quality of life assessment questionnaire

- The SF36 is a validated Quality of life Medical Outcomes Study 36-items General Health Survey questionnaire
- The questionnaire consists of 36 questions forming 8 multi-item scale including physical functioning, role limitations- physical, role limitation- emotional, bodily pain, general health, vitality, social functioning and mental health
- The SF 36 validity is now well established and it has been used in several large studies
- The SF 36 has been adapted for use with older adults
- The questionnaire is measured on a 0 to 100 (good health) scale, self-administered with help provided when needed and takes about 10 minutes to complete

questionnaires. The first study by Eriksson et al. investigated measurements of nutritional status and health-related quality of life. The author's objective was to relate a well-established questionnaire of nutritional status (MNA) to a likewise well-established questionnaire of health-related quality of life (SF-36) in community dwelling, free-living and, healthy 70–75-year-old persons. Before an interview, the MNA and SF-36 questionnaires were filled in by 128 participants from a sample of 262 subjects. Their results showed that the MNA worked well as a measurement in this sample. Many MNA aspects correlated with the SF-36 scales. The correlations between MNA total score and the eight SF-36 scales varied from.27 to.62. This correlation was partly due to the fact that MNA has questions of health but also to the fact that there is an empirical relation between nutrition and health. The authors concluded by saying "The MNA measurement is applicable to a healthy, free-living elderly population and parts of the MNA can be interpreted as measurements of health-related quality of life. Low values of SF-36 could also be used as predictors of risk of malnutrition, although further studies are required to confirm this result". The second study was a cross-sectional survey to determine the independent association of nutritional risk with HR-QOL in frail older adults. Data were collected by interviewer-administered questionnaire. Nutritional risk was measured by SCREEN (Seniors in the Community: Risk Evaluation for Eating and Nutrition) and HR-QOL by perceived health status and report of number of days in the past month where physical or mental health was not good, or where activities were limited. Frail ($n = 367$) seniors were recruited from 23 community service providers. A wide variety of covariates were also measured. Multivariate modelling based on a conceptual model was used to identify factors associated with HR-QOL. The results showed that nutritional risk appears to be a significant and important factor associated with HR-QOL. Other significant covariates were: falls, social supports, social activity, health behaviours, pain and medication use. Nutritional risk as measured by SCREEN appears to be a significant covariate in explaining differences in HRQOL among frail older adults. Further work should determine if nutritional risk predicts changes in HR-QOL over time. The third study evaluated the scored Patient-generated Subjective Global Assessment (PG-SGA) tool as an outcome measure in clinical nutrition practise and determine its association with quality of life (QoL). This was a prospective 4-week study assessing the nutritional status and QoL of ambulatory sixty cancer patients aged 24–85 years receiving radiation therapy to the head, neck, rectal or abdominal area. Outcome measures were scored PG-SGA questionnaire, subjective global assessment (SGA), QoL (EORTC QLQ-C30 version 3). According to SGA, 65.0% (39) of subjects were found to be well-nourished, 28.3% (17) moderately or suspected of being malnourished and 6.7% (4) severely malnourished. PG-SGA score and global QoL were correlated ($r = -0.66$, $P < 0.001$) at baseline. There was a decrease in nutritional status according to PG-SGA score and SGA; and a decrease in global QoL after 4 weeks of radiotherapy. There was a linear trend for change in PG-SGA score and change in global QoL between those patients who improved (5%) maintained (56.7%) or deteriorated (33.3%) in nutritional status according to SGA. There was a correlation between change in PG-SGA score and change in QoL after 4 weeks of radiotherapy. Regression analysis determined that 26% of the variation of change in QoL was explained by change in PG-SGA.

192.4.3   Effects of Nutritional Support on Quality of Life

Poor nutrition may lead to ill health and ill health to poor nutrition. For example, many studies have found that lower self-perceived heath/quality of life and/or symptoms of depression increased risk of malnutrition and that malnutrition leads to poor quality of life and increased depression symptoms. So identifying priorities for management remains a challenge. Prior to coming into hospital elderly people in the community are more likely however, to have premorbid decrease in energy or calorie intake, less lean body mass and impaired immune response, which may be associated with poor nutritional. Their nutritional status is likely to deteriorate further as the result of the catabolism associated with the acute illness. This is compounded further by the demands of the sometimes-prolonged period of rehabilitation. Nutritional depletion during rehabilitation, however, may be more serious than during acute illness, since rehabilitation periods may extend over weeks and months, and weight loss, although less marked than in the early catabolic phase may be greater overall. In 1971, a study compared nutrient intakes of long stay, acutely ill and rehabilitation patients, and showed that energy and protein intakes were lowest in the latter group. A clinical review by Caro and colleagues on the effects of nutritional intervention on quality in adult oncology patients reported that nutritional intervention should be integrated into oncology care because it increases tolerance and response to treatment, decrease complications and improve quality of life by controlling symptoms such as nausea, vomiting, pain. Quality of life has also been found to be related to nutritional status in dialysis patients. Providing individualized nutritional counselling improves many components of quality of life, compared with standard nutritional care, in the stage prior to dialysis treatment. A recent randomized placebo-controlled study has reported that nutritional supplementation of older people during acute illness and convalescence/rehabilitation period significantly improves quality of life. The improvements in quality of life indices was accompanied by significant improvements in biomarkers of nutritional status in the supplement group, which were evident at 6 weeks and sustained at 6 months (Table 192.4 and Fig. 192.3). Improvement of micronutrients status such as vitamin B12 and red-cell folate would be the most plausible explanation for the improvement in well-being of our study population. Although there are well-known changes in micronutrients status in old age that significantly correlate with adverse physical outcomes such as cardiovascular, disease, cerebrovascular disease, impaired immune function and bone health all contributing to the development of frailty less is known of a relationship between B12, folate and quality of life. There is however evidence of a strong link between B12/folate status and depression in older adults.

The lack of statistically significant differences in anthropometeric measures between the supplement and placebo group could be due to the short time frame of the supplementation and to inherent difficulties in measuring these nutritional indices in ageing patients. This is especially true for studies in the elderly, being affected by age-related changes, disability, illness and injury. Another plausible explanation for our results would be that mild subclinical nutritional deficiencies, which are known to be common even in relatively healthy persons, which otherwise would have gone unnoticed in our supplement group, have been corrected, hence the clinical benefit. This trial has demonstrated that nutritional supplementation of hospitalized older people does lead to a clinically important benefit.

In conclusion, the number of older people is growing rapidly worldwide and looks set to continue to increase further in the future act on quality of life for older people. This has created a need for additional knowledge of age-related changes relevant to nutrition which has importance in the treatment and prevention of diseases and in maintaining good health and quality of life in an ageing population. Evidence is emerging of a link between undernutrition and poor quality of life in older people and that improvement in nutrition status leads to improvement in quality of life but there is an urgent need for more research in this field. The prospect of the effects of improved nutritional status of older people quality of life could have an important and a substantial health and economic impact.

192.5 Application to Other Areas of Health and Disease

Undernutrition can adversely affect physical, psychological and behavioural function and this can have major social and economic implications. Evidence is emerging of a link between undernutrition and poor quality of life in older people and that improvement in nutrition status leads to improvement in quality of life. Older people should therefore be advised to eat a balanced diet containing a variety of nutrient-dense foods; more fruits, vegetables and grains; foods containing adequate amounts of calcium and vitamin D. Widespread implementation of this strategy could have a substantial economic impact and improve mental health for older people.

Summary Points

- Many societies worldwide have experienced a considerable increase in the number of elderly people.
- Ageing, disease, life style, and environmental factors account for many of the changes observed in older people.
- There is a growing recognition that age-related physiological changes may predispose to protein-energy undernutrition, in the elderly particularly in the presence of other 'pathological' factors associated with ageing; such as social, psychological, physical, and medical factors, the majority of which are responsive to treatment.
- This has created a need for additional knowledge of age-related changes relevant to nutrition, which has importance in the treatment and prevention of diseases and in maintaining good health and quality of life in an ageing population.
- Evidence is emerging of a link between undernutrition and poor quality of life in older people and that improvement in nutrition status leads to improvement in quality of life but there is an urgent need for more research in this field.

Key Points of Diet, Nutrition and Quality of Life in Older People

1. A healthy older person's dietary patterns and the food eaten are not likely to be that much different from what is known about those of younger age.
2. The majority of 'pathological' factors associated with ageing; such as social, psychological, physical and medical factors, which may predispose to undernutrition, are responsive to treatment.
3. New evidence is emerging of a link between undernutrition and poor quality of life in older people and that improvement in nutrition status leads to improvement in quality of life.
4. Future research should focus on the role of adequate nutrition and active life in prevention and treatment of disease and improving quality of life in the ageing population.
5. Older people should be advised to eat a balanced diet containing a variety of nutrient-dense foods; more fruits, vegetables and grains; foods containing adequate amounts of calcium and vitamin D and this may need to be monitored in certain individuals.

HRQoL   Health-related quality of life
PN   Parenteral nutrition
QoL   Quality of life
WHO   World Health Organization

193.1 Introduction

Many diseases that are curable from a medical standpoint cannot be healed by medicine as yet. This channels patients presenting such disorders into a condition that is defined as chronic. A chronic disease is characterised by the need to manage it in the long term to undergo complex, long-term, therapeutic interventions from the onset of complications subsequent to the treatment itself. Chronicity is almost always accompanied by a worsened health condition, following the progress of the basic disease. The ability to diagnose a disease or a condition of deficiency (e.g. malnutrition) is considered a positive factor – from a biomedical viewpoint – as it enables to plan a series of interventions focused on managing the physical health of the subject. When an acute disease is diagnosed, the process is scheduled, medical treatments are decided in advance and healing can be achieved during a certain time interval. This encourages patient compliance. The acute disease alters the life of the subject for a defined period of time. Moreover, social, physical changes and alterations in the framework and habits of the patient are limited in time and can therefore often be managed. The situation concerning the diagnosis and treatment of chronic diseases from which the patient will not heal is quite different. The consequences of the chronic disease influence all aspects of the life of a subject, affecting him psychologically, socially and contextually. Disease characteristics can change in time, producing several types of complications, new symptoms and new therapeutic needs. In this case, the biomedical approach alone for scheduling and evaluating interventions will not suffice

anymore because the aspects involved are many. The needs, feelings and expectations of both the patient and his relatives become key factors in treatment, which entails taking care of the whole patient and not only of his body. A typical example of treatment, combined with a chronic disease is HEN, which is administered to subjects who cannot be fed by mouth due to an underlying disease and who are sent home on artificial nutrition (AN) after a certain period of hospital treatment. The possibility of sending home patients with chronic diseases that prevent food intake by mouth has basically changed home health care. It has changed the economic conditions of health-care institutions, and also raised ethical issues on the risk of therapeutic obstinacy. Home care is highly beneficial for those who were either not receiving appropriate treatment or were forced to stay long in hospital. HEN has become a therapeutic option that considerably lengthens the life of patients who were previously doomed to malnutrition, in some cases even significantly postponing the time of death. But this very outcome and its clinical (patients whose basal disease deteriorates slowly and progressively), ethical (should therapy be terminated? when?) and social implications have an impact on the patient as a whole (Buchman 2005). Taking for granted that therapeutic results and actions must be evaluated with the appropriate clinical, anthropometric, blood-chemical monitoring systems and equipment to provide the patient with the best physical conditions possible given the basal disease, it would be naive to theorise that only physiological parameters are indicators of the state of well-being of a patient undergoing HEN, since this treatment becomes part of the life of the patient in various moments of the day, and for very long periods, if not forever. Hence the idea of shifting focus from a biochemical or biomedical model, which considers the illness from a purely objective standpoint, to a model that can deal with the patient in all his facets, considering his broader biopsychosocial framework. This chapter describes the reference theoretical framework, treatment characteristics and impact on both subjects and their lives of a transition to artificial nutrition from oral feeding. It defines quality of life and health-related 'quality of life' (QoL), evaluating the importance of measuring the 'health-related quality of life'' (HRQoL) in patients who are sent home on enteral artificial nutrition. The chapter briefly describes standardised tools that are most used according to literature for the evaluation of HRQoL and the possible problems found in measuring this parameter.

AN comprises artificial parenteral nutrition (PN) and artificial enteral nutrition (EN). PN consists in using venous catheters to administer nutrients directly into the bloodstream through a peripheral or central venous access. EN allows nutrients to be administered directly into the gastrointestinal system with special probes that are inserted either through the nose or stomies created through the abdominal wall.

This chapter will specifically enlarge on EN by analysing aspects of the impact of treatment in the daily life of subjects.

193.2 The Theoretical Framework: A Biopsychosocial Approach

The World Health Organization (WHO) has long invited medicine to adopt a new approach to the evaluation and management of chronic diseases (WHO 1986). According to this theory, the correct approach and management of a chronic disease demands a biopsychosocial approach that centres treatment on the patient and his relatives who become the lead actors in the management of the disease. In medical literature, the 'biochemical model' (that evaluates the objective alterations of the patient) is increasingly integrated into the holistic model that can consider the viewpoint of the patient (e.g. how he experiences his disease and subsequent treatment and effects on daily life) (Aspinwall and Staudinger 2003). This approach shifts focus from the disease 'of the body' to the

disease 'of the patient' who is deemed a person with an inner world of his own and lives in a specific physical and social framework. Adopting this overall standpoint, the therapeutic intervention is managed along with the patient who becomes the active protagonist of his decisions, and even the idea of wellness is considered from a subjective viewpoint, conversely to the directive and prescriptive intervention of the biomedical approach. The 'biopsychosocial' model combines the medical and psychosocial models of health to implement an intervention that issues from a 'reasonable dialogue' with the subject under treatment and his relatives. Focus is not on the disease anymore but on health, which is deemed as an attempt to create new balances to reach physical, psychological and subjective wellness, starting from the sociocultural framework the individual belongs to.

Even treatment-based relations change in this context. While in the acute patient, especially at the time of diagnosis, the biomedical approach defines the operator as the competent person who, in a directive and prescriptive framework, is entrusted with the most appropriate decisions required to define the disease, in chronic patients treatment-based relations develop over a prolonged period of dialogue with the patient, assuming therapeutic features in a broad sense. The health care operator and the user are the two key actors of the relationship. The operator is trained on diagnostic, prognostic, treatment and prevention techniques, but only the user has direct experience of the disease, of the social framework in which he lives and of his values and preferences. The operator must know where the patient lives, his attitude towards health and treatment and his expectations to directly establish relations with the patient and work on the treatment. This is implemented in a new perspective in which the organic disease and subjective experience of the user concerning the disease have the same importance.

193.3 Eating and Feeding

Sharing food is an essential factor in social relations and friendship. The intake of food, the food-related attitude and the act of eating itself have complex and varied features that continuously intersect the biological framework with the affective and social life of the individual. Therefore, the type of food shared, meal characteristics and rate of occurrence are very strong indicators and components of affective bonds. They are directly related with the construction and reproduction of emotional relations, converging to form a basic element in the life of a subject. In various societies food is a way of establishing bonds, managing power and defining roles. Several messages that do not merely stop at the level of nutritional function but can be inserted into the complex and circular biopsychosocial interpretative model move through the symbology of food that is prepared, offered and accepted. When a disease makes it impossible for a patient to eat again, causing him to resort to tube feeding it is easy to imagine the deep lifestyle changes subsequent to the diagnosis of a chronic disease and the intervention of AN as treatment and prevention of malnutrition.

This chapter defines the concept of the intrinsic artificiality of EN, considering the attitude of the patient towards the mode of administration and not towards the type of 'food' used, which can be natural like home-made blended foods, or an industrial item that is produced and packaged in a totally artificial framework. According to this definition, home-made blended foods infused through a nasogastric tube possess the therapeutic traits of artificiality, while an artificial substance taken by mouth (e.g. an industrial product for patients with Crohn's disease) is, by the same definition, a natural food that has no therapeutic valency. As a matter of fact, the person who 'eats by mouth' can manage food both in a specific (e.g. choose the food from a menu) and social sense (e.g. organise a dinner to close a business), as he can share it with others in the most diverse frameworks. This can paradoxically occur with an industrial product for oral use that is administered to a patient who

presents a specific disease, which requires him to take special oral food. He can, however, sit down at table, experience lunch as a social moment and on some occasions even let another person taste the artificial food. Conversely, the need to infuse either blended or industrial food through a tube, which deprives the patient of the sense of taste and smell, modifies the feeling of satiety and, especially, refrains the patient from attending social food-sharing moments – if only for the embarrassment of having to expose the terminal part of the PEG to others – expresses in itself the concept of artificiality of enteral nutrition.

Therefore, this chapter will hereinafter designate as 'eating' everything that is taken by mouth and has implicit repercussions on the affective, social, cultural and biological framework. It will designate that which is commonly and historically called 'food' and which envisages the act of eating. AN and, especially, EN (including HEN), instead, designate all calories and macro- and micronutrients that are infused through a tube to ensure nourishment to the body, but which deprive the person of the psychosocial implications of "eaten food". Hence, AN envisages important clinical monitoring, requires informed consent to position the tubes, the continuous use of nutripumps to infuse food, specific result indicators and blood chemistry monitoring.

These concepts make it easy to understand that artificial nutrition is an example of therapeutic intervention in which the integrated and holistic dimension that creates wellness is damaged, and subjective balances are modified.

EN shifted to the domestic framework (HEN) requires specialist health-care skills (e.g. evaluation of the need, choice of nutritional mixture and route of administration), presupposes continuous contact with health-care operators and the acquisition of some specific management skills on the part of both the patient and his family (caregivers). The therapeutic intervention that modifies 'eating' and turns it into 'nutrition' (namely EN) does not necessarily prevent the patient from performing routine daily tasks. Some patients go on working and travelling. But to maintain their normal productive activities through HEN, it certainly generates new biological, emotional and relational variables.

Moreover, the social and affective characteristics of food are not the only factors that must be considered in the transition from eating to AN, as there are other forms of change associated with sensory deprivations such as, for instance, the loss of the taste and smell of food, altered body image (e.g. stepping into the swimming pool with the PEG) or interference in certain frameworks of life of the subject (e.g. sexuality). The life characteristics of these subjects, their emotional and psychosocial difficulties, the physical and practical obstacles they face in carrying out their tasks, the complications and the reactions of relatives are all factors that must be considered and evaluated in planning home-based interventions and treatment.

A special subgroup of patients is the one formed by subjects in a permanent vegetative condition that was mainly caused by cerebrovascular accidents or degenerative diseases, such as Parkinson's syndrome or Alzheimer's disease. In such subjects (who were defined as 'non-competent'), the concept of quality of life evaluation necessarily shifts to the relational and environmental framework, such as the impact of treatment and home care, on their caregivers (Hebert et al. 2007), and the situation is evaluated by operators on the basis of clinical scales (Fayers and Machin 2001).

193.4 Biomedical Aspects of Enteral Nutrition

As already mentioned, enteral nutrition entails introducing either industry-produced nutrients (calories, macro- and micronutrients) or processed foods (e.g. blended foods and chopped foods) with the assistance of a 'tube' (nasogastric tube, NGT; percutaneous gastrostomy, PEG; surgical jejunostomy, SJ; nasojejunal tube, NJT; percutaneous jejunostomy, PEJ; surgical gastrostomy SGS). It therefore either improves or maintains an adequate nutritional condition by treating or preventing malnutrition

and its complications in single organs and systems, influencing the risk of complications and altering the risk of death for patients (NICE 2005; Lochs et al. 2006; Bankhead 2007).

HEN is a set of organisational modes for EN administration at home when the clinical condition of the patient is stable, and his social and family framework can guarantee the safety and efficacy of treatment outside the hospital on a home care regime.

HEN has the same indications as EN administered in the hospital but it allows treatment to be administered at home, thus avoiding long stays in hospital and reintegrating the patient into his family, social and, at times, work-related framework (Lochs et al. 2006; Bankhead 2007).

193.4.1 Epidemiology

Epidemiological studies on enteral nutrition at home are still few due to the few registers or databases appointed to collect such data. This data estimates a progressive increase in HEN with a growth trend of over 20% in the past. A multicentre, retrospective study promoted by the European Society of Parenteral and Enteral Nutrition to evaluate indications and practice of HEN in 23 centres in eight European countries in 1998 highlighted an incidence of 163 cases/10^6 inhabitants/year (range: 62–457 cases/10^6 inhabitants/year). The paper reported that the main indication for HEN was the presence of dysphagia (84.6%), and the main diseases associated with the request were neurological (49.1%) and neoplastic (head and neck region: 26.5%) (Hebuterne et al. 2003). Despite this important rise in HEN, its incidence and prevalence is extremely varied and diversified, and depends on the clinical condition and organisation of the reference territory (Jones et al. 2007; Paccagnella et al. 2008).

Compared with the epidemiological data of HEN, the method was applied to patients hospitalised as *nursing home residents (NHRs)* in few cases. A recent survey carried out in the USA found that about 34% of the 1.4 million NHRs require some assistance to eat (Centers for Medicare and Medicaid Services 2005). It is currently estimated that about 2–34% of NHRs are nourished by tube feeding (Mitchell et al. 2003).

Our data on NHRs who underwent enteral nutrition (period: 2000–2005) revealed that 6.6% of all subjects were fed by means of tubes, with an incidence of 223.4 cases/10^6 inhabitants/year and a prevalence of 279.4 cases/10^6 inhabitants (Morello et al. 2009). If the study considers the entire population of patients aged >65 years who undergoes HEN (including 664 subjects at home in the period 2001–2006) (Fig. 193.1), a mean incidence of 269.9 cases/10^6 inhabitants/year can be noticed, with a prevalence of 313.5 cases/10^6 inhabitants. If the prevalence study is based on patient age in

Fig. 193.1 Incidence of diseases leading to HEN (664 subjects > 65 year at home)

this sample group, there would be 95.8 cases/10^6 inhabitants for patients aged 66–75 years, 151.3 for those aged 75–85, 116.0 for those aged 86–95 and 17.7 for patients aged >95 years.

193.4.2 Medical Indications for Treatment

National and international guidelines agree that EN is the first choice method in all conditions, which recommend AN as they have adequate anatomofunctional gastrointestinal integrity. This is based on the fact that EN is more physiological, is worsened by fewer complications (especially infections), costs less and can be managed with greater ease. The transit of nutrients along the intestine safeguards its trophism, either conserving or restoring the integrity of the absorbing surface.

Table 193.1 specifies when a patient should undergo EN. EN (just as HEN) must basically either prevent or reduce the risk of malnutrition (or undernutrition) that can act synergically with the basic disease, increasing the risk of complications and of the decease of patients. Table 193.2 reports the physical and psychosocial consequences of hyponutrition. Contraindications to EN are intestinal occlusion or subocclusion, chronic intestinal ischaemia, high flow jejunal or ileal fistulae, untreat-

Table 193.1 Indications for EN (Amended by the National Institute for Health and Clinical Excellence, NICE 2005)

EN should be considered for patients when
• The patient has eaten very small amounts for the last 5 days or more, or
• The patient is very unlikely to eat more than very small amounts for the next 5 days or more (whatever current BMI or history or weight loss), or
• The patient has a BMI <18.5 kg/m² (ref. range: 20–25 kg/m²), or
• The patient has unintentionally lost >10% body weight within the previous 3–6 months, or
• The patient has a BMI <20 kg/m² and unintentionally lost >5% within the previous 3–6 months, or
• The patient has poor absorptive capacity, is catabolic and/or has high nutrient losses and/or has a condition that increases their nutritional needs (i.e. hypermobility)

This table specifies when a patient should undergo EN
The criterion, amended by NICE 2005, includes reduction of food intake, fasting, weight loss, low BMI, alteration of absorptive capacity and condition of increasing nutritional needs

Table 193.2 Same physical and psychosocial effects of undernutrition in chronic patients (Amended by the National Institute for Health and Clinical Excellence, NICE 2005)

Adverse effect	Consequence
Impaired immune responses	Risk of infections
Impaired wound healing	Surgical wound dehiscence, development of post-surgical fistulae, anastomotic failures, risk of wound infections and ununited fractures
Reduced muscle and respiratory muscle strength, and fatigue	Inactivity, inability to work, poor self-care; abnormal muscle (or neuromuscular) function; poor cough pressure, risk of chest infections; difficulty weaning malnourished patients from ventilators
Inactivity	Predisposition for pressure sores and thromboembolism especially in bed-bound patients
Water and electrolyte disorders	Cardiac arrhythmias, muscle pain, increased vulnerability to refeeding syndrome, and iatrogenic sodium and water overload
Vitamin deficiencies	Specific vitamin deficiency states (e.g. Wernike–Korsakoff syndrome), osteoporosis
Impaired thermoregulation	Hypothermia and falls, especially in the elderly
Impaired psychosocial function	Apathy, depression, self-neglect, hypochondriasis lack of self-esteem, poor body image, lack of interest in food, deterioration in social interactions

Undernutrition causes *many consequences for human organs and systems with many physical and psychosocial adverse consequences*

able vomiting, paralytic ileum and/or intense diarrhoea and severe alterations in intestinal function subsequent to enteropathies or deficiencies in the absorbing surface (DiBaise and Scolapio 2007).

The same indications reported in Table 193.2 apply to the home-based patient who undergoes HEN. However, this requires concurrent suitable clinical and environmental conditions, a patient with a stable clinical condition, the possibility of managing the basic disease at home, suitability of the house to ensure correct management and the presence, in patients who are not self sufficient, of a caregiver or of nursing care at home. Lastly, as discussed below, since HEN interferes considerably in the life of the patient and his family, it requires the informed consent of the patient and a correct evaluation of the economic and psychological cost for the patient and his relatives, considering the prognosis of the basic disease and/or the results that can really be obtained with HEN.

193.4.3 Enteral Feeding Routes of Access

Once HEN is recommended, the clinical condition of the patient has been evaluated, the anatomy and functionality of the digestive system and envisaged duration of treatment have been defined and the ideal access route for tube feeding of nutrient mixtures must be established.

Many types of enteral feeding tubes can be used to deliver nutrition to the stomach or upper gastroenteric tract. In practice, enteral feeding tubes can be divided into two main categories: (a) those positioned through the nose (nasogastric, nasoduodenal and nasojejunal tubes), which are generally recommended for EN that is scheduled for at most 30 days; (b) those requiring minor surgery (percutaneous endoscopic gastrostomy, PEG; percutaneous endoscpic jejunostomy, PEJ), which are recommended for EN >30 days (Bankhead 2007). An epidemiological study conducted in Europe estimated that 813 on 1,3972003 patients undergoing HEN (58.2%) wore a PEG, 410 (29.3%) an NGT, 76 (5.4%) underwent surgical jejunostomy and 3.4% other means of access (Hebuterne et al.).

In our experience, PEG and SNG were the main access routes chosen by patients undergoing HEN either at home or in a nursing home, but the NGT is used more than the PEG (Paccagnella et al. 2008; Morello et al. 2009). Figure 193.2 reports the incidence of use for the main types of enteral feeding tubes in 664 patients aged >65 years treated by our unit in the period 2001–2006.

Fig. 193.2 Enteral access device from 2001 to 2006 (664 subjects > 65 year at home). *NGT* nasogastric tube, *PEG* percutaneous gastrostomy, *SJ* surgical jejunostomy, *NJT* nasojejunal tube, *PEJ* percutaneous jejunostomy, *SGS* surgical gastrostomy

In some clinical situations as, for instance, tumours in the head and neck region under chemoradiotherapy, PEG is to be preferred to NGT to enhance patient mobility because it is less visible and has a lower impact on the quality of life (Arends et al. 2006). Placing of the PEG for prophylactic purposes prior to the implementation of radiochemotherapy treatment proved effective, in these cases, in reducing the risk of malnutrition (Cady 2007). However, in our experience, similar results have been obtained with the NGT as long as the patient follows a treatment and monitoring track that is monitored by specialists and is proposed on the first medical examination of the patient (Paccagnella et al. 2009).

193.4.4 Complications of HEN

The progress of placement techniques and improvements in management have achieved success percentages of 90–95% and 95–98%, respectively, for SNG and PEG. But management of these medical aids is not free of complications (Iyer and Crawley 2007). Data published in literature reports several mechanical complications related to SNG and PEG placement, such as mechanical traumas (haemorrhages, perforations) and inhalation of food into airways (1.8%). Migration (16–41%) or dislocation of the tube and mechanical malfunction such as kinking, cracking and breaking are more common and can occur in 6–20% of cases. A frequent complication is an occluded tube (20%) (Iyer and Crawley 2007).

Placement of a PEG can cause endoscopic complications such as bleeding (0.02–0.06%), oesophageal perforation (0.008–0.04%) and inhalation (0.3–1.0%). Unintentional dislocations can occur in 1.6–0.4% of cases, and a clogged PEG tube is often reported (45%). A serious but not common complication is the buried bumper syndrome (1.5–1.9%). Gastrocolocutaneous fistula, small bowel, liver and splanchnic injury occur rarely (Schrag et al. 2007).

A retrospective study conducted on a cohort of 55 patients wearing a PEG highlighted that the most common complications recorded during a period of 25.9 months were granulation tissue (67%), broken or leaky tube (56%), leakage around the tube site (6%) and stomal infection requiring antibiotics (45%) (Crosby and Duerksen 2005). Infections at the site of the stomy are a frequent complication, whose incidence varies from 5% to 30% and can be reduced by antibiotic prophylaxis. Necrotising fasciitis is rare (Iyer and Crawley 2007).

EN often causes gastrointestinal complications, such as nausea (10–20%), diarrhoea (30%), abdominal distension and pain, constipation, gastroesophageal reflux and vomiting. Mechanical and gastrointestinal complications can be associated with metabolic complications, such as the refeeding syndrome (RS), alterations in the electrolyte and water balance and hypo/hyperglycaemias (DiBaise and Scolapio 2007).

A very rare complication described in literature in patients wearing a PEG is tumour implantation or metastasis at the site of stomy (Iyer and Crawley 2007). Risk factors that increase mortality in patients subject to PEG placement after the age of 75 have been defined in recent years. Urinary infections and past episodes of pneumonia (ab ingestis) have recently been associated with diabetes mellitus, chronic obstructive bronchopneumopathy and low blood levels of albumin.

193.4.5 Enteral Formulas

Enteral tube feeding formulas are designated by the US Food and Drug Administration (FDA) as medical foods: 'a food which is formulated to be consumed or administered enterally under the

Table 193.3 Main types of formulas for EN

	Polymeric	Elemental or semi-elemental
Proteins	Whole or hydrolysed proteins	L-aminoacids, tripeptides
Carbohydrates	Maltodextrins, polysaccharides, oligosaccharides	oligosaccharides (<10 glucose molecules)
Lipids	LCT, or LCT + MCT	MCT + LCT (50:50)
Osmolarity	Iso-osmolar	Hyperosmolar
Lactose, gluten	Present at times	Always absent
Fibre	Present at times	Always absent
Palatability	Acceptable	Poor
Costs	Contents	High

Enteral formulas can be divided into two categories: polymeric or elemental and semi-elemental formulas. These formulas are different in proteins, carbohydrates, lipids, osmolarity, presence of lactose and gluten, fibre, palatability and costs

supervision of a physician and which is intended for the specific dietary management of a disease or condition for which distinctive nutritional requirements, based on recognized scientific principles, are established by medical evaluation' (Bankhead et al. 2009).

Enteral formulas are industrially prepared mixtures that fully meet the need for macronutrients (i.e. proteins, lipids and carbohydrates), micronutrients (i.e. vitamins, mineral salts and trace elements) and water in patients who cannot meet daily requirements via oral intake but possess a functional digestive system (DiBaise and Scolapio 2007; Chen and Peterson 2009). They usually contain 1.0 Kcal/ml, but there is a higher calorie version containing 1.5 or 2 Kcal/ml. In our experience, in over 65 subjects, the mean infused calories is 23.3 ± 6.0.

Enteral formulas can be divided into two categories: polymeric or elemental and semi-elemental formulas (Chen and Peterson 2009) (Table 193.3). Polymeric formulas can be hypocaloric, normocaloric, hyperproteic, hypoproteic, energising, fibre-enriched, age-specific (e.g. paediatric), with a high content of soluble fibre and FOS, with natural blended foods, enriched with immunomodulating agents. There are also disease-specific formulas (e.g. for diabetics and for patients with respiratory failure). Enteral tube feeds can be administrated continuously with a nutripump, or discontinuously (boluses). As already mentioned, the PEG and tubes can be used to administer mixtures, water and drugs (Magnuson et al. 2005).

193.4.6 Outcome

Several studies have been undertaken to examine the effect of enteral nutrition. A review of literature reported a 1-month mortality rate of 8–41%, a 1-year mortality rate of 40–65% after feeding tube placement and a median survival rate that was well under a year. The largest study, comprising 81,105 patients, reported mortality rates of 23.9%, 63% and 81.3% at 1 month, 1 year and 3 years, respectively, among medicare beneficiaries who were discharged after gastrostomy placement.

Our data conducted on 482 nursing home residents who were administered EN during the period 2001–2005 reported an overall survival rate of 85.3% at 1 month, 50% at 1 year and 36% at 3 years. Median survival exceeded 13 months (Morello et al. 2009). Outcome and life expectancy with HEN depend on the condition of the patient and the medical situation.

Schneider et al. (2001) proved that age is an independent factor, which influences mortality. The chances of being alive at 1 year were 88% in children, 47% in adults (16–70 years) and 30% in older patients (>70 years). 5.5 per cent patients in the population analysed remained dependent on HEN, 32.6% resumed full oral nutrition, 20.2% died during the first month on HEN and 35% died after

more than 1 month on HEN (219 ± 257 days). This poor outcome was also influenced by the severity and nature of the underlying disease. In the USA, 59% of cancer patients and 48% with neurological swallowing disorders died 1 year after commencing HEN (Hebuterne and Schneider 2005).

193.5 Psychosocial Aspects of Home Enteral Nutrition

193.5.1 Evaluating Quality of Life and Health-Related Quality of Life

Aspects related to the cost of treatment, complications, mortality and prognosis cannot be considered as the only indicators to evaluate the efficacy of a treatment. Chronic patients should achieve psychological wellness that is commonly defined as 'quality of life' (QoL). In this sense QoL can be deemed as the modern operative term that defines the concept of 'happiness'. When QoL is mentioned without further specifications, it will embrace all factors that contribute towards it, but direct actions on the quality of life – even to improve it – must refer to a series of 'indicators'.

The wellness study, namely QoL evaluation, can also be applied to a condition of imbalance and discomfort to explore the daily impact of a disease or treatment on the life of everybody, on relations, mood and self-awareness. Health is deemed as the subjective, overall well-being of the patient, making room for his daily experiences and subjective viewpoint. During a disease, especially a chronic condition, reference is made to a concept that is more wide ranging than quality of life, namely health-related quality of life (HRQoL). It is 'the subjective assessment of the impact of disease and treatment across physical, psychological, social and somatic domains of functioning and wellbeing' (Reviky et al. 2000). In our case, for instance, the impact of HEN on subjects presenting a chronic disease and on their caregivers must be evaluated. In these special conditions, an individual develops a personal evaluation of what good quality of life is on the basis of his physical conditions, and depending on his personality profile, mode of coping and attitude towards health. HRQoL can be distinguished from QoL in that it concerns itself primarily with those factors that fall under the purview of health-care providers and health-care systems.

193.5.2 Measuring HRQoL

The HRQoL evaluation has several therapeutic goals and advantages, and implies the use of measurement scales and statistical correlations that embrace several domains. The most widespread compound measurements are HRQoL profiles generated by self-administered scales, which can be used to measure cross-sectional differences in quality of life between patients at a point in time (discriminative instruments) or longitudinal HRQoL changes in the same patient during a period of time (evaluative instruments). Both discriminative and evaluative instruments must be validated. There are two basic approaches to quality-of-life measurement available, namely generic instruments that provide a summary of well-being and HRQoL, and specific instruments that focus on problems associated with single disease conditions, patient groups, functional areas, or specific treatments applied. Approaches are not mutually exclusive. Of the many questionnaires available, the SF-36 (Ware et al. 1993) and Psychological Wellbeing Questionnaire (Ryff and Keyes 1995) stand out for the considerable availability of data on their validity and reliability. Especially, the SF-36 questionnaire is short and easy to complete is validated in many countries, and is therefore often used for comparative

studies of data. Other self-administered scales, like the Satisfaction profile (SAT-P; Majani and Callegari 1998), have a 'user-friendly' structure and only require brief administration and scoring times. It has an analogical, non-verbal response and is ideal for administration to both the elderly and subjects with writing problems.

The use of standardised instruments saves time and efforts required to perfect new custom-made instruments. There are no specific scales to evaluate the impact of HEN on HRQoL. Loeser et al. (2003) constructed an 'ad hoc' scale created by crossing a specific PEG impact evaluation module in conjunction with the QLQ-C30 scale for evaluations carried out during their study. But this scale has not been validated as yet. However, it confirms the need for specific instruments for subjects treated with home enteral nutrition.

193.5.3 Non-Standardised and/or Qualitative Instruments: Semistructured Interviews and Subjective Evaluation scales

Authors are increasingly integrating these standardised scales with semistructured interviews (for qualitative evaluations) or non-standardised scales to extend the information collected. Semistructured interviews were, for instance, used to analyse the impact on QoL in patients wearing PEGs (Brotherton et al. 2006). Other cases required a list of the advantages and disadvantages perceived during HEN treatment (Paccagnella et al. 2007) or scales to evaluate subjective tolerance to nutritional techniques (Roberge et al. 2000). Aspects of environmental impact have also been evaluated, since the therapy is a treatment that must be administered in the home of the patient. In our recent paper (Paccagnella et al. 2007) we used the Environmental Impact Exam (EIE), a questionnaire that was specially designed to study the perception of the living environment in patients and relatives during the illness, on their return home.

193.5.4 Why Measure the Quality of Life in HEN

The concepts of QoL and of HRQoL are central in the contemporary bioethical debate. Several controversies are in progress in medical and bioethical literature concerning placement of feeding tubes in patients presenting chronic diseases. These controversies centre on the decision concerning therapy, and also on the subjects involved in the same decisions, on ethical and legal aspects and on the role of various members of the multidisciplinary team in appropriately defining the characteristics of patients who need treatment with feeding tubes. The organisation that HEN requires can be naturally modulated or evaluated in response to the insurance and/or financial system provided by the country that envisaged it. Some questions should be asked in this framework. Is there a way of offering patients a quality intervention that can reduce risks associated with HEN? Is it possible to find a model that marries the culture of medicine with the current patient-centred approach? Which parameters, irrespective of the clinic, could show appropriate relations between the efficacy of the intervention, its cost and the well-being of the single patient?

Feeding tubes are unattractive and low-profile 'button' type tubes are the choice for gastric or jejunal feeding in some, especially the young. For feeding, low-profile tubes require brand-specific adapters or extension tubes that can wear out over time; hence, patients will need a supply of these. Regular gastric tubes may occasionally be too long and cumbersome, interfering with activity,

clothing, and moving. AN-related changes are many, and the subject must be actively involved in preparing his return to his life and home. The therapeutic nutrition programme can be adequate for hospital treatment, but it must be adapted and specially designed for the patient when he is sent home to ensure integration – as far as possible – with the characteristics and conditions of his life and work (see Box 193.1). The use of syringes, pumps and other medical aids must be discussed and evaluated with the patient to suit his preferences (for instance, many patients who use the pump prefer night feeding). All these aspects lead to evaluate, along with the patient, the impact of treatment on his quality of life in order to implement all improvements required.

Box 193.1

Two Stories of Hen

Mrs. Piera is 75 years. She cannot eat due to a tumour in the larynx that caused her to undergo several laryngectomies with subsequent progressive dysphagia. Every morning Mrs. Piera goes out to buy bread and the newspaper. She is autonomous and keeps her house and self in order. She regularly meets her friends and often plays with her grandchildren. She infuses nutrients and water into her PEG four times a day. For Mrs. Piera, HEN is a byword for autonomy and an acceptable quality of life. She has a positive attitude towards the PEG.

Carlo is 45 years. He suffers from a significant gastroparesis with chronic abdominal pain. He has undergone multiple surgeries for duodenal ulcers and obstructions. He is unmarried and lives alone. He has only one PEG through which he is slowly infused a nutrient and water almost the whole day. He must do the same at night. His abdominal pains often force him to stay in bed and prevent him from working for days, from going out, from meeting friends or a woman to form a family. His attitude towards HEN is ambivalent.

193.6 HEN and Its Impact on HRQoL

As already mentioned, HRQoL measures the combination between clinical, objective and measurable data, and subjective evaluations. Several studies (Terrel et al. 2004; Brotherton et al. 2006; Paccagnella et al. 2007; Bozzetti 2008) report the significant impact on QoL that, especially, surfaces concerning psychological and emotional factors associated with the inability to eat, taste and share food with others, the subsequent exclusion from family and social life, the inability to share the non-nutritional aspects of food with the social functions that eating food with others implies. Such inconvenience must certainly be associated with the specific characteristics of the treatment, which removes all eating-related factors and requires acceptance of treatment centred solely on feeding, something patients consider as one of the major disadvantages of the treatment. First difficulties arising from PEG feeding include symptoms such as vomiting, diarrhoea, infection of the PEG site and leakage that are reported as problems impacting on QoL by patients who wear a PEG (Table 193.4). Patients also report several psychosocial inconveniences. In fact, if on the one hand they are relieved of the pressure to consume an oral diet, and appreciate recovery of physical wellbeing and are less concerned over the risks related to their health (e.g. they are less stressed by problems related to dysphagia or risks related to malnutrition), on the other hand they are disturbed by several psychosocial effects related to PEG that have an impact on their QoL (Table 193.5). Three review articles evaluate the latest studies in the field of HRQoL and HEN (Brotherton and Judd 2007; Bozzetti 2008; Sampson et al. 2009) concluding that clearly tube feeding has an impact

Table 193.4 Symptoms associated with enteral feeding subjectively perceived as impacting on QoL (Roberge et al. 2000)

Low-impact symptoms	Intermediate-impact symptoms	High-impact symptoms
Nausea	Pain	Fatigue
Vomiting	Dyspnoea	
Constipation	Insomnia	
Diarrhoea	Appetite	

Enteral feeding can cause symptoms of different kind that can be differently tolerated. This table indicates the main symptoms experienced by patient and the degree of impact as subjectively experienced divided by low-, intermediate- and high-impact symptoms

Table 193.5 Psychosocial symptoms, subjectively perceived, as PEG-related problems impacting on QoL (Bannermann et al. 2000; Roberge et al. 2000; Verhoef and Van Rosendaal 2001; Malone 2002; Gee et al. 2005; Brotherton et al. 2006; Paccagnella et al. 2007; Rogers et al. 2007)

Problems with sleep

Difficulty in finding a place to feed

Missing being able to eat and drink

Problems in social occasions when food is shared

Perception of negative attitudes of others towards feeding them

Feeling a burden to family members

Poor body image

Fear about feeding tubes

Sensory deprivation

Grief

Anger

Depression

Frustration

Limitations concerning social life and travel

Interference with family life

Interference with intimate relationships

Interference with social activities

Interference with hobbies

Discomfort experienced while dressing and washing and restricted choice of clothing

In the table are summarized the main inconvenience perceived by patients wearing a PEG. Data are collected with quantitative and qualitative measures and describe all the daily discomforts expressed by patient in managing artificial nutrition

on the patient's quality of life. But these reviews underscore a varied and heterogeneous picture of the HRQoL impact of HEN. The differences depend on several factors, such as variable factors related with the underlying primary diagnoses, access routes, and measuring instruments that produce results that are not always consistent and comparable. Underlying diseases significantly, but not exclusively, include acute (e.g. stroke and head injury) and degenerative (e.g. dementia, Parkinson's disease and lateral sclerosis) neurological disorders. However, subjects undergoing PEG also count patients with cancer in the head, neck or oesophagus, and patients with cystic fibrosis. Hence, literature describes a very heterogeneous population – in terms of basic diagnosis – of subjects undergoing HEN. Even access routes can be of various types. In the studies mentioned, most patients were fed via PEG, but some studies recruited patients with NGT or NJT. All these differences are an obstacle to defining a coordinated, comparable picture of results, and we can only describe some common emerging themes. But not all results were consistent. In fact, some studies back the theory that HEN is deemed to help maintain QoL although it may be at a reduced level, especially when it is measured in time (Klose et al. 2003) and found PEG subjectively perceived as

useful in maintaining QoL over time, especially in the younger subjects (Weaver et al. 1993). This study found an interesting discrepancy between evaluations made by family members concerning the benefit of the procedure for the patient, and their refusal of applying the procedure to themselves if they were in the same situation. Even subjective opinions of patients on the impact of HEN present some ambivalences that reveal both perception of the utility (or inevitability?) of treatment ('I cannot do without it'), and an evaluation of its cost in terms of changes brought in their daily lives. Such ambivalences also surfaced in the assessment of other physical features and of the impact of the treatment and, especially, of inconveniences related to the use of stomies and tubes on the physical image. An interesting point surfaces from a longitudinal study, whose authors report that, though most subjects and caregivers have no second thoughts over the decision to have a PEG, this does not necessarily indicate better QoL (Verhoef and Van Rosendaal 2001). In the study conducted by Sampson et al. (2009) that analysed the impact of HEN in subjects presenting dementia, the authors concluded that despite the very large number of patients receiving this intervention, there was insufficient evidence to suggest that enteral tube feeding was beneficial in patients with advanced dementia in influencing survival, quality of life, prevention of bed sores, nutritional and functional condition and behavioural and psychiatric symptoms.

All reviews of latest contributions to relations between HEN and HRQoL lead to disappointing conclusions. In short, the data reveals that patients acknowledge the life-saving function of the therapeutic intervention of HEN, but they also declare that tube feeding finally came to dominate their lives and was associated with an appreciable burden of treatment (Jordan et al. 2006). We think that this depends on several factors, especially the fact that eating does not only involve the intake of food, but is associated with complex factors – as mentioned – the lack of which causes psychosocial deprivation in the life of subjects. This is added to the emotional impact (anticipatory grief) generated by basic diseases.

193.6.1 Problems and Limits of the Evaluation of HRQoL

Considering the discussion so far, it is hard to evaluate the effect of HEN on the QoL of a subject without taking into account the emotional impact of the basic disease, which is often chronic and has a fatal prognosis. Another problem that should be considered when analysing the aforementioned reports concerns the use of different measurements and scales, which makes it rather difficult to conduct a comparative study. Even the problem of access routes that are neither consistent nor identical in terms of management in these studies is not negligible. Different tubes can produce different reactions both in terms of symptoms and of emotional experience related to the tolerance of treatment and the image of self. Moreover, the number of subjects enrolled in many studies is less than the representative sample. Again, despite the hope of evaluating the progress of the long-term impact on QoL, longitudinal studies have struggled with loss of patient numbers at the time of follow-up data collection. A recent review (Marin Caro et al. 2007) centred on nutritional intervention and QoL in adult oncology patients found that no study is reported to prospectively investigate the effects of EN on QoL.

193.6.2 Caregivers

The term caregiver indicates the person who attends to either disabled or sick people, namely professional caregivers and family caregivers are those who look after a person in need. The difference between the two roles concerns their theoretical and practical background, but above all it relates to their motivational features. The professional caregiver's motivation is occupational, whereas a family

caregiver is in a position he or she has not freely chosen, and which constitutes an additional role arising from the illness of a loved one. Therefore, family caregivers have to cope with the challenge of a role they were not prepared to take on. Taking care of a sick family member requires a strong commitment that can change in time. Since care recipients are mainly attended to by family caregivers, irrespective of the presence of an external support, focus must be on them, also because the sick person's overall well-being highly depends on the psychophysical status of the family member who is taking care of him. The term 'burden' indicates the overall impact of caring responsibilities on the caregiver, who might feel demoralised, isolated and trapped in the role. Therefore, while assessing care needs, it is also essential to consider the demands of informal caregivers and anything else that might support them in this delicate community care task, both in 'material' and 'moral' terms.

193.6.3 The Viewpoint of Caregivers

Some studies analysed the effect on the subjective well-being of caregivers in managing HEN in various chronic patient types. The scope of these studies was to evaluate the impact of home care that significantly involved caregivers. Caregivers manage all treatment prescribed for non-competent subjects; hence, the importance of evaluating the impact of home care on them and of assessing whether social support, such as help from a family member, hospital assistance and professional help, could have some effect in reducing the caregiver's burden. Although caregivers are constantly under a lot of stress, there seems to be a strong link between the physical and cognitive disabilities of the patient and the extent of his daily needs, and the well-being of caregivers (Douglas et al. 2005). Studies compared HRQoL in patients and their caregivers. SAT-P test results reveal that the group of caregivers does not differ from the group of patients concerning perceived satisfaction in QoL. In particular, the scores of males fall within the normal range in the considered functions, while females – the majority of caregivers – seem to suffer a greater perceived cost in the management of patients. Perceived satisfaction on sleep-eating-leisure functions and at physical and psychological levels are below the average, when compared to the control group. Caregivers underlined different advantage and disadvantage concerned HEN (Table 193.6) even if management services are always deemed adequate and competent and all caregivers have been pleased by the service received (Silver and Wellman 2002; Brotherton et al. 2006; Paccagnella et al. 2007).

Although more attention has been paid to the viewpoint of caregivers, and there is greater awareness of the risk of the burden of managing a chronically ill person at home, less attention is paid to understanding the kind of support required to reduce the stress of caregivers. When the location of therapy is shifted from the hospital to the home of patients, the assessment of the impact of managing therapy should take into account all facilitating features that can be activated.

193.6.4 Health-Care Operators

There are no specific comparative studies on the viewpoint of health-care operators and those of patients or caregivers. Evaluations are often based either on clinical data or on instruments such as, for instance, the Karnofky index that does not cover all areas of autonomy and quality of life evaluation of the subject. The important factor in evaluating the quality of life of the patient after the therapeutic intervention concerns the need to train operators to make a biopsychosocial evaluation of subjects in order to provide an intervention designed to suit both the effects on the body of the person and on the person as a whole.

Table 193.6 Main disadvantages and advantages of HEN pointed out by caregivers (Brothertorn et al. 2006; Paccagnella et al. 2007)

Main disadvantages	Main advantages
Seeing the missing sensory aspects of nutrition in the patient	Improved physical conditions
Problems in physical/sexual relations between adults	General comfort/practicality of HEN
Problems due to emotional relations between the patient and his caregiver	Hope in the patient's survival
Remarks on the limited freedom of the caregiver himself	Feel less anxious or fearful of complications of eating by mouth
Lack of autonomy of the patient	To have the relative back home
Technical difficulties associated with HEN management	
QoL of patients considered boring due to the loss of pleasure generated by food and the act of eating	
Lack of quality of life	
Problems caused by reduced patient mobility	
Strong commitment to treatment management, which diminishes their own autonomy	

In the table are listed the main advantages and disadvantages pointed out by caregivers of HEN patients as subjectively perceived. To each subject was asked to point out the main disadvantages and the advantages, as they perceived it, in managing the home enteral nutrition of their relative. Results are then categorised into main classes of disadvantages and advantages by different judges. It is a qualitative method to evaluate the impact of home enteral nutrition at home and to have more information about quality of life of caregivers. In the table are pointed out main results

193.7 The Link Between HEN, QoL and ethics

Hebuterne (2005) presents us with questions on HEN that force us to consider its use: Is it well tolerated by the patient? Does it improve the clinical condition of the patient or does it only maintain it unchanged? Does it improve the quality of life of the patient or does it leave it unaltered? Does it improve the outcome of the patient and his survival? These questions make room for many considerations, and do not make it easy to formulate univocal answers. National and international scientific societies have long wondered about the ethical aspects of artificial nutrition.

To date, it is a matter for discussion whether AN must be deemed as a medical act or a compulsory caregiving intervention. In 2005,2005 the case of Terry Schiavo fuelled an international debate. The patient was in a permanent vegetative condition, and died after suspension of PEG-based HEN. The suspension, which was authorised by judiciary authorities on request of the husband, supported the former wish of the patient (Charatan). Even our clinical experience counts several cases of patients in whom the decision to commence HEN raised more than a few questions and doubts (Box 193.2).

It is interesting to notice that a study conducted in the early 1990s by Solomon et al. (1993) and based on interviews with 1,146 doctors and nurses, found that while the feasibility of using a ventilator or any other end of life support was questioned, there was extensive consent in not discontinuing nutrition and hydration. On the other hand further studies (Callahan et al. 1999) report that home care with HEN is not preceded by appropriate information for the patient or his relatives, and that relatives and other care givers request doctors to especially use the PEG (Table 193.7).

Over the past 20 years, the debate has been enriched by extensive literature, and every scientific society specialised in these features of home care enlarge on the ethical aspect of HEN in their guidelines. Basically, all agree on the advisability of suspending HEN when it becomes 'futile treatment'. Unfortunately, the concept of 'futile treatment' lacks a consistent definition, though some of them consider it as either ineffective or incapable of achieving a desired goal or result, despite heroic efforts (Andrews and Geppert 2007). On the other hand, it is very hard to establish 'if' and 'when'

Box 193.2

The case of Paola

Mrs. Paola, aged 70 years was diagnosed with left parietal meningioma: a benign tumour for which she underwent surgery. At 74, she underwent surgery again for a recurrence. The next year, following a left sylvian infarction she became completely hemiparetic and aphasic. During the next months she became totally dependent on the care of her relatives. At 77, she developed a third recurrence of the tumour that the neurosurgeons of her city deem inoperable. Therefore, the relatives decided that Paola should undergo surgery again in the neurosurgery department of another country. During the postoperative phase a complication forced Paola to undergo further resection surgery of the tumour. At that point Paola was totally unconscious, bed-bound and fed with an NG tube. When she returned to her city, a neurologist wrote: 'The patient is drowsy. She opens her eyes only under intensive stimulation. Pain stimuli evoke movement in the left lower limb. She does not answer verbally, nor can she understand when spoken to.' The picture is compatible with a permanent vegetative condition. At the age of 78 a PEG was positioned for HEN, as requested by her relatives.

One year elapsed from the placement of the PEG to her death. The survival of Paola was influenced by the HEN, but did this prolong her life or her agony?

Photo: Paola at the time of PEG placement.

Table 193.7 Key features of home enteral nutrition

1. HEN is a set of organisational modes for EN administration at home and has the same indications as PN.
2. HEN is administered to subjects who cannot be fed by mouth due to an underlying disease and who are sent home on artificial nutrition (AN) after a certain period of hospital treatment.
3. HEN must basically either prevent or reduce the risk of malnutrition (or undernutrition) that can act synergically with the basic disease, increasing the risk of complications and of patient decease.
4. Enteral feeding tubes can be divided into two main categories: (a) those positioned through the nose (nasogastric, nasoduodenal and nasojejunal tubes), recommended for at most 30 days; (b) those requiring minor surgery (percutaneous endoscopic gastrostomy, PEG; percutaneous endoscopic jejunostomy, PEJ), which are recommended for EN > 30 days.
5. Enteral tube feeding formulas are divided into two categories: polymeric or elemental and semi-elemental are industrially prepared mixtures that fully meet the need for macro- and micronutrients and water in patients who cannot meet daily requirements via oral intake but possess a functional digestive system.
6. SNG and PEG placement causes several mechanical complications such as mechanical traumas (haemorrhages, perforations) and inhalation of food into airways.
7. Literature reported a 1-month mortality rate of 8–41%, a 1year mortality rate of 40–65% after feeding tube placement, and a median survival rate that was well under a year.

HEN should be implemented, depending on the HRQoL evaluation of a patient. This seems absolutely unacceptable when the patient lacks self-awareness. A paradox that we experience daily, and which is already documented in the USA (Hoefler 2000), is that many people are inclined to make their relatives (e.g. elderly parents and children in a permanent vegetative condition) undergo HEN even when some cases risk the administration of futile treatment, but the same people usually say that they would not like to undergo HEN or other forms of hydration, when they are questioned about what they would choose for themselves.

The fact remains that in most European countries, in America and in Asia, AN (to which HEN belongs) is not deemed as a basic duty of care – such as 'eating', considering the theories explained so far – but as a 'medical treatment', whose implementation always requires the consent of the patient or of his relatives (NICE 2005), and which can be discontinued on the basis of clinical reasons or administered for a palliative purpose, depending on the clinical condition of the patient.

193.8 Future Developments

Many quality of life measurements that are widely used are limited in their ability to record the quality of life of individual patients. These limitations depend on the structure and content of the measurements, how they were developed and their weighting systems. Some of these problems can be overcome by using individualised measurements, but these have their own problems which need further attention. A compromise could lie in using recently developed standardised measurements that are sufficiently wide ranging to include most facets of life that are important to any patient, but which also use direct weighting systems. This should lead to an individualised assessment of patient quality of life. The extent to which such measurements mirror the quality of life of an individual requires further assessment, and the clinical utility and interpretability of these measures must also be established.

Concluding, the themes that surfaced from the studies analysed assuredly require further study, but they provide important descriptions of the psychological and social life of the patient, clarifying the key factors that must be considered by all operators in clinical practice.

193.9 Applications to Other Areas of Health and Disease

The recent biopsychosocial approach promoted by the World Health Organization wants us to consider the person from a 'global' perspective, taking into account the physiological, psychological and social implications of any treatment administered. In special conditions as chronic treatment as HEN (Home Enteral Nutrition) an individual develops a personal evaluation of what good quality of life is on the basis of his physical conditions, and depending on his personality profile, mode of coping, and attitude towards health. For chronic diseases patients should achieve psychological wellness that is commonly defined as quality of life" (QoL) or health-related quality of life (HRQoL). Therefore, all chronic diseases that need a prolonged treatment such as artificial nutrition should be evaluated on health-related quality of life. It is important to choose measures that are diffusely shared to be able to compare results of different studies and to make a follow-up of the evaluation whenever possible.

Using measures of health-related quality of life studies represents a new promising field to improve the impact of the therapy in chronic patients and to understand the different subjective outcomes.

Summary Points

- In the chapter we point out the difference between eating and feeding and we designate as 'eating' everything that is taken by mouth and has implicit repercussions on the affective, social, cultural and biological framework. It designates that which is commonly and historically called 'food' and which envisages the act of eating.
- Enteral nutrition is an example of therapeutic intervention (feeding) in which the integrated and holistic dimension that creates wellness is damaged, and subjective balances are modified. AN designates all calories and macro- and micronutrients that are infused through a tube to ensure nourishment to the body, but which deprive the person of the psychosocial implications of 'eaten food'.
- Patients undergoing home enteral nutrition should achieve psychological wellness that is commonly defined as 'quality of life' (QoL). In these cases of chronic condition, reference is made to a concept that is more wide ranging than quality of life, namely health-related quality of life (HRQoL).
- The data reveals that patients acknowledge the life-saving function of the therapeutic intervention of home enteral nutrition, but they also declare that tube feeding finally came to dominate their lives and was associated with an appreciable burden of treatment.
- To date, it is a matter for discussion whether artificial nutrition must be deemed as a medical act or a compulsory caregiver intervention.

Key Terms

Biopsychosocial approach: An approach promoted by the World Health Organization that centres treatment on the patient and his relatives who become the lead actors in the management of the disease. This approach shifts focus from the disease 'of the body' to the disease 'of the patient' who is deemed a person with an inner world of his own and lives in a specific physical and social framework.

Quality of life quality of life (QoL): is used in health care to refer to an individual's emotional, social and physical well-being, including their ability to function in the ordinary tasks of living.

Health-related quality of life: The wellness study can also be applied to a condition of imbalance and discomfort to explore the daily impact of a disease or treatment on the life of everybody. HRQoL refers to patient outcome measures that extend beyond traditional measures of mortality and morbidity to include such dimensions as physiology, function, social activity, cognition, emotion, sleep and rest, energy and vitality, health perception and general life satisfaction.

Home enteral nutrition: AN comprises artificial parenteral nutrition (PN) and artificial enteral nutrition (EN). EN allows nutrients to be administered directly into the gastrointestinal system with special probes that are inserted either through the nose or stomies created through the abdominal wall. Home enteral nutrition is when the treatment is moved to the home of the patients and it is often administered by a caregiver.

Caregivers: The term caregiver indicates the person who attends to either disabled or sick people, namely professional caregivers and family caregivers are those who look after a person in need.

IFN-gamma	Interferon gamma

194.1 Introduction

Anorexia and weight loss are common in patients with cancer and carry a tremendous impact on the social and psychosocial aspects of cancer care. Studies in patients with advanced disease have suggested that as many as 80% of patients experience anorexia, or loss of appetite, and as many as 82% experience weight loss (Poole and Froggatt 2002). This symptom and sign have major psychosocial ramifications for patients.

194.2 Impact of Anorexia and Weight Loss

Anorexia and weight loss have ramifications relevant to patients' prognosis and quality of life. Dewys and others conducted the first major study to support the prognostic significance of weight loss in cancer patients. Focusing upon 3041 patients treated on 12 Eastern Cooperative Oncology Group protocols, these investigators observed that weight loss of >5% of baseline weight prior to the start of cancer treatment predicted a shortened survival (Table 194.1). Patients with such weight loss also manifested lower response rates to chemotherapy. Weight loss tended to correlate with performance status (Dewys et al. 1980). Along these same lines, a study in which a questionnaire was administered to 1115 patients with advanced cancer, showed that a patient's own assessment of his or her nutritional status, including their own opinion of their appetite and food intake, carried prognostic

Table 194.1 Weight loss is associated with major differences in survival in cancer patients (Adapted from Dewys et al. 1980)

| Weight loss and early death			
Median survival (weeks)			
Cancer	No weight loss	Weight loss	*P*-value
Lung, small cell	34	27	<0.05
Lung, non-small cell	20	14	<0.01
Breast	70	45	<0.01
Colon	43	21	<0.01
Prostate	46	24	<0.05

Fig. 194.1 Anorexia and weight loss in cancer patients are closely linked to survival and quality of life

significance (Loprinzi et al. 1994). Thus, for the patient, the patient's family, and for the team of health care providers, loss of appetite and loss of weight predict a shortened survival.

This latter point is an important one. Indeed, cancer patients and their families find this sign and symptom distressing. Patients typically rank loss of appetite within their top ten most bothersome symptoms (Walsh et al. 2000). Anorexia is often intimately related to other frequently bothersome symptoms including weakness, fatigue, depression, and anxiety. Furthermore, many health care providers underestimate how distressing anorexia and weight loss are to patients and families (Tanghe et al. 1998) (Fig. 194.1).

A number of observations suggest that weight loss leads not only to physical decline, but can also lead to deterioration of emotional, psychological, and social quality of life. A recent observational study by Reid et al. highlights some of the issues with which patients struggle as a result of anorexia and weight loss. In interviews with 15 cachetic cancer patients and their caregivers, certain themes emerged. One of these was the "visuality of cachexia." Patients expressed concern about what they described as a "wasted" appearance. This issue led some to withdraw and lessen their social interactions due to embarrassment about their appearance or the desire to avoid the unwanted attention. Some also relayed that the change in their appearance led to a loss of self-identity. A second theme was that many patients recognized their cachexia as a manifestation of their declining health. Of interest, patients were more likely to recognize that the weight loss was related to the cancer while family members were more likely to ascribe it to altered taste and felt that it could be reversed by feeding. Patients and families also expressed frustration that their health care providers did not do more

to try to ameliorate these symptoms. Some viewed this as a lack of concern or a lack of complete competence. A third theme was "conflict over food." Caregivers tended to be more concerned about their loved one's weight loss and tended to focus on food as a way of restoring health. Many patients felt pressure to eat in order to satisfy their caregivers and avoid conflict (Reid et al. 2009).

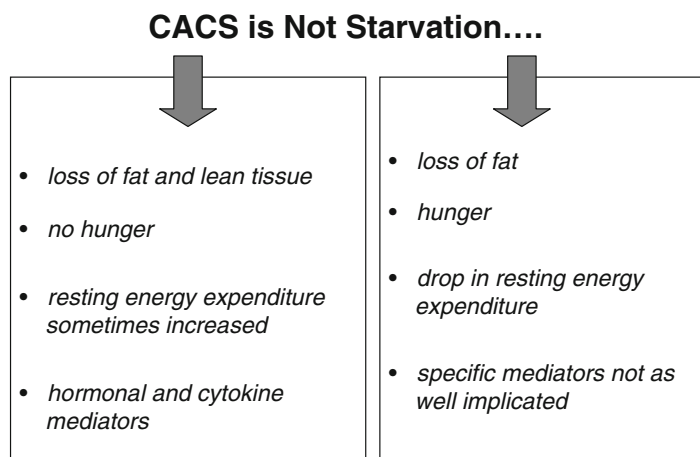
Who is more concerned about the foregoing: the patient or the family? In a survey of 199 cancer patients receiving home care, Hopkinson found that when asked about their level of concern, 34% expressed concern about weight loss and 44% expressed concern about decreased intake. However, if a family member assisted the patient with the survey, the "patient" was more likely to report concern about both weight loss (59%) and decreased intake (53%) (Hopkinson et al. 2006) – an observation that suggests that family members may be contending with more heightened concerns than the patient. Providing the same message, a smaller study of women caring for their partners with advanced cancer again found that the patient's anorexia and weight loss was more of a concern for the caregiver (Strasser et al. 2007). It is clear from many of these observations that eating is deeply woven into our social culture. Some have suggested that female caregivers struggle more with the anorexia of their loved ones as they view food preparation as part of their role and a necessary part of nurturing (Holden 1991). There is also concern that the caregiver may consider a patient's rejection of food as a personal rejection of the love and attention that he/she provides by means of the preparation and serving of the food (Reid et al. 2009).

In Holden's survey of advanced cancer patients with cachexia, caregivers again reported weight loss to be of greater concern than patients. Some of these caregivers expressed concern that weight loss would be the direct cause of death and would occur if oral intake did not improve. The patients themselves were more likely to express concern about pain, dyspnea, weakness, and fear of death (Holden 1991). In their respective series, both Holden and Strasser identify that tension can arise when the patient and caregiver are at different points in acceptance (Holden 1991; Strasser et al. 2007). Other studies of advanced cancer patients have also found that too much encouragement by the family or caregiver to eat can create tension (McClement et al. 2003). In the Holden study, 64% of patients expressed appreciation of their caregiver's efforts to offer food while 28% reported that their caregiver pushed too hard, and such efforts evolved into anger and conflict. She also found that both patients and caregivers grieved over the loss of mealtimes as an opportunity for social interaction (Holden 1991).

Many who have studied the psychosocial ramifications of anorexia and weight loss have suggested that perhaps, if patients and families had a better understanding of why the anorexia and weight loss existed, it would be easier to cope and accept.

194.3 Pathophysiology of Cancer-associated Anorexia/Cachexia

Thus, there is a clear need to spend time with cancer patients and their families and to explain that loss of appetite and loss of weight is "not their fault." In fact, the complex pathophysiology of this sign and symptom should allow patients and their families to shift their focus away from blaming each other with a more apt focus on healing.

It is clear that a number of causes of anorexia and weight loss are a direct result of the cancer or its treatment. Mechanical problems created by the tumor may lead to dysphagia, obstruction, malabsorption, or other related problems. These issues are particularly relevant to patients with head and neck cancer or malignancies of the gastrointestinal tract. Certain treatments, such as chemotherapy and radiation can exacerbate these symptoms, causing mucositis or constriction of the esophagus or other bowel-related symptoms such as nausea, vomiting, diarrhea, or constipation. Similarly, surgery can also exacerbate such mechanical problems, also resulting in dysphagia, other obstructive symptoms, or


CACS is Not Starvation….

- *loss of fat and lean tissue*

- *no hunger*

- *resting energy expenditure sometimes increased*

- *hormonal and cytokine mediators*

- *loss of fat*

- *hunger*

- *drop in resting energy expenditure*

- *specific mediators not as well implicated*

Fig. 194.2 There are major physiologic differences between cancer-associated anorexia and starvation

short-bowel symptoms. For many patients, appetite will also be affected by an altered sense of taste, dry mouth, or mucositis that frequently occur as treatment side effects. Other symptoms that are common in cancer patients including pain, fatigue, and depression may contribute to poor appetite and weight loss as well. For these reasons, many cancer patients do eat less and studies have demonstrated that cancer patients who are suffering weight loss do in fact consume fewer calories (Bruera et al. 1984).

Despite these, many secondary causes of anorexia and weight loss, multiple studies suggest that the problem is more complex and driven by a disordered pathophysiology which is commonly termed the "cancer-related anorexia cachexia syndrome." The cancer-related anorexia cachexia syndrome (CACS) is felt to result from the interplay between the tumor and the host (Baracos 2000), and most commonly, it is defined among patients with incurable or treatment-refractory malignancies. In contrast to classical starvation, the CACS represents a metabolic derangement which results from more than a decline in caloric intake (Fig. 194.2).

194.4 Altered Resting Energy Expenditure

A cogent example of how CACS differs from starvation is found in assessments of resting energy expenditure (REE). It appears that many cancer patients suffer from a hypermetabolic state, whereas in starvation, metabolism slows. In one study, 66 patients with lung cancer were compared to 33 matched healthy controls. The patients with lung cancer were found to have increased REE and when adjusted for fat-free mass, those with small-cell lung cancer had a more profound increase in REE then those with non-small-cell lung cancer or healthy controls (Staal-van den Brekel et al. 1997).

194.5 Changes in Nutrient Metabolism

Altered carbohydrate metabolism is thought to be part of the cancer-related anorexia cachexia syndrome as well. Many solid tumors produce excess lactate that must be converted to glucose through the liver's Cori cycle. Glucose turnover via the Cori cycle is increased in cachetic cancer patients in comparison to healthy controls (Tisdale 2000). This gluconeogenesis pathway makes inefficient use

of ATP (Inui 2002). Cancer patients with weight loss have been noted to have a 40% increase in hepatic glucose production in contrast to the reduced hepatic production observed in persons with anorexia nervosa (Tayek 1992).

The loss of fat that occurs in many cancer patients does not come as a surprise. The abnormalities of lipid metabolism observed in cancer patients include increased lipid catabolism, decreased lipolysis, and decreased activity of lipoprotein lipase an enzyme that clears triglycerides from the plasma (Inui 2002). There is evidence of further dysregulation in that cancer patients will continue to oxidize fatty acids even in the presence of glucose (Tisdale 2001).

The abnormalities of protein metabolism are perhaps the most striking feature of the cancer-related anorexia cachexia syndrome. In the CACS, there is a profound loss of lean body mass in contrast to the weight loss of classic starvation where the body uses fat to spare muscle tissue. Skeletal muscle biopsies in cachetic cancer patients have shown both decreased protein synthesis and increased protein degradation (Lundholm et al. 1976). Other studies have shown that many of these cancer patients have increased synthesis of secretory, or acute-phase reactants, by the liver (Emery et al. 1984). These observations have led to speculation that perhaps the demand for amino acids to fuel the increased synthesis of acute phase proteins is met by the increased breakdown of skeletal muscle (Inui 2002). Other investigators have suggested that perhaps part of the muscle breakdown in cancer patients may be secondary to a marked decrease in activity levels as it is well known that severe deconditioning leads to sarcopenia (Skipworth et al. 2007). In all likelihood, a combination of both occurs. Further mechanisms leading to abnormal protein metabolism have not been fully elucidated, but multiple mediators have been suggested (Baracos 2000).

194.6 Cytokine Mediators

Cytokines are hormone-like proteins that are produced by a variety of immune cells and play a major role in immune function. Over time, it has been observed that many of the metabolic derangements present in cancer patients are similar to those seen in persons with infection. Since this observation, cytokines have been studied extensively in an attempt to clarify their role in CACS. The cytokines that have been best studied in cancer-associated cachexia include TNF-alpha, IL-1, IL-6, and IFN-gamma. Studies have shown that the cachexia seen in cancer can be reproduced by administration of cytokines to animals. These animals manifest increased rates of protein degradation, decreased protein synthesis, and decreased amino acid uptake, which lead to a decrease in skeletal muscle protein mass (Argiles and Lopez-Soriano 1999). There is also direct stimulation of adipocyte lipolysis through inhibition of lipoprotein lipase (Tisdale 2008). Further studies have shown that these metabolic derangements can be counteracted by administration of monoclonal antibodies that neutralize cytokine activity (Matthys and Billiau 1997).

194.7 Hormonal Mediators

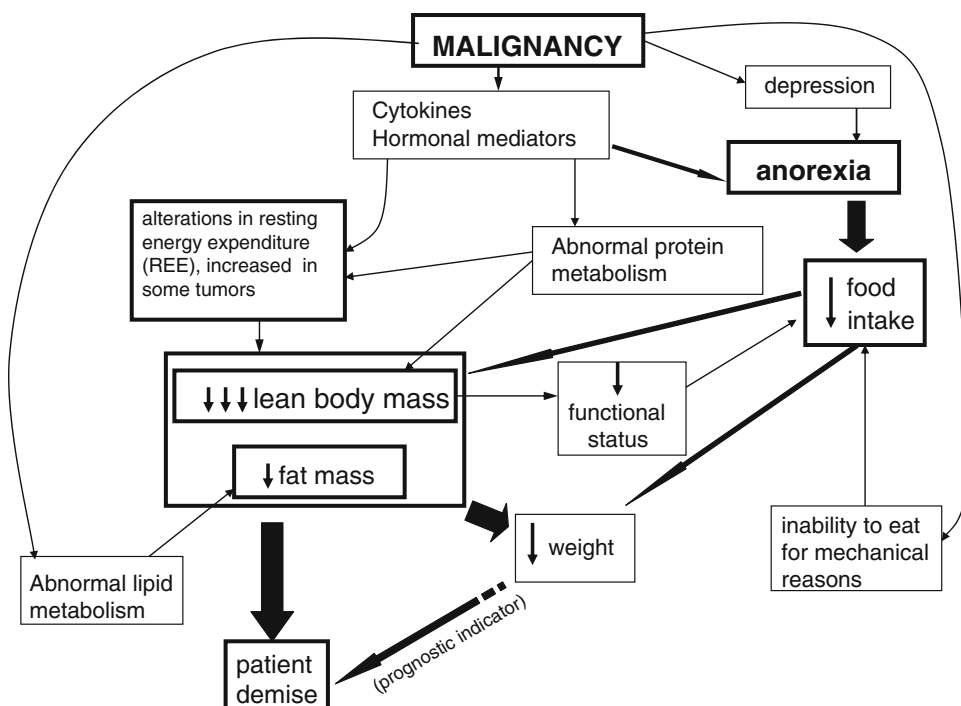
Hormonal mediators including leptin, neuropeptide Y, and the melanocortin pathway have also been named as possible contributors, but further study is needed. Leptin is a hormone secreted by adipose tissue to regulate weight. In healthy individuals, weight loss leads to decreased leptin levels as part of an adaptive response to starvation. Within the brain, decreased leptin levels increase signals to eat and suppress energy expenditure by the body (Inui 2002). In a mouse model, administration of certain cytokines resulted in an increase in serum leptin levels (Sarraf et al. 1997). Neuropeptide Y is a potent orexigenic hormone. In a study of tumor-bearing rats, there was impaired release of this


Fig. 194.3 Pathophysiology of CACS. Advanced malignancy leads to anorexia, weight loss, and patient demise through several interrelated pathways

hormone within the periventricular nucleus (McCarthy et al. 1993). The melanocortin system is a principle regulator of body weight and maladaption of this signaling system has been described in some anorectic states. In one study, rats that were anorectic from prostate cancer increased their food intake and gained weight after receiving a melanocortin receptor antagonist (Wisse et al. 2001). In another study, mice that lacked a melanocortin receptor were resistant to sarcoma-induced anorexia and weight loss despite tumor progression (Marks et al. 2001) (Fig. 194.3).

194.8 Treatment

Multiple studies have focused on remedies for CACS, which have included behavioral interventions, pharmacologic agents, and caloric supplementation. These authors strongly believe that in treating CACS, no one intervention can reverse all aspects of this syndrome and thoughtful one-on-one interactions between the patient and the health care provider are of the utmost importance in helping patients cope.

194.9 Dietary Counseling

A few studies have evaluated the role of dietary counseling in patients with cancer and weight loss. Ovesen et al. looked at 105 cancer patients who were receiving chemotherapy. Half these patients were randomized to receive regular dietary counseling by a trained dietician during the first 5 months of treatment. Patients who underwent dietary counseling did in fact eat more. However, the counseled patients did not increase their weight, live longer, or manifest an improvement in quality of life

(Ovesen et al. 1993). A subsequent meta-analysis by Halfdanarson et al. reviewed five trials of dietary counseling that involved a standardized quality of life measurement. A variety of cancer patients were involved in these trials including patients receiving treatment with both palliative and curative intent as well as patients receiving chemotherapy, radiation therapy, or surgery. Three of these individual trials reported a benefit in quality of life for the patients receiving dietary counseling while two did not. When these five trials were viewed in aggregate, there was only a trend toward benefit in improved quality of life. The authors concluded that there may be certain patients who benefit from such counseling and that the trend toward improved quality of life provides justification for further study (Halfdanarson et al. 2008).

194.10 Treating the Underlying Problem

The National Comprehensive Cancer Network guidelines recommend that the first step in treating cancer-associated anorexia is to diagnose and treat all possible causes of secondary anorexia. As previously described the CACS is complex and multifaceted. It therefore behooves us to manage mechanical problems as feasible, aggressively palliate nausea and vomiting, and consider a trial of metaclopromide, when appropriate, to aid bowel motility. Palliation of pain, diarrhea, and constipation are also important. Depression can certainly affect appetite and should be treated. Some anecdotal reports suggest that mirtazapine or an atypical anti-psychotic agent can lead to weight gain independent of its antidepressant effects. Good symptom palliation is an important aspect of cancer care and may also lead to improved appetite, weight, quality of life, and psychosocial welfare.

Effective treatment of the underlying malignancy can lead to marked improvement in symptoms including anorexia and weight loss. This phenomenon is well recognized by oncologists. Geels et al. evaluated 300 breast cancer patients who reported symptoms and completed quality of life questionnaires. Thirty eight percent of these women reported anorexia during the pretreatment questionnaire and 91.7% of patients who experienced a complete or partial response to treatment reported improvement in their anorexia. Of all the symptoms reported, anorexia was the most likely to improve. (Geels et al. 2000). Unfortunately, the vast majority of patients with metastatic cancer eventually find themselves contending with disease that has become refractory to antineoplastic therapy.

194.11 Pharmacologic Treatment

Multiple agents have been studied for their ability to treat CACS. These have shown varying degrees of success and further agents are being evaluated. To date, corticosteroids and progestational agents have provided the best results.

194.12 Corticosteroids

The landmark study evaluating the role of corticosteroids was that of Moertel and others published in 1974. These investigators randomized 116 patients with advanced gastrointestinal cancer, poor dietary intake, and a life expectancy of less than 2 months to treatment with dexamethasone at either 0.75 mg or 1.5 mg four times a day versus placebo. After 2 weeks, more than half the patients treated with dexamethasone reported increased appetite and greater than a quarter reported increased strength. There was no survival benefit seen in any one group (Moertel et al. 1974). This was followed by three further placebo-controlled studies that showed improvement in appetite in patients with

advanced cancer treated with corticosteroids. Of note, none of these studies reported benefit in terms of weight gain (Loprinzi et al. 1999). One of these studies did report improved quality of life for women with terminal cancer receiving methylprednisolone (Popiela et al. 1989).

The mechanism of action resulting in improved appetite is not known but may involve an effect on inflammation. Many speculate that the benefits patients experience with short courses of corticosteroids may be related to more than just improved appetite as these agents are used for palliation of many other symptoms common in advanced cancer patients including nausea, fatigue, and depression (Shih and Jackson 2007).

Unfortunately, longer-term use of corticosteroids can lead to bothersome side effects including myopathy, ulcers, increased infections, decreased bone mineral density with resultant increased fracture risk, fluid retention, cushingoid features, and adrenal insufficiency.

194.13 Megesterol Acetate

Megesterol acetate is a progestational agent that was noted to cause increased appetite and resultant weight gain in women with breast cancer taking it as anti-neoplastic therapy.

The first large randomized trial evaluating megesterol acetate in patients with CACS was performed by Loprinzi et al. in which 133 patients were randomized to either megesterol acetate or placebo. Sixteen percent of the patients in the megesterol acetate group gained more than 15 pounds versus only 2% (n = 1) in the control group. When evaluating the average rate of weight loss, it was less in the megesterol acetate group at 1.2 pounds per month versus 2.4 pounds per month in the control group (Loprinzi et al. 1990). A later study by this same group showed that the weight gained was primarily due to an increase in adipose tissue and a small amount of fluid gain rather than an increase in lean body mass (Loprinzi et al. 1993b). A subsequent dose finding study suggested that 800 mg daily gave the best benefit to side effect response. The authors suggested that given the potential side effects, starting at a lower dose and increasing as needed would be appropriate (Loprinzi et al. 1993a).

Whether this benefit of weight gain leads to larger benefits in terms of overall survival or quality of life is less clear. A study of megesterol acetate versus placebo in 243 patients receiving chemotherapy for small-cell lung cancer evaluated participant's toxicity, treatment response, survival and quality of life. The megesterol acetate group had less nausea and more weight gain but, also had an inferior response to treatment and showed a trend toward inferior survival. There was no change in quality of life scores over time in either group (Rowland et al. 1996). These results show that despite increases in weight and improvements in appetite, megesterol acetate does not appear to improve survival.

Megesterol acetate has been approved by the US Food and Drug Administration for anorexia and weight loss in persons with AIDS and approved for cancer cachexia in most European countries. It is commonly used for this indication in the USA.

194.14 Megesterol Acetate Versus Corticosteroids

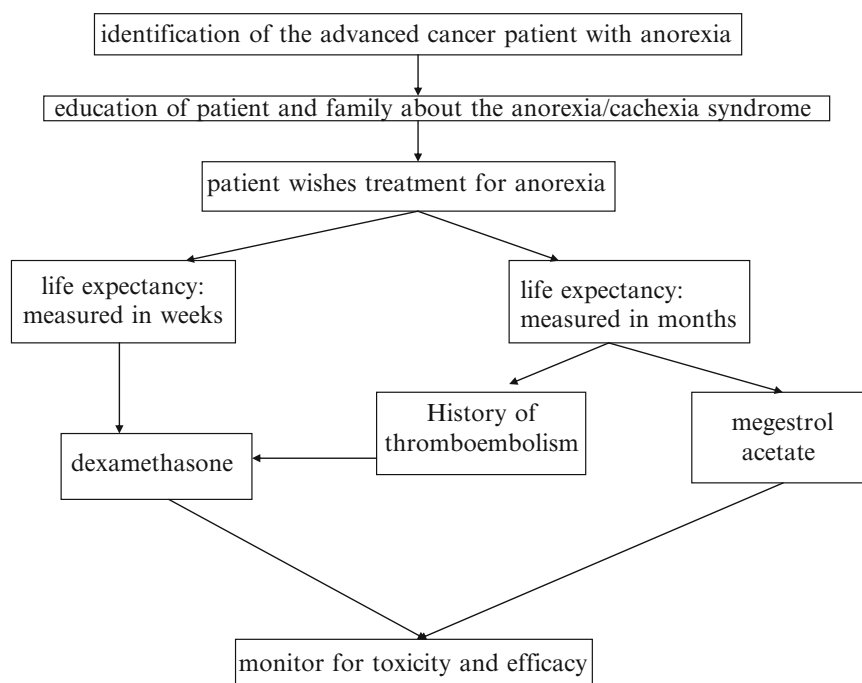
A study comparing megesterol acetate to corticosteroids was performed by Loprinzi et al. in 496 patients with cancer-associated weight loss. Patients were randomized to megesterol acetate 800 mg daily versus Dexamethasone 0.75 mg four times daily versus the anabolic steroid Fluoxymesterone, which was found to be ineffective. Dexamethasone and megesterol acetate had similar efficacy in terms of appetite improvement reported in 60–70% of participants completing questionnaires. There was a trend toward increased weight in the megesterol acetate group as compared to the others. Dexamethasone had more toxicity in terms of peptic ulcers, myopathy, and cushingoid changes. Thirty six percent of


Fig. 194.4 Choosing an appetite stimulant. Guidelines for choosing an appetite stimulant in the appropriate patient

participants receiving Dexamethasone discontinued treatment due to these effects. There was a higher incidence of thromboembolism (5%) in the megesterol acetate group versus 1% in the Dexamethasone group. Twenty five percent of participants in the megesterol acetate group discontinued therapy. There was no significant survival difference between the study arms and no effect on quality of life scores (Loprinzi et al. 1999). This study and its report of side effects have led to the consensus that dexamethasone is the preferred agent in patients with a poor prognosis and short life expectancy. These patients tend to benefit from steroids in terms of increased energy, appetite, and overall well-being over the short term and often do not live long enough to experience the longer-term side effects. Megesterol acetate, on the other hand, is better tolerated over a longer time duration and also shows a trend toward improved weight gain. This agent is contraindicated in persons with a history of thromboembolism (Fig. 194.4).

194.15 Agents Requiring More Investigation

Melatonin is a pineal hormone involved in neuroendocrine regulation and may have anti-TNF activity as well. Some have also suggested that it has "oncostatic" effects (Lissoni et al. 1997). An initial study by Lissoni et al. evaluated supportive care versus supportive care plus melatonin 20 mg nightly in 100 patients with metastatic solid tumors. He found no difference in food intake between the two groups, but less weight loss in the melatonin group. TNF levels were higher in the supportive care alone group (Lissoni et al. 1996).

Thalidomide is a second immunomodulatory agent that has been evaluated in CACS as well as in AIDS-associated cachexia. This drug has been shown to decrease production of TNF in both in vitro and in vivo models (Bruera et al. 1999). In a study of 50 patients with advanced pancreatic cancer and weight loss, thalidomide 200 mg daily was shown to attenuate weight loss and the loss of lean body mass as compared to placebo (Gordon et al. 2005).

Androgens are known for their potential to increase muscle and lean body mass in healthy individuals. Oxandrolone has been found to be beneficial in maintaining weight in patients with catabolic conditions including HIV-associated muscle wasting, burns, trauma, and chronic obstructive pulmonary disease (Orr and Fiatarone 2004). A study comparing Nandrolone to placebo in patients with HIV-associated weight loss resulted in increased lean body mass and improvement in perceived overall health (Storer et al. 2005). None of these agents have been well tested in persons with cancer and further studies are needed to evaluate the longer-term safety and efficacy.

Other agents that may hold promise and are in the early stages of testing include ghrelin, carnitine, and anti-myostatin agents. Anecdotal reports or an understanding of the pathophysiology of cancer-associated cachexia have led to the testing of multiple agents including cannabinoids, fish oils, and anti-TNF agents, none of which have shown benefit in randomized trials.

194.16　Decision to Use an Appetite Stimulant

There is hope that one of these agents will emerge and show a strong benefit for patients with CACS. At the current time, our ability to manage this symptom complex remains limited. Patients and families frequently ask about appetite stimulants and for some patients these agents may be appropriate. We would recommend that the following criteria are met before prescribing an agent: 1) All secondary causes of anorexia and weight loss have been addressed. 2) Patients have been counseled about the side effects and relative benefits of these agents. 3) It is also important to understand the motivation that the patient has for requesting an appetite stimulant and ensure that they not chastise themselves for their inability to eat normally and maintain their weight. For some patients, an in-depth discussion that anorexia and weight loss are not their fault, provides considerable relief (Fig. 194.5).

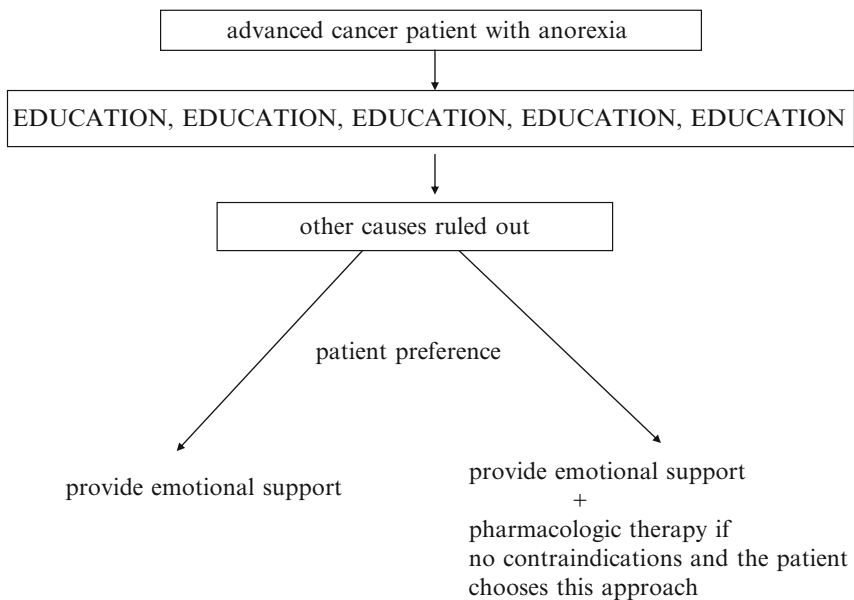

Fig. 194.5 Approach to the patient with advanced cancer and anorexia. This figure highlights the importance of patient education and treating reversible causes of anorexia and weight loss prior to prescribing an appetite stimulant. The choice to use such an agent should be left to the patient, but all patients require emotional support from their health care providers

194.17 Parenteral Nutrition

Patients and families may ask about parenteral nutrition. North American and European registry data from the 1990s indicate that 40% of the nearly 6000 patients receiving home parenteral nutrition were cancer patients. The most common malignancies were gastrointestinal and gynecologic as these often lead to the most common indications for use including bowel obstruction, fistula, or short bowel syndrome (Mackenzie and Gramlich 2008). Studies over the years have shown that this intervention is beneficial only in select circumstances.

A meta-analysis performed by Klein et al. in 1986 was one of the first major studies to lend insight to this question. Their meta-analysis looked at 28 smaller prospective trials of parenteral nutrition in cancer patients. The studies included patients treated with surgery, chemotherapy, radiation therapy, and a single study of no therapy. A pooled analysis of the surgical trials showed a significant decrease in major surgical complications and in hospital mortality which was 50% less than that of the group not receiving such nutritional support. Pooled analyses of patients treated with chemotherapy revealed a nonsignificant decrease in survival and worse response to treatment in the group receiving parenteral nutrition as compared to controls. In patients receiving radiation therapy, there was no benefit in either the parenteral nutrition or control groups in tolerance of treatment or survival. The study group was left to conclude that parenteral nutrition may have a role in surgical patients, particularly those with gastrointestinal malignancies, but probably should not be used routinely in nonsurgical cancer patients (Klein et al. 1986). Further studies have come to similar conclusions about the benefits of parenteral nutrition in select surgical patients with gastrointestinal malignancies. A later meta-analysis by McGeer et al. examined the role of parenteral nutrition in patients receiving chemotherapy. They again found no benefit in favor of nutritional support, but did find that it lead to higher rates of infectious complications (McGeer et al. 1990).

Further studies have examined the role of parenteral nutrition in patients with advanced cancer. Torelli et al. looked at 26 patients with limited life expectancy due to advanced cancer. These patients were receiving parenteral nutrition as an adjunct to medical therapy or as a supportive care maneuver. They found that parenteral nutrition had no bearing on outcome and did not improve the quality of life for the majority of patients who received it (Torelli et al. 1999). Hoda et al. published the Mayo Clinic series of 52 patients with incurable malignancies sent home on parenteral nutrition from 1975–1999. The most common reasons for parenteral nutrition were obstruction, short bowel syndrome, malabsorption, and fistula. Only two patients in this series received parenteral nutrition for anorexia. The median time to death was 5 months after starting parenteral nutrition but, sixteen patients lived for longer than a year. This study suggests that parenteral nutrition may be appropriate for certain very select cancer patients but that it is extremely difficult to predict who these patients might be (Hoda et al. 2005).

An observational study by Orrevall et al. interviewed patients with advanced cancer, and their caregivers, who were receiving parenteral nutrition due to anorexia. In their series, it was out of desperation over poor appetite and weight loss that caused many to turn to parenteral nutrition. This led to decreased conflict over food and gave family members a sense of relief. It also led to improvement in patients' weight, energy, level of activity, and quality of life. These investigators also noted that much of the positive effect that patients and families experienced was due to the support provided by the advanced home care teams that were involved with administering the parenteral nutrition (Orrevall et al. 2004, 2005).

These studies have led many, including these authors, to conclude that parenteral nutrition should not be routinely offered but can be considered only for very select patients. These may include perioperative patients with gastrointestinal malignancies and patients with mechanical problems where starvation is likely to be the cause of death before the tumor-related death occurs. It is also important

Key Features of CACS

Manifestations
- Anorexia
- Weight loss
- Shortened survival
- Weakness and fatigue
- Decreased quality of life
- Anxiety for patients/families
- Strain on relationships

Causes
- Decreased caloric intake
- Cancer and/or its treatment
- Increased resting energy expenditure
- Abnormal nutrient metabolism
- Cytokines and hormonal mediators

Coping Strategies
- Dietary counseling
- Appetite stimulants
- EDUCATION
- Showing empathy
- Refocus on nurturing
- Psychosocial support

Fig. 194.6 Key features of CACS. Summary of key features of cancer-associated anorexia cachexia syndrome and mechanisms for coping

to again point out that cancer-associated anorexia can be a multifaceted problem and unlikely to be remedied by providing caloric support alone. The reason that these select patients may benefit suggests that their weight loss is not completely due to the CACS. Orrevall's small study does raise an interesting question about the benefit of parenteral nutrition for patients with anorexia and also drives home an important point about how patients benefit from further support by health care providers (Fig. 194.6).

194.18 Helping Patients Cope with CACS

As we have previously described, there is no simple solution for this complex problem. For this reason, perhaps, the efforts of health care providers should be focused on how to best help patients and their caregivers to cope.

An observational study by Hopkinson and Corner evaluated 232 patients with advanced cancer receiving home care and examined their responses to CACS. These investigators found that responses ranged from acceptance to self-action. Patients expressed the view that they should be "good patients" in that they should be trying to eat and should also eat certain healthy foods. Some patients took supplements and tried special diets in attempts to be proactive and remain in control. The nurses working with these patients frequently felt that they had little to offer. Some nurses avoided discussing diet because they did not want to bring up a topic that generated anxiety. Other nurses spent time on re-focusing patients towards feeling comfortable with either eating or not eating based upon what was enjoyable to them and not feeling anxious or guilty about the choice (Hopkinson and Corner 2006).

A further observational study by McClement et al. evaluated the response of family members to the anorexia of their loves ones' with advanced cancer. Some caregivers chose a mentality of "fighting back" while others chose a path of "letting nature take its course." She found that, although the families who embraced the mentality of "fighting back" had good intentions, their loved one often became angry or upset by the pressure to eat. The families comfortable with letting nature take its

course would focus their efforts on other nurturing activities or just being present. Many of these patients expressed appreciation for their care and lack of coercion to eat (McClement et al. 2003).

What becomes clear from all of these observational studies is that patients and their families need more then just high-tech interventions (and perhaps they do not need these at all), they need psychosocial support. Orrevall et al. learned that patients receiving HPN benefited greatly from the health care providers who rendered this service, perhaps as much or even more than they did from the nutrition itself (Orrevall et al. 2005).

After conducting interviews with patients and families with advanced cancer, both Holden and Reid stress the importance of education (Holden 1991; Reid et al. 2009). Patients and families should be told that anorexia and weight loss are a part of the process of advanced cancer and something over which they likely have little control. If successful, this will take some pressure off patients and their caregivers so that the latter may refocus on other ways to nurture. Above all, patients and caregivers must have the ongoing support of their health care providers to help find the best way for each patient to contend with anorexia and weight loss in order to maintain the best quality of life possible.

Summary Points

- Anorexia and weight loss are common in patients with cancer.
- CACS has ramifications directly relevant to prognosis and quality of life.
- CACS is a multifactorial process due to altered pathophysiology and secondary processes.
- It is important to treat the underlying malignancy and all secondary causes of anorexia and weight loss as best able.
- Consider pharmacologic, behavioral, or nutritional interventions for select patients.
- Ultimately, it is important to support patients and caregivers in efforts to cope by providing education and reassurance.

Key Terms

Anorexia: The symptom of poor appetite.
Cachexia: Non-volitional loss of weight, and body mass often associated with weakness and fatigue.
Performance status: A rating that attempts to quantify the general well-being of a patient with cancer in order to judge their ability to tolerate treatment.
Quality of life: A person's overall sense of well-being and contentment.
Pathophysiology: The changes in normal bodily functions secondary to disease.
Cytokines: Hormone-like proteins that are produced by a variety of immune cells and play a critical role in cellular communication.
Palliative: Treatment undertaken with the intent of controlling symptoms rather than the disease process.
Corticosteroids: Steroid hormones that are produced in the adrenal gland or synthetically and are involved in several cellular processes. Also used as an appetite stimulant or to palliate a variety of other symptoms.
Megesterol acetate: A progestational agents that can be administered as anti-neoplastic therapy or as an appetite stimulant.
Parenteral nutrition: Intravenous feeding.

Chapter 195
Quality of Life Assessment in Prader–Willi Syndrome

Pietro Caliandro, Graziano Grugni, Domenica Taruscio, Yllka Kodra, and Luca Padua

Abbreviations

BE	Behavior emotional
BP	Bodily pain
CH	Change health
CHQ-PF50	Child Health Questionnaire-Parent Form 50
FA	Family activity
FC	Family cohesion
GBE	Global behavior emotional
GGH	Global general health
GH	General health
MCS	Mental Composite Score
MH	Mental health
MMS	Mini-Mental State
PCS	Physical Composite Score
PE	Parental emotional
PF	Physical functioning
PHS	Physical Score
PSS	Psychosocial Score
PT	Parental time
PWS	Prader–Willi syndrome
QoL	Quality of life
RE	Role – emotional
REB	Role – emotional behavior
RP	Role – physical
SE	Self-esteem
SF	Social functioning
SF-36	Short Form-36
VT	Vitality

195.1 Introduction

Prader–Willi syndrome (PWS) is a neurogenetic disorder, characterized by neonatal hypotonia, mental and motor development retardation, hypogonadism, hyperphagia, morbid obesity, and dysmorphic facial features starting in late infancy or adolescence (Holm et al. 1993). Table 195.1 summarizes the most typical clinical aspects of PWS. The incidence of PWS is estimated to be 1:26,676 and the population prevalence is 1:76,574 (Vogels et al. 2004). The syndrome is caused by the delation of a specific gene in the paternally inherited chromosome 15q11q13 (Goldstone 2004).

Prader–Willi syndrome patients present a complex clinical picture and a consequent increased morbidity and mortality (Butler et al. 2002; Schrander-Stumpel et al. 2004; Thomson et al. 2006). In order to provide good assistance, an early diagnosis and a multidisciplinary approach to the disease are fundamental (Eiholzer and Whitman 2004). The multidisciplinary team involved in the care of Prader–Willi syndrome patients and their families should include several medical and nonmedical professional figures such as child psychiatrists, pediatric endocrinologists, clinical geneticists, orthopedic specialists, educational psychologists, and social workers. But all these professional figures should know what the patient wants and what kind of relationship there is between the traditional clinical outcome measures and the patient's perspective. Over the last 2 decades, clinical researchers emphasized the need for a thorough evaluation of patient's QoL in order to study the impact of chronic illnesses and their treatments on the patient's life (Guyatt et al. 1993).

The need for standardized measures of such items stimulated an extensive and rigorous process, allowing the development of validated patient-oriented instruments (Ware et al. 1994). This new approach may be very useful in the chronic and genetic syndromes involving the physical, emotional, psychological, cognitive, and social aspects of patients' life.

195.2 Concepts on QoL Assessment

QoL of PWS patients has been assessed using validated patient-oriented tools (Caliandro et al. 2007): (1) the Short Form-36 (SF-36) (Apolone et al. 1997) and (2) the Child Health Questionnaire-Parent Form 50 (CHQ-PF50) (Ruperto et al. 2001), according to the patient's age. CHQ-PF50 was used to evaluate patients from 6 to 14 years old, while SF-36 was used in patients older than 14. SF-36 consists of 36 questions covering the general health status of patients (Ware et al. 1994). This questionnaire

Table 195.1 Key features of Prader–Willi syndrome

- Prader–Willi syndrome is a complex syndrome caused by the delation of a specific gene in the paternally inherited chromosome 15q11q13
- The clinical picture is very complex and it needs a multidisciplinary approach
- Neonatal and infantile central hypotonia with poor suck gradually improves with age
- Feeding problems are typical in infancy with the need for special feeding techniques and poor weight gain
- Excessive or rapid weight gain on weight-for-length chart is common after 12 months but before 6 years of age; central obesity occurs in the absence of intervention
- Facial features are distinctive – dolichocephaly in infants, narrow face/bifrontal diameter, almond-shaped eyes, small-appearing mouth with thin upper lip, downturned corners of mouth (three or more required)
- Hypogonadism presents features depending on age
- Global developmental delay before age 6; mild to moderate mental retardation or learning problems in older children
- Hyperphagia/food foraging/obsession with food

provides eight specific categories of physical and emotional scores: Physical Functioning (PF), Role – Physical (RP), Bodily Pain (BP), General Health (GH), Vitality (VT), Social Functioning (SF), Role Emotional (RE), and Mental Health (MH), summarized in two main scores: Physical Composite Score (PCS) and Mental Composite Score (MCS). Very low scores for PCS indicate severe physical dysfunction, distressful bodily pain, frequent tiredness, and an unfavorable evaluation of health status. Very low scores for MCS indicate frequent psychological distress, and severe social and role disability due to emotional problems.

The Child Health Questionnaire (CHQ-PF50) is a generic QoL tool that measures child's physical, emotional, and social well-being with or without disability above the age of 5 years, and it consists of domains representing the most essential components of a child's QoL (Landgraf et al. 1996). The CHQ-PF50 is a parent-completed questionnaire. CHQ-PF50 consists of 50 items covering the general health status of patients with the aim to assess the effects of intervention being a quick and easy QoL measure used in conjunction with other more functionally based outcome measures. CHQ-PF50 provides 15 specific categories of physical and emotional scores (4 specific categories regarding patient's parents: Parental Time (PT), Parental Emotional (PE), Family Activity (FA), Family Cohesion (FC) and others concerning children: Physical Functioning (PF), Role – Physical (RP), Bodily Pain (BP), Global General Health (GGH), General Health (GH), Change Health (CH), Role – Emotional Behavior (REB), Behavior – Emotional (BE), Mental Health (MH), Global Behavior – Emotional (GBE), Self-esteem (SE) summarized into two main scores: Physical Score (PHS) and Psychosocial Score (PSS). Very low scores for PHS indicate severe physical dysfunction, distressful bodily pain, frequent tiredness, and unfavorable evaluation of the health status. Very low scores for PSS indicate frequent psychological distress and severe social and role disability due to emotional problems. Higher CHQ-PF50 scores (0–100) indicate better health.

One of the main differences between the SF-36 and the CHQ-PF50 is that the SF-36 is a patient-oriented questionnaire, while the CHQ-PF50 is a parent-completed questionnaire. Therefore SF-36 is useful only in patients with a good Mini-Mental State (MMS) (with a score higher than 24), and who are able to fill in the questionnaire. The CHQ-PF50, instead, is useful also in patients with an important cognitive impairment because it is a parental form questionnaire and therefore parents are requested to evaluate the QoL of their children.

Both questionnaires must be administered in accordance with standardized methodologies (Padua et al. 1998; Andresen et al. 2000), before any contact with physicians. More details on QoL assessment are available in the Table 195.2.

Table 195.2 Key features of quality of life (QoL) assessment

- The evaluation of patient's quality of life (QoL) is useful to study the impact of chronic illnesses and their treatments on the patient's life
- Different kind of questionnaire assessing QoL are available
- Generic questionnaires assess the general aspects of QoL. The most used tools are the Short Form-36 item questionnaire (SF-36) and the Child Health Questionnaire-Parent Form 50 (CHQ-PF50). The SF-36 is used in adults and the CHQ-PF50 is subjects from 6 to 14 years old
- Disease-specific questionnaires are ones which assess the impact of specific features of a single pathology on QoL. An example is the Boston Carpal Tunnel Questionnaire (BCTQ) specific for carpal tunnel syndrome or the Myasthenia Gravis Questionnaire (MGQ) specific for myasthenia gravis
- Region- or site-specific questionnaires are based on the concept of a single functional unit, such as the upper extremity. The questionnaire Disability of the Arm, Shoulder and Hand (DASH) scores assess the ability of the upper limb
- The QoL questionnaires must be chosen according to the pathology we want to study
- The most useful choice is the association of a generic questionnaire with a disease or site specific questionnaire (when available)

195.2.1 QoL of PWS Patients According to SF-36 and CHQ-PF50 Scores

Both in patients older and younger than 14 years, the physical and mental aspects of QoL are involved when compared with the healthy Italian subjects. In patients older than 14 years old, only the sub-score "Vitality" shows any statistical difference. On the other hand, in patients who were 14 years old or younger, "Bodily Pain" and "Family Cohesion" did not show statistically significant differences when compared with the same scores of the Italian norms. Tables 195.3 and 193.4 report the mean value and, in parenthesis, the standard deviation of the SF-36 and CHQ-PF50 scores. Those data are obtained from a sample of 29 patients (Caliandro et al. 2007). Twenty patients, older than 14 years (mean age 26.45 years; range 15–35; SD 7.54, 13 females and 7 males), were evaluated by SF-36, 9 patients who were 14 years old or younger (mean age 11.67 years; range 5–14; SD 3.00, 4 females and 5 males) were evaluated by the CHQ-PF50.

195.2.2 Correlation Between SF-36 Scores and Clinical Features

The impairment of QoL is mainly influenced by specific clinical aspects. The main score PCS and the sub-score PF are negatively related with the weight at the moment of the observation (respectively p: 0.02, Spearman −0.56 and p: 0.03, Spearman −0.49); as the weight is higher the physical function is more impaired (Figs. 195.1 and 195.2). The sub-score PF is also negatively related with the height (p: 0.02, Spearman –0.53).

GH is positively related to the weight at birth (p: 0.003, Spearman 0.76); as the birth weight is higher, the general health is better.

The main score MCS and the sub-score RE are positively related to birth weight (respectively p: 0.047, Spearman 0.58 and p: 0.02, Spearman 0.64); the mental aspects of QoL are less impaired in patients with a higher birth weight (Fig. 195.3). VT is positively related to the age of patients (p: 0.03, Spearman 0.48).

MH and MCS are lower in patients with characteristic facial features (respectively p: 0.003 and p: 0.003) (Fig. 195.4). MH is also lower in patients with narrow hands with straight ulnar border (p: 0.005) and in patients with osteoporosis (p: 0.02). SF is lower in patients with hypopigmentation (p: 0.048). VT is lower in patients with speech articulation defects (p: 0.01). SF and BP are lower in patients with unusual skill jigsaw puzzles (respectively p: 0.02 and p: 0.007).

195.2.3 Correlation Between CHQ-PF50 Scores and Clinical Features

Comparing CHQ-PF50 and clinical picture, FA and PHS are lower in patients with characteristic facial features (respectively p: 0.04 and p: 0.04) and in patients with decreased fetal movement or infantile

195.3 Conclusion

Prader–Willi syndrome (PWS) is a genetic disorder characterized by extreme obesity accompanied by other, multisystem clinical manifestations encompassing both physical and behavioral/cognitive abnormalities (Holm et al. 1993). A lot of studies focused on the correlations between the phenotypic

aspects and the genetic findings (D'Angelo et al. 2006; Dennis et al. 2006) and on the relationship between phenotype and the risk of cardiac and respiratory problems, fractures, leg ulceration, sleep disorders, and scoliosis (Butler et al. 2002). The multidimensional problems of patients with PWS cannot be treated with a single intervention and benefit from a team approach to optimize outcomes. In this contest, patient's perception about his pathology is important in solving everyday problems and improving patient's QoL.

In the sample of patients older than 14 years, QoL is intensely impaired both in the mental and physical aspects. About the correlation between the QoL assessment and clinical findings in patients older than 14 years, the physical aspects of QoL are mainly influenced by weight; the higher the weight, the worst is QoL regarding the physical aspects. Unexpectedly, a more severe obesity does not cause more impairment of QoL due to emotional aspects. On the other hand, mental aspects are negatively and mainly influenced by the presence of characteristic facial features and positively influenced by the birth weight; the higher the weight at birth, the lower is the impairment of QoL due to mental aspects. A possible explanation is that patients with a higher birth weight have less probability to develop those phenotypic characteristics which mainly cause an involvement of mental aspects of QoL. Indeed, comparing patients with and without characteristic facial features, the second ones, which have a more important involvement of mental aspects of QoL, have a higher birth weight. However, we are not able to explain if the birth weight influences the development of some pathognomonic phenotypic aspects and related emotional problems or if the birth weight is a phenotypic aspect which is influenced, as the facial phenotype, by genetic factors or by mother's alimentation.

Also in patients who were 14 years old or younger, QoL is impaired in both physical and mental aspects. In these patients, BP and Family Cohesion (FC) have no significant differences when compared to the same scores of the Italian norms. In other words, PWS patients do not experience limitations due to pain. As expected, also QoL of parents' is impaired. Indeed, a PWS patient influences parents' time, emotional life and everyday activities (the sub-scores Parental Time – PT, Parental Emotional – PE and Family Activity – FA are impaired), but FC is not influenced.

It is interesting to observe that the sub-score BP is impaired in patients older than 14 years and not impaired in patients younger than 14 years. A possible explanation might be that the CHQ-PF50 questionnaire is filled by parents and they might have some difficulties in evaluating an extremely personal sensation like pain.

In patients younger than 14 years, the physical aspects of QoL are mainly influenced by the presence of decreased fetal movement/infantile lethargy and the presence of characteristic facial features. It is interesting to note that patients with a high MMS have a low self-esteem; they have more knowledge of their body and their pathology and, therefore, need more psychological aids.

195.4 Applications to Other Areas of Health and Disease

The evaluation of Quality of Life (QoL) may be very useful in the chronic and genetic syndromes involving the physical, emotional, psychological, cognitive, and social aspects of patients' life in order to study the impact of chronic illnesses and their treatments on the patient's life. The assessment of QoL is particularly important in diseases with a multi system impairment. The multidimensional problems of patients cannot be treated with a single intervention and benefit from a team approach to optimise outcomes. In this contest, patient's perception about his/her pathology is important in solving every day problems and improving patient's QoL.

Summary Points

- Prader-Willi syndrome (PWS) is a genetic disorder characterized by extreme obesity accompanied by other, multisystem clinical manifestations encompassing both physical and behavioral/cognitive abnormalities.
- In PWS patients older than 14 years, QoL is intensely impaired both in the mental and physical aspects.
- In PWS patients older than 14 years, physical aspects of QoL are mainly influenced by weight; the higher is the weight the worst is QoL regarding the physical aspects. Unexpectedly, a more severe obesity does not cause a more impairment of QoL due to emotional aspects.
- In PWS patients older than 14 years, mental aspects are negatively and mainly influenced by the presence of characteristic facial features and positively influenced by the birth weight; the higher is the weight at birth the lower the impairment of QoL due to mental aspects.
- In patients younger than 14 years the physical aspects of QoL are mainly influenced by the presence of decreased fetal movement/infantile lethargy and the presence of characteristic facial features.
- Patients younger than 14 years and with a high MMS have a low self esteem; they have more knowledge of their body and their pathology and therefore, they need more psychological aids.

Key Terms

- **Short Form-36 (SF-36):** A questionnaire to assess general aspects of quality of life in adult subjects.
- **Child Health Questionnaire-Parent Form 50 (CHQ-PF50):** A questionnaire to assess general aspects of quality of life in children younger than fourteen years old.
- **Mini Mental State (MMS):** A test to evaluate the cognitive ability of subjects.
- **Physical Composite Score (PCS) and Mental Composite Score (MCS):** The two main scores of the SF-36 questionnaire. Very low scores for PCS indicate severe physical dysfunction, distressful bodily pain, frequent tiredness and an unfavourable evaluation of health status. Very low scores for MCS indicate frequent psychological distress, and severe social and role disability due to emotional problems.
- **Physical Score (PHS) and Psychosocial Score (PSS):** The two main scores of the CHQ-PF50 questionnaire. Very low scores for PHS indicate severe physical dysfunction, distressful bodily pain, frequent tiredness and unfavourable evaluation of the health status. Very low scores for PSS indicate frequent psychological distress, and severe social and role disability due to emotional problems.

196.1 Introduction

Oropharyngeal dysphagia results in high mortality, morbidity, and economic costs. Epidemiological data are scant estimates of the prevalence of dysphagia among individuals older than 50 years, and range from 15% to 22% (Lindgren and Janzon 1991). Within health-care institutions, it is estimated that 15% of patients in short-term care hospitals and up to 60–70% of nursing home occupants have feeding difficulties (Groher and Bukatman 1996).

196.2 Etiology and Epidemiology

The prevalence of dysphagia in certain pathologies has been reviewed, with the following incidences: rheumatic disease (rheumatoid arthritis 28%; polymyositis 12–54%), neurological disease (Huntington's disease 95%), multiple sclerosis (frequency varies depending on the location of the lesion, 48–100%), cerebral palsy (27%), stroke (20–100%), Parkinson's disease (50%), and in the general population (20%) (Kuhlemeir 1994).

The prevalence of dysphagia is usually more frequent in neuromuscular disease, tumor or surgery involving the head, neck, and upper limbs (Martin 1991). It is typical for brain pathologies (affected) to affect the oral phase of swallowing, while the esophageal phase is affected by local disease (Table 196.1).

Table 196.1 The relationship between dysphagia caused by specific diseases and the three phases of deglutition

Phase of deglutition	Dysphagia
Esophagus phase	Head and neck tumors, cervical injuries
Pharynx phase	Stroke, multiple sclerosis (multiple), cerebral palsy, amyotrophic lateral sclerosis
Oral phase	Neuromuscular diseases that affect motility or sensibility of muscles related with deglutition

This table shows the affects of dysphagia caused by other named specific diseases on the three phases of deglutition

Neurological disease is the leading cause that must be considered in a patient with dysphagia. Stroke is probably the most frequent cause of dysphagia, affecting the oral phase of deglutition and presenting with aspiration pneumonia as a major complication (Kidd et al. 1995). In patients with acute cerebrovascular injury, bilateral involvement is typically present in dysphagia, it affects mainly the oral apraxia deglutition, where the patient has forgotten how to swallow but retains physical ability to swallow. Dysphagia can be overcome during the course of a spontaneous recovery of the neurological condition; for others it is important to be prepared to undertake deglutition rehabilitation and all appropriate measures to prevent aspiration.

Patients with multiple sclerosis show an alteration in the myelin alterations that trigger the neurological problems in this disease, and the deglutition problems, too. Symptoms of dysphagia and frequency may vary depending on the location of the lesion; these patients are in advanced forms (subsidiary gastrostomy) of supplemented intake (Buchholz 1987). Neurodegenerative diseases such as Parkinson's disease with a dysphagic course are also a frequent cause of aspiration pneumonia (Kirshner 1989). We can also include in this group of neurodegenerative diseases disorders such as Alzheimer's dementia and Huntington's disease.

The motor neuron pathologies are a group of diseases in which there are is decreased numbers of neurons that govern the motor activity in different muscle groups. The most common type is amyotrophic lateral sclerosis, where there are a considerable number of motor neurons in the brain and spinal cord. In patients afflicted with this entity, dysphagia often presents as one of the first symptoms, usually in the first 4–5 months (Negus 1994).

Other diseases affecting the nervous system may also present with clinical dysphagia as a symptom of the worsening of the clinical course of the disease. In infections such as poliomyelitis, residual damage may present as dysphagia of pharyngeal phase. Myotonic dystrophy produces facial and pharyngeal muscle weakness, resulting in a secondary dysphagia. Also in dystonia and dyskinesia (involuntary movements and contractions), if there is involvement of the facial, oral, or lingual palatopharyngeal muscles, then there are problems with swallowing. Closed head injuries and brain tumors can affect neurons that influence the oropharyngeal motility, introducing additional problem such as swallowing disorders.

In addition to the above-mentioned diseases and conditions, it must be remembered that certain drugs affect the mechanism of swallowing through various mechanisms. Thus, there are drugs that lower the pressure of the lower esophageal sphincter (alpha-blockers, anticholinergics, barbiturates, beta-adrenergic, dopamine channel blockers, calcium, nitrates, alcohol, and caffeine), while another group of drugs increases the pressure of this sphincter (antacids, alpha-adrenergic agonists, beta-adrenergic antagonists, cholinergic agonists, and prokinetics). Other drugs may worsen swallowing by altering the level of consciousness (alcohol, antiepileptics, antidepressants, antihistamines, antitussives, antipsychotics, antiemetics, and steroids). Finally, there are drugs that can cause dysphagia secondary to the production of esophagitis (quinidine, aspirin, nonsteroidal anti-inflammatory drugs, vitamin C). The correct evaluation of a patient with dysphagia, therefore, requires not only a neurological history, together with the use of imaging techniques, but also must take into account not only any but all medications being taken by the patient.

196.3 Diagnosis of Dysphagia

In many cases the clinical signs of dysphagia are very obvious, as shown in Table 196.2, with evident symptoms, while at other times the signs are less evident and manifest as indirect symptoms (Table 196.3). In certain situations, it can be difficult to achieve a reliable diagnosis of this entity.

One technique to make a more objective diagnosis of an impairment of the swallowing is video-fluoroscopy with barium (Levis and Kidder 1996). This procedure uses small volumes of high-density barium mixed with food of different consistencies to provide radiographic evidence of oral and pharyngeal swallowing. This technique is not only useful to note the diagnosis of impaired swallowing, but also in planning the therapeutic strategies for these patients. If the patient's diagnosis requires an evaluation of the role of the vocal cords, the technique of choice is endoscopy (Perlman and Van Daele 1993), as this technique allows an excellent assessment of the dynamics and paralysis of the pyriform sinus and valleculae, and also the presence of a delayed onset of the pharyngeal stage.

Another technique used is the determination of pressures obtained by pharyngeal manometry; however this technique is used in research protocols and not in clinical practice (Castell 1993; Klahn and Perlman 1999).

There are times in everyday clinical practice when there are no available techniques for the study of dysphagia; thus the presence of symptoms may be used to both directly and indirectly support the diagnosis in combination with certain techniques of physical examination. The examination of the V nerve is made using a tongue depressor and a small sharp instrument slipped in the facial surface. The VII nerve examination is performed by having the patient smile. The IX nerve exam is conducted by having the patient say "AH," which requires elevation of the palate, it also (uses the reflection of) enables a check of the vomiting reflex by touching the back wall of pharynx with a swab. The vagus and IX nerves were examined by having the patient protrude his or her tongue; tongue lateralization indicates injury of these nerves. It is also necessary to explore the cough reflex and the cognitive level for a full study of the patient's situation; all of these examinations and assessments of the mechanism of deglutition in patients with suspected dysphagia have proven useful in the management of the problem (Odderson et al. 1995).

Table 196.2 Relationship between the clinical symptoms of dysphagia and the three phases of deglutition

Phase of deglutition	Symptoms
Esophagus phase	Vomiting, regurgitation, reflux
Pharynx phase	Stagnant and motionless liquid and solid intake (a lot of) deglutition effort with various food, pain with deglutition, aspiration of food
Oral phase	(Bad) poor control of tongue, reduction in the closed lips, facial muscle weakness, failure to drink from a cup

This table integrates a list of the clinical symptoms of dysphagia with the three phases of deglutition

Table 196.3 A list of the indirect clinical affects on the person of dysphagia

Refusing to eat
Aversion to food
Repeated episodes of pneumonia
Weight loss
Anorexia
Malnutrition
Dehydration

This table provides a list of the indirect clinical affects that are secondary to dysphagia

196.4 Therapeutic Approach to the Problem

Once the patient has been diagnosed with dysphagia, the patient must be nourished in a safe manner, while putting in place different strategies to address the therapeutic swallowing disorders. Treatment of these patients requires a multidisciplinary approach involving radiologists, gastroenterologists, dieticians, nurses, social workers, and a nutritionist to lead the group.

The first priority is to conduct a proper nutritional assessment of the patient to decide the right route of access, so that in patients unable to ingest a minimum of 50% of their caloric and protein requirements by mouth, nutrition should be given by enteral nasogastric tube (NGT) (Fig. 196.1), transpyloric tube (TPT) (Fig. 196.2), percutaneous endoscopic gastrostomy (PEG) (Fig. 196.3), or parenteral access. Usually the NGT tube is used, but if the enteral route is to be used for more than 3 weeks, PEG is indicated (Fertl et al. 1998; Annoni et al. 1998).

Fig. 196.1 Fine bore tube used for enteral feeding. Picture of a fine bore tube used for enteral gastric tube feeding, the most frequent enteral access for enteral nutrition
Fig. 196.2 Transpyloric tube for enteral feeding to the duodenum. Picture of a transpyloric tube which delivers enteral feeds to the duodenum for increase nutrient absorption. Indicated for use in patients with a high risk of aspiration
Fig. 196.3 Percutaneous endoscopic gastrostomy tube (PEG tube). Picture of Percutaneous Endoscopic Gastrostomy tube (PEG tube), indicate for use in patients requiring more than 3 weeks of enteral nutrition
Fig. 196.4 X-ray of chest with gastric tube feeding in situ. Copy of x-ray of chest with gastric feeding tube in situ. Correct position to ensure tube is in the stomach to prevent aspiration should be confirmed by x-ray prior to commencement of feeding

Radiographic (control to assess the right situation of this device must be realized) assessment is often needed (Fig. 196.4). Enteral nutrition has proven its usefulness in a highly prevalent group of patients with dysphagia, such as patients with stroke. It is reported that there was a decrease in mortality at 3 months of using a polymeric formula during 4 weeks after a stroke,

10% versus 30% in the supplemented group (Duncan et al. 1996; Mitchell et al. 1997; Nyswonger and Helmchen 1992).

Patients with oral nutrition intake problems must make an oral nutrition effort in successive stages by changing the texture of food. It should be noted that according to different international guidelines for patients with dysphagia, these patients should receive diets with modification of the texture in a phased way. This means starting with a first phase, in which thick purees are administered, and they are not allowed liquids, including water; a second phase, in which they are allowed some fruit drinks, but not water; a third stage, which includes the previous purees, e.g., eggs, cooked fish, and vegetables; and a fourth phase, which allows any fluid intake and solid food except food which is granular (e.g., corn and rice); the fifth phase is intended to be a return to a normal diet. Taking into account the difference in consistency of food in these stages, the utility of these products is clearly shown to fulfill a function that is not only nutritious, but also to assist in swallowing by changes in the texture of the dish (Hunter 1996).

Therefore, it is assumed that supplementing the diet of these patients with oral lyophilized products will help to achieve better nutrition and therefore a decrease in hospital stay and complications. Sometimes it is impossible to achieve the proper texture of foods in each phase for a given patient, so various companies have marketed nutritional products that have come to form part of a new concept known as "basic food," which adapts and makes changes in food texture and nutrition in an effort to achieve optimal quality of life in patients with these specific nutritional requirements. These new products include first courses, main courses, and desserts; in some of these cases, the products have been lyophilized from natural sources, while retaining their nutritional characteristics with regard to micronutrients (de Luis and Aller 2003). Our group has performed several investigations with these products so as to assess the reconstitution with water (de Luis et al. 2002), along with acceptability to the patient (in terms of different characteristics such as smell, taste, color, and especially texture). In another work, we have compared a group of patients on a soft diet versus a conventional lyophilized diet, and the latter obtained higher scores in all assessed characteristics, especially in terms of excellent texture (de Luis et al. 2001; de Luis et al. 2006a).

196.5 Implications on Quality of Life

Quality of life may be defined as a patient's appraisal of, and satisfaction with, his or her current level of functioning compared with what is perceived to be possible. Evidence regarding the quality of life provides patients with a comprehensible measure of the functional consequences that result from the complex interaction between disease and treatment. Quality of life is impaired in patients with dysphagia and nutrition problems (Fig. 196.5). In some studies, low body mass index, indicating protein caloric malnutrition, was found to negatively influence quality of life in older adults (Crogan and Pasvogel 2003).

Our group has completed a study exploring the influence of nutritional status and oral dietary intake on quality of life in elderly patients with dysphagia (de Luis et al. 2006a). Quality of life (QoF) was assessed using the well-validated SF-36 questionnaire (Brazier et al. 1992). The SF-36 QOL questionnaire is a self-administered questionnaire containing 36 items which takes about 5 min to complete. It measures health on eight multidimensional measures, covering functional status, well-being, and overall health (Table 196.4).

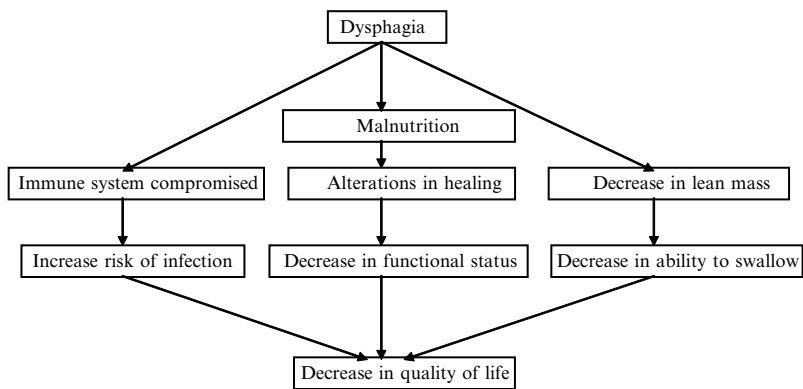
The SF-36 health status questionnaire showed a score of 96.3 ± 9.9 points in our patients with dysphagia (de Luis et al. 2006b). Correlation analysis showed a positive correlation among (the next) certain parameters and the SF-36 score (carbohydrate intake, $r = 0.51$; $p < 0.05$), (protein intake, $r = 0.4$; $p < 0.05$), and (caloric intake, $r = 0.5$; $p < 0.05$). Anthropometric and biochemical parameters did not have any correlation with the SF-36 score. In the multivariate analysis with a dependent variable (SF-36 score), only carbohydrate intake remained in the model adjusted for body mass index, albumin,


Fig. 196.5 The clinical symptoms and wider affects of dysphagia and their relationship to changes in quality of life. Diagram showing the clinical symptoms and wider secondary affects of dysphagia and their relationship with changes in quality of life

Table 196.4 A list of the key features of the SF-36 quality of life measure

Items	36
Domains measured	Physical functioning, role limitation due to physical problems, bodily pain, general health, vitality, social functioning, role limitation due to emotional and mental health problems
Mode of administation	Self-administered
Properties	Designed from the Medical Outcomes Short Form Health Survey. Validated for measuring the health status of people over 14 years of age in terms of their physical and mental health functioning it is provides a subjective measurement of eight of the most common health related concepts which allows useful comparisons of these key health concepts across client groups. It is considered to be a general measure and as such does not focus on specific conditions but has been succesfully validated in a variety of physical and mental health conditions
	An updated version of the SF-36 (the SF36v2) was produced in 1996 this version adopted a five-level response format for respondents
	Abbreviated 12-item SF-12 version is also available

This table provides a list of the key features and pieces of information about the SF36 quality of life measure for those unfamiliar with its use

age, and sex, with an increase of 0.1 (CI 95%: 0.01–0.191) SF-36 point with each 1 g of carbohydrate intake. Our patients with dysphagia had normal weight and body mass index accompanied by a moderate depletion in serum proteins. QOL was related to dietary intake, and was unrelated to anthropometric or biochemical parameters.

Dietary intake in our patients showed low intake of certain vitamins and minerals as well as total energy. However, a proper distribution of macronutrients was observed. Carbohydrate, caloric, and protein intake patterns were positively correlated with quality of life as defined by the SF-36 score. QOL is clearly an important consideration in clinical outcome. In previous studies, no benefit in

quality of life by the administration of oral dietary supplements to patients was detected (Keele et al. 1997). However, Beattie et al. (2000; Isering et al. 2004) reported a benefit on QOL in malnourished patients with oral supplementation.

This study demonstrated a positive correlation among the energy and protein and carbohydrate intake patterns with quality of life. This association does not indicate a direct relationship, but a good nutritional status is likely to improve the quality of life. We recommend further studies, particularly cross-sectional and intervention trials are required in this area. This study is the first to show a correlation between quality of life and carbohydrate intake in a multivariate model. A cross-sectional study (Demark-Wahnefried et al. 2004) reported that the consumption of a diet rich in fruits and vegetables was associated with higher levels of physical functioning and quality of life among older cancer patients.

Ponzer et al. (1999) reported that half of the elderly women with hip fractures displayed signs of protein-energy malnutrition and this was associated with a low quality of life. No relation was detected between anthropometric and biochemical parameters and quality of life in our population. However, in the study of Crogan and Pasvogel (2003), low BMI, indicating protein-caloric malnutrition, was found to negatively influence the quality of life in nursing home patients. Further studies are needed in this topic area to elucidate these interesting relationships.

196.6 Applications to Other Areas of Health and Interest

This area of health care has considerable implications for other health specialists (Fig. 196.6), for example:

1. Radiologists, to help with the diagnosis of these types of patients with the newly emerging techniques such as videofluroscopy with barium.
2. Gastroenterologists who need to pursue enteral access to enteral nutrition (transpyloric tubes or percutaneous endoscopic gastrostomy).

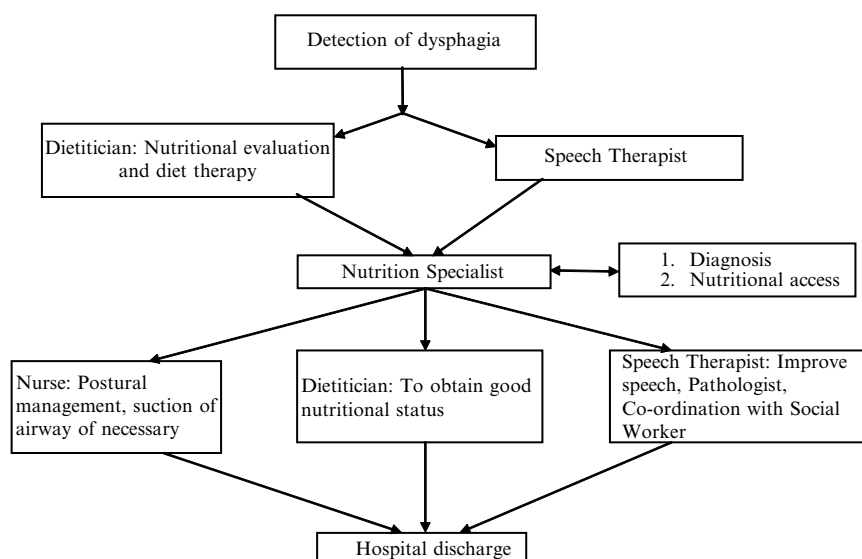

Fig. 196.6 The specialists and their role in the treatment of the person with dysphagia. Diagram showing the different specialists working within dyspaghia treatment and their role in the diagnosis and treatment of the person with dysphagia

3. Dieticians, for assessing the right dietary intake and to improve the different phases of oral diet.
4. Social workers, to improve the quality of life after hospital discharge.
5. Speech specialists, to improve language recovery after neck surgery.

Summary Points

- Dysphagia is a nutritional problem of first order in a negligible proportion of patients; treatment requires a multidisciplinary approach in which a nutrition specialist plays an important role.
- There are new diagnostic techniques (videoflouroscopy with barium) that are necessary (for knowing balancing exploration) examination with conventional clinical techniques that will enable us to make a better diagnosis of the patient.
- It is also necessary to take into account lyophilized nutritional products that can improve the recovery of these patients.
- Some studies have demonstrated that the quality of life in this type of patients is related to dietary intake, and could be improved with nutritional supplementation.

Definition of Key Terms

Aspiration pneumonia: A type of lung inflammation resulting from the aspiration of food, liquid, or gastric contents into the upper respiratory tract.

Apraxia: A group of cognitive disorders characterized by the inability to perform previously learned skills that cannot be attributed to deficits of motor or sensory function. The two major subtypes of this condition are ideomotor (see apraxia, ideomotor) and ideational apraxia, which refers to loss of the ability to mentally formulate the processes involved with performing an action. For example, dressing apraxia may result from an inability to mentally formulate the act of placing clothes on the body. Apraxias are generally associated with lesions of the dominant parietal lobe and supramarginal gyrus.

Dysphagia: Difficulty in swallowing which may result from neuromuscular disorder or mechanical obstruction. Dysphagia is classified into two distinct types: oropharyngeal dysphagia due to malfunction of the pharynx and upper esophageal sphincter; and esophageal dysphagia due to malfunction of the esophagus.

Enteral nutrition: Nutritional support given via the alimentary canal or any route connected to the gastrointestinal system (i.e., the enteral route). This includes oral feeding, sip feeding, and tube feeding using nasogastric, gastrostomy, and jejunostomy tubes.

Gastrostomy: Creation of an artificial external opening into the stomach for nutritional support or gastrointestinal compression.

Quality of life: A generic concept reflecting concern with the modification and enhancement of life attributes, e.g., the physical, political, moral, and social environment; the overall condition of a human life.

197.1 Introduction

The body mass index (BMI) is calculated by dividing weight in kilograms, by height in meters squared, using the following equation: BMI = weight (kg)/height^2 (metres^2). The ideal BMI of an adult is 20 to 24.9. Individuals with BMI of 25–29.9 are considered overweight. Obesity is defined as a chronic condition associated with a BMI of 30 or more, and results in increased morbidity and mortality (Table 197.1). The World Health Organization (WHO) classifies obesity into three categories (Table 197.2; Ellison and Ellison 2008).

Obesity epidemic has reached alarming levels in the world. In the United States, two thirds of adults are overweight, one third are obese (Pohl et al. 2006), and approximately 5% of the population are morbidly obese (DeMaria 2007). Obesity and associated medical conditions cost the health system in the United States a staggering US$100 billion per year (Ellison and Ellison 2008), which is roughly equal to 10% of the medical expenditure (Livingston and Fink 2003). The socioeconomic impact of the obesity epidemic is similar to that from poverty, smoking, or alcohol abuse (Peter et al. 2005).

According to the Foresight Report in 2007, the United Kingdom has the fastest increase in the disease in Europe, with prevalence rates comparable to the United States. Three quarters of the

Table 197.1 Key features of obesity

1.	Obesity is a complex multifactorial chronic disease in which several factors interplay in poorly understood mechanism, resulting in physical, social, and psychological impairments.
2.	Genetic, hormonal, psychological, social, and behavioral factors such as dietary habits and physical inactivity are the major players in the development of obesity.
3.	Obesity carries significant risks to the health, leading to physical comorbidities (e.g., diabetes mellitus), psychological comorbidities (e.g., depression), and social impairments (e.g., social isolation).
4.	The prevalence of obesity in the world has been steadily rising.
5.	Treating obesity and obesity comorbidities is expensive. In the USA alone, obesity costs the health system US$100 billion per year.
6.	Nonsurgical approach of behavioral modification interventions and pharmacotherapy will fail in 90% of obese patient within 5 years. Bariatric surgery provides the only effective and sustainable approach to treat morbid obesity.
7.	Obesity has a major impact on quality of life that has the potential to improve with treatment.

This table lists the key facts of obesity including the basic concept of obesity, mechanisms of developing obesity, health risks of obesity, cost of obesity, treatment of obesity and quality of life in obesity

Table 197.2 WHO classification of obesity

Class	Description	BMI (kg/m^2)
Class one	Mild obesity	30–34.9
Class two	Severe obesity	35–39.9
Class three	Morbid obesity	≥40

This table lists WHO classes of obesity

population are overweight, and one quarter are obese. Obesity costs the UK economy UK£7 billion and the NHS UK£2 billion per year. It is expected that obesity will cost the UK economy UK£45 billion and the NHS UK£6.5 billion in 2050 (Butland et al. 2007).

197.2 Etiology

Obesity is a complex multifactorial disease in which genetic, psychological, social, and behavioral factors such as dietary habits and physical inactivity interact in a poorly understood mechanism (Pohl et al. 2006). Other factors currently under investigation, which may be responsible for obesity and obesity comorbidities, include chronic inflammatory state, gut hormones modulation, and calcium and vitamin D interactions (Major et al. 2008).

The familial tendency of obesity, high concordance for obesity in identical twins and the increased risk of obesity in certain ethnic groups may indicate a genetic predisposition for obesity (Pohl et al. 2006). Obesity genes have been isolated, which may explain why the nonsurgical treatment of obesity will not provide significant and sustainable weight loss for more than a year (Balsiger et al. 1997; McTigue et al. 2003).

Binge eating is rapid consumption of a large amount of food. Grazing is eating smaller amounts of food continuously throughout the day. Chronic low-grade anxiety may manifest as grazing, meanwhile binge eating may result from more intense emotions such as anger (Glinski et al. 2001). Behavioral studies revealed three eating patterns in obese patients: sweet eaters (consumption of food high in calories such as fat and sugar), volume eaters (consumption of large portions), and sedentary lifestyle (lack of exercise and physical activity).

197.3 Obesity Comorbidities

In morbidly obese patients, the prevalence of diabetes mellitus, hypertension, high cholesterol, arthritis, and poor general health is higher compared to normal weight individuals (Table 197.3; Gould et al. 2006). An overweight person, with a BMI of over 25, will have higher risk of diabetes mellitus compared to those with a BMI of less than 25 (Colquitt et al. 2005). It is estimated that in obese patient, for every 1 kg increase in weight, the risk of diabetes increases by 4.5% (Wolf and Colditz 1998). The risk of metabolic syndrome consisting of insulin resistance, hypertension, and hyperlipidemia is higher in an overweight population, leading to increased risk of heart disease and stroke (Pohl et al. 2006). The lifelong risk of hypertension will double as the BMI increases from 25 to 35 (Presutti et al. 2004). Obesity is associated with increased risk of a number of malignancies including breast, colon, prostate, endometrial, kidney, and gallbladder (Colquitt et al. 2005; Pohl et al. 2006).

Obesity is associated with increased risk of death (Fig. 197.1; Calle et al. 2003). Obesity results in more than 400,000 deaths in the United States each year (DeMaria 2007), which is second only to

Table 197.3 Obesity-related comorbidities

Metabolic: Type 2 diabetes mellitus, hyperlipidemia, metabolic syndrome
Cardiovascular: Hypertension, coronary artery disease, peripheral vascular disease
Respiratory: Sleep apnea, asthma
Neurological: Stroke
Hematological: DVT, PE
Gastrointestinal: Fatty liver, cirrhosis, gallbladder disease, gastroesophageal reflux disease (GORD)
Musculoskeletal: Osteoarthritis, low back pain, disc disease
Dermatological: Dermatitis
Increased risk of cancer and cancer related deaths
Gynecological: Dysmenorrhea
Obstetrics: Preeclampsia
Infertility
Poor health related quality of life
Psychological: Depression, anxiety

This table lists some of the commonly encountered obesity comorbidities

Fig. 197.1 Relationship between BMI and mortality. The diagram shows positive linear relationship between BMI and mortality

smoking as a cause of death (Presutti et al. 2004). It is predicted that obesity is likely to overtake smoking as the leading cause of death (Mokdad et al. 2004; Gould et al. 2006). Morbidly obese patients may suffer from a 22% reduction in their life expectancy, which is equivalent to the loss of approximately 12 years of life (Buchwald et al. 2004).

197.4 Bariatric Surgery

Modest weight reduction has been shown to have beneficial effect on the cardiovascular system, cholesterol level, and blood sugar (Table 197.4; Colquitt et al. 2005). Clinical trials showed that behavioral changes result in 4% of weight loss compared to 8% with pharmacotherapy (Matarasso et al. 2007; Wee 2009), and 90% of obese patient treated nonsurgically will relapse within 5 years (Salem et al. 2005). Bariatric surgery has been shown to be more effective than the nonsurgical approach, and weight reduction is sustainable beyond 1 year (McTigue et al. 2003). Bariatric surgery also led to resolution or improvement of obesity comorbidities in a substantial majority of patients and produced a significant reduction in mortality (Table 197.5; Buchwald et al. 2004; Sjostrom et al. 2004, 2007; Gould et al. 2004; DeMaria 2007; Ashrafian et al. 2008).

Table 197.4 The effects of 10 kg weight loss

10 mmHg reduction in systemic blood pressure
20 mmHg reduction in diastolic blood pressure
91% reduction in angina symptoms
33% increase in exercise tolerance
10% reduction in cholesterol
15% reduction in LDL
30% reduction in triglycerides
8% increase in HDL
30–50% reduction in fasting blood sugar
15% reduction in glycosylated hemoglobin (Hb A_{1c})
50% reduction in the risk of developing diabetes
20% reduction in mortality
30% reduction in diabetes-related deaths
40% reduction in obesity-related cancer deaths

This table demonstrates the effects of 10 kg weight reduction on the cardiovascular system, cholesterol level, blood sugar and mortality

Table 197.5 Outcome of bariatric surgery

The measured outcome	Percentage (%)
Excess weight loss	61.2
Diabetes mellitus resolved	76.8
Diabetes mellitus resolved or improved	86.0
Metabolic syndrome resolved	80.0
Hypertension resolved	61.7
Hypertension resolved or improved	78.5
Hypercholesterolemia improved	70.0
Obstructive sleep apnea resolved	83.6
Obstructive sleep apnea resolved or improved	85.7
GORD resolved or improved	87.5
Mortality reduction	31.6–53

This table demonstrates bariatric surgery outcome in terms of resolution or improvement of obesity comorbidities

Bariatric surgery has been traditionally classified according to the mechanism of action into restrictive (e.g., gastric balloon, gastric band, sleeve gastrectomy, vertical banded gastroplasty), malabsorptive (e.g., biliopancreatic diversion – Scopinaro procedure, duodenal switch) or restrictive–malabsorptive (e.g., gastric bypass; Fig. 197.2; Buchwald 2002; Gould et al. 2006). Many of these procedures can be performed laparoscopically, safely and effectively (Nguyen et al. 2005). National guidelines recommend bariatric surgery for individuals who have a BMI of 40 or more, or a BMI of 35 or more and suffer from obesity comorbidity. Other requirements for surgery include failure of the medical management and the ability to understand the consequences and risks of surgery (Brolin 2002; Presutti et al. 2004; Colquitt et al. 2005; Anon. 2006; DeMaria 2007).

Bariatric surgery is contraindicated in patients suffering from active substance abuse, and uncontrolled major psychiatric disorder (Brolin 2002; Presutti et al. 2004). Extremes of age are not a contraindication to bariatric surgery (Peter et al. 2005; Treadwell et al. 2008). Complications specific to bariatric surgery may arise early in the postoperative period or later, months or years after the operation (Table 197.6; Buchwald et al. 2004; Presutti et al. 2004; Colquitt et al. 2005; Gould et al. 2006; DeMaria 2007; Ellison and Ellison 2008).
Fig. 197.2 Demonstration of gastric band and gastric bypass. Demonstration of the commonly used bariatric procedures: (**a**) Gastric band and (**b**) gastric bypass

Table 197.6 Complications recorded following different bariatric procedures

Complications (bariatric procedure)	Percentage (%)
Band slippage (Lap-band)	13.7
Wound infection (Gastric bypass)	3–6
Incisional hernia (Gastric bypass)	0.5–8.6
Bowel obstruction (Gastric bypass)	2
Anastomotic leak (Gastric bypass)	1
Operative mortality for purely restrictive procedure	0.1
Operative mortality for gastric bypass	0.2–0.5
Operative mortality for biliopancreatic diversion	1.1

This table lists some of the commonly seen complications following bariatric surgery

197.4.1 Overview of Health-Related Quality of Life in Bariatric Surgery

Health is defined by the World Health Organization (WHO) as a state of complete physical, psychological, and social well-being. Therefore, quality of life assessment should measure the functioning and well-being of the physical, mental, and social aspects of one's life (Mathus-Vliegen and de Wit 2007). Obesity has the potential to adversely affect the quality of life. Accordingly, attention needs to be placed to understand the health issues from the patient perspective; to be able to evaluate the patients' subjective experience of symptoms and their impact on quality of life. The results of studies in which patients' experiences and perspectives have been evaluated will help the clinicians to better understand that obesity and bariatric surgery outcomes are important to the patient. Consequently, resources can be directed toward treatments most valued by patients (Reaney et al. 2008).

197.4.2 Quality of Life Versus Health-Related Quality of Life

There is no universally accepted definition (Foster 2006; Costanza et al. 2008) or measurement (Costanza et al. 2008) of quality of life. One simple definition of quality of life is emotional, social, and physical well-being; spiritual satisfaction; and ability to function in the ordinary tasks of living (Livingston and Fink 2003; Fallowfield 2009). Quality of life is subjective, multidimensional, and dynamic. The subjectivity of quality of life arises from the fact that each person rates his or her own quality of life from a unique self-perspective, based on his or her own feelings, experiences, and priorities. Each person's assessment of their own quality of life will change over time, depending on their priorities, experiences, and circumstances in a given time, which explains the dynamic property of quality of life (Reaney et al. 2008). The multidimensional aspect subdivides into health-related and non-health- or environment-based domains (Table 197.7). The domains measured by health-related quality of life have the potential to improve with treatment. On the contrary, the domains of non-health quality of life, which can adversely affect health, are unlikely to improve with the appropriate medical care (Spilker and Revicki 1999).

Health-related quality of life consists of health status and health perception. Health status measures the degree of well-being or illness by measuring the functional impairment, symptoms, and occasionally objective measurement of the signs. Health perception reflects the patients' perception of their condition or treatment and its effects. It is the more difficult of the two components to measure, as it relies on patients' subjective assessment. A health-related quality of life instrument should produce meaningful data by displaying satisfactory psychometric criteria such as validity, reliability, specificity, sensitivity, and responsiveness to change. Validity is the extent to which the items in an instrument assess all relevant aspects of targeted concepts. Content validity is a fundamental concept of the instrument's validity, as there is no point saying that an instrument has excellent reliability and sensitivity if it does not measure what it is supposed to measure (Reaney et al. 2008).

Table 197.7 Examples of the domains measured in both types of quality of life

Health-related quality of life	Nonhealth-related quality of life
Functional status e.g. the ability to dress	Environment, e.g., quality of water
Mental health (psychological) and emotional well-being, e.g., depression	Personal resources, e.g., capacity to form friendships
Social engagement and occupational ability, e.g., engagement in activities	
Physical state and symptom state, e.g., pain	

This table shows examples of the different domains or aspects of life measured in health related quality of life and non health related quality of life

197.4.3 Applications to Other Areas of Health and Disease

Bariatric surgeons often make implicit subjective judgments on patients' quality of life; however, few of them will use explicit objective assessment of the quality of life by using health-related quality of life instruments. In addition, when health-related quality of life has been recorded as secondary endpoint of clinical trials, results have rarely modified the overall interpretation of the trial (Contopoulos-Ioannidis et al. 2009).

Obesity carries detrimental effects on the quality of life through physical, psychological, and social impairments (Fig. 197.3). Potential domains of health-related quality of life that might be adversely affected by obesity are illustrated in a proposed conceptual framework (Fig. 197.4).

197.4.4 Health-Related Quality of Life Instruments Used in Bariatric Research

It is important to differentiate between generic health-related quality of life instrument and condition-specific instrument. For example, obesity-specific instrument measures the impact of obesity and weight loss on the individual's health-related quality of life. In bariatric surgery, objective measurement of weight loss has been the standard common practice; nevertheless, subjective assessment of health related quality of life has been less standardized.

A systematic literature review examined instruments used to assess health-related quality of life in bariatric patients, and analyzed their suitability with reference to a proposed conceptual framework.

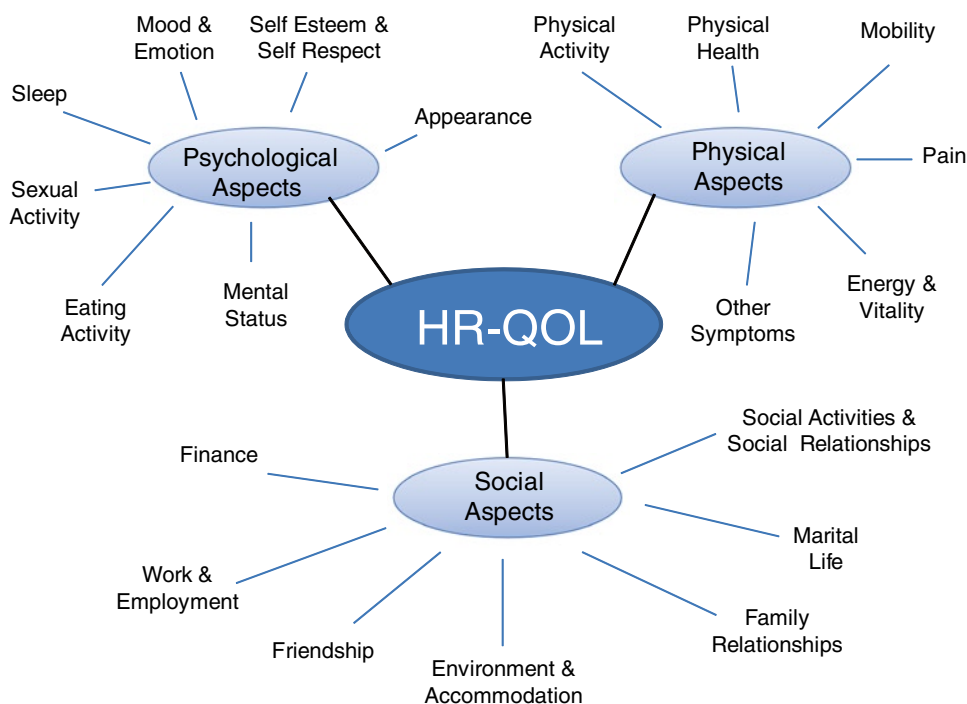
**Fig. 197.3** Relationship between obesity, obesity comorbidities, and quality of life. The graphical model illustrates a proposed relationship between obesity and the physical, psychological and social comorbidities. The demonstrated vicious cycle clearly carries detrimental effects on the health related quality of life. The various etiologic factors contributing to the development of obesity are also shown in this model


Fig. 197.4 A proposed conceptual framework of domains of bariatric-specific quality of life. A proposed conceptual framework demonstrates the potential domains or aspects of health related quality of life that might be adversely affected by obesity, obesity comorbidities and bariatric surgery

The framework identifies 20 fundamental domains of health-related quality of life pertinent to bariatric patients, which are almost equally distributed among the three main aspects of the framework; namely: the physical aspects (six domains), the psychological aspects (seven domains), and the social aspects (seven domains) (Fig. 197.4). The framework provides better insight into the problems of obesity, and equally important, a window to explore the patient experience after the operation; whether that experience was as good as anticipated (e.g., weight loss or resolution of the comorbidities) or bad (e.g., complications).

Generic health-related quality of life instruments contain many irrelevant items and overlook significant pieces of information. Obesity-specific instruments, on the other hand, do not include all the relevant domains important to the bariatric patient (Table 197.8). Therefore, the currently available instruments, whether generic or obesity-specific, will underestimate the full impact of obesity and bariatric surgery on health-related quality of life. This fact has been acknowledged by bariatric researchers, as they administered more than one health-related quality of life instrument in their studies, which is time-consuming, will increase the number of irrelevant items, and still will not pick up all the important domains (Reaney et al. 2008).

197.4.5 Generic Health-Related Quality of Life Instruments

There are hundreds of health-related quality of life instruments and patient-reported outcome instruments; however, the most commonly used instruments in bariatric surgery are SF-36 and EQ-5D.

Table 197.8 The domains of the commonly used health-related quality of life instrument in bariatric surgery

Aspect of life		Generic instrument					Obesity-specific instrument						
		SF-36	EQ-5D	NHP	WHOQL	MANSA	BAROS	IWQOL	OSQOL	HRQL	OWLQOL	OAS-SF	SOS

	Family relationships	P			P	P							
	Environment/ accommodation				P	P							
	Friendship	P			P								
	Work				P	P	P	P		P			
	Finance				P	P							

This table compares commonly used health related quality of life in bariatric surgery against the domains in the proposed conceptual framework. The table clearly shows that these instruments are lacking important domains as informed by the framework

The Short Form (36) Health Survey (SF-36) is one of the most commonly used generic health-related quality of life instruments, which has been used literally in thousands of studies (Livingston and Fink 2003). Health economics use it as a variable in the quality-adjusted life year (QALYs) calculation to determine the cost-effectiveness of a health treatment. SF-36 instrument consists of 36 validated items distributed among eight scaled domains of vitality, physical functioning, bodily pain, general health perceptions, physical role functioning, emotional role functioning, social role functioning, and mental health (Anon. 2009).

EuroQoL (EQ-5D) is a commonly used, validated, short, generic health survey instrument, composed of five items including mobility, self-care, usual activities, pain/discomfort, and anxiety/depression. It provides a single index value that can be used in clinical and economical evaluation of health care (Anon. 1990). World Health Organization Quality Of Life (WHOQOL 100) assesses generic health-related quality of life over a 2-week recall period. It includes 100 items which have been reduced to 26 validated items in WHOQOL-BREF instrument, covering four domains of physical health, mental health, social relationships, and environment (Anon. 1998).

197.4.6 Obesity-Specific Quality of Life Instruments

To evaluate health-related quality of life of a specific condition or disease, the use of condition specific instrument is preferable to a generic instrument, because it will provide better psychometric properties, namely, content validity. In addition, the attribution factor is better in condition-specific instrument. This concept can be explained by the following example: When using generic instruments, obese patients will rate their general health, sleep, social activity, etc. without direct reference to obesity, which will make the rating susceptible to external influence from other conditions or factors. However, the use of obesity-specific instruments will filter out external influences as it will only rate the impact of obesity (Reaney et al. 2008).

Despite the increased recognition of the advantages of condition-specific instruments and the limitations of generic instruments, relatively few obesity-specific and bariatric-specific instruments have been developed and are ready for use. Moreover, their use in bariatric surgery has not become a frequent practice. Bariatric Analysis and Reporting Outcome System (BAROS) evaluates the results of bariatric surgery by analyzing three domains: weight loss, changes in comorbidities, and health-related quality of life. The quality of life instrument used in BAROS is the validated quick six-item questionnaire (Moorehead et al. 2003).

Impact of Weight on Quality of Life (IWQOL) has 74 items developed at Duke University to measure eight domains of health, social interpersonal interaction, work, mobility, self-esteem, sexual life, daily living activities, and comfort with food (Kolotkin et al. 1995; Mathus-Vliegen and de Wit 2007). There are some concerns regarding its reliability and validity (Livingston and Fink 2003). The IWQOL has been reduced to 31-item psychometrically sound and clinically sensitive instrument (Kolotkin et al. 2001). Obesity-Specific Quality of Life (OSQOL) is a validated 11-item instrument covering four domains of physical state, vitality, and desire to do things; relations with other people; and psychological state (Le Pen et al. 1998; Mathus-Vliegen and de Wit 2007).

Health-related Quality of Life (HRQL) is a validated 55-item instrument looking at five domains of general well-being, health distress, and depression, self-esteem with three major levels of functioning (self-regard, physical appearance, and work productivity), physical and social activities (Mathus-Vliegen et al. 2004; Mathus-Vliegen and de Wit 2007). Unfortunately, this lengthy, time-consuming instrument is unreliable when administered serially on patients with stable weighs (Livingston and Fink 2003). Obesity and Weight Loss Quality of Life Instrument (OWLQOL) and Weight-Related

Symptom Measure (WRSM) has two parts: part one records the patient's feelings about their weight, including 17 items, and part two records 20 items about weight-related symptoms and how much they bother the patient (Niero et al. 2002). Both have been shown to display good internal consistency, test–retest reliability, and convergent validity (Mathus-Vliegen and de Wit 2007).

Obesity Adjustment Survey is an instrument with a huge collection of 95 items from the Mental Health Inventory, the Sickness Impact Profile, and the Eating Inventory, which was condensed into a shorter 20-item survey (Butler et al. 1999; Livingston and Fink 2003). Obesity Adjustment Survey Short Form (OAS-SF) is a sensitive and valid measure of obesity, though it is limited, as it only measures psychological distress aspect of health-related quality of life (Butler et al. 1999; Livingston and Fink 2003; Mathus-Vliegen and de Wit 2007). The Bariatric Quality of Life Index (BQL) is a 30-item measure of well-being in bariatric surgery patients, which is a validated instrument ready for clinical use (Weiner et al. 2005). Obesity-Related Well-Being Scale (ORWELL 97) questionnaire is a simple, valid (Mathus-Vliegen and de Wit 2007), and reliable measure of obesity health-related quality of life, which can be used in current clinical practice. It consists of measuring two subscales: ORWELL 97–1, which is related to psychological status and social adjustment, and ORWELL 97–2, which is related to physical symptoms and impairment (Mannucci et al. 1999).

197.5 Conclusion

Various aspects of the morbidly obese patients' life can be adversely affected, though much remains to be understood to be able to measure it scientifically and accurately. Most of the bariatric literature either did not report the quality of life outcome, or the quality of life outcome has not been given the appropriate weight and importance. Numerous generic and obesity-specific instruments have been developed and used on bariatric patients over the years; nevertheless, none of them proved to be without limitations. In particular, the content validity of the used instruments, which is a vital element when it comes to deciding the type of instrument to be used, has been below the standards. Obese patients need to be given the opportunity to decide the severity of impairment on their quality of life, based on their own experience and criteria. Only then the full impact of morbid obesity and bariatric surgery can be assessed. A proposed conceptual framework detailing all the pertinent domains can be used to develop a new bariatric-specific instrument. Such an instrument will display excellent content validity and cover all the potential aspects that might be impacted by morbid obesity and bariatric surgery.

Summary Points

- *Obesity* is a complex and poorly understood multifactorial chronic condition associated with a BMI of 30 or more, and results in increased morbidity and mortality. The World Health Organization classifies obesity into severe obesity with BMI of 35–39.9 and morbid obesity with BMI of 40 or more.
- *Obesity* carries significant risks to the live of affected individual including physical, psychological, and social *comorbidities.* Higher BMI carries higher risks to health, to the extent that an almost linear relationship exists between the BMI and mortality.
- *Prevalence of obesity* in the world is on the rise, with no signs of slowing. The numbers are expected to double every 5–10 years if no active measures are instituted immediately. Obesity costs the health system in the United States a staggering $100 billion per year.

- *Nonsurgical approach* to induce weight loss in obesity, consisting of behavioral modification interventions (diet, physical exercise, and lifestyle change) and pharmacotherapy, will fail in 90% of patients within 5 years. *Bariatric surgery* provides the only effective and sustainable approach to treat morbid obesity and reverse its adverse effects.
- Bariatric procedures may be restrictive (e.g., gastric balloon, gastric band, sleeve gastrectomy, vertical banded gastroplasty), malabsorptive (e.g., biliopancreatic diversion – Scopinaro procedure, duodenal switch), or restrictive–malabsorptive (e.g., gastric bypass).
- There is no universally accepted definition or measurement of *quality of life.* However, it can be looked at as a subjective, multidimensional, and dynamic measurement of an individual's emotional, social, and physical well-being; spiritual satisfaction; and ability to function in the ordinary tasks of living.
- Quality of life and *health-related quality of life* have been wrongly used synonymously. Health-related quality of life measures specific aspects or domains of quality of life that have the potential to improve with treatment. It is consists of health status and health perception.
- Health-related quality of life instrument should produce meaningful data by displaying satisfactory *psychometric criteria* such as validity, reliability, specificity, sensitivity, and responsiveness to change. *Content validity* is a fundamental concept of an instrument's validity.
- Health-related quality of life instruments are either *generic or condition-specific*. When evaluating health-related quality of life of a particular condition, the use of condition specific instrument is more appropriate because it displays better content validity.

Definitions of Key Terms

Body Mass Index (BMI): is measured by dividing weight in kilograms, by height in meters squared. Ideal BMI of an adult is 20 to 24.9. Individuals with BMI of 25–29.9 are considered overweight and BMI of 30 or more are considered obese.
Obesity: is a chronic condition associated with a BMI of 30 or more and results in increased morbidity and mortality. Obesity can be further classified according the BMI into severe obesity and morbid obesity.
Obesity comorbidity: is condition either caused or aggravated by obesity. It includes physical, psychological, and social comorbidities.
Bariatric surgery: is conducted on the stomach or the intestine to help severely obese and morbidly obese patients to lose weight. The word "bariatric" originated from the Greek root *baro*, which means weight, as in barometer; and suffix *iatrics* which means treatment, as in pediatrics.
Health: is a state of complete physical, psychological, and social well-being.
Quality of life: is a descriptive term that refers to an individual's emotional, social, and physical well-being; spiritual satisfaction; and their ability to function in the ordinary tasks of living.
Health-related quality of life: relates to aspects or domains of quality of life that have the potential to improve with treatment.
Content validity: is the extent to which an instrument measures the intended content area.
Obesity-specific instrument: is an instrument that measures the impact of obesity and weight loss on the individual's health-related quality of life.
Bariatric-specific instrument: measures the impact of obesity, weight loss, and bariatric surgery on health-related quality of life of the severely obese and morbidly obese patients.

Chapter 198
The Impact of Dietary Restrictions on Quality of Life in Kidney Disease

Cheryl Glover, Pauline Banks, Amanda Carson, Mick P. Fleming, and Colin R. Martin

Abbreviations

CAPD   Continuous ambulatory peritoneal dialysis
CKD   Chronic kidney disease
ESRD   End-stage renal disease
GFR   Glomerular filtration rate
HRQoL   Health-related quality of life
KDQOL   Kidney Disease Quality of Life Questionnaire
NICE   National Institute for Clinical Excellence
QALY   Quality-adjusted life year
QoL   Quality of life
RRT   Renal replacement therapy

198.1 Introduction

The key facts concerning chronic kidney disease are summarized in Table 198.1.

198.2 Chronic Kidney Disease (CKD)

A person has chronic kidney disease (CKD) if they have kidney damage or a glomerular filtration rate (GFR) of less than 60 for 3 months or more; GFR being a measure of kidney function (National Kidney Foundation 2002). CKD can be divided into five stages (see Table 198.2). These stages are classified according to evidence of kidney damage and level of kidney function, measured by GFR. Stage 5 of CKD is also called end-stage renal disease (ESRD) and it is at this stage that renal replacement therapy is required to sustain life (National Collaborating Centre for Chronic Conditions 2008).

Table 198.1 Key facts of chronic kidney disease

1. The primary function of the kidney is to maintain a stable interior milieu by the selective retention and elimination of water, electrolytes and other solutes.
2. If kidney function is lost, the patients enter a stage of ESRD.
3. ESRD is incompatible with life unless kidney function is replaced by dialysis treatment or kidney transplantation
4. Hemodialysis is the default therapy for patients in ESRD.
5. Peritoneal dialysis is the other major treatment used in ESRD.
6. Transplant provides the best long-term outcome.
7. A rigorous treatment regime must be followed in terms of all three of the Renal Replacement Therapies.

This table lists the key facts of Chronic Kidney Disease including the function of the kidney, which patients need renal replacement therapy and the types of therapy available
ESRD end-stage renal disease

Table 198.2 Stages of chronic kidney disease (Modified from the National Kidney Foundation (USA) Kidney Disease Outcomes Quality Initiative (K/DOQI) guidelines, 2002)

	Description	GFR
1	Kidney damage with normal or increased GFR	≥90
2	Kidney damage with mild decrease in GFR	60–89
3	Moderate decrease in GFR	30–59
4	Severe reduction in GFR	15–29
5	Kidney failure or end-stage renal disease	<15

The stages of kidney disease as determined by glomular filtration rate (GFR)

198.3 End-Stage Renal Disease (ESRD)

There are currently over 45,000 people receiving some form of Renal Replacement Therapy (RRT) in the United Kingdom (Farrington et al. 2008). This number is expected to increase, as it has done in the past few decades (Cross Party Group on Renal Disease 2005). This increase is being caused by advances in health care which have helped to improve survival rates in the ESRD population. It is also due to the rise in diabetes, which is one of the causes of renal failure. These factors also coincide with the growth of an aging general population; the incidence of renal failure increasing with age (Cross Party Group on Renal Disease 2005).

There are three choices for RRT available to those with ESRD: conservative care, dialysis (hemodialysis or peritoneal), and kidney transplant.

Conservative or palliative care is considered in cases where dialysis may not prolong life. Such patients that may choose to opt for symptom control without dialysis include those that suffer from extensive comorbidities or the very elderly (Levy et al. 2006).

Transplant provides the best long-term outcome for patients with ESRD. However, the shortage of organs, unsuitability for transplant, and organ rejection can mean that many patients spend a number of years on dialysis.

The two modes of dialysis are very different. For a summary see Table 198.3.

In addition to the actual dialysis process, dialysis patients are also required to take any medications that are required and also adhere to fluid and dietary restrictions.

Patients of any chronic disease face challenges from the disease itself, from side effects, and other restrictions imposed by treatment regimes. Therefore, the aims of management extend beyond the strictly medical aspects of treatment (Cross Party Group on Renal Disease 2005). In the past 2

Table 198.3 Types of dialysis currently available

	Hemodialysis	Continuous ambulatory peritoneal dialysis (CAPD)	Automated peritoneal dialysis (APD)
Method	Blood is transferred from the body into a machine which filters out waste products and passes this filtered blood back into the body	Uses the body's own filtration. A catheter is inserted into the patients peritoneum into which dialysis fluid is infused. Dialysis and filtration occur across the peritoneal capillaries. Fluid is in place for 4–6 h, removed, and then replaced for the process to begin again	Same process as CAPD; however APD involved the use of a machine to fill and drain the abdomen, usually while the patient is asleep. For some an exchange must also be carried out during the day
Frequency	Usually 3 sessions of approximately 4 h/week	3 to 5 times a day. The exchange process takes 30–40 min	Every 24 h, overnight
Location	For most in a hospital although can be performed at home	At home by the patient or a carer	At home by the patient or a carer

The main types of dialysis that are currently available. Irrespective of the most appropriate type of dialysis modality chosen, each form of dialysis incurs a significant burden to the patient

decades, there has been a shift in medicine to the aim of providing more holistic care. In light of this, the issue of patient quality of life (QOL) is becoming increasingly important, with QOL now an essential outcome in clinical studies.

198.4 Quality of Life (QOL) and Health-Related QOL (HRQOL)

Quality of life is a well-known and well-used phrase, but there have been many definitions put forward for the term and there is no consensus on the exact meaning. Bowling (2005) suggests that "in general terms quality can be described as a grade of goodness" (p.7). Quality of life has been studied in relation to many different aspects of life, including objective terms such as income, subjective terms such as happiness and well-being, and in collective terms such as equality (Phillips 2006). The definition that seems to encompass all these aspects has been given by the World Health Organization Quality of Life Group (WHOQOL), which state that QOL is an

> individual's perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, values and concerns…[it includes]…physical health, psychological state, level of independence, social relations, personal beliefs and their relationship to salient features of the environment. (WHOQOL 1995).

Health-Related Quality of Life (HRQOL) narrows down the focus to those aspects of life affected by health. HRQOL may be studied for many different reasons, including the comparison of the effectiveness of different treatments, the cost-effectiveness of treatments in terms of Quality-Adjusted Life Years (QALYs) and in order to provide a more holistic view of the patient to enable treatment regimes to be tailored to individual needs.

198.5 The Impact of End Stage Renal Disease (ESRD) on QOL

Advances in technology have meant that people with renal disease can survive for longer. With the increase in survival rates, combined with the growing number of people with renal disease, quality of life has become increasingly important in this population.

Identifications of predictors of HRQOL could make it possible to intervene in some way with the aim of increasing the HRQOL in people with renal disease, while HRQOL is an important outcome in itself, higher quality of life is also associated with lower hospital utilization and mortality in this patient group (Bass et al. 1999).

The areas of life suggested to have an impact on HRQOL in ESRD are numerous and broad:

- Freedom/control/independence (Bass et al. 1999; Juergensen et al. 2006)
- Social relationships (Juergensen et al. 2006) including family relationships (Bass et al. 1999; Wuerth et al. 2007)
- Anxiety (Bass et al. 1999)
- Role (Bass et al. 1999; Juergensen et al. 2006) including work (Juergensen et al. 2006)
- Energy (Bass et al. 1999)
- Body image (Juergensen et al. 2006)
- Sexual relations (Juergensen et al. 2006; Bass et al. 1999)
- Mental attitude/mood (Bass et al. 1999)
- Sleep (Wuerth et al. 2007; National Collaborating Center for Chronic Conditions 2008)
- Cognitive function (Klahr et al. 1983)
- Finances (Pedrini et al. 1996; National Collaborating Center for Chronic Conditions 2008; Fouque 2009)
- Recreation and exercise (Ash et al. 2006)
- Relationships with medical staff (Middleton et al. 1999)
- Patient education (Burge et al. 1979)
- Physical symptoms (Hays et al. 1994; Fernstrom et al. 1996)
- Physical function (Ware and Sherbourne 1992; Bass et al. 1999)
- Pain (Kaplan De-Nour and Czaczkes 1972; Banks, in prep)

Additional QoL burdens specifically for dialysis include:

- General dialysis issues (Henkel 2006)
- Dietary restrictions (Vlaminck et al. 2001)
- Scheduling of dialysis sessions and time restrictions

Based on our review of the literature, we have drafted a conceptual framework of the aspects of life that are impacted by ESRD (Fig. 198.1).

Fig. 198.1 Framework of health-related quality of life measurement in ESRD. The impact of ESRD on HRQoL is multi-factorial and represents an interactive complex process between many domains of patient experience

198.6 The Necessity of Dietary and Fluid Restrictions

According to the National Institute for Clinical Excellence (NICE 2010),

> diet … is one of the cornerstones in the treatment of CKD [Chronic Kidney Disease]. (p. 95)

A major role of the kidneys is to excrete waste products. In CKD, the ability of the kidneys to perform this function is reduced and therefore dietary restrictions are required to compensate (to a certain extent) for this.

The comorbidities and complications involved in CKD and ESRD are such that each individual is truly individual, and dietary restrictions must be tailored to individual needs. Dietary restrictions and modifications depend on the stage and nature of the kidney disease and must coincide with any existing dietary restrictions such as those for diabetes.

The relationship between diet and kidney disease is multifaceted; diet is important in treating CKD on its own and in order to prevent other conditions, however kidney disease itself has an effect on appetite and the numerous dietary restrictions can affect quality of life.

198.6.1 Restrictions

Protein has been recognized as having a negative effect on renal disease for over a century now and there have been numerous studies on the effects of a low protein diet on both diabetic and nondiabetic renal patients. A meta-analysis of these studies concluded that protein restriction slows the progression of renal disease and death in both of these groups. A recent Cochrane Review on nondiabetic patients found that a protein-restricted diet in patients with chronic kidney disease reduced the occurrence of death by 32%, compared with higher or unrestricted protein intake.

Conversely, patients once on dialysis are now recommended to consume a diet rich in protein, especially those on peritoneal dialysis because proteins in the body can be passed out through the dialysis fluid. As the dialysis fluid contains dextrose, peritoneal patients are also recommended to reduce their intake of food that is high in fat in order to prevent weight gain.

Patients are also recommended to restrict foods containing sodium, phosphorous, and potassium (in the case of hemodialysis). The reduction of sodium in the diet is recommended to keep blood pressure down and also to reduce sodium-induced thirst as fluid restrictions are also necessary. High levels of phosphorous can cause osteoporosis and high levels of potassium can cause an arrhythmia.

Patients on hemodialysis are greatly restricted on the amount of fluids that they consume. This is because healthy kidneys work continuously to remove excess fluid but the hemodialysis machine only has a limited time to attempt to remove 2–3 days worth of excess fluid. As well as liquids, patients are restricted in their intake of food that has a high fluid content such as soup and certain fruit. Excess fluid can cause breathing difficulties, high blood pressure, and heart disease. Patients using peritoneal dialysis are also restricted in their fluid intake but not to the same extent as those on hemodialysis. See Table 198.4 for a summary of dietary restrictions in both hemodialysis and peritoneal dialysis.

Inadequate intake and loss through dialysis, and of course the insufficiency of the kidneys to perform their usual functions, lead to vitamin deficiencies among dialysis patients and care must be taken to ensure patients receive enough vitamins through their diet or supplements.

Restricted diets can be unpalatable and time-consuming to prepare and so impair a person's quality of life and for these reasons NICE recommends solid reasoning for such restrictions.

For a more comprehensive explanation and rationale of nutritional guidelines and how to apply them to individual cases in renal disease, see Ash et al. (2006) or Fouque et al. (2007).

Table 198.4 Restrictions associated with different types of dialysis

Hemodialysis	Peritoneal Dialysis
↓ Fluid intake greatly	↓ Fluid intake
↑ Protein	↑ Protein
↓ Sodium	↓ Sodium
↓ Phosphorous	↓ Phosphorous
↓ Potassium	No potassium restrictions
No specific fat restrictions	↓ Fat

Restrictions associated with different types of dialysis. Irrespective of the dialysis modality undetaken by the patient, fluid and dietary restrictions represent a significant burden to the quality of life of the individual

198.6.1.1 The Effects of Kidney Disease on Appetite and Malnutrition

Patients with chronic kidney disease often suffer from reduced appetite, which becomes more apparent as the disease progresses. This reduction in appetite may be caused partly by a loss in taste sensitivity which has been demonstrated both in CAPD patients and hemodialysis patients. A study by (Fernstrom 1996) replicated these effects but found that this reduced taste sensitivity could also be seen in predialysis patients when compared to controls.

Reduced appetite contributes to malnutrition, which is common in CKD. It should be noted that malnutrition can also be caused by a very low protein diet which, although shown to reduce death in renal disease, when linked to malnutrition can have very negative effects. Indeed, malnutrition is associated with increased mortality among dialysis patients. In a large study of over 3,500 people, caregiver assessment of undernourishment and low Body Mass Index (BMI) were found to be independent predictors of mortality; with BMI remaining a significant predictor 5 years from initial measurement. The effects of malnutrition further emphasize the importance of diet in this group of patients.

Maintaining the correct balanced diet for the individual with kidney disease may be of benefit to their medical health but the restrictions and modifications on diet can affect their day-to-day quality of life (Fig. 198.2).

198.6.1.2 The Effects of Dietary and Fluid Restrictions on Quality of Life in Renal Patients

Dialysis patients can lose freedom and control in many aspects of their lives, not least in that of their diets. The effects of dietary and fluid restrictions on QOL in the renal population has been recognized so much so that the most commonly used renal specific measure of QOL, the Kidney Disease Quality of Life Questionnaire (KDQOL) includes questions on these areas.

A large study of hemodialysis patients showed that indicators used for measuring nutritional status such as appetite and energy intake are strongly associated with health-related quality of life as measured by the SF-36. These effects exist even after controlling for comorbidities and dialysis dose.

The evidence of the effects of dietary restrictions on QOL comes primarily, however, from qualitative studies using focus groups and interviews. In one such focus group study, which had the aim of identifying concerns about dialysis, both patients and health-care providers identified dietary restrictions as an issue that affected quality of life. In this study, there were more comments on dietary restrictions than social relationships, anxiety, energy and sleep among others, showing the importance of dietary restrictions on the lives of the patients. One patient commented, "I would love to get back to eatin' what I want."

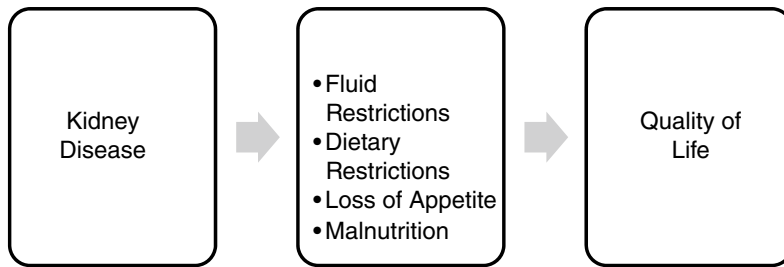
And a health-care provider commented that "It's not an easy diet by any means … it affects life's little pleasures."


Fig. 198.2 How kidney disease affects quality of life as a function of dietary factors. Kidney disease affects quality of life in many ways however a key treatment impact on the experience of quality of life concerns the dietary and fluid restrictions which are a necessary part of the regimen

An earlier study by Kaplan de-Nour stated that diet is a constant source of frustration to patients, with the fluid restriction being especially difficult. In this study, patients reported trying to keep occupied all day in order to avoid drinking.

The dietary restrictions do not just affect the patient with renal disease, but also those around them. In a study by Banks, one carer for a renal patient kept returning to the issue of food (interestingly her husband, who was the renal patient did not mention it at all):

> I found it really hard knowing everything changes, everything about a person changes … their eating habits have to change … and learning, learning about food and the amount a lot because he can only take a 1,000 ml a day learning to adjust to everything what that entails …we were given a list of foods to avoid but I wish I'd had somebody to guide me along, lots of little paths you know not just one big one but lots of little paths. [In the hospital]… I was taking him in fruit everyday and his potassium went … really high and it's learning all those things that you don't associate that you think is okay. I found all that a hard lesson to learn and I'm still learning … and sometimes find it hard.

This same carer talked about diet and fluid restrictions in terms of,

> Lots of all those silly little things that you don't think of … that are so important, that play such a big part in our lives.

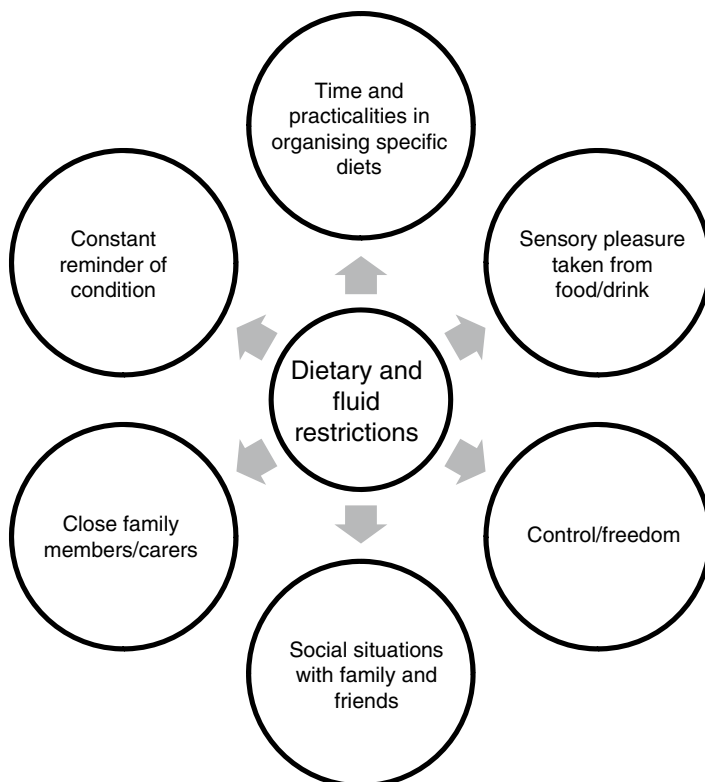
The same carer commented on how hard the fluid restrictions were on her husband:

> …sometimes he gets cross and because he can't drink I don't mean alcohol drink I mean he said yesterday I could've stuck my head under the tap and never stopped drinking…. I could've drunk gallons today you know gallons I just didn't want to stop and he finds that hard.

Fluid and dietary restrictions do not just affect the pleasurable sensations of taste and the quenching of thirst, but are also important in social situations. And, the importance of social support in kidney disease and quality of life is well known. The impact of dietary or fluid restrictions on the quantity or quality of social contact has not yet been investigated. The social implications, and also the effects on family, of fluid restrictions are commented on by a renal patient here:

> speaking/counselling is so very important so that there is somebody who your partner apart from me can actually talk to about what it means in their life how the changes will be how the fact that when you have a fluid restriction what that means for the whole family it's not just you it means that they don't go to the pub, every time you go out to your friends house the first thing people say to you – do you want a cup of tea/do you want a drink…. Because I think it's like an alcoholic oh have one drink it'll be alright have one drink, so you have that going on or they give you a mug of coffee like enormous and I mean I don't have the will power to go well I'll just have 2 sips and sit it to one side. So it's educating your family so that they know that you have to be involved with weenie tea cups. You know and just so that you know what a fluid restriction means it's not just drinking it's everything.

Dietary restrictions affect the lives of those with renal disease in such an all-encompassing way. In this same study by Banks this is demonstrated by a renal community nurse repeatedly highlighting

Fig. 198.3 Areas of life experience affected by dietary and fluid restrictions. Life experience is significantly affected by dietary and fluid restrictions which are a necessary and important part of a comprehensive and inclusive treatment package for patients with kidney disease


that fluid and dietary restrictions was one of the common issues that people brought up to her and asked her questions about.

> I think they always worry, is the diet right, should they be eating this, should they be drinking that?

Figure 198.3 summarizes a number of the key areas of life experience that the dietary and fluid restrictions in ESRD can impact on.

It has been suggested that the issue of dietary restrictions may be more important in elderly renal patients, where quality of (remaining) life may be more important. This article highlighted the practice in a nursing home of educating residents about the consequences of diet on their renal disease, and then honoring the resulting dietary decisions made by the residents.

It could be suggested that the preoccupation with dietary and fluid restrictions, as well as indicating the impact they have on quality of life, could also indicate a desire to regain some form of control over a disease that takes away so much control from the lives of the patient and their family. So it seems that dietary and fluid restrictions might impact on quality of life both directly and indirectly.

198.6.1.3 Noncompliance with Dietary and Fluid Restrictions

Noncompliance rates for dietary and fluid restrictions in ESRD vary across studies, but on the whole are considered high. A study of over 500 patients, using a specially designed instrument to measure adherence to diet and fluid restrictions, found 72% of hemodialysis patients reported mild to very severe non-adherence with fluid guidelines and 81% reported mild to very severe non-adherence with diet guidelines. More research is needed to identify reason for noncompliance. The recognition

of the effects of dietary and fluid restrictions on quality of life is very important and there are things that can be done to minimize these effects. In one particular study, individualized nutritional counseling actually improved quality of life in predialysis patients compared to standard nutrition care.

198.7 Conclusions

The quality of life issues in ESRD are wide ranging and include issues on appetite and dietary restrictions. The list of dietary restrictions and nutritional advice for this group is long and highly individualized, depending, among many other things, on dialysis modality and existing comorbidities. These restrictions greatly affect patient quality of life and also to an extent the lives of close family members. This should be considered when providing nutritional advice to those people that live with ESRD – patients and carers. As the interest in quality of life grows in the area of ESRD, the impact of dietary and fluid restrictions need to be recognized for their importance and for the significant effects that they have.

Summary Points

- Quality of life issues in ESRD are broad and complex, and include issues on appetite and dietary restrictions as part of the treatment battery.
- Dietary restrictions and nutritional advice for this group is extensive and highly individualized.
- Dietary restrictions and nutritional advice for this group is dependent on dialysis modality and existing comorbidities.
- Dietary restrictions greatly affect patient quality of life.
- Quality of life must be considered when providing nutritional advice to those people that live with ESRD, including not just patients but also their carers and significant others.
- Interest in quality of life is developing in the area of ESRD as is the relationship of psychosocial variables to dietary and fluid restrictions.

Definitions of Key Terms

Continuous Ambulatory Peritoneal Dialysis: is a form of dialysis that takes place inside the abdomen using the peritoneum via a process of osmosis to remove metabolic toxins. A catheter is surgically implanted to facilitate the process.
Chronic Kidney Disease: is a term that refers to the gradual and usually permanent deterioration in normal renal functioning.
End-stage Renal Disease: is the end point of chronic renal disease where the kidneys fail to function at a level to support the essential body functions.
Glomerular Filtration: is considered to be the best test for measuring the functioning of the kidneys. It is an estimate of how much blood passes through the glomeruli over a specified period of time, usually 1 min.
Health-Related Quality of Life: is a multidimensional, subjective, and (preferably) self-administered health construct.

Quality of Life: is a measure of how much a person enjoys a range of normal life activities and possibilities. It can be seen as a feeling of satisfaction with life and/or a feeling of general well-being of a person.

Renal Replacement Therapy: is a treatment used when the kidneys are unable to function adequately. The specific procedures can include dialysis either Hemodialysis or peritoneal and continuous hemofiltration.

Quality-adjusted Life Year: is a measurement that considers both the quality of life and the length of a person's life. It is used as a measure of disease burden for health economists to evaluate the value for money of a treatment.

Chapter 199
Huntington's Disease: Quality of Life and Diet

Glenn R. Marland and Colin R. Martin

Abbreviations

BMI	Body Mass Index
CAG	Cytosine, adenine, and guanine
DVLA	Driver Vehicle Licensing Authority
EHDI	European Huntington's Disease Initiative
HD	Huntington's disease
HDA	Huntington's disease Association
HDQoL-C	Huntington's disease Quality of Life Battery for Carers
PEG	Percutaneous endoscopic gastrostomy feeding
QoL	Quality of life

199.1 Introduction

Huntington's disease (HD), an incurable disorder of the central nervous system, is distinct in being a mental illness of identified genetic etiology. It is caused by a single defective autosomal dominant gene (Harper 1996). Transmission through a dominant gene means only one HD gene is needed, each child having a 50% risk, in contrast to transmission from a recessive gene when two genes are required, one from each parent. As the gene is autosomal, both genders are equally at risk (Fig. 199.1). The gene has been identified since 1993, and has a 100% expression rate (Meiser and Dunn 2000), meaning that those having the gene that live long enough will develop HD (The Huntington's Disease Collaborative Research Group 1993); there are no unaffected carriers as occurs in conditions transmitted through recessive genes. If the gene is not passed on, then the disease will not be inherited and that individual's children are not at risk. New gene mutations are very rare and are anyway not confined to those with HD in the family. An accurate predictive test has also been available since 1993. Symptom onset is usually between the ages of 35 and 55, but it can occur at any age including infanthood; juvenile onset is defined as any age below 10 (Quarrell 1999).

This figure shows the transmission of the Huntington's disease gene and represents a 50% probability. Squares represent males and circles represent females. Shapes with a glow represent inheritance of the Huntington's disease gene

Research is still to delineate the molecular pathogenesis, although it is known that the disease is linked to an expansion of polyglutamine in the novel protein Huntingtin (Zhang et al. 2005). All genes produce proteins, and the particular protein product of the HD gene is known as Huntingtin (The Huntington's Disease Collaborative Research Group 1993). Huntingtin is normally associated with healthy functioning of the nervous system, but the mutated variant present in HD is linked to damage and ultimately destruction of neuronal tissue (Bentley 1999). This damage occurs particularly in the basal ganglia and cerebral cortex, and leads to the subsequent physical and psychological changes (HDA fact sheet 1 2008), so destructive to Quality of Life (QoL). The gene is located on the short arm of chromosome 4 and is known as IT15. It is composed of three DNA bases cytosine, adenine, and guanine often abbreviated to CAG. The building block of the protein coded as CAG is called glutamine, hence "polyglutamine" or too many CAG repeats is associated with HD (Quarrell 1999). Although there are CAG repeats in healthy individuals, repeats of 36 or more are linked to HD. The higher the number of CAG repeats, the more there is likely to be an earlier onset of the condition, and this is more likely to occur when the disease is inherited from the father (Kirkwood et al. 2001). The predictive test cannot ascertain the age when the symptoms will manifest; a neurologist can only make a clinical judgment. There are also a number of approaches to testing for HD (Fig. 199.2). HD has an inexorable progression being chronic and neurodegenerative in nature. It has motor, cognitive, and psychiatric symptoms (The Huntington's Disease Collaborative Research Group 1993), but medical curative treatment is fruitless (Raphael et al. 2004); death occurring 15–30 years after symptom onset (Hart and Semple 1990).

Worldwide prevalence has been estimated to be 10 in every 100,000 people (Quarrell 1999), but this means that 1 in every 1,000 is affected by HD as a family member or friend, so the effects on QoL are pervasive. Also because of its genetic transmission, clusters occur in particular regions, for example, Tasmania (Quarrell 1999) and the west of Scotland (McGill 2003). The historical tendency in Britain to export those regarded as deviant to the colonies contributed to this clustering effect in the new world. George Huntington, an American GP in Long Island, observed involuntary dance-like (choreiform) movements in some of his patients. He also noticed that for some the condition seemed to be inherited. It is unclear who first observed this tendency as both his father and grandfather were GPs before him in the same locality and he was taken out on home visits by his father (Quarrell 1999). The symptoms of HD have also been noted in texts from the middle ages (Kolb and Whishaw 1995). The identification of this distinct disease was credited to George Huntington, however, through his

publication "On Chorea" in 1872 in the Philadelphia-based *Medical and Surgical Reporter*. Most of this paper was devoted to chorea caused by infection, which was common at the time; only on the last page did he describe the hereditary form (Quarrell 1999).

HD is complex and multifaceted, severely and diversely impacting on QoL throughout its course. As its effects are diverse, it is convenient to consider these in early, middle, and late stages, although they are idiosyncratic affecting each individual, family, and carers differently. The late or palliative stage can have a long duration, and there is a compelling argument that quality of life could be enhanced by applying similar palliative approaches common in conditions such as cancer (Travers and Partington 2004). Although the need to maintain adequate diet throughout these stages is a clinical imperative, the specific nutritional requirements are unclear (Rae et al. 2009). A characteristic of HD is unintended weight loss, but the cause is unknown (Aziz et al. 2008), however diet and dietary supplements represent a key component of a comprehensive treatment package for HD (Fig. 199.3).

It is likely, however, to be multifactorial and related to decreased calorific intake from dysphagia, increased energy expenditure due to the physical activity associated with almost constant involuntary movement (Pratley et al. 2000; Gaba et al. 2005) and an underlying hypermetabolic state (Aziz et al. 2008). User–carer groups play an increasingly important role in raising awareness and pressing for a cure. The famous American folksinger Wood Guthrie had HD; his second wife Marjorie formed the Committee to Combat Huntington's disease in 1967, the year of Woody's death (Quarrell 1999). Due to the work of Mauveen Jones, whose father had HD, a similar organization 'Combat' developed in the UK, although it has now changed its name to the Huntington's Disease Association (Quarrell 1999).

199.2 Quality of Life and Diet

Tsuang and Vandermey (1980, p. 100) give a particularly vivid summary representing the devastation that HD wreaks on QoL. "A crueler disease than Huntington's could hardly have been devised by a committee of devils." The notion of stages in HD has been used (Quarrell 1999; Hoffman 1999; Kirkwood et al. 2001) as an illustrative guide. Presentation in each individual, however, is idiosyncratic and not everyone experiences all symptoms. Rating scales, for example, the Unified Huntington's Disease Rating Scale (Huntington's Study Group 1996) can help in the assessment process. The stages of Huntington's disease are shown in Table 199.1.

Table 199.1 Stages of Huntington's disease

Stages of HD	
Early stage	Initial onset of symptoms that are usually psychiatric in nature, family members may report that the affected person has changed in personality and this may involve sexual promiscuity. Lack of concentration, memory lapses and depression can occur even years before the onset of motor symptoms. Psychosis can also be a precursor. Death is unusual, except by suicide. The person becomes increasingly irritable with themselves and others. Weight loss is apparent and persists throughout the course of the disease. Chorea (Greek for dance)-form involuntary movements start to occur and may precede or follow psychiatric symptoms; they usually cease when the person is sleeping. Bradykinesia (slowness of voluntary movement) is evident and can be detected diagnostically when observing the person flicking their eyes from side to side rapidly as possible. Handwriting becomes difficult and eventually illegible. The gait is characteristic with wide legs and staggering ungainly movement. Speech starts to be affected both in rhythm and rate and may become slurred. As the disease shades into the middle stage, it is unlikely that employment will be maintained.
Middle stage	Motor symptoms are now in the ascendency with marked involuntary movements and clumsiness, and there is increasing dependence on help with activities of daily living. Involuntary movements affect large muscle groups of limbs face and trunk. Speech may be incoherent or the person may become mute. Swallowing becomes increasingly difficult and may cause choking. There is a triad of movement difficulties: chorea, bradykinesia and dystonia. Dystonia manifests as abnormally slow and prolonged contractions of muscles. Sleep is restless. Loss of drive and volition may be mistaken for laziness. Epilepsy is particularly associated with juvenile HD. Some people become progressively rigid and do not experience the usual degree of involuntary movements also most characteristic in juvenile onset.
Late stage	Dependence on others in daily living. Voluntary movement is possible only with extreme effort. Dystonia and rigidity increase in magnitude. Weight loss is marked. Incontinence of both feces and urine is common. Secondary conditions such as bronchial pneumonia are often the cause of death.

This table summarizes the key stages in the progression of Huntington's disease. The symptom profile is broad and idiosyncratic but follows an inevitable trajectory toward extreme incapacitation and, ultimately, death

199.2.1 Early Stage

On the face of it, genetic testing seems desirable and takes the form of a blood test usually in the UK in a regional genetics service. Genetic testing, however, has proved to be a mixed blessing, having an array of affects on QoL. The provision of counselling and support in preparation for and post testing is associated with QoL. Mariscal et al.'s (2009) Spanish prospective multicenter study with 18 participants showed that those who accepted the predictive test had a trend of decreased scores on QoL and no difference in scores of anxiety and depression compared to those who rejected the test (hospital depression and Euro QoL scales were used). For those who know they are at risk, QoL can be undermined, even when presymptomatic, because of the inevitable worry and tendency to interpret every accident or clumsy action as a sign of disease onset.

Even the early stage of HD is characterized by loss and declining QoL. It is known that genetic discrimination is associated with inheritable diseases and Bombard et al. (2009) have demonstrated that in relation to HD, the earlier the gene is identified, the sooner the discrimination begins. Their self-report survey with a study sample of 233 at risk, but currently asymptomatic individuals (response rate of 80%) evidenced that this discrimination was in family, social, and insurance domains. Muto and Nakai's (2009) ongoing qualitative study in Japan suggests that the stigma of HD is also strongly internalized by those at risk. So far, only 18 participants have been recruited, but they report a tendency to put off visiting hospital even when they experience subtle physical changes; they procrastinate about diagnostic testing. If employment is lost, then help may be required as to benefit entitlement and voluntary agencies may provide this.

The ability to drive will also be lost as the disease progresses. In the UK, the law is that the Driver and Vehicle Licensing Authority (DVLA) must be informed when a medical condition affects ones fitness to drive (Quarrell 1999) and this must be relevant or prospective disability (HDA, Fact sheet 13 2008). The onus of responsibility is on the individual that if presymptomatic they are not obliged to contact the DVLA, but must do so at onset of symptoms (HDA, Fact sheet 13 2008). The difficulty each individual faces is deciding when this stage has been reached, despite the denial process inevitable when disease progression outpaces psychological adjustment.

Although the cause of unintended weight loss is unknown, Aziz et al. (2008) postulate that it is related to a hypermetabolic state and that other signs and symptoms in the early stage are unlikely to contribute. Their evidence comes from following up 379 participants from the European Huntington's Disease Initiative (EHDI) and they found that higher CAG repeat number scores were associated with a faster decrease in body mass index (BMI). Two studies (Pratley et al. 2000; Gaba et al. 2005) examining energy expenditure and physical activity using indirect calorimetry over a 24 h span found that compared to controls total energy expenditure was 11–14% higher in subjects with early- to mid-stage HD, and this at the time was attributed to increased physical activity during waking hours. Weight loss leads to a general weakening and decrease in feelings of wellness and therefore of QoL (Nance and Sanders 1996). It is of clinical significance that this occurs despite adequate or even increased calorific intake (Morales et al. 1989; Van der Burg et al. 2008), and that it begins to manifest in gene carriers who are presymptomatic (Mochel et al. 2007).

Although the need for an adequate calorific intake, usually of around 5,000 calories daily, throughout the course of the condition is a clinical imperative, clear guidelines on the number and components of calories required is not available to clinicians and further research is indicated (Rae et al. 2009). The HDA (Fact Sheet 5 2008), however, does make useful recommendations based on practical experience in their published fact sheets. They recommend, for example, drinking 1 pint of full cream milk each day as a source of protein and adding 2 ounces of skimmed milk powder to add calories. It is a common and often early sign of neurodegenerative conditions such as HD to experience olfactory impairment (Hawkes 2006). The loss of the sense of smell diminishes QoL, and even early in the

disease process diminishes the enjoyment of food. Being underweight impacts on QoL and increases the risk of infection, muscle wasting, and lethargy (HDA Fact Sheet 5 2008). Recurrent thoughts of suicide are common and these are often acted upon.

199.2.2 Middle Stage

Although the early stage of HD is associated with sexual promiscuity, it has long been observed clinically that sexual dysfunctions and infertility are frequent (Fedoroff et al. 1994) as the condition progresses. It is also known that the severity of the condition is correlated to declining plasma testosterone levels (Markianos et al. 2005). HD poses a challenge to the entire multidisciplinary team, but the assessment and caring role of nurses is particularly needed as the disease progresses and has been described as pivotal (Kent 2004). Sometimes diagnosis is not made until this stage (Quarrell 1999). Although medicines such as neuroleptics and antidepressants are often prescribed, as always in terms of QoL, there is a cost to pay in side effects. Particular care must be taken with neuroleptics as some side effects such as rigidity and slowness of movement may be mistaken for symptoms. There is a constant need to maintain a safe environment and this should be adapted to promote safety in anticipation rather than reacting to incidents, although known trigger factors of behavioral problems should be avoided. Speech therapy is invaluable in reviewing swallowing difficulties on an ongoing basis. Preventive strategies for choking should be devised as should the management of choking episodes so that all hospital staff or carers are confident in working within an agreed care plan. This should include but go beyond proficiency in the Heimlich maneuver. Again the HDA fact sheets give very useful practical advice. Dietician input is also essential both to help ensure a high-calorific diet and also on the type and preparation of food to ameliorate swallowing problems. Although weight loss is integral to the disease process, it will be exacerbated by insufficient diet. Although people with HD are not innately more susceptible to dental abnormalities, they tend to have more dental problems (HDA Fact Sheet 8 2008). Involuntary movements, inability to coordinate opening the mouth, apathy, and low mood are just some of the contributory factors to this issue. The causes of potentially poor dietary intake are several and diverse (Table 199.2).

199.2.3 Late Stage

This stage is often characterized by total reliance on others for all activities of daily living. Care is likely to be provided in residential services, but may still be provided at home with 24 h care by family

Table 199.2 Common causes of poor diet

Common causes of inadequate diet	
Physical	The fine dexterity necessary to prepare food will diminish and eventually be completely lost. The ability to chew and swallow food is compromised as is the hand and eye coordination necessary to eat unaided. Often there is difficulty in taking an appropriate portion of food, which can be chewed successfully. Poor dental health.
Psychological	The mean age of onset of HD is 42, an age associated with independence, maturity, and productivity; it is psychologically hard to accept the dependence symbolized by being fed by others. Low mood and depression, often associated with HD, may diminish appetite and enjoyment of food.
Social	The embarrassment of eating in front of other people may lead to the avoidance of meal times.

This table summarizes the key physical, psychological, and social causal factors of poor diet and nutritional status in Huntington's disease

Table 199.3   Behavioral changes associated with Huntington's disease

Behavioral change
• Emotions liability
• Reduced empathy
• Aggression
• Excitement
• Depression
• Apathy
• Challenging and antisocial behavior
• Anger

This table summarizes the key behavioral changes associated with Huntington's disease. There is no typical behavioral profile, and the patient may experience any combination of these behavioral changes within a dynamic, changing context

and Social Care and District Nursing services. Aubeeluck et al. (2009) investigated the impact of HD on the QoL of family carers. The QoL of 45 family carers was measured using the HDQoL-C (Aubeeluck and Buchanan 2007). This validated tool invites carers to independently reflect on their lives in the last 2 months. The results showed a significant difference between self-reported QoL of current main carers in comparison to those who no longer maintained main carer roles. Full-time carers also reported a significantly lower QoL than part-time carers. The qualitative data suggested that carers often and increasingly neglected their own needs as the disease progressed. Although QoL can only be perceived by the individual, it is hard to imagine that for the person with HD this is anything but invariably low. There has been a call in the literature for palliative services and approaches to be applied to neurodegenerative conditions (McLeod 2001; Oneschuck 2001) including HD (Travers and Partington 2004).

By this stage, difficulties with eating and drinking are magnified and compounded. It is essential to allow time for chewing and swallowing. Inadequate hydration is likely to result in a myriad of effects such as urinary tract infection, constipation, disorientation, and reduced skin integrity. There is an increasing risk, however, of aspiration as well as of choking. Eventually PEG feeding may be necessary. HD predisposes to pressure sores because of incontinence, involuntary and constant movement, weight loss, and the potential for inadequate hydration adds to this toxic formulae. Specially adapted chairs are available that help to prevent accidents caused by involuntary movement and which can help to prevent pressure being confined to specific body areas (Quarrell 1999). Although global dementia is often attributed to the late stages, clinically it has been observed that awareness of environment and ability to understand are preserved much more than in other conditions bracketed under the label of dementia and therefore stimulation, for example, watching favorite TV programs, is required to maintain QoL. Behavioral changes in the patients with HD are broad and complex, and the main changes associated with psychological health are shown in Table 199.3.

199.3   Conclusion

HD profoundly impacts QoL for the individuals and their family and carers. There are a constellation of symptoms. Although these present idiosyncratically as they arise because of damage in the basal ganglia and the cerebral cortex, the ability to control voluntary movement and also limit movements that are involuntary are common. Emotional changes and psychiatric symptoms are

almost invariably part of the syndrome. Personality can seem to change even before the onset of these symptoms and weight loss can also occur at this time probably as part of a hypermetabolic state. HD presents challenges to the full multidisciplinary and multiagency teams throughout its course in early, middle, and late stages not least being the need to maintain adequate calorific intake.

Summary Points

- HD is incurable, and death occurs around 20 years after onset of symptoms, so QoL is affected for a long period for the individual, carers, family, and friends.
- HD is transmitted by a single autosomal dominant gene with a 100% expression rate a predictive test has been available since 1993.
- HD is a chronic degenerative condition with an array of motor, cognitive, and psychiatric symptoms that are best illustrated in early, middle, and late stages.
- Loss of life and social skills combine with stigma to contribute to the feelings of hopelessness and isolation making the risk of suicide high.
- The cause of the unintended weight loss is likely to be multifactorial and related to decreased calorific intake from dysphagia, increased energy expenditure due to the physical activity associated with almost constant involuntary movement, and an underlying hypermetabolic state.
- Dietary considerations are intrinsic to any consideration of QoL; although weight loss is part of the disease process attention to calorific intake is essential, the HDA provide invaluable advice.

Definitions of Key Terms

Huntington's disease: is an incurable, autosomal, dominant, inherited, degenerative condition of the central nervous system. It has psychiatric, motor, and cognitive symptoms, with mean age of onset of 42, but can affect people of any age, including infants and octogenarians.

The Huntington's Disease Association: is a voluntary group committed to promoting awareness of the condition and pressing for a cure. It was established initially in the USA but has inspired similar organizations throughout the world.

Body Mass Index: is a statistical measurement that compares an individual's height and weight. It is defined mathematically as a person's body weight divided by the square of their height and remains the most widely used tool to calculate weight problems within a population sometimes for insurance purposes. A BMI of 18.5 to 25 is regarded as optimal and below 18.5 indicates the person is underweight as is commonly the case in HD.

Percutaneous endoscopic gastrostomy: feeding is when nutrition is given through a tube which passes into the stomach through the abdominal wall. This means that nutrition can be provided despite swallowing or chewing difficulties. This is sometimes required in the later stages of Huntington's disease.

Quality of life: is a term used to denote the general well-being of an individual or a society. It has both subjective and objective aspects and these can be expressed in a quality-of-life index.

LOV List of values (a list or scale of questions developed by Kahle (1983) to identify the influence of personal values on behavior)
CSPI The Center for Science in the Public Interest

200.1 Introduction

Although food is a vital part of the chemical process of life, the manner in which people choose the foods that they eat is subject to a wide variety of external and internal influences, ranging from socio-cultural conditioning to the effects of the media (Pyke, 1970; Chang, 1977; Visser, 1992; Keane and Willetts,1994; Getley, 1995). While weight, health, diet, and exercise receive constant media and governmental attention, very little is known about why consumers choose one food over another or about the influence of body image in the food consumption process (Rozin, 2000). Consequently, there is a need for an empirically based understanding of the factors that influence food purchasing and consumption behavior. In this chapter, we examine the influence of body image, vanity, and personal values in the food-purchasing and consumption decisions of young women in the age range of 18–30 years. We then discuss the results of an empirical investigation that unearthed a number of healthy and unhealthy consumption practices that young women engaged in as a means to achieve their perceived body image ideals.

200.2 Body Image, Vanity, and Personal Values

Body image is described by Thompson (1993) as personal perceptions of the way our bodies appear, which we form in our minds. Body image is therefore psychological in nature, involving perception, imagination, emotions, and physical sensations (Lightstone, 1999). As a result, it is sensitive to changes in mood, environment, and physical experience and is heavily influenced by self-esteem.

B. O'Mahony (✉)

e-mail: Barry.OMahony@vu.edu.au

While Thompson (1997) acknowledges the impact of psychological processes in the formation of perceived body image, he asserts that the media plays a significant role in the formation of peoples' perceptions of what is acceptable. Noting a trend in popular women's magazines toward increasing slenderness of models as well as an increase in articles and advertisements addressing dietary issues, he concludes that this has provided women with the ideal body image goal. Moreover, Thompson (1997) asserts that the media is one of the most powerful and effective communicators of the thin ideal due to the popularity of television, movies, and magazines. This ideal has, in turn, been proposed as a modulating force in the amount and type of food that is consumed (Rozin, 1996; Thompson, 1997).

Netemeyer et al. (1995) also recognize the importance of psychological processes in the development and marketing of products and services. Their work concentrates on vanity, which they describe as a fixation, and this fixation can involve both physical appearance and the achievement of personal goals. Their research shows that physical appearance has a marked influence on consumer behavior, and that this can lead to both positive and negative consumption behavior.

Netemeyer et al. (1995) assert that marketing practitioners are aware of the importance of both physical and achievement vanity, and this is reflected in advertising themes that highlight product ownership as a status symbol or measure of achievement (Table 200.1).

In addition to media, advertising, and vanity, perceived body image is influenced by our reflection in the mirror, feedback from others, sociocultural values, self-talk, and mental pictures (Goward, 1993). Rokeach (1968) explains that values are enduring and that they guide our actions and judgments in specific situations. Personal values in the consumption process lead the consumer beyond immediate goals to end states of existence.

Vinson et al. (1977) assert that values are responsible for the selection and maintenance of the ends or goals toward which individuals strive. In the context of this chapter, Getley (1995) asserts that people will make choices about food depending on their values. For example, if they value nutritional gain from food, they will make particular choices, which will reflect this value. Moreover, Rokeach (1968) reports that various combinations of values significantly differentiate individuals. Personal values, therefore, have a major influence on people's lifestyle, interests, outlook, and consumption priorities (Table 200.2).

Although studies have identified a number of variables that may influence food consumption decisions including culture (Chang 1977; Flandrin and Hyman, 1984; Bourdieu, 1986; Mennell, 1985; Visser, 1986), taste (Douglas, 1978; Marshall, 1995; Wright et al., 2001), social status (Bourdieu,1986; Rozin, 1996), health and nutrition (Anderson et al., 1995; Stockley, 1991, Mikela, 2000), food trends (Goody, 1982; Mennell, 1985; Marshall, 1995; Sassen, 1998), marketing (Hall et al., 2001), convenience (Sassen, 1998, Mikela, 2000), religion (Sherrat, 1995; Rozin, 1996; O'Mahony, 2004) and gender (Thompson, 1993; Raats et al, 1995). In a recent comprehensive

Table 200.1 Key features of vanity

Netemeyer et al. (1995) assert that vanity comprises the following four trait aspects:
- An excessive concern for physical appearance.
- A positive (and perhaps inflated) view of one's physical appearance.
- An excessive concern for personal achievements.
- A positive (and perhaps inflated) view of one's personal achievements.

Using this framework Netemeyer et al. (1995) have conducted a raft of studies in order to develop and validate a series of scaled questions specifically designed to measure each of these element of vanity. The resulting "Vanity Scale" is a useful and valuable research tool for the conduct of quantitative studies.

This table provides an explanation of the vanity scale and the construct which it comprises. The scale has been used in a variety of previous quantitative studies and thus the variables have been validated. It is an accepted research instrument within the discipline of marketing and consumer behavior

Table 200.2   Key features of personal values

Personal values have a direct impact on purchasing and consumption decisions. This means that people will make choices about food purchasing and consumption that fit with their personal values. For example, if they and are concerned for their physical well-being, they will make purchasing and consumption decisions that reflect this value. Rokeach (1968) was among the first to report that various combinations of values differentiate individual preferences. His work, produced the Rokeach Value Survey, an instrument used to measure values which comprises 18 instrumental values and 18 terminal values. More recently, however, Rokeach's scales has been modified into a smaller set of nine, person oriented, terminal values. The reduced list relates more directly to a person's daily life roles and situations and is known as the List of Values or LOV scale. This scale has subsequently been validated across a variety of consumer studies and these studies have confirmed that values have a major impact on purchasing and consumption decisions. Examples include Beatty et al. (1985); Kahle (1986); Muller (1989); Kamakura et al. (1991); Kamakura and Novak (1992); Blamey and Braithwaite (1997); Jago (1998), and Hall et al. (2001)

This table explains the key features of personal values and discusses the origins of the value-oriented scales. The table describes how early work in this area has resulted in a reduced list of values (the LOV scale) specifically designed for consumer behavior research. The table also provides references for a number of previous studies where the scale has been used in consumer research

investigation, O'Mahony and Hall (2007) combined these variables with the vanity scale of Netemeyer et al. (1995) and Kahle's (1983) List of Values (LOV) scale in a mixed methods study that explored issues such as dieting, food avoidance, and other strategies that are invoked by young women in order to maintain or improve their physical appearance.

200.3 Review of Procedures

For the qualitative phase of their study, O'Mahony and Hall (2007) selected a non-probability, convenience sample of 50 female respondents in the age group of 18–30 years. They then conducted interviews using a semi-structured interview schedule, where respondents were asked a series of questions about their food consumption, dietary and food avoidance habits. This research phase yielded some interesting results in its own right; however, one of the strengths of the research was that the insights that were uncovered helped to explain the results of their follow-up quantitative survey, which utilized a questionnaire that incorporated both the vanity and LOV scales.

This study involved 500 female respondents who were recruited via a non-probability snowball or referral sampling method. Respondents were asked to rate each question, from one anchored as not important at all, to seven anchored as extremely important.

Overall, 488 valid questionnaires were obtained from 243 respondents between the ages of 18 and 24 years and 245 between the ages of 25 and 30 years. As can be seen in the figures below, a good representation of demographic characteristics was achieved (see Figs. 200.1, 200.2, and 200.3).

200.4 Summary of Analyses

O'Mahony and Hall (2007) conducted an exploratory factor analysis, and confirmed the appropriateness of this procedure for their data, using the Kaiser–Meyer–Olkin measure of sampling adequacy as well as Bartlett's test of sphericity. The resulting factor analysis uncovered eight factors; however, the most dominant factor related to physical appearance and body shape (see Table 200.3).
Fig. 200.1 It shows the age range of respondents. Of the sample of 488 respondents, 49.8% (or 243 respondents) were in the age range of 18–24 years, while 50.2% (or 245 respondents) were in the age range of 25–30 years
Fig. 200.2 The figure shows respondents' employment status. The sample was divided into three employment categories. These were full-time employed, part-time employed, or not employed. As can be seen, nearly 80% of respondents were employed and 37.3% of those employed were employed on a part-time basis
Fig. 200.3 It provides a summary of respondents' cultural background. Respondents were categorized as Anglo-Celtic/Australian, European, or Asian; however, cultural background was not found to be influential in purchasing or consumption decisions

Table 200.3 The factors of influence

Factor	Total	% of variance	Cumulative (%)
Appearance	8.527	24.367	24.363
Time	3.597	10.277	34.640
Marketing	2.915	8.328	42.968
Price	2.256	6.447	49.415
Food qualities	1.893	5.409	54.824
Cultural	1.690	4.828	59.652
Environmental	1.407	4.006	63.658
Filling food	1.075	4.006	67.664

This table presents the results of the factor analysis, which provided eight factors with eigen values greater than 1 and accounted for an acceptable 66.7% of variance. The most dominant factor in this analysis related to physical appearance and body shape

Table 200.4 List of values and vanity

Variable	Security	Belonging	Fun	Warm relationships	Accomplishment	Well-respected	Vanity
Improve physical appearance	X	X		X		X	X
Help lose weight	X			X		X	X
Effect on body shape	X	X	X		X	X	X
Avoid high fat		X	X		X	X	X
Effect on physical shape			X			X	X
Maintain physical shape	X	X	X			X	X
Diet when had wrong foods						X	X
Fear of weight gain	X					X	X
Exercise to compensate for wrong foods		X				X	
Calorie conscious							X
Avoid high carbohydrates	X	X				X	X
Think about health benefits		X	X		X	X	X
Low in cholesterol	X	X					X

This table shows the results of the analysis of variance and identifies significant differences between the two categories of the top box analysis associated with the variables physical appearance factor and items from the list of values and vanity scales

X identifies significant differences observed at the .05 level using ANOVA

Cronbach's alpha was used to assess the internal reliability of this factor and a most acceptable score of .867 was achieved, showing that the physical appearance factor and the variables that it comprises were important considerations for young women and that these variables could be connected with either the consumption or avoidance of particular food products. O'Mahony and Hall (2007) further found that the influence of physical concerns, operationalized in the vanity scale and values, through the LOV scale, were also linked to body image (Table 200.4).

Not surprisingly, the study found that those that were strongly influenced by vanity scored highly on the variables related to the physical appearance and body shape factor. These variables included improvement in physical appearance, weight shedding, effect on body shape, avoidance of high fat, effect on physical shape, maintenance of physical shape, diet on consumption of wrong foods, fear

of weight gain, calorie consciousness, avoidance of high carbohydrates, and consumption of foods low in cholesterol.

It was also found that there was a connection between the variables that make up the LOV scale and physical appearance. These findings are of interest because the values of security, belonging, fun and enjoyment, warm relationships, accomplishment, and respect were linked with physical appearance and body shape. Moreover, the findings were evident regardless of age, employment status, culture, or religious background. The qualitative phase of the research provides further insights into a more complete understanding of these findings. One respondent explained, for example, that appearance was her primary concern when purchasing or consuming food. She explained that she got lazy at times, but did try to eat healthy foods. Although she valued self-image and tried to restrict her food intake to achieve her image goals, she often broke out and consumed foods that she believed were not healthy.

Others linked the value of fun and enjoyment with their purchasing and consumption behavior, stating that they sought enjoyment from eating and that for them mealtimes had to be a pleasurable experience. They expressed the view that they did not want to eat the same foods but sought variety in their consumption. An important component of the enjoyment of mealtimes was sharing the experience with family and friends. As a result, they sought food that was interesting and could enhance the shared experience. Thus, the value of warm relationships was associated with the sharing of meals as well as the content of those meals.

The value of accomplishment also featured in the qualitative study. Respondents linked physical appearance with accomplishment, self-fulfillment, and achievement of goals. This finding links with what Netemeyer et al. (1995) refer to as achievement vanity in that respondents felt that physical appearance may have an impact on goal achievement.

The link between physical appearance, body shape, and the value of being respected was also explained. Respondents described this as a need to look attractive. Respondents also felt that portraying a healthy image and having a good figure was important in order to be well respected.

The views of these young women in relation to what was required to improve physical appearance were also of interest. For example, all respondents felt that there was a negative link between body shape and junk food, while fruit and vegetables were considered healthy. Cutting out fat and junk food was the main strategy employed by these respondents in order to achieve body image ideals and this strategy included avoidance of favorite foods. Some respondents cut meat from their diet as a means to achieving body image goals; however, they were concerned about a lack of iron and other nutrients. Others confided that they skipped entire meals to try to maintain body shape, often eating only during the day, with no evening meals or dinner. Others categorized creamy sauces as bad food and suggested that these should be replaced with tomato-based sauces. In addition to the perceived effect of healthy eating on body shape, respondents asserted that eating healthy food made one feel better about oneself, highlighting a link between consumption and self-confidence. One respondent explained that if one looked good, it gave one confidence, adding that if she started to gain weight, she lost confidence and did not feel good about herself.

Respondents also felt that most healthy foods did not fill you up and explained that they often felt unsatisfied after eating. When this occurred, the temptation was to grab a packet of chips or some other unhealthy snack alternative, especially in outdoor situations where there was a perceived lack of control over the food supply. This led to high levels of guilt for most respondents and, as a result, exercising to compensate for eating the wrong foods was prevalent. The main catalyst for guilt leading to strenuous, compensatory exercise was chocolate, and this was closely followed by snack foods. In some cases, an already punishing gym schedule was increased, depending on the perceived level of unhealthy consumption that had been engaged in.

200.5 Summary of Implications

The O'Mahony and Hall (2007) study highlights the links between perceived body image and food-purchasing behavior, showing that personal values, vanity, physical health, and physical shape are indeed major factors of influence in the purchasing and consumption decisions of 18–30-year-old women. It also confirms that respondents engage in healthy and unhealthy consumption practices in order to achieve their perceived body image ideals. Consuming food that was low in fat and exercising were perceived to be healthy practices, while unhealthy practices included dieting and the avoidance of entire meals.

The link between fear of weight gain and personal values was an important finding. When unhealthy foods were consumed, respondents were racked with guilt, and they felt concerned that if their physical appearance was not in line with their body image ideal, they would lose their sense of security, sense of belonging, and respect. Thus, peer pressure was a significant motivator in the quest for an ideal body image. For this reason, many respondents punished themselves by engaging in activities designed to counteract what they perceived to be unhealthy consumption. This included abstaining from favorite foods, avoiding carbohydrates, and exercising to compensate for eating what they perceived to be the wrong foods.

For these young women, therefore, body image is indeed a psychological state, and food-purchasing and consumption decisions are connected to both their physical and psychological well-being. Their perceptions of what are good and bad foods are linked, however, with their understanding of the effect that these foods will have on physical shape and not on nutritional value. This could mean that many young women of childbearing age are not getting the nutrition that is needed to remain healthy. Although significant, it is possible that this group is not fully aware of the link between nutrition and physical health. Stockley (1991) maintains, for example, that the terms in which dietary advice is presented are not easily understood. This is supported by more recent work by Kozup et al. (2003), who found that consumers had difficulty in interpreting food labels, and the Center for Science in the Public Interest (CSPI, 1997) published concerns about a general lack of knowledge about the fat content of meals among the public and among nutritionists.

Body image is a dynamic concept, however, and can be shaped by the media. Koval (1986) notes, for example, that the ideal body shape has changed dramatically over the last 100 years passing though stages such as the rounded hips portrayed in works of art, to the full figure portrayed by actors such as Marilyn Monroe in the 1960s to the more recent extremely thin portrayal of women in the media. As a result, there is a need for continual research into this dynamic concept and it is suggested that future research involving women of different age groups would provide further valuable insights into this phenomenon.

200.6 Application to Other Areas of Health and Disease

Effective treatment of illnesses that result from food consumption behavior relies on a full understanding of the factors that influence food-purchasing and consumption decisions. Exploring the links between perceived body image and food-purchasing behavior can assist in this understanding. The study profiled in this chapter shows that personal values, vanity, physical health, and perceived body image were major factors of influence in the purchasing and consumption decisions of 18–30-year-old women. It was also identified that respondents to these studies engaged in healthy and unhealthy consumption practices in order to achieve their perceived body image ideals. There are opportunities to extend this research to gain a more comprehensive understanding of the influence

of perceived body image on purchasing and consumption decisions on women in different age groups and to extend the research to men. The finding that body image can take precedence over nutrition in consumption decisions is also of relevance.

Summary Points

- Body image is a psychological process.
- Perceptions of body image are inextricably linked with personal values.
- Vanity effects perception of body image.
- Physical appearance is most important to those respondents that value belonging, warm relationships, respect, and security.
- Respondents engaged in strategies to achieve or maintain body shape.
- Respondents experience guilt when they have consumed what are perceived to be the wrong foods.
- Respondents punish themselves by avoiding food, skipping meals, dieting, and exercising.

Definitions of Key Terms

Body image: Refers to personal perceptions of the way our bodies appear, which we form in our minds.

Vanity: Refers to a fixation that can involve both physical appearance and the achievement of personal goals.

Personal values: Enduring, inherent values that guide our actions and judgment in specific situations. In the consumption process, personal values lead the consumer beyond immediate goals to end states of existence.

Mixed methods: Mixed method studies involve both qualitative and quantitative data collection methods studies. In general, a qualitative phase is used to collect data on an unexplored topic and the results are used to conduct a more comprehensive quantitative study.

Non-probability sampling: Non-probability sampling is a sampling technique that does not involve random selection but rather selects respondents on the basis of what they can contribute to the research. In most cases, a purposive sample is obtained by selecting respondents with specific characteristics (e.g., age and gender) to provide insights into a particular phenomenon.

Chapter 201
Factors Influencing Body Image During Adolescence

Abbreviations

BMI   Body mass index
SEM   Structural equation modeling
SES   Socioeconomic status

201.1 Introduction

Over the years, research has implicated a number of developmental (e.g., pubertal timing), psychological (e.g., self-esteem), and sociocultural (e.g., culturally-defined and transmitted messages regarding attractiveness) factors in the development and maintenance of body image disturbance and related issues in adolescents. In this chapter, we will focus exclusively on sociocultural factors that affect adolescent body image, using the Tripartite Influence Model of body image and eating disturbance as our conceptual framework. We will begin by providing some background information on body image and body image disturbance, and offer an explanation as to why adolescents may be particularly vulnerable to the latter. Then, we will explicate the role of the media in transmitting messages to adolescents regarding culturally defined and encouraged images of attractiveness that suggest that females have thin bodies and males have lean, muscular bodies. Next, we will discuss the direct and indirect influences of parents and peers, including appearance-related teasing and criticism and modeling of eating- and weight-related behaviors, which may serve to reinforce media-transmitted messages. Finally, we will highlight the role of cultural factors such as acculturation and the connection between body image disturbance and other areas of health.

201.2 Body Image and Body Image Disturbance

Defining body image is so "tricky" that Thompson et al. (1999) pointed out the existence of 16 different terms used interchangeably by researchers and clinicians (Table 201.1). The common consensus, however, is that body image is a complex, multidimensional construct (Thompson et al. 1999)

Table 201.1 Terms used interchangeably with "body image"

Weight satisfaction	Body dysphoria
Size perception accuracy	Body dysmorphia
Body satisfaction	Body schema
Appearance satisfaction	Body percept
Appearance evaluation	Body distortion
Appearance orientation	Body image
Body esteem	Body image disturbance
Body concern	Body image disorder

This table lists the 16 terms commonly used interchangeably with "body image". For definitions of these terms refer to: Thompson et al. (1999)

that relates to how an individual feels about and perceives his/her body. Body image is believed to play a vital role in determining one's quality of life (Cash 1994) and is influenced by physiology, psychological factors, and society (Rierdan and Koff 1997). Body image disturbance has been measured by examining cognitive components, such as negative attitudes about the body or unrealistic expectations for appearance; behavioral components, such as avoiding perceived body scrutiny from others (e.g., avoiding being seen in a bathing suit); and perceptual components where body size perceptions are evaluated (Thompson et al. 1999).

201.3 Adolescence as a Period of Increased Vulnerability

Although body image disturbance and eating disorders can theoretically develop in any individual, they tend to be most prevalent among adolescents (Table 201.2). While puberty strictly refers to the period during which adolescents gain reproductive capability, it encompasses all physical changes experienced by adolescents (Steinberg 2005). One important physical change associated with puberty is the change in body composition. While body fat increases in both sexes during puberty, the increase for girls is faster and much more obvious (Steinberg 2005). Thus, even when they are within a healthy weight-range, adolescent girls may become overly concerned with their weight and appearance.

Changes in body composition lead to changes in appearance and self-image, which can lead to changes in behavior (Steinberg 2005). Whether the biological changes brought about by puberty cause the individual to look more attractive or more awkward, changes in appearance may lead to changes in the way others view and react to the adolescent. Unfortunately, the impact of this attention may cause the adolescent to become confused and self-conscious in his/her new body. While boys move from a "culturally undesirable state" during puberty to a culturally encouraged one – from being short and thin to tall and muscular – girls undergoing puberty lose the thinness associated with prepubescent adolescence (Steinberg 2005). This is a great loss, given the emphasis the society in which we live places on physical attractiveness in the form of a thin figure.

The physical changes associated with puberty are not the only changes responsible for the increased susceptibility of adolescents to body-related concerns. Due to cognitive changes associated with puberty, adolescents' thinking becomes less grounded in fact and more highly based on deductive reasoning (e.g., Wiseman et al. 2005). Thus, if adolescents perceive something to be a desired behavior or image, they may deduce that their acceptance by others depends on whether they are able to imitate the desired behavior or image. Adolescents' belief that everyone is watching and judging them stems from their newfound ability to think about thinking, or engage in metacognition.

Table 201.2 Key features of adolescence

1. Puberty is marked not only by changes in:
    (a) Body composition
    (b) Primary and secondary sex characteristics
    (c) Circulatory, endocrine, respiratory, and other systems within the body; but also by increased awareness among adolescents of how their own bodies look in comparison with their peers' bodies
2. Cognitively, adolescents are able to reason at a higher level, able to take account of multiple perspectives as they make decisions; however, they may be hindered in their decision-making by:
    (a) Continuing development of the frontal cortex of the brain and an overactivation of the limbic system, which may be associated with heightened emotions (Steinberg 2008)
    (b) A tendency toward egocentrism, which is associated with heightened self-consciousness and a feeling that one is unique or special (Steinberg 2008).
3. As a result of physical maturation, increasing social pressures, and emerging personal values and decision-making abilities, adolescents are faced with new developmental tasks (Havighurst 1952) that relate to social interactions such as:
    (a) Forming relationships with peers of both sexes
    (b) Appreciating one's body
    (c) Achieving emotional independence
    (d) Understanding one's social role as a man or woman
    (e) Engaging in socially responsible behavior
4. However, "storm and stress" is more likely to be heightened during adolescence as compared to childhood or adulthood (Arnett 1999); it is characterized by:
    (a) Conflicts with parents
    (b) Mood disruptions
    (c) High rates of risk behaviors

This table provides a brief description of the physical, cognitive, and social/behavioral changes associated with adolescence

According to Elkind (1967), this ability not only leads to increased introspection and self-consciousness, but also to self-absorption or adolescent egocentrism. Elkind defines adolescent egocentrism as the inability to discriminate between one's own cognitions and concerns and those of others. Adolescents falsely believe that their behavior and appearance are the focus of everyone else's attention (Elkind 1967) and, thus, may feel the need to look a certain way in order to be accepted and judged positively by those around them.

201.4 An Overview of the Tripartite Model

Sociocultural theories of body image disturbance "examine the influence of common or culture-wide social ideals, expectations, and experiences on the etiology and maintenance of body image disturbance" (Heinberg 1996, p. 32). Although the majority of sociocultural influence research has focused on the impact of the media, it is important to note that messages portrayed therein are not the sole contributors to body image disturbance and disordered eating among adolescents. All adolescents are exposed to the media, but not all develop poor body image and/or disordered eating patterns. Individual differences may be accounted for by more proximal influences. Messages portrayed by the media become particularly problematic when they are reinforced by more immediate sociocultural agents such as parents (Dunkley et al. 2001) or peers.

Recent work in our lab has focused on testing a theoretical model that includes a variety of sociocultural factors. Our model, the Tripartite Influence Model (Table 201.3), asserts that three formative influences (family, peers, media) lead to the development of body dissatisfaction and eating disturbances

Table 201.3 Key features of the Tripartite Model

1. Media, parental, and peer influences can lead to the development of body dissatisfaction and eating disturbances directly, and also indirectly, through internalization and comparison.
2. Internalization of appearance ideals and comparison to others (especially upward comparisons to those who are more attractive, thinner, etc.) can lead to increased body dissatisfaction.
3. Body dissatisfaction is associated with increased disordered eating behaviors (i.e., restriction and bulimia). It is also related to psychological distress and more severe forms of psychopathology.

This table describes the key features of the Tripartite Model and how, according to this model, influences such as those exerted by the media, parents, and peers can lead to increased body dissatisfaction among adolescents

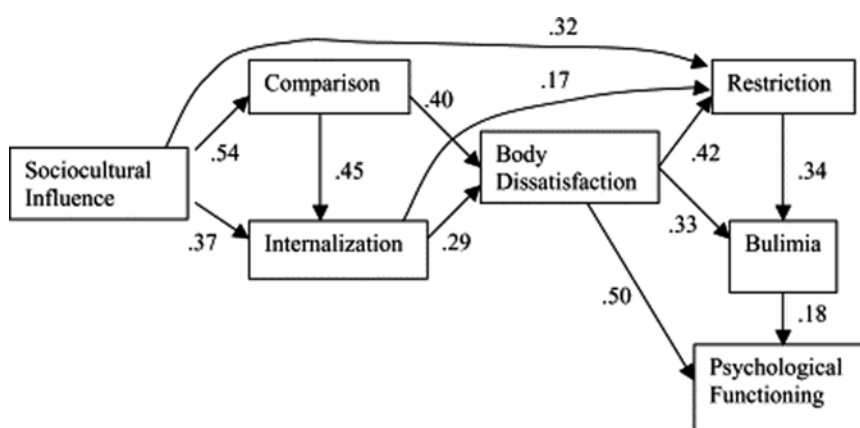

Fig. 201.1 The Tripartite Influence Model of body image and eating disturbance: Final SEM model with standardized path coefficients (Reprinted from Keery et al. 2004. Copyright (2004), with permission from Elsevier). *SEM* structural equation modeling

directly, and also indirectly, through two mediational mechanisms (appearance comparison, internalization of appearance ideals) (Thompson et al. 1999). Appearance comparison refers to a tendency to compare one's own appearance to others – typically, the comparison is an upward comparison (i.e., to someone who is more attractive, thinner, etc.) and, therefore, is likely to lead to a decrease in appearance satisfaction. Internalization refers to a process whereby one has endorsed or brought into a message or view, to the point that it becomes part of their belief system. In terms of the internalization of appearance ideals, this means that someone believes that it is important to try to look like the ideal images promoted via the media.

We have conducted a series of studies with adults and adolescents using structural equation modeling (SEM) to test the directionality of the hypothesized relationships in the Tripartite Model (van den Berg et al. 2002; Keery et al. 2004; Shroff and Thompson 2006a). Figures 201.1 and 201.2 illustrate the findings from Keery et al. (2004) and Shroff and Thompson's (2006a) studies with two large samples of adolescent girls. In both cases, the data indicate that the formative influences have both a direct and mediated effect (through comparison and internalization) on body image and eating disturbance.

In the sections that follow, we provide a more detailed account of the research on the three formative influences that compose the Tripartite Model (media, parents, peers). These factors are actually multidimensional, involving many different social and interpersonal influences on an adolescent's body image.

201.5 Media Influences

Over the last 20 years, a great deal of empirical work has documented the negative effects of media exposure to unrealistically thin images on body image dissatisfaction and eating disturbances (Thompson et al. 1999; Thompson and Smolak 2001; Smolak and Thompson 2009). Media exposure may consist of a variety of sources, including print media (e.g., magazines), TV, movies, and internet. In this section, we briefly review some of the large-scale studies to illustrate descriptively some of the effects then turn our attention to the recent work consisting of prospective investigations.

Young girls are often exposed to magazines that contain unrealistic images of thinness and attractiveness, along with messages that it is important for them to focus on appearance (Cusumano and Thompson 1997). In fact, surveys suggest that perhaps 50% of elementary school girls read teen magazines weekly (Thompson and Smolak 2001).

A large-scale study by Field et al. (1999) examined over 6,900 adolescent girls (aged 9–15) and found that frequency of reading of women's fashion magazines was associated with the intensity of their weight concerns. Grigg et al. (1996) surveyed over 800 Australian adolescent girls and found that 87% wanted to look like the media-promoted slender ideal.

Young girls and boys are also exposed to images and messages regarding the importance of appearance through television and movies. A relatively new form of media, the internet, provides another route for exposure. Although there is no research to date on the internet with young individuals, research with college students indicates that young women often seek out sites (pro-anorexia and pro-eating disorder) that contain information that glamorizes thinness (Harper et al. 2008) and this exposure is correlated significantly with body dissatisfaction.

In perhaps the most comprehensive prospective study to date, Field et al. (1999) conducted follow-up studies at 1 and 7 years with her original sample (Field et al. 2001, 2008). These researchers found that a key predictor of the onset of weight concerns at 1 year was wanting to look like media figures. At 7 years, attempting to look like these media images and dieting predicted the onset of binge-eating. Dohnt and Tiggemann (2006) evaluated very young girls (5–8) prospectively, finding that the viewing of appearance-oriented TV, but not magazines, predicted a decrease in body image satisfaction 1 year later.

Research on the effects of media on body image has largely been focused on adults (see Thompson 2009) and this work has clearly documented the negative effects on body image, via correlational, experimental, and prospective analyses (see Levine and Murnen 2009). This type of conclusion cannot currently be made based on the rather limited work with adolescents (see above); however, the emerging evidence is suggestive of a strong influence on body image. The findings noted earlier with the Tripartite Model (Keery et al. 2004; Shroff and Thompson 2006a) and the recent prospective studies (Dohnt and Tiggemann 2006; Field et al. 2008) are encouraging developments in this area of research that require replication and extension.

One of the limitations of work in this area is that many studies use a single measure of media. In actuality, there are many different dimensions of media influence, including: exposure to images (or messages), gathering information from media sources, feeling pressure from media, and internalizing media influences. In our work, we have conceptualized media as multidimensional and developed scales to capture multiple components through our Sociocultural Attitudes Towards Appearance Questionnaire (Thompson et al. 2004). A multidimensional assessment model of media influence should be considered by researchers for future work in the area of media and adolescent body image.

201.6 Parental Influences

Although youth tend to turn away from their parents and toward their peers for advice and guidance during adolescence, research suggests that "parental relationships retain their relevance and remain a powerful predictor of adolescent body dissatisfaction" (Bearman et al. 2006, p. 238). Parental behavior may influence adolescents' body image and weight-related behaviors either directly (e.g., appearance-related commentary and teasing, encouragement to diet) or indirectly (e.g., modeling of weight-related behaviors, parent–adolescent relationship). In the following sections, we review the research on the various direct and indirect ways that parents may affect adolescents' body image (Table 201.4).

201.6.1 Appearance-related Feedback and Commentary

In an attempt to determine the origins of appearance-related feedback and commentary received by adolescents, McCabe et al. (2003) conducted a series of in-depth interviews with 40 adolescent boys

Table 201.4 Examples of parental influences on adolescents' body image

Direct influences
Appearance-related teasing and criticism
Pressures to modify appearance (e.g., encouragement to lose weight)
Indirect influences
Social support/connectedness
Parent body mass index (BMI)
Parent body image
Parent–adolescent relationship
Modeling of disordered eating and appearance concerns

This table lists potential parental influences on adolescents' body image. The influences have been divided into those that are directly related to adolescents' weight and/or appearance and those that are believed to exert a more indirect effect

and 40 adolescent girls. They found that when parents make comments about their children's bodies, they tend to focus on the overall appearance of their daughters' versus the functionality of their sons' bodies. Most maternal comments were considered by their daughters and sons to be positive, encouraging, and supportive. While the majority of girls also reported receiving messages from their fathers in regards to their bodies, very few boys reported having received such messages. When messages from fathers were received, they were also categorized as primarily positive and supportive.

When negative messages were received by girls, they tended to interpret them as being supportive (mothers) or downplayed their seriousness (fathers; McCabe et al. 2003). Overall, girls reported a higher number of negative messages (73 total) than boys (13 total), which led the researchers to conclude that boys may be protected from such messages. Another possible explanation is that boys may be less attuned to such messages and, therefore, less likely to detect them than girls (McCabe et al. 2003). In fact, when adolescent boys were asked to describe the extent to which they felt their parents, siblings, friends, and the media influenced their feelings about their bodies, the majority of the boys claimed that none played an important role in determining their body image (Ricciardelli et al. 2000). A minority of the boys reported that their mothers (25%) and fathers (25%) exerted some influence on their feelings about their body shape and size. Messages about muscles from fathers have been related to boys' body image and satisfaction with body parts; messages from mothers about shape have been found to predict the latter (Stanford and McCabe 2005).

General feedback from mothers and fathers on the size and shape of their children's bodies has been found to predict body image satisfaction in their daughters and sons, respectively (McCabe and Ricciardelli 2003). These results provide some evidence for the gender-linked transmission model, which posits that fathers exert greater influence on sons and mothers exert greater influence on daughters (Wertheim et al. 1999). Earlier research that suggests that increased paternal commentary is associated with increased weight dissatisfaction among adolescent girls (Keel et al. 1997), and more recent research that suggests that maternal commentary is associated with increased weight and body dissatisfaction among adolescent boys (Vincent and McCabe 2000; Stanford and McCabe 2005), are inconsistent with this model.

201.6.2 Teasing and Criticism

Appearance-related teasing is another direct influence that can have adverse effects on adolescent body image. According to a retrospective study, 72% of female college students indicated that they had experienced appearance-related teasing or criticism during childhood or adolescence (Cash 1995). Participants further indicated that these experiences were moderately (29%) or more (42%) upsetting and that they occurred over an average period of approximately 6 years. Given the average length of time to which females were subject to these events, and the fact that facial features and weight (i.e., heaviness) were the primary targets, it is not surprising that 71% of participants reported that their current perceptions and feelings about their bodies were at least partially affected by their experiences of teasing.

In terms of offenders, some of the worst teasers tend to be family members. In one study, 23% of adolescent girls reported having at least one parent who teased them about their appearance (Keery et al. 2005). Results are mixed, however, when it comes to the frequency of teasing by mothers versus fathers. Retrospective accounts by female college students suggest that mothers not only tease more than fathers, but are also more likely to be deemed the worst of teasers (Cash 1995). Research conducted with adolescent females, however, indicates that fathers tease more than mothers and that modeling of such behaviors by fathers is associated with increased teasing by siblings (Keery et al. 2005).

Whether the teaser is the mother, father, or a sibling, girls who report teasing by family members score higher on measures on body dissatisfaction, social comparison, internalization of the sociocultural ideal of thinness, depression, and disordered eating. They also tend to report lower levels of self-esteem (Keery et al. 2005). It is important to note, however, that the "appraised severity of these interpersonal experiences – their perceived frequency, longevity, and emotional impact at the time" appears to be more influential in predicting body image than the mere presence or absence of teasing (Cash 1995, p. 127). Although less research has been conducted on the effects of teasing on boys, teasing by fathers and mothers about weight does not seem to predict adolescent boys' body image (Schwartz et al. 1999).

201.6.3 Modeling of Weight-related Behaviors

One particularly relevant form of weight-related behavior that parents model for their adolescents is dieting. While parent dieting did not predict increases in body dissatisfaction in early- or middle-adolescent girls or boys over a 5-year period (Paxton et al. 2006), such parental behavior has been associated with more behavioral indicators of body and weight concern. For instance, girls who report maternal dieting are more likely to have engaged in both healthy and unhealthy behaviors to control their weight than girls who do not report maternal dieting, even after controlling for body mass index (BMI), race, grade, and socioeconomic status (SES; Vincent and McCabe 2000; Keery et al. 2006). In a smaller sample of adolescent girls from New Zealand, maternal dieting did not influence daughters' dieting behaviors; however, girls who reported paternal dieting were more likely to have engaged in extreme weight control behaviors (i.e., skipping meals, crash dieting; Dixon et al. 1996).

201.6.4 Pressures to Modify Appearance

Parental modeling of dieting does not seem to be as important in predicting adolescent body- and weight-related attitudes and behaviors as encouragement to diet (Wertheim et al. 1999, 2002). Although most parents report that they never encourage their daughters to lose weight (mother 61%, father 58%), about a quarter of parents admit that they encourage their daughters to lose weight either sometimes (mother 14%, father 16%) or often (mother 11%, father 9%; Wertheim et al. 1999). While the aforementioned study focused exclusively on adolescent girls, more recent research suggests that sons and daughters are equally likely to be recipients of parental encouragement to diet (Wertheim et al. 2002).

Not surprisingly, encouragement to diet is highly correlated between mothers and fathers, indicating that parents are relaying similar messages and values to their adolescents about the importance of attaining the thin-ideal (Wertheim et al. 1999). Maternal encouragement, body-related compliments, dieting, and criticism, however, add unique predictive ability to models predicting adolescent girls' eating behaviors – even after controlling for the same paternal variables. Furthermore, daughters' reports of maternal encouragement to lose weight predict daughters' eating behaviors above and beyond paternal reports of the same variables. These results suggest that while both parents play a role in reinforcing societal messages of attractiveness, mothers tend to exert greater influence on their daughters than fathers and – perhaps more importantly – daughters' perceptions of encouragement are more important than the actual presence or absence of encouragement (Wertheim et al. 1999).

More recent research further supports the role of mothers as the primary agents of their children's socialization. In two studies of Australian adolescents, perceived pressure from mother (Ricciardelli and McCabe 2001) and parent encouragement to lose weight (Ricciardelli and McCabe 2003) predicted body dissatisfaction in boys and girls. In contrast, pressure from father to lose weight was only predictive of body dissatisfaction in boys (Ricciardelli and McCabe 2001). Perceived pressure from family to lose weight was also associated with body image and eating attitudes and behaviors in a US sample of adolescents (Ata et al. 2007), but was not found to be predictive of body dissatisfaction among older adolescents prospectively (Presnell et al. 2004).

201.6.5 Parent–adolescent Relationship

Adolescents' perceptions of their relationships with their parents have been associated with their dieting attitudes and behaviors and body image both concurrently and longitudinally. Short-term (i.e., 1-year follow-up) longitudinal research with early-adolescent girls indicates that parental relationships that are lower in warmth and higher in conflict are associated with less healthy dieting and a more negative body image, while more positive parental relationships are associated with a more positive body image (Archibald et al. 1999). A more recent study, that followed adolescents over a period of 3 years, found that decreases in mothers' intimacy and increases in mother–daughter conflict were related to increased weight concerns among girls across the course of adolescence (May et al. 2006). Similarly, girls, but not boys, who report greater parent–child connectedness (i.e., extent to which they perceive love from and closeness to their parents) and acceptance by their mothers and fathers appear to be less dissatisfied with their bodies concurrently (Barker and Galambos 2003) and over a period of 5 years (Boutelle et al. 2009). While the mother–son relationship does not appear to affect boys' weight concerns, conflict with fathers has been associated with increased weight concerns in adolescent boys and girls (May et al. 2006). The more prominent connection between parent–adolescent relationships and girls', as compared to boys', body concerns may be due to the relatively greater importance emotional support (especially from mothers) and connectedness play in the development of female adolescents (Geuzaine et al. 2000).

201.6.6 Concluding Points

Although the research is not entirely consistent in terms of whether mothers or fathers play the most salient role, it is clear that parents can affect adolescent body image. The mechanisms by which parents may exert influence can be either direct or indirect. Regardless of whether parents are reinforcing societal messages via modeling or teasing, it is important to keep in mind that "young people's *perceptions* of parents' weight-related attitudes and behaviors may be more relevant to adolescent body dissatisfaction, weight concerns, and weight control behaviors than parents *actual* attitudes and behavior" (Keery et al. 2006, p. 106).

201.7 Friend/Peer Influences

During adolescence, both males and females become more peer-oriented, as reliance on friends for support and approval increases significantly. With this increased intimacy comes the sharing of thoughts and behaviors among friends. Close friends are likely to be similar both in terms of their

body image and their eating behaviors during adolescence (Paxton et al. 1999; Hutchinson and Rapee 2007). Cliques may be a key place where adolescents generate their own body image perceptions. Adolescents are in a social context where it is easy to compare themselves to peers in relation to their eating behaviors and the way that they talk and think about their own bodies. Not only do peers have an influence on adolescents' body perceptions in these direct ways, but also the peer social context can indirectly influence body perceptions and attitudes. For example, concerns about attracting romantic partners, finding friends, or participating in sports with peers may engender an orientation to one's body or appearance. Friends influence adolescents' body image by eliciting appearance-related cognitions through direct means by causing social comparisons, engaging in appearance-related conversations, modeling eating behaviors, and through teasing, and also through indirect means by engaging with adolescents in a social context where they may become more aware of their appearance. In the following sections, we outline the various direct and indirect ways that peers affect adolescents' attitudes about their appearance and their bodies.

201.7.1 Social Comparisons

Even what we have called the direct effects of social comparisons with peers can vary in how directly peers influence one another. Friends may make comparisons for adolescents (i.e., "I think those jeans look much better on her than on you") or adolescents may observe their peers and make the comparisons themselves (i.e., "I wish that I could wear those skinny jeans that my friend has"). We will discuss the direct comparisons made by others below under the section on teasing and criticism. These influences are not unrelated, however. When adolescent girls report that they are teased by their friends about their appearance, that their friends are preoccupied with weight and dieting, that they often have conversations about appearance with their friends, and that they see their friends as key influences on their ideas about weight loss and the perfect body, they are more likely to compare their own appearance to the appearance of others (Shroff and Thompson 2006b). In fact, Shroff and Thompson (2006b) found that higher levels of social comparisons help to explain the links between peer influence (i.e., peer teasing, preoccupation, conversations) and adolescent girls' body dissatisfaction. When adolescent girls individually report making more social comparisons, their body image concerns are higher; in addition, when friendship groups are characterized by having higher levels of social comparisons, friends in the group are more likely to be dissatisfied with their bodies (Paxton et al. 1999).

201.7.2 Appearance-related Conversations

Focus group research with early adolescent girls indicates that "fat talk," namely discussion about body shape inadequacy that often includes the "I'm so fat" statement, is common discourse and helps to bond girls together (Nichter 2000, p. 46). Adolescents may actually feel pressure from peers to engage in this fat talk; however, whether they actually engage in the conversation is related to adolescents' perceptions of their own bodies and their actual weight because they may not want to bring attention to their bodies when they are overweight or underweight (Nichter 2000). Fat talk is not the only type of appearance-related conversation among peer groups; and it is important to acknowledge that boys also have appearance-related conversations with friends (Jones et al. 2004). Adolescent boys who talk with friends about how their bodies look in clothes and what they would like their bodies to look like are more likely to internalize media ideals about muscularity, which is associated with greater

body image dissatisfaction (Jones et al. 2004). Adolescent girls who are more likely to talk with their peers about how they look generally – in terms of such topics as clothes and make-up or looking their best – in addition to body shape, are more likely to report low body-esteem, internalization of media messages about thinness, and body dissatisfaction (Jones et al. 2004; Clark and Tiggemann 2007). Clark and Tiggemann's (2007) cross-sectional research on early adolescent girls from Australia suggests that appearance schemas mediate this relationship between peer conversations and body dissatisfaction. They found that appearance-related conversations with peers enhance the salience of appearance in terms of self schemas and in terms of what adolescents spend their time thinking about, which then increases their body dissatisfaction (Clark and Tiggemann 2007). Their longitudinal research indicates that adolescents who engage in more appearance-related conversations with peers are also more likely to internalize appearance ideals and have more appearance-related self schemas 1 year later (Clark and Tiggemann 2008). Talking with friends about what to wear or about how one looks may prime adolescents to internalize negative messages and transfer cognitions about appearance to their understandings of self – these conversations may continue to have effects over time.

201.7.3 Teasing, Criticism, and Pressures to Modify Appearance

When adolescents share comments with peers about appearance, these experiences can be particularly damaging to adolescents' body image when they receive criticism or are teased about their appearance. Both boys and girls who report that they are teased by same-sex and opposite-sex peers – either about the size, shape, or build of their bodies, or specifically about their weight for girls or muscularity for boys – are more likely to report increased internalization of media ideals and body image dissatisfaction (Jones et al. 2004). This research suggests that teasing from family and peers reinforces the societal value of appearance and emphasizes desirable physical attributes (Jones et al. 2004). As previously mentioned, retrospective research by Cash (1995) involving female college students suggests that it is the frequency, longevity, and emotional impact of the teasing that is associated with adolescents' feelings about their bodies. Notably, male adolescents perceive appearance-related pressure and teasing at levels that are similar to or higher than females (Jones and Crawford 2006), and appearance-related criticism by peers is significantly positively related to boys', as well as girls', body dissatisfaction (Jones et al. 2004). Research on boys from middle and high schools in China revealed that adolescents who perceive more sociocultural pressures from peers, parents, or the media related to appearance and more appearance-related teasing were more likely to report concerns about being fat (Jackson and Chen 2008). Perceptions of the evaluations of others may be just as important as actual criticism in terms of the effects on adolescents' body image, as this perceived evaluation may influence body image by increasing the feelings of pressure perceived by adolescents to modify their appearance (Ata et al. 2007). For both boys and girls, feeling pressures from peers and family to either lose weight or gain muscle is associated with a greater discrepancy between their actual body size and shape and their ideal body size and shape (i.e., what they'd like their bodies to look like; Ata et al. 2007).

201.7.4 Modeling of Eating Behaviors

Along with having conversations about food and being exposed to appearance-related criticism, the peer group is likely to be the place where disordered eating is modeled, particularly among girls. In friendship cliques of girls characterized by high levels of dieting and extreme weight loss behaviors, as well as heightened concerns and conversations about weight and dieting, social comparisons, and

pressures from peers to be thin, members of the clique, on average, have more body image concerns and more disordered eating (Paxton et al. 1999; Hutchinson and Rapee 2007). Girls' own levels of dieting and extreme weight-loss behaviors can be predicted from their friends' self-reports of their eating behaviors (Hutchinson and Rapee 2007).

201.7.5 Indirect Effects of Peer Social Contexts

The social context of peers may also be an environment where, indirectly, adolescents may become more attuned to how they appear in front of others. For adolescents, simply wanting to be accepted by peers and to fit in may be associated with a desire to change their appearance. Lower peer acceptance, perceived social support, and friendship intimacy are associated with poor body image among adolescent females (Gerner and Wilson 2005). In contrast, having social support from friends and acceptance may help adolescents rise above sociocultural pressures and feel more positively about their bodies by fostering resilience (Stice et al. 2002; Ata et al. 2007).

Social situations, like romantic relationships or engaging in sports, may bring appearance concerns to the forefront. Girls who are romantically involved with boys have poorer body image than those who are not romantically involved (Compian et al. 2004). When adolescent girls perceive that being thin will positively impact their friendships with boys (e.g., popular boys will like them more; they will be more popular among boys and gain more recognition among male friends), they are more likely to have body image concerns and experience body dissatisfaction (Gerner and Wilson 2005).

For boys, the social context that is particularly likely to bring about body dissatisfaction is sports. Adolescent boys who express body dissatisfaction or a desire to modify their bodies are more likely to do so in the context of their experiences participating in a particular sport (Ricciardelli et al. 2006). It may be that boys perceive that it is more socially acceptable to express these concerns in relation to sports, as opposed to other situations such as romantic relationships.

201.7.6 Concluding Points

As seen in Table 201.5 and in the previous sections, peers may influence adolescents' body image in both direct and more indirect ways. Based on the research summarized above, it is clear that adolescents

Table 201.5 Examples of peer influences on adolescents' body image

Direct influences of peers through interactions and modeling
Social comparisons
Appearance-related conversations
Appearance-related teasing and criticism
Pressures to modify appearance
Modeling of disordered eating and appearance concerns
Indirect influences of peer social contexts
Social support
Romantic relationships
Sports

This table lists potential peer influences on adolescents' body image. The influences have been divided into those that are believed to exert a direct effect through interactions between adolescents and their peers and peer-modeling, and those such as social contexts, which are believed to exert a more indirect effect

care very much about how they think their peers view them, and there is a strong link between adolescents' perceptions of their peers' appraisals and how adolescents feel about their own bodies. Worrying about fitting in with peers in general, seeking relationships with same-sex and opposite-sex peers, and participating in different activities with peers may also bring about appearance-related concerns; however, social support and close friendships may serve to help adolescents cope with pressures and to feel better about their bodies.

201.8   Cultural Factors

Historically, researchers have focused on body image concerns in predominately White/Caucasian US samples with growing interest in the presentation differences among males and females. Yet, little research has focused on the racial and ethnic differences of body image in both males and females (Grabe and Shibley Hyde 2006) and there is growing awareness regarding the impact that social and cultural variables have on body dissatisfaction and disordered eating (Crago and Shisslak 2003). Earlier studies suggested that body image dissatisfaction was highest among White females; however, more recent findings have suggested that the incidence of disordered eating and body image concerns among cultural groups may vary according to age and acculturation status (Roberts et al. 2006) whereas others suggest that differences are minimal in adolescence (Shaw et al. 2004). Adolescence is a time when youth are particularly susceptible to the influence of culture, as many seek clarification of ethnic identity and attempt to align with culturally-dictated appearance norms. In the following sections, we review the literature regarding cultural factors influencing body image during adolescence (Table 201.6). Moreover, the influence of acculturation and acculturative stress in the context of body image dissatisfaction will be highlighted.

201.8.1   Cultural Factors by Race/Ethnicity

The majority of the literature comparing body image dissatisfaction among different race/ethnic groups has focused on Black–White differences in females. When compared to White adolescents, African-American adolescents report significantly lower awareness of appearance-related dominant societal standards and significantly lower internalization of those standards (Abrams and Cook Stormer 2002). A recent meta-analysis revealed that Black females demonstrated greater body image

Table 201.6   Examples of cultural factors influencing adolescents' body image

Racial/ethnic background

Caregiver educational attainment (socioeconomic status)

Acculturation (parental and adolescent)

Acculturative stress

Body mass index (BMI)

Peer group composition

Culturally-oriented television viewing

This table lists cultural factors that may influence adolescents' body image. Some of these factors are directly related to the adolescent (e.g., adolescent acculturation), while others exert indirect influences via the adolescent's parent(s)/caregiver(s) (e.g., socioeconomic status)

satisfaction (global and weight related) than White females across all effect sizes (Roberts et al. 2006). Moreover, studies have found greatest racial differences occurring during the early 20's (Roberts et al. 2002; Grabe and Shibley Hyde 2006), suggesting that later adolescence/young adulthood is a time of significant social comparison and interpretation or consolidation of ethnic norms. One explanation for the differences may lie in the cultural socialization of Blacks versus Whites. Whereas Black adolescents are more likely to describe the ideal woman in terms of personality traits (e.g., strong), White adolescents describe physical traits (e.g., hair and height) as preferable (Parker et al. 1995). Similarly, Black males tend to report a preference for a medium to larger frame and more satisfaction with and pride in their bodies than White males. However, Black adolescents may be more likely to engage in extreme weight loss and muscle gain strategies (Ricciardelli et al. 2007) and binge eating (Johnson et al. 2002) than White males.

Research investigating Hispanic adolescent females' body image is inconsistent; however, meta-analytic findings indicate that there are no differences between Hispanic and White females on measures of body dissatisfaction, with Hispanic females reporting higher body dissatisfaction than Black females (Grabe and Shibley Hyde 2006). Research on inpatient samples indentifies different findings. In comparison to Caucasian adolescent females, Hispanic and African-American females are less likely to report body image dissatisfaction and dietary restraint (White and Grilo 2005). Similar findings were reported by Barry and Grilo (2002), who found that Caucasian females displayed greater body disapproval and body image disturbance than Hispanic and African-American adolescents. Reports of body image in Hispanic adolescent males do not appear to differ from those of White males. Hispanic boys are more likely to participate in both normative and extreme weight loss strategies, binge eat, and engage in weight/muscle gain behaviors to a greater frequency than White males (Ricciardelli et al. 2007).

The general pattern of findings related to Asian adolescent females suggests that they maintain similar body image concerns as White females (Grabe and Shibley Hyde 2006). Research on Asian adolescent males is inconsistent and scarce, but implies no differences when compared to White males on measures of body image and weight loss. Asian males report binge eating and desire for weight gain more than White adolescent males (Ricciardelli et al. 2007).

A discussion regarding the impact of culture on body image is not complete without mentioning the intertwined effects of SES. While cultural upbringing influences subsequent internalized appearance-related norms, SES affects the extent to which these norms are reinforced and maintained. For example, Black and White adolescent females whose caregivers have higher educational attainment (college or greater) are more likely to report greater awareness of societal standards than girls with caregivers reporting lower educational attainment (high school or less; Abrams and Cook Stormer 2002).

Overall, research investigating racial and ethnic differences in body image is limited and future research is warranted. The existing literature suggests that Black and Hispanic females demonstrate greater body image satisfaction, less awareness, less internalization, but greater binge eating than White and Asian-American females. Less is known regarding males' attitudes and perceptions, but the findings to date are suggestive of similar weight-related concerns, increased muscularity, and binge eating in ethnic populations to a greater extent than White males.

201.8.2 Acculturation

At its most basic level, individual acculturation is defined as the resulting process when an individual from a different cultural background interacts with members of a receiving culture (e.g., mainstream). Following repeated interactions, the individual exhibits subsequent changes in beliefs, values,

and/or practices. While the process of acculturation is behavioral, there are psychological challenges and outcomes that result from the act of becoming acculturated. When there is some difficulty in the process, acculturative stress occurs, with major incompatibilities contributing to psychopathology (Berry 1997). Both cultural and psychological variables work to impact the level of acculturative stress.

The bulk of the literature examining the relationship between acculturation and body image has focused almost exclusively on Hispanic youth. Adolescents experiencing acculturative stress rate themselves as less physically attractive than White youth (Hawley et al. 2007). Hispanic youth who are at risk for being overweight or are overweight report greater body dissatisfaction than normal weight youth, with greater discrepancies occurring in male samples (Ayala et al. 2007). One reason for body image concerns in youth may be related to the US desire for thinness, which is less common in Hispanic cultures that value full-figured bodies. More acculturated youth have been found to prefer thinner figures than less acculturated youth, with females showing a stronger preference than males (Olvera et al. 2005). Hispanic adolescents who report greater agreement with socially prescribed norms of beauty and thinness are more likely to exhibit disordered eating and compensatory behaviors (Ayala et al. 2007). Patterns of body dissatisfaction also differ by gender. When compared with more acculturated males, Hispanic males who are less acculturated are more dissatisfied with their looks, perhaps due to the devaluation of the Hispanic appearance and internalization of the White thin ideal (Nieri et al. 2005). Finally, patterns in body image satisfaction are also influenced by the level of parental acculturation. As parents acculturate to the dominant culture, they are more likely to be influenced by media and societal norms regarding weight. For example, Olvera and colleagues (2005) found that mothers who were more acculturated preferred and rated thinner body types as more attractive than less acculturated mothers. As a result, girls of more acculturated mothers were more likely to select a thinner body type as the representative ideal. Thus, parent and adolescent acculturation and acculturative stress serve to influence body image satisfaction in Hispanic youth. More research is necessary to determine the impact of acculturative factors in other ethnic groups.

Aspects of acculturative stress may also be related to peer relationships and the media. As noted in the previous sections, peers and the media can have a significant influence on appearance-related concerns in adolescence. Along that line, peer group composition has been implicated in moderating the effects of race/ethnicity on body image perceptions. When adolescent females maintain a group of mixed racial/ethnic friends, they are more likely to report higher internalization of societal standards than those with less diverse friends. Moreover, African-American girls with mixed friends report higher awareness and internalization of appearance-related norms than African-American females without mixed friends, with similar trends occurring for Hispanic females (Abrams and Cook Stormer 2002). Thus, it is important to recognize that peer relationships work to magnify acculturative stress and body image dissatisfaction.

Additionally, it is well documented that mainstream television viewing is associated consistently with decreased body image in adolescents. Schooler (2008) found that when Hispanic girls viewed Black-oriented television frequently, they were more likely to report greater body image satisfaction. Therefore, when media features ideals that are supportive of cultural norms, body image concerns decrease.

201.8.3 Concluding Points

Cultural and acculturative factors influence the incidence of disordered eating and body image perceptions among ethnic youth. Adolescence is regarded as a time where culture may be incompatible

with societal norms. In turn, supportive networks are necessary in order to negate the message of thin as ideal.

201.9 Applications to Other Areas of Health

Research has clearly linked adolescents' body image, specifically body dissatisfaction, with a myriad of negative outcomes, including psychological distress and more severe forms of psychopathology. More specifically, body image has been linked to depression, negative affect, low self-esteem, eating disorders, and body dysmorphic disorder (Stice and Bearman 2001; McCabe and Ricciardelli 2003; Steinberg et al. 2004). Body image disturbance has also been associated with risky sexual behaviors (Gillen et al. 2006) and substance use (Palmqvist and Santavirta 2006).

201.10 Future Research

A wide variety of social and interpersonal influences have been shown to have an impact on adolescents' body image. The bulk of research has targeted three formative influences: media, peers, and parents. We reviewed a wide range of studies that evaluated one or more of these factors and the relationship with body image. There is a great deal of support for all three influences; however, many future research avenues remain open. For instance, although a few studies have evaluated the unique contribution of each of the three influences within one study (e.g., Keery et al. 2005; Shroff and Thompson 2006a), much more work needs to be done in this regard with younger samples, boys, different ethnicities, and cross-culturally. Additionally, few studies use a wide range of indices of sociocultural influence, limiting the ability to discern which particular aspect of media, peer, or parental influence is uniquely associated with body image disturbance. Finally, we need much more prospective and experimental work; to date, the great majority of work has been of a correlational nature.

Summary Points

- Body image issues can develop at any point throughout the lifespan, but are most common during adolescence.
- Sociocultural theories of body image disturbance examine the influence of factors such as parents, peers, and the media.
- Peer and parent influences on adolescent body image can be either direct (e.g., appearance-related teasing) or indirect (e.g., via social context).
- The media contribute to adolescent body image by transmitting messages regarding culturally-defined ideals of attractiveness.
- Existing research on racial and ethnic differences in body image suggests that Black and Hispanic females demonstrate greater body image satisfaction and binge eating than White and Asian-American females.
- Body image disturbance has been linked to eating disorders, depression, negative affect, low self-esteem, risky sexual behavior, and substance use.

Definitions

Acculturation: Behavioral processes whereby one adapts to a new culture; can lead to subsequent changes in beliefs, values, and/or practices.

Acculturative stress: Psychological tension that may be experienced as a result of difficulties encountered during acculturation.

Adolescence: Developmental period typically considered to range from age 13–17.

Appearance comparison: Comparing of one's appearance to the appearance of another in order to derive information about the former.

Body mass index: One of the most commonly used measures of overweight and obesity, calculated by dividing a person's weight (in kilograms) by their height (in meters squared).

Body image: Broad concept including feelings, thoughts, and perceptions about one's body.

Body dissatisfaction: The affective component of body image.

Body image disturbance: Poor body image characterized by negative feelings about one's body or appearance.

Body dysmorphic disorder: Psychological disorder characterized by obsession with a perceived flaw in one's appearance.

Internalization: Incorporation of socially transmitted messages into one's self-concept.

Socioeconomic status: Relative social standing based on factors including education and income.

Chapter 202
Body Image and Eating Disorders Among Immigrants

Nan M. Sussman and Nhan Truong

Abbreviations

APA   American Psychiatric Association
ED   Eating disorders

202.1 Introduction

Eating disorders are generally defined as a disturbance in the perception of body shape resulting in restrictive or binge eating/purging patterns (Mintz and O'Halloran 2000). Extant literature had conceptualized eating disorders as culture-bound syndromes (Prince 1985), manifested in two disorders described in the DSM-IV: anorexia nervosa and bulimia. Anorexia is defined as a disorder in which the individual is resistant to maintaining a minimally normal weight, has an intense fear of gaining weight, and has infrequent menstrual periods (American Psychiatric Association 1994); bulimia is defined as a disorder in which the individual has recurrent episodes of excessive binge eating, a strong sense of lack of control, and recurrent compensatory behaviors (e.g. use of laxatives, enemas, vomiting, excessive exercise (APA 1994)). In the extreme, both syndromes can lead to death by starvation. Moreover, these eating disturbances have been understood as specific to Western culture as, in general, women in cultures removed from Western media exposure (Akiba 1998) or economic development and modernization (Lee and Lee 2000) had higher body esteem and lower fat concerns. Significant levels of disordered eating have been found in the USA, Britain, Canada, and Australia with lower prevalence in Western Europe and rare occurrences in Africa and Latin America.

202.2 Cultural Differences in Body Ideal

Culture, it appears, influences both attitude toward body shape in general, evaluation of one's own body, and eating behaviors. While body shape, size, and weight are essential elements of physical attractiveness for many cultures, each differs in their preferences. Kenyans (Furnham and Alibhai 1983)

e-mail: nan.sussman@csi.cuny.edu

and Ugandans (Furnham and Baguma 1994), for example, rated larger female figures more favorably than did British women, who found female anorexic figures appealing. Similarly, Cogan, Bhalla, Sefa-Dedeh, and Rothblum (1996) found that women from Ghana were more likely to rate larger body sizes as ideal compared to US students. Caribbean women of African descent maintained this preference with studies finding obesity associated with satisfaction, wealth, and happiness (Simeon et al. 2003). Little normative data exists about Central and South American women in their home country although there is speculation that the body ideal is shorter and rounder than the US ideal. Mexican-Americans, for example, are heavier than their White nonHispanic counterparts, and children who were overweight had a stronger affiliation to Mexican culture (Ayala et al. 2007).

In traditional Chinese culture, heavy women were evaluated positively (Nasser 1988) and some contemporary Chinese women view plumpness as a component of the ideal female body shape (Chen and Swalm 1998). Current studies of Hong Kong Chinese adolescent females find, in comparison with American adolescents, similar body dissatisfaction but lower drive for thinness, and among college-aged Chinese women, lower body dissatisfaction and drive for thinness (Leung et al. 2004). Chinese women also consistently score lower on self-esteem scales which may be attributed in part to the self-effacing nature of Chinese values (Bond and Cheung 1983). Scant research has investigated normative body image among Eastern European women. However, in a comparison of the link between slimness and sexual attractiveness of women rated by Finnish and Russian men, researchers found the slim ideal was held by the Finnish but not the Russians (Haavio-Mannila and Purhonen 2001).

Some studies have also examined the role of ethnicity within a single country in shaping body preferences. Results indicate that, within the US, Asians and Whites prefer the thin body ideal and Hispanics and African-Americans tend to prefer a larger body size (Molloy and Herzberger 1998). Black women tend to be less preoccupied with dieting and weight loss and less negative about their body image than White and Latin American women (Cash and Henry 1995; Miller et al. 2000). Also, African-American women perceived themselves to be more sexually attractive, have higher self-esteem, and higher body esteem than the other ethnic groups (Miller et al. 2000).

There is support among many studies correlating poor body satisfaction with increased risk or prevalence of eating disorders. In the USA, thinness is a core body ideal and is highly valued (Garner et al. 1980). Unfortunately, this ideal is often unattainable and results in negative evaluations of one's body. Two concepts which have been developed to assess the subjective self-perception of the body, commonly referred to as body image, are body esteem, an overall evaluation of one's body, and satisfaction with individual parts of the body. General self-esteem is also associated with both body image and eating disorder risks (Mintz and Betz 1988).

202.3 Body Image and Eating Disorders

The majority of American women tend to overestimate their body size, and thus view their bodies in self-deprecating ways (Lewis and Donaghue 1999) which results in general dissatisfaction with their bodies (Cash and Henry 1995) and poor self-esteem (Matz et al. 2002). America's obsession with thinness combined with body dissatisfaction, which has consistently been demonstrated to be a risk factor in eating disorders (Altabe and Thompson 1992), has resulted in negative physical health consequences for an estimated seven million (predominantly white) females in the USA who are afflicted with eating disorders (EDs) (Eating Disorder Statistics 2003) and many more who are at risk for disordered eating. Among White US women, EDs were correlated with low body esteem (Striegel-Moore et al. 1993) and low self-esteem (Joiner and Kashubeck 1996) among other factors. It is estimated that 1.15 million people in the UK have an eating disorder.

This link between body dissatisfaction, low body or self-esteem, and disordered eating is not found uniformly in other countries or among immigrant samples. Chinese (Pan 2000) and Japanese (Mukai et al. 1998) women had lower body esteem than US women but not greater rates of eating disorders and Doan (2001) found that self-esteem and eating disorder symptomology were unrelated among East Asian-Americans. Among Indian female adolescents, decreased appetite and excessive weight loss is found but not accompanied by body image disturbances or fear of becoming fat (Khandelwal and Saxena 1990). Additionally, Afro-Caribbean British women, compared to Caucasian British, were less likely to have feelings of depression or anxiety related to disordered eating attitudes (Dolan et al. 1990). However, among Chinese-Australian women, eating pathology was associated with lower levels of satisfaction with the body. In summary, culture shapes its citizens' preferences for body shape and size, evaluation of body against a cultural norm (body image), and the association between body attitudes and eating behaviors. Therefore, in this chapter, the literature will be reviewed by world region.

202.4 Immigration and Cultural Transitions

Rapid cultural changes in the world, coinciding with the expanded influence of Western culture and increased immigration, have shifted our current thinking and understanding of eating disorders from culture-bound to culture-transition syndromes (see Table 202.1). Transitions may take place within a culture as Western values and attitudes have permeated domestic perspectives of body image. For example, Khandelwal and Saxena (1990) indicate that India is increasingly influenced by Western values and may result in anorexia being more prevalent. Transitions also take place within an individual's psychological attitudes, values, and behaviors as one migrates from home country to host country. Among the new values and norms to which immigrants are exposed are those pertaining to the culturally ideal body type and standards of physical attractiveness. Thus, one question posed by researchers is "What is the effect of immigration and its consequences for body image and the risks for eating disorders?"

Table 202.1   Key facts about immigration

1. In 2005, world immigration totaled 190,633,564
2. Of the top ten countries that were recipients of migrants, eight were Western economically developed countries (USA, Russia, Germany, France, Canada, UK, Spain, Australia).
3. Regions of origin of immigrants:

To	From	Percent of total immigration to host country (%)
USA	Mexico	30
	East and Southeast Asia	18
	Central America	8
France	North Africa	47
Canada	East and South Asia	12
UK	South Asia	15
Spain	South America	18
Australia	Asia	7
Germany	Europe	50

This table provides recent demographic statistics on immigrant country of origin and country of destination

Table 202.2 Definitions and explanations

1. **Acculturation:** Although the concept is complex, we refer to the adoption of thoughts, attitudes, values, and behaviors of the host culture. Acculturation has been measured employing single variables such as length of residence in the host country, and multi-item scales of language use.
2. **Body image:** Body image refers to an evaluation of one's body (positive or negative) that involves feelings about his/her body in relation to the body ideal. Some concepts employed to measure body image include body parts dissatisfaction/satisfaction, body dissatisfaction/satisfaction and body esteem.
3. **Eating disorder:** Eating disorder in this chapter has referred to the clinical syndromes anorexia nervosa and bulimia, as well as risk for the development of eating disorders, maladaptive eating attitudes and behaviors, and eating pathology.
4. **Immigrant:** Immigrant refers to individuals who moved from their country of birth and settled in the host country. We distinguished between individuals who migrated to the host country, referred to as "immigrants" or "first generation immigrants" and individuals who were born in the host country but had immigrant parents, referred to as "second generation immigrants".
5. **Host country:** The country to which the immigrant migrated and settled. This term is in contrast to the home country, the country to which the immigrant was born.

This table lists five terms and their definitions that are used often in the chapter. The definitions will improve the understanding of the research discussed in the text of the chapter

Immigrants undergo a process of cultural transition in which their attitudes, beliefs, values, and behaviors change as they adapt to their new home country. This adaptation process is referred to as acculturation (see Table 202.2), although recent conceptualizations suggest a more complex and nuanced intersection of maintenance of attitudes from the country of origin and adaptation of attitudes from the new home country (Trimble 2003). Growing attention has been paid to the role of multi-directional acculturation on the mental and physical health of immigrants living in the USA, Australia, and Britain. A second research question asks "Will the process of immigration uniformly influence all migrants or will the level of individual acculturation to the host country affect body attitudes and eating behaviors?" Speculation is that both individual level and cultural level variables modify the effect of immigration on body image and eating disorders.

Findings from the past literature are equivocal. Immigration to a Western country has been identified as a possible risk factor in eating disorders (Geller and Thomas 1999) as has been the increased acculturation level. The latter has been found among Hispanic-American girls (Gowen et al. 1999) and other acculturated ethnic minority women (Cachelin et al. 2000; Chamorro and Flores-Ortiz 2000).

Other studies find no link between acculturation and eating disorders among Asian- and Chinese-American women (Haudek et al. 1999; Pan 2000). Among East Asian immigrants, acculturation did not predict desire to be thinner, feelings of guilt after eating, or fear of being overweight (Barry and Garner 2001). Huang (2001) found that only Asian-American women, who more strongly identified with White American culture, were more likely to engage in compensatory weight loss behavior but not binge eating. Among African-Americans, evidence demonstrates that they are less likely to internalize the thin ideal than Asian or White Americans (Shaw et al. 2004).

These inconsistencies may be explained by examining residential patterns of immigrants. Urban dwellers who are surrounded by ethnic peers and thus less influenced by the dominant culture's body standards may be buffered against body dissatisfaction and risks for eating disorders. In two studies, Caribbean-Americans (Sussman et al. 2007) and Mexican-Americans (Fisher et al. 1994) who lived in ethnic urban enclaves revealed lower anxiety, higher self-esteem, and a few ED symptoms than those peers living in suburban or more integrated neighborhoods.

This chapter, in addition to reviewing the literature by world region of the immigrant, will also report the effects of acculturation. It should be noted that measures of acculturation vary dramatically among studies: some include a unitary measure while others are multi-dimensional; some use self-report assessments and others are archival. These variations make direct comparisons and syntheses troublesome.

202.4.1 Immigrants from Asia

Very few studies have examined body image and eating disordered attitudes and behaviors of non-clinical Asian sample populations within their own countries. Kayano et al. (2008) examined eating attitudes and body dissatisfaction among Filipino, Omani, Japanese, Indian, and Euro-American adolescents. Not surprisingly, both male and female European youth indicated the greatest desire to be thin compared to the other groups. However, Filipino males and females and Indian females indicated greater maladaptive eating attitudes than their European counterparts. Among Filipinos, non-hunger related motivational eating patterns have been shown as a result of "demographic changes, economic development, and nutritional transitions" (p. 23). These motivations include the environment, such as being surrounded by delicious foods, eating socially, particularly among family and friends, and emotional eating due to loneliness, depression, and anxiety. Eating disordered behavioral patterns among Indians may be due to belief aspects of their Hindu religion, which include vegetarianism. Perhaps the greater their beliefs in Hinduism, the more likely they are to follow a strict vegetarian diet which in turn leads to higher disordered eating attitudes. Among the female Japanese adolescents, maladaptive dieting and a desire to be thin occurred when there was an increase in body mass index (BMI). Among the Filipino, Indian, and Japanese Asian groups, the Japanese adolescents appeared to have the healthiest eating attitudes and behaviors overall. This may be due to the relatively low BMI in Japanese female adolescents, and therefore they were satisfied with their bodies and felt no need to diet or be thin.

202.4.1.1 Body Image and Eating Disorders

Studies on Asian immigrants have generally shown that migrating to Western countries such as the USA and European countries has led to lowered body image and greater risk for eating disorders. Waller and Matoba (1999) examined the relationship between emotional eating and disordered eating among Japanese women who were born and currently reside in their home country, Japanese women who have lived in the UK for at least 9 months and currently reside in the UK, and British women living in the UK. Japanese women living in the UK showed a relationship between emotional eating and bulimic attitudes, similar to the patterns found in the British women. However, this association was not found in the Japanese women in Japan. In another study comparing Chinese women from Hong Kong and Chinese women from mainland China (Lee and Lee 2000), Chinese women from Hong Kong adopted the Western beauty ideal, were slimmer, had greater body dissatisfaction, and greater eating disorder behaviors. In another study by Mujtaba and Furnham (2001), British Asian immigrant females from Pakistan reported higher levels of risk for developing eating disorders compared to Pakistani females in Pakistan. In Choudry and Mumford's (1992) study, Pakistani immigrants living in the UK showed a higher prevalence of bulimia than Pakistanis residing in their home country. Thus, for Asian women moving to the West, immigration itself appears to be a risk factor for EDs.

202.4.1.2 Acculturation Effects

A closer examination of the process of immigration has shown that more acculturated Chinese immigrants to Western culture report lower body satisfaction and lower eating disorders. Among immigrant Chinese-Americans born in Taiwan, China, and Hong Kong, participants who were less Chinese (more acculturated) on the Chinese Orientation subscale showed lower body satisfaction

(Cheng 2001). In another study of Chinese undergraduate students who were primarily born in Hong Kong (10% were US born) and lived in the USA, females who were bicultural or mostly American (high acculturation) on the Suinn-Lew Acculturation Scale reported significantly greater bodily perfectionism and higher eating disorder scores than females who were very or mostly Asian (low acculturation) and males (Davis and Katzman 1999).

Some researchers have examined underlying psychological mechanisms through which acculturation plays a role in body image and eating disordered attitudes and behaviors. Humphry and Ricciardelli (2004) found that in their sample of primarily Asian-Australian immigrants who were born in China, Hong Kong, Malaysia, and Singapore (7% were Australian-born), women who had a weak Chinese identity (high acculturation) on the Ethnic Identity Scale did not differ from those with a strong Chinese identity (low acculturation) on eating disorder attitudes. It was only when high acculturated Chinese-Australian females perceived more pressure to lose weight from their father or best friends that they showed greater eating disorder attitudes than their low acculturated counterparts. In the same study, women who reported a high Chinese identity and higher parental care showed higher levels of eating disorders. In another study on Chinese immigrants living in New Zealand, two aspects of acculturation, values toward other groups and interpersonal distrust, mediated the relationship between positive or healthy appraisal of perfectionism and eating disorders (Chan and Owens 2006). Here, a positive appraisal of perfectionism appears to serve as a buffer between adopting the values, attitudes, and behaviors of the host culture and the development of eating disorders.

Other studies have indicated that acculturation does not play a role in the body image and eating disorders. In a study on East Asian immigrants by Barry and Garner (2001), acculturation was not related to wanting to be thin, guilt from eating, afraid of being overweight, and worrying about having fat on the body. In another study (Pan 2000), among Chinese-American women acculturation did not correlate with body image attitudes, eating attitudes, and eating behaviors. In Soh et al.'s (2007) study of Northern European and East Asian women with and without eating disorders, acculturation was not related to eating concerns among East Asian Australians and Singaporean Chinese women. Based on the National Latino and Asian American Study, acculturation – defined as US born versus immigrant, number of parents born in the USA and length of residence in the USA – did not predict eating disorders within the past 12 months (Nicdao et al. 2007). In two studies employing the Suinn-Lew Asian Self-Identity Acculturation Scale (SL-ASIA), one on South Asian-American women who were predominantly Indian (89%) and second generation (79%) (Iyer and Haslam 2003), and the other on Korean immigrant women to the USA (18%) and second generation Korean-American women (82%) (Jackson et al. 2006), acculturation was not related to risk for developing eating disorders. Iyer and Haslam (2003) also found that the SL-ASIA was not associated with body image disturbance in their sample of South Asian-American women.

Researchers have examined other variables that may contribute to body image and eating disorders among this ethnic population. For Asian women, not only do societal pressures to be thin play a role in eating disordered behaviors, but also intrafamilial relations and conflicts. In Humphry and Ricciardelli's (2004) sample of predominantly Asian-Australian immigrants, parental bonding and physical appearance also predicted eating disorder attitudes, such that Chinese-Australian women who reported high parental overprotection and less satisfaction with their physical appearance tended to show higher eating disorder attitudes.

Among British Asian females who were predominantly Muslim second generation immigrants from India- and Pakistan-born parents (Furnham and Husain 1999), conflicts with parents over socializing – going out and choice of friends – correlated with higher risk for eating disorders. Similarly, in a study of British Asian female immigrants from Pakistan and Pakistani females in Pakistan, greater conflict with parents and greater overprotection from parents were associated with higher risk for developing eating disorders (Mujtaba and Furnham 2001). British Asian immigrants had greater conflict with parents, greater overprotection from parents, and higher risk for developing eating disorders

than their Pakistani counterparts. In a study of South Asian US immigrant women (31%) and American born South Asian women (69%), three aspects of teasing, overall appearance, weight and shape, and ethnicity were related to body dissatisfaction and eating disorders (Reddy and Crowther 2007).

The current paradigm around eating disordered behavior and attitudes is understood to be culture transition rather than culture-bound. In many countries, Western cultural values and ideas around the thin body ideal have influenced their culture's body image ideal. Interestingly, unique symptoms associated with eating disorders have been evidenced in India (Khandelwal and Saxena 1990). Here, anorexia and bulimia are less prevalent than in countries where thinness and body image is emphasized. Whereas anorexia is generally found to be correlated with negative body image, this is not the case among this population. Rather, hysterical symptoms have been found to correlate with anorexia. This may be a result of poor socioeconomic conditions, where poverty and famine are among the main concerns in the everyday lives of these people.

202.4.2 Immigrants from Central and South America

The USA is the largest recipient of immigrants from Central and South America and these residents, collectively referred to as Hispanics, are the largest immigrant group in the USA; Mexican-Americans form the majority. Attempts to estimate the frequency of ED among this population has resulted in conflicting figures: One study indicates that 4.3% of Mexican-American women suffer from Bulimia, similar to Caucasian Americans (Lester and Petrie 1998) while another study concludes that Hispanic have more severe binge eating compared to White and Black Americans (Fitzgibbon et al. 1998). Among Mexican-American women, the relationship between body esteem/satisfaction, acculturation, and eating disorders is also inconsistent. One study found no effect of acculturation on body esteem (Schwartz et al. 1998); one found no effect of body satisfaction on bulimia symptomology (Lester and Petrie 1995); and two others found that body dissatisfaction was positively related to anorexia and bulimia (Joiner and Kashubeck 1996; Straeter 2002). More consistent were the results examining the association between acculturation to the USA and ED: Three studies found that acculturation did not predict ED (Joiner and Kashubeck 1996; Kuba and Harris 2001; Lester and Petrie 1995) while Chamorro and Flores-Ortiz (2000) report that more acculturated women had more disordered eating. However, each of these studies used different measures of acculturation (one used a US Eurocentric scale and two others used generation as a proxy for acculturation – second generation women, presumed to be more acculturated, compared to first generation) which weakens comparisons.

Puerto Rican immigrants in New York and Cuban immigrants in Florida form two other large groups who have been investigated. In a qualitative study of 12 women from both ethnic groups, those who immigrated at a young age and were assumed to be more acculturated to US culture were more dissatisfied with their bodies (Smith 2001). In another study, among Cuban-American women, body dissatisfaction was linked to ED but acculturation was not (Rodriguez-Hanley 2004).

202.4.3 Immigrants from Russia and Eastern Europe

In Eastern Europe, the thin body ideal is not emphasized as it is in Western countries and thus striving for extreme thinness and accompanying eating disorders are less frequent. Few studies have examined the role of acculturation on body image and eating disorders among Eastern European immigrants. Some studies have found that the more acculturated to Western body ideals Eastern European immigrants became, the more negative was their body image and the higher their eating disordered attitudes and

behaviors. Greenberg, Cwikel, and Mirsky (2007) examined risk for developing eating disorders in both male and female native Israeli and immigrant European college students living in Israel. The majority of the immigrants came from the former Soviet Union (93%), mostly Russia and Ukraine. The immigrants were separated into two groups, veteran immigrants with a length of residence in Israel of approximately 9.5–12.5 years, and new immigrants with a length of residence of about 1.5–2.5 years. In general, the native Israeli and veteran immigrants indicated a higher prevalence for eating disorder attitudes. Veteran female immigrants showed a higher risk for developing eating disorders than the new female immigrants. Differences in female immigrant groups were found to be the greatest with bulimia. This suggests that Russian and Ukrainian female immigrants who live in Israel for a longer length of time are more likely to adopt the thin ideal and standards of a Westernized culture and are therefore more at risk for developing eating disorders than those who recently immigrated to Israel. The researchers suggest that the lack of prevalence for eating disordered attitudes among the new immigrants may be because they are less likely to have served in the Israeli Defense Forces, the Israeli army, which would expose them to maladaptive eating behaviors and attitudes. Also among the veteran immigrants, prolonged exposure to Western media may have influenced their eating attitudes and behaviors.

Bulik (1987) presented two case studies of Eastern European women who were new immigrants to the USA with their families. Before both women immigrated to the USA they were not preoccupied with the desire to be thin. However, within 2 years after living in the USA, they developed eating disorders, one with bulimia and the other with anorexia nervosa. Both women left their country during their adolescence and adapted to American culture quickly. Adopting a sense of independence from the family conflicted with the traditional family values of their own culture. This led to feelings of guilt. Also, these two women played conflicting family roles, the loyal child and the parent. Since their parents decided to immigrate to the USA, both women had no choice in leaving their home country. As obedient children, they followed their family's decisions. When they moved to the USA, they became translators for the family since they were the most fluent in English. As a result, they felt like they were the parent in the family as well. Feeling conflicted with their family roles and guilt over wanting independence, both women felt a sense of emptiness. Moreover, they felt like they did not fit in with American society and a lack of acceptance when they first moved to the USA. Through the media and interactions with peers, they learned that being thin was a way to gain social status, approval, and acceptance. They began to base their self worth on the slenderness of their body and their control of food intake.

Pavlova, Uher, and Papevoza (2008) interviewed six young Czech female sojourners to the USA and echoed similar experiences of isolation in their host country as one of the trajectories through which they either developed eating disorders or worsened their eating disorder symptoms.

In contrast to the previous studies described, one study found that acculturation plays a role in body image among Eastern European immigrants, but less so in eating disordered attitudes. Sussman, Truong, and Lim (2007) found that Eastern-European immigrant women who identified less with their birth country (more acculturated) indicated lower body esteem and were less satisfied with their body parts. US born European women exhibited higher risk for eating disorders than the Eastern-European immigrant women, but the difference was not significant.

202.4.4 Immigrants from Europe

The flow of immigrants from Europe to other regions of the world is light. During the 1990s, there was a significant migration from Ireland to UK, Canada, and the USA. However, this group was not included in any studies of body image and ED. Geller (2005) found that in their sample of second-generation Greek and Italian women living in Canada, greater internalization of the Western

thin ideal was predictive of higher risk for eating disorders. Greater conflicts with their family and higher levels of perfectionism also led to higher risk for eating disorders. Although not directly related to eating disorders, higher body mass index was related to more extreme weight loss behaviors.

Since the creation of the European Union and the loosening of immigration policies, there has been considerable immigration within Europe although few studies have examined these populations. For example, Germany has been the destination country of more than 7 million immigrants, about 50% from Europe, but none of these immigrant groups have been investigated regarding eating disorders. In one of the few studies investigating trans-European movements, Kirchengast and Schober (2006) found that migrant children from Turkey and the former Yugoslavia to Vienna and Austria were found to have a higher prevalence of being overweight and obese.

202.4.5 Immigrants from the Middle East

There is little normative information about the body image and ED risks or behaviors among women in Middle-Eastern countries. In one of the few studies, Abdollahi and Mann (2001) found that in their sample of Iranian women living in Iran and in the USA, exposure to Western media, length of residence in the USA, and language use were not associated with disordered eating symptoms and body image issues. The researchers suggest that the lack of differences in body image and eating disorder symptoms between the two groups may be due to the high Westernization of Iran prior to the Islamic revolution in 1978, which is evident in the familiarity with Western culture among the participants' parents. Also, the Iranian population in Los Angeles is large, and this may serve as a buffer against the effects of exposure to Western body image ideals.

Other factors that influence body image and eating disorders among Middle-Eastern immigrants include independence, control, sexuality, religion, and familial and individual personality factors. Timimi (1995) describes the process by which adolescent Arab female immigrants develop eating disorders: their yearning for independence and seeking pleasure in the self conflicts with their family traditions and expectations, as well as their Muslim religion and identity. These conflicts lead to feelings of guilt and depression, and therefore they may seek solace in food constraints as a way to purify the Muslim self. These maladaptive eating behaviors then result in the development of anorexia nervosa.

202.4.6 Immigrants from the Caribbean and Africa

In the Caribbean and Africa, the body ideal tends to deviate substantially from the Western thinness ideal. One Caribbean woman described the body image ideal in her home country, "A women can almost never be too fat. Even if I had weighed 80 kg, men would have found me more attractive than if I were thin." (Willemsen and Hoek 2006, p. 353). In a study of South Asian, African, and mixed adolescents living in Trinidad, a greater percentage of overweight African adolescents were satisfied with their body size than the South Asian and mixed overweight adolescents (Simeon et al. 2003). Similarly, in a study on cross cultural differences in body image perceptions among Kenyan Asian immigrant females living in Britain, Kenyan British females, and British females, the Kenyan Asian immigrant group perceived the larger female body shapes more positively and the thin female body shape more negatively than the other groups (Furnham and Alibhai 1983). This difference in beauty ideal may stem from the poor socioeconomic conditions of these developing countries, whereby overweight and normal body size signify wealth and having a healthy body (Simeon et al. 2003).

Very few studies have investigated the effects of immigration on body image and eating disorders among this population. Willemsen and Hoek (2006) presented a rare case study of a Caribbean Antillean woman who immigrated to the Netherlands and subsequently developed anorexia nervosa through adopting the thin beauty ideal there, primarily through television. Other case studies of Caribbean and African women with eating disorders describe their struggles with separation from their parents, as well as family and sexual conflicts (Geller and Thomas 1999).

In general, however, Caribbean and African female immigrants tend to display a lower prevalence of eating disorders and greater body satisfaction than Westerners. In Sussman, Truong, and Lim's study (2007), Caribbean immigrant women were more satisfied with their body parts than Eastern-European immigrant women (see Fig. 202.1). Moreover, Caribbean immigrant women had the lowest

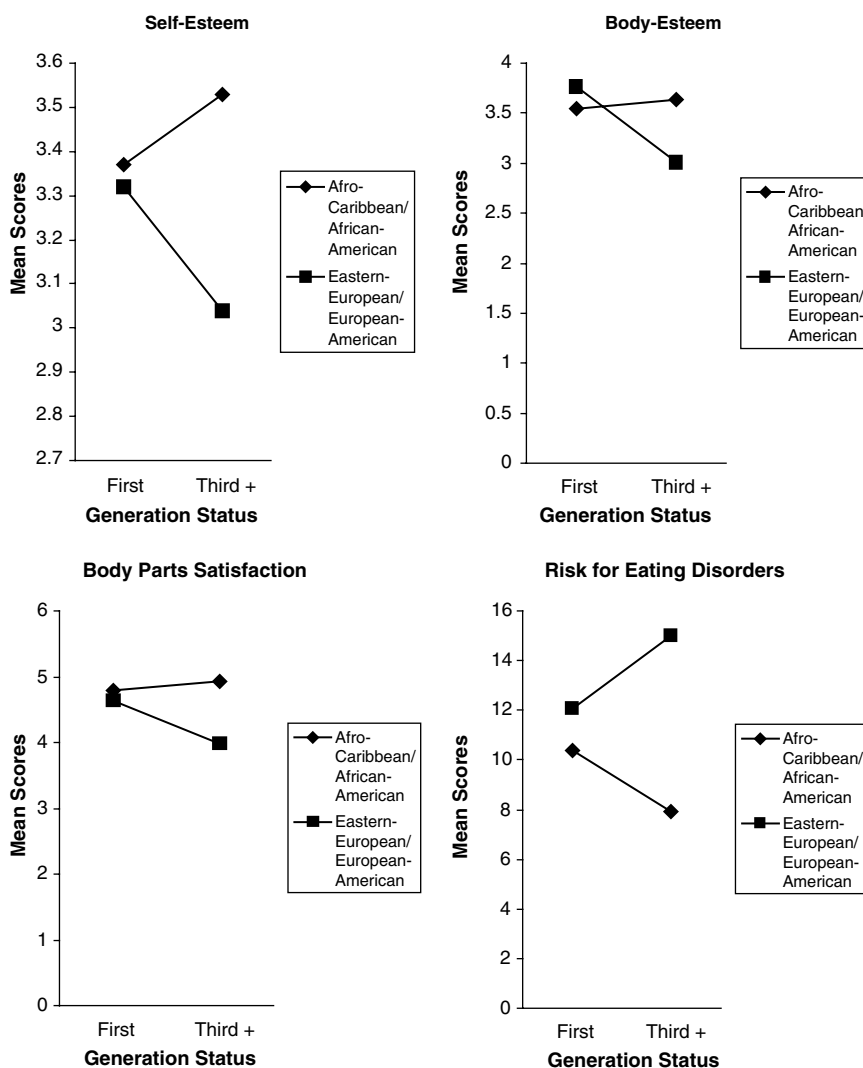

Fig. 202.1 Ethnicity moderating effects of acculturation (Sussman et al. 2007). This figure shows the moderating effects of country of origin for immigrants to the USA. As Caribbean immigrant women became more acculturated to the USA (first generation compared to third + generations), they had higher self-esteem, body esteem, and body parts satisfaction, and lower risk for eating disorders. However, as Russian immigrant women became more acculturated to the USA, they had lower self-esteem, body esteem, and body parts satisfaction, and were at higher risk for eating disorders

risk for eating disorders compared to Eastern European and Chinese immigrant women. This may in part be due to the fact that the Caribbean immigrant women resided in neighborhoods that were primarily Caribbean immigrants. Therefore isolating themselves away from the Western thinness ideal may have served as a buffer against developing a negative body image. In another study of first generation immigrant Jamaican-American women and US born African-American women, both groups did not differ in body satisfaction and both displayed similar body ideals (Williams 2007). However, the Jamaican-American immigrant women displayed a higher drive toward thinness. The higher drive to be thin among the immigrant group may in part have resulted from their experiences of acculturative stress, which was found to be related to concerns over one's body image.

202.5 Summary

The effects of immigration to Western countries on body image, risks for ED, or ED symptomology vary by cultural group. Among Asian immigrants, lower body esteem was often associated with greater risks for ED while for Central and South American immigrants, the correlation was equivo-cal. Immigration does not appear to negatively affect the body satisfaction of Caribbean or African immigrant women (see Table 202.3).

The level of acculturation to the host country was predicted by many researchers to be positively associated with ED or risks for the syndromes – the higher the acculturation, the higher the risk for the disease. This variable too was modified by home cultural group. The experience of Asian immi-grants generally supported the prediction whereby the more acculturated women had disordered eating or higher risks for ED. The data from Central and South American women were inconsistent although predominantly demonstrated no relationship between the level of acculturation and ED. Caribbean immigrants had the lowest incidence of ED in part because they acculturated the least. It

Table 202.3   Key points of eating disorders among immigrants

1. Eating disorders such as anorexia and bulimia had been found primarily among women in Western countries. In extreme forms, these diseases result in death. These syndromes were based on an idealized body type of extreme thinness which was perceived as attractive. The majority of the nonwestern world did not hold extreme thinness as an ideal female form.

2. World wide immigration has grown in the last two decades primarily from the developing countries to the West. One question posed by mental health and other health professionals was what would be the effect of immigration to the West on women's attitudes toward their bodies, risks for and prevalence of eating disorders. In general terms, research finding indicate that there is not a uniform effect of immigration. Women from Africa and the Caribbean do not appear to be negatively affected by immigration while Asian immigrants to the West tend to have lowered body image and greater risks for eating disorders.

3. Immigration's effect on body dissatisfaction and eating disorders can be modified by the extent to which the immigrant has acculturated or adapted to the host country. The more they live in integrated neighborhoods, have adopted attitudes of the host country toward body ideals and the attractiveness of thinness, the more likely they will be dissatisfied with their bodies and engage in disordered eating. Russian immigrants were found to be affected by acculturation level to the West either with body dissatisfaction or eating disorders. However, other studies examining Asian and Central and South American immigrants found that acculturation levels did not affect disordered eating. So high acculturation to the host country does not necessarily result in poor mental and physical health. Other factors also shown to affect their mental health include family conflicts and parental overprotection.

This table explains the general factors that influence the development of body dissatisfaction and eating disorders among women in Western countries. Since there are hundreds of thousands of women from other regions of the world immigrating to the West, many studies have examined whether these women are at risk for negative attitudes toward their bodies and for eating disorders

Table 202.4 Summary points

- Eating disorder symptoms include dissatisfaction with one's body which results in near-starvation eating behaviors or bingeing/purging patterns. Extreme forms can result in death.
- Until recently, eating disorders were found almost exclusively in Western countries due primarily to the emphasis of extreme thinness as a standard of beauty.
- Ideal body sizes, features, and standards of beauty vary from culture to culture.
- As a culture becomes more exposed to Western media and the thinness ideal, eating disorders begin to appear primarily among young women.
- Much research has focused on how immigration to the West affects women's body ideals, dissatisfaction with their bodies, risks for eating disorders and prevalence of the syndrome.
- Another research question focused on how the level of adjustment to the host country (acculturation) affects body dissatisfaction and eating disorders.
- Results indicate that the culture of the immigrant influences how the immigrant reacts, Russian and Asian immigrants are the most dissatisfied with their bodies and the more they have adapted to values and attitudes in the West, the more likely that they will suffer from eating disorders.
- Caribbean and African immigrants, despite having body ideals that are very different from those in the West, are the most satisfied with their bodies and least likely to suffer from eating disorders.
- Health and mental health professionals should be aware of culture and acculturation and their affect on eating disorders when interviewing or treating an immigrant patient.

This table summarizes each of the major points in the chapter in the order that they are presented. These points also summarize the major research findings regarding immigration and body image and risk or prevalence of eating disorders

Table 202.5 Suggestions for future research

1. More studies need to test "pure" first generation immigrant samples on acculturation and other sociocultural factors that affect body image and eating disorders.
2. Further investigate sociocultural factors that influence body image and eating disorders among immigrants in countries that have been little researched, such as in Central and South America, the Middle East, and Caribbean and Africa.
3. More studies need to conduct cross-cultural comparisons on body image and eating disorder pathologies between individuals of a specific ethnicity residing in their native home country and a second group of individuals of the same ethnicity who immigrate to a Western host country.
4. Conduct studies on body image and eating disorders among immigrants across several countries employing the same acculturation measures.
5. Conduct studies that employ more powerful methodologies, such as longitudinal studies that examine influence of acculturation and other sociocultural factors on body image and eating disorders among immigrants across different time points.

This table provides suggestion for future research studies by including a larger number of countries and limiting weaknesses in current methodologies

is speculated that living in separate ethnic enclaves buffered them from the dominant culture's body ideal that differed from the normative ones in Africa or the Caribbean (see Table 202.4).

Ironically, for many of the immigrant women, the less acculturated they were, the healthier they were, at least with regard to body image and eating habits. However, we caution drawing many generalizations from the data. Lack of standardization of assessment instruments, inconsistent operational definitions of variables, and methodological weaknesses hamper the ability to integrate the growing literature on this topic. Increased care must be taken to improve the validity and comparability of the research. See Table 202.5 for suggestions for future research directions.

202.6 Applications to Other Areas of Health and Disease

While admitting to the limitations of the research, we suggest that physicians and mental health specialists pay attention to the cultural background, immigration status, level of acculturation, and familial relationships when conducting intake interviews. As discussed in this chapter, some countries such as in Eastern Europe are not as concerned with the slim body ideal as in Western countries, and in the Caribbean and Africa the body ideal deviates substantially from the Western ideal. Cross cultural comparison studies between a group of individuals from a specific ethnicity residing in their native home country and another group of individuals from the same ethnicity who immigrated to a Western host country have shown significant differences in their body image and eating disordered pathology. Some studies have shown that the level of acculturation plays a role in body image and eating disorders, such that the more the immigrant adopts the attitudes, thinking, values, and behaviors of the Western host country, the more they will be at risk for developing eating disorders. Finally family conflicts, specifically with the parents, have been found to contribute to body image concerns and eating disorders.

Also, we have to be aware that the EDs may be presented differently in different countries and may be triggered by different variables than those shown in the USA, UK, and other Western countries where EDs have been prevalent. Case studies in India have shown that eating disorders manifest in different and unique symptoms from those in Western countries.

"My Body Is My Template": Why Do People Suffering from Anorexia Nervosa See Their Bodies Differently?

Naresh Mondraty and Perminder Sachdev

Abbreviations

ACC	Anterior cingulate cortex
AN	Anorexia nervosa
BN	Bulimia nervosa
BIID	Body integrity identity disorder
EBA	Extrastriate body area
FBA	Fusiform body area
fMRI	Functional magnetic resonance imaging
IPL	Inferior parietal lobule
MPFC	Medial prefrontal cortex
SPL	Superior parietal lobule
TPJ	Temporo-parietal junction

203.1 Introduction

In Western societies, feminine beauty has become synonymous with thinness. It is therefore unsurprising that the desire to lose weight and be thin becomes manifest in the preadolescence years and reaches a pathological crescendo in a few unlucky young women (Sachdev 2009). Paradoxically, "feeling fat" is a very common experience among women in general, not only among those who diet but also among women who do not concern themselves unduly with weight issues (Striegel-Moore et al. 1986; Cooper et al. 2007). This has contributed to misconceptions that anorexia nervosa (AN) falls within this normal experience and is a choice made by the sufferer.

In AN, a sufferer does not see her skeletal body as it really is. When asked about her body, she does not just *think* she is fat, but also *sees* and *feels* herself as fat. This disturbance of self-evaluation often focuses around the abdomen, buttocks, and thighs. Though the self body image is grossly distorted, this erroneous perception does not extend to judging the figures of other people (Cash and Deagle 1997). The "experiencing of fatness" and "fear of fatness," paired with low body weight, is pathognomonic of *true* AN. The focus of the discussion in this chapter is on this group. There is a

e-mail: naresh.mondraty@wesleymission.org.au

subgroup of patients without this body size distortion, no less unwell, who are considered as atypical presentations (Ramaciotti et al. 2002).

The sufferer in true AN is plagued with extreme thoughts, urges, and emotions that are congruent with the perceptual distortion; the accompanying behaviors and explanatory rationalizations are equally bizarre. Patients will often restrict their intake to a few hundred calories a day, exercise for several hours or purge food, losing a significant percentage of body weight over a few months. The fear of fatness and the perceptual distortion are not alleviated by weight loss and can increase as weight continues to fall.

The conscious tactile-kinesthestic (felt) awareness of one's own body is referred to as *body schema*. This definition was developed in the early twentieth century as neurological conditions were being described in which patients experienced their bodies as having markedly changed (Head 1918). *Body image* can be envisaged as a conscious dynamic multifaceted construct of the body with physical, perceptual, visceral, emotional, and cognitive dimensions. There is no single entity as "The Body Image" (Fisher 1990). Body image subsumes this definition of body schema.

Hilde Bruch was one of the first to develop the idea of body image disturbance in AN by including the perceptual accuracy of the body size, accuracy of recognizing visceral stimuli, and the emotional reaction to the body (Bruch 1973). Most importantly, she conceived that body image was in constant interaction with biological, psychic, and social forces. Bruch herself states, "the expression body image is so widely used in psychiatric evaluation that it surprising how vague the concept is." There are arguably two components to the body image distortion in AN: a perceptual disturbance. Congenitally blind children have distorted body images (Kinsbourne and Lempert 1980) but very few develop AN (McFarlane 1989). This may reflect the extent social forces, via the visual media, play in the internalization of body ideals. Body image is constructed through societal values and vice versa.

There are arguably two components to the body image distortion in AN: a perceptual disturbance by which individuals overestimate their body size or distort its shape, and a cognitive dissatisfaction with one's body size or appearance (Rosen 1990). However, even the latter attitudinal component involves emotional, cognitive, and visceral elements.

The difference between body schema and body image can easily be illustrated by the neuropsychiatric disorder – Body Integrity Identity Disorder (BIID; Brang et al. 2008). It is characterized by an intense desire for amputation of a specific healthy limb. This disowning begins in childhood and there is a stable precise line where amputation is desired. The limb is "missing" in the body schema. Over time, intense negative emotions toward the limb develop and the person develops a negative body image, leading some to mutilate the disowned limb. In cases where amputation has been carried out, the subject is often satisfied and comfortable in their new body. Ultimately one needs to accept that body image is a theoretical construct and refer specifically to facets within it. The perceptual error in true AN is a *disturbance in size awareness* and in the sufferer leads to *body size distortion.* Bruch appropriately placed "disturbance in size awareness" within the body image constellation as she recognized that the degree of disturbance is influenced by parallel disturbances in the visceral, emotional, and cognitive dimensions.

Some body schema disturbances can be accounted for purely by neurobiological explanations. The disturbance in body size awareness can be explained plausibly only by adding psycho-social factors to a neurobiological hypothesis. A significant biological contribution to AN is suggested by the stereotyped constellation of symptoms, the substantial heritability, and the small percentage (0.3–1.5%) of women in the general population who go on to develop the illness (Kaye 2008). The convergence of emerging neuropsychiatric research with psychosocial data allows development for explanatory models for the disturbance in body size awareness.

203.2 Psychological Studies

Research into body image distortion in AN has explored the attitudinal and perceptual components separately. There is a variety of rating scales to measure attitudes to one's body. Schematic figural scales such as the Body Image Assessment (Williamson et al. 1989) require the subject to select from a range of figures or silhouettes, the best fit for their perceived and ideal size. The discrepancy between the perceived and ideal is recorded as the measure of dissatisfaction. Questionnaires such as the Body Shape Questionnaire (Cooper et al. 1987) assess body dissatisfaction caused by feelings of being fat.

Studies trying to quantify the perceptual disturbance have used variants of video distortion, mirrors, calipers, and lens on whole bodies (Skrzypek et al. 2001). An extensive meta-analysis of body image disturbance concluded that attitudinal body dissatisfaction measures produced substantially larger effect sizes than perceptual size estimation inaccuracy (Cash and Deagle 1997). Some perceptual studies have shown that a subgroup of AN sufferers does overestimate the size of their bodies but overall the results have been inconsistent. A study of 100 women with AN, using video distortion on a life-size screen, showed only 20% clearly overestimated their size (Probst et al. 1998). AN patients do not show disturbances in other perceptual tasks. There is no evidence of any difference in appraisal of neutral object size or in estimation of the body forms of other women (Cash and Deagle 1997). One can conclude that AN women do not have a physiological disturbance in their visual perception. The findings support the hypothesis that body size awareness is an integration of perceptual, emotional, cognitive, and visceral components combined with self-mentation.

203.3 Prodrome to Body Size Distortion in AN

There is evidence of a disturbance in size awareness in girls prior to developing AN. People who develop AN report feeling fat even when they were regarded as healthy children (Bruch 1973). A body image develops that is associated with negative self-evaluation, particularly in terms of a lack of attractiveness (Cooper et al. 2007). Prospective studies have shown that healthy girls with the highest body dissatisfaction, perceived fatness, and weight concerns are most likely to develop eating disorders (Killen et al. 1996).

AN usually occurs between ages 15 and 19 in postpubertal women (Herpertz-Dahlmann 2009). As a normal physiological response to puberty, there is an increase in appetite, accompanied by a growth spurt and fat deposition in the breasts, hips, thighs, and subcutaneous tissue (Tanner 1990). Body weight on average increases by 40%, with a substantial deposition of fat tissue, in girls between age 11 and 13 (Tanner and Whitehouse 1977). This is a time of massive role change as among other factors the young woman's body becomes sexualized in a social sense. Paradoxically while her appetite is increasing and her body is becoming feminized, she has internalized the societal view that slimness is highly prized. As such, dieting is a common behavior in this age group (Keel et al. 2007). Longitudinal studies of the healthy population suggest that weight and shape concerns develop through childhood and become common by late adolescence in girls (Marchi and Cohen 1990).

The small percentage of young women who are at greatest risk of developing true AN seem to have a disturbed body image prepubertally. Both perceptual and attitudinal aspects of body image may be exacerbated due to psychiatric (e.g., mood and anxiety disorders), psychological (e.g., trauma), and social reasons (e.g., conflict at home and school). The decision to diet is made as actual body size and appetite increase, and body image worsens for a number of psycho-social reasons.

These women have the cognitive style (Roberts et al. 2007) to be successful dieters/restricters and lose several kilograms of weight over a short period of time. The "distorted size awareness" is clinically detectable after this weight loss. There may be a differential vulnerability in brain tissue to the effects of starvation, nutritional deficiencies, and hormonal disruption.

203.4 Body Image Processing in Healthy Women

The following discussion will focus on body image processing in healthy women. This allows for later development of explanatory models of abnormal body image processing in AN. When a young woman evaluates her *own* body (see Fig. 203.1a) a fronto-parietal network is activated. This network involves coactivated regions processing body schema and body ownership. The converging evidence from lesion and neuroimaging studies points to the parietal lobe as the storehouse of body templates (Wolpert et al. 1998), with all incoming body-related sensory stimuli referenced against it. In contrast to the somatotopic maps in the anterior parietal cortex (Penfield and Rasmussen 1950), it is hard to characterize precise body-related functions in the posterior parietal cortex. This region of the cortex is highly differentiated with defined subareas (Nickel and Seitz 2005). The anterior part of the superior parietal lobule (SPL) receives somatosensory information while the posterior part receives visual information. The supramarginal gyrus integrates somato-sensory information with visual information (Rizzolati et al. 1998). It is likely that parallel processes occur locally in neuronal clusters and are integrated supramodally. The right hemisphere seems to play a stronger role in body-related processes and holistic aspects of vision (Springer and Deutsch 1998).

Combining these poly-sensory body templates into the *embodied self* requires coactivation of a right fronto-parietal network. (Keenan and Gorman 2007; Hodzic et al. 2009). The right middle frontal lobe is activated for self-referencing but is also involved in executive functions such as attention (Macrae et al. 2004; Sachdev et al. 2008; Hodzic et al. 2009). The right frontal area is considered part of a network dedicated to the representation of self (Sugiura et al. 2006). The prefrontal cortex

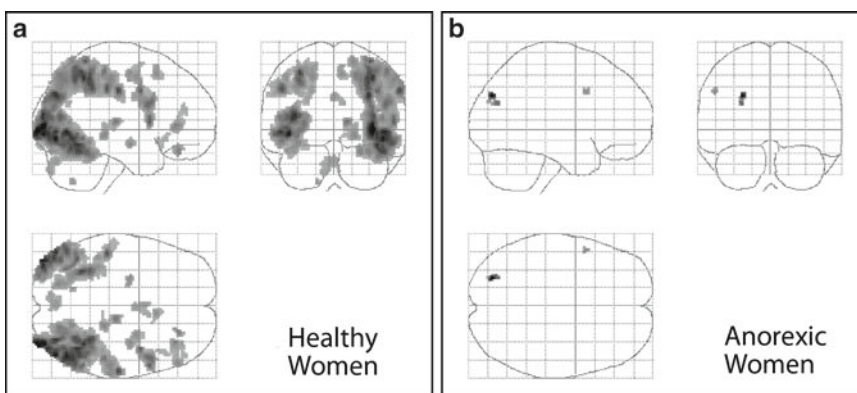

Fig. 203.1 Processing of own body. (**a**) When a young woman evaluates her *own* body widely distributed regions of the brain are coactivated. The network includes areas in the parietal, frontal, and occipital lobes and processes body schema and body ownership. The parietal lobe supramodally integrates polysensory information and acts as a storehouse of body templates. (**b**) The processing of *self* by anorexic women is quite discrepant. Whereas a widely distributed network is activated in healthy women, far fewer regions are activated in AN women, as if the brain was inhibiting the level of processing. In addition, there is decreased activation in the insula, the prefrontal cortex, and precuneus compared with healthy controls
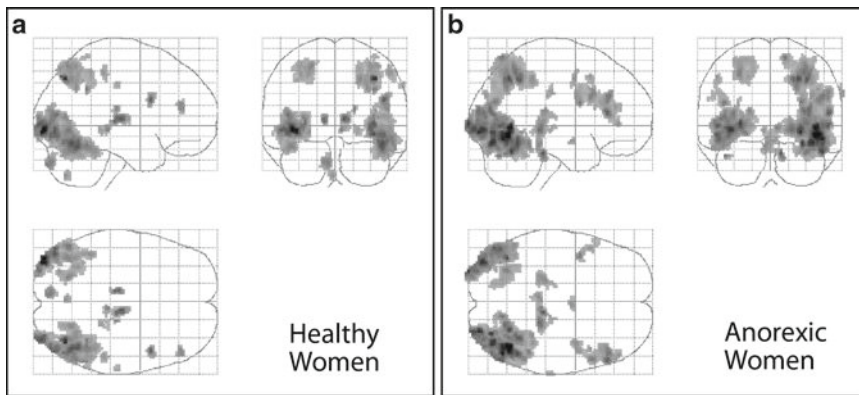

Fig. 203.2 Processing of nonself body. (**a**) In healthy women the brain utilizes some of the same neural resources including the extrastriate body area (EBA) and the fusiform body area (FBA). Processing self and nonself, in particular the parietal and occipital lobes. The human body seems to be the preferred stimuli for a number of regions in the extrastriate visual cortex

serves as a mental space (working memory) where body schema, emotions, and attitudes can be manipulated (LeDoux 1996).Within the parietal lobe, three regions, the right inferior parietal lobule (IPL), the right tempo-parietal junction (TPJ), and the precuneus are implicated in creating this sense of agency (Blanke et al. 2005; Uddin et al. 2006; Tsakiris et al. 2008; Legrand and Ruby 2009).

The concept of body image includes emotional and attitudinal components. The regions of interest include the insula, cingulate gyrus, amygdala (emotional system), and the hippocampus (internalized attitudes to the body). During self body processing, the insula is activated in healthy women (Sachdev et al. 2008). The insula has a unique contribution to make to body image as it acts as an integrating centre (Craig 2009). It is involved in interoceptive perception including pain, hunger, satiety, and information from the viscera. It is reciprocally connected with the parietal lobe via the somatosensory cortex and the IPL. Somatoparaphrenia can occur from insula damage (Vallar and Ronchi 2009) suggesting that body processing is shared with the parietal lobe. The metarepresentation of subjective feelings is contained in the anterior insula. It is linked with the anterior cingulate cortex (ACC) which serves as the motor representation of emotion (Craig 2009). These connections make the insula well-placed to integrate body interoceptive, body schema, and emotional information.

The act of observing *another's* body has little functionally in common with self-processing. Parsimoniously, the brain utilizes some of the same neural resources, in particular the occipital lobes and IPL (see Fig. 203.2a). This is consistent with the IPL's higher integrative function in the association cortex. The human body seems to be the preferred stimuli for a number of regions in the extrastriate visual cortex (Peelen and Downing 2007). Though they both respond to whole and body parts, the extrastriate body area (EBA) preferentially responds to body parts and the fusiform body area (FBA) to whole bodies suggesting different functions. There is an absence of insula activation (Sachdev et al. 2008). This supports the role of the insula in self rather than nonself processing.

203.5 Body Image Processing in AN

Women with AN seem to process the bodies of *other* women in the same way that healthy women do (see Fig. 203.2b). There is activation of the visual cortex, the extrastriate visual areas, the posterior parietal cortex, and the frontal lobes. This is important as it shows that there is no fundamental
Fig. 203.3 Cortical areas involved in self body evaluation. Self body evaluation activates widely distributed areas in the cortex. The anterior parietal lobe (postcentral gyrus, (**b**) contains various somatotopic maps concerned with localization and shape of the body surface and posture within the body. The role of the posterior parietal cortex in body-related functions is less well understood. The anterior part of the superior parietal lobule (**c**) receives somatosensory information while the posterior part receives visual information from the occipital lobe (**g**). The inferior parietal lobule is divided into the supramarginal gyrus (**d**) and angular gyrus (**e**). The supramarginal gyrus integrates somatosensory information with visual information. The *embodied self* requires coactivation of a right fronto-parietal network. Within the parietal lobe, three regions – the right inferior parietal lobule (**d, e**), the right tempo-parietal junction (**h**), and the precuneus (**f**) – are implicated in creating the sense of agency. The right frontal area is considered to be part of a network dedicated to the representation of self, and the prefrontal cortex (**a**) serves as a mental space, where body schema, emotions, and attitudes can be manipulated

disturbance in the functional neuronal architecture in the anorexic brain in relation to body image processing. When healthy women look at other women, there was a reduced signal in the medial prefrontal cortex (MPFC) whereas there was increased activation in this region in anorexic women. Activation of the MPFC may be related to the metacognitive process of mentalizing about oneself (Johnson et al. 2002). Neuroimaging results suggest that the MPFC is being engaged by AN patients because they compare themselves intensely with other women's bodies, which reflects the clinical experience (Sachdev et al. 2008).

However, the processing of *self* by AN patients is quite discrepant (see Fig. 203.1b). Whereas a widely distributed fronto-parietal network is activated in healthy women, far fewer regions are activated in AN women, as if the brain was inhibiting the level of processing. In addition, there is decreased activation in the insula, the prefrontal cortex, and precuneus compared with healthy controls (Fig. 203.3).

203.6 Explanatory Models for Body Image Disturbance in AN

The following models are neurobiological accounts for body image disturbance and body size disturbance. Using available evidence they focus on various regions of potential dysfunction that are *not* mutually exclusive. Rarely, AN is mimicked by brain lesions in the cortical and subcortical regions (Uher and Treasure 2005). These lesions have been in the frontal and parietal lobes and have presented with typical AN psychopathology. This does suggest that body image relies on a widespread network which can be disturbed with damage to connecting white matter tracts or directly to neuronal correlates. The explanatory models are not irreconcilable with psychosocial formulations.

203.6.1 Parietal Lobe Dysfunction and Distorted Templates

The *existence* of multiple body schema templates is supported by diverse clinical presentations following damage to the right parietal lobe (Berlucchi and Aglioti 1997). Multiple supernumerary phantom limbs and somatoparaphrenia can develop together or separately following damage to the right SPL (Vallar and Ronchi 2009). A bizarre clinical picture arises in which the person delusionally attributes ownership of their paralyzed arm to someone else and claims the phantom arm as real. A number of case studies have described the existence of "articulated" phantom limbs in subjects who suffer from congenital absence of limbs (Funk et al. 2005). In a study using plasticine modeling, congenitally blind children did internalize a representation of their bodies but compared with that of sighted children, it was impoverished and systematically distorted (Kinsbourne and Lempert 1980). These examples suggest that there are preformed templates in the right parietal lobe that are malleable and can be distorted.

There is some evidence that body size awareness is a template. Disturbances in size awareness in obesity vary depending on the age of onset. People who become obese as adults have a more realistic awareness of body size than those who suffer lifelong obesity (Bruch 1973). Exaggerated size perception occurs in healthy children, adolescent girls, and adults (Killen et al. 1996; Cooper et al. 2007). Bruch (1973) refers to adults with exaggerated interpretations of curved flesh as "thin fat people." Hypometabolism in parietal regions has been found in resting studies (Delvenne et al. 1997) and in body processing in AN (Uher et al. 2005). Structural studies do suggest that temporal and parietal regions are vulnerable to persisting damage (Castro-Fornieles et al. 2009). It is possible that small functional neuronal clusters in the posterior parietal lobe (right SPL, right IPL, and precuneus) operate in parallel, and in conjunction with the insula and medial frontal cortex, give the conscious experience of body schema and body size.

The small percentage of young women at greatest risk of developing AN have some degree of size distortion. The prodromal templates may be distorted due to genetic or other biological forces. The young women internalize the socio-cultural bias against fatness, and develop strong body dissatisfaction. The speed and extent of weight loss in the still developing brain seems to "lock in" the distortion by affecting vulnerable region(s) via starvation, nutritional deficiencies, and hormonal disruption. The distorted body size cannot be updated by real-time information. Neither the fear of fatness nor the experience of fatness is alleviated by weight loss and can persist after weight recovery. This suggests that the distorted template is not a function of low weight.

There are numerous examples including somatoparaphrenia, supernumerary phantom limbs, and BIID that show that the human brain has the capacity to use bizarre rationalizations to fit its templates regardless of contradictory data. The word phantom is used in various body schema disturbances. Experientially, the young woman is trapped in a fat phantom body, with varying degrees of insight to her predicament. Despite objective facts such as weights or reliable contrary evidence from trusted friends and family, the young woman will trust her phantom body.

203.6.2 Insula Hypofunction and Body Integration

There are certain factors that make the insula a region of interest, in particular its links with other brain regions. The insula integrates interoceptive, body-related, and self-related information. The insula has been recognized as a key region involved in the representation of the body schema (Bonda et al. 1995), with its ability to integrate information from multiple sensory modalities (Schneider et al. 1993). Somatoparaphrenia can occur from insula damage suggesting that body processing is shared with the parietal lobe. Resting studies in AN have found hypometabolism in the insula
Fig. 203.4 Insula hypofunction and body integration. The concept of body image includes emotional and attitudinal components. The regions of interest include the insula (**b**), cingulate gyrus (**a**), and the amygdala comprising the emotional system and the hippocampus for the internalized attitudes to the body. The insula lies within the Sylvian fissure and has a unique contribution to make to body image as it acts as a limbic integrating centre. It is involved in interoceptive perception which encompasses bodily sensations including pain, hunger, satiety, and information from the viscera. It is reciprocally connected with the parietal lobe via the somatosensory cortex and the inferior parietal lobule. The metarepresentation of subjective feelings is contained in the anterior insula. It is linked with the anterior cingulate cortex which serves as the motor representation of emotion. These connections make the insula well placed to integrate body introceptive, body schema, and emotional information. Insula hypofunction in anorexia nervosa may compromise the efficient integration of information resulting in body size distortion and disturbed hunger/satiety signals

(Kojima et al. 2005). In AN there is decreased activation of the insula in self body processing (Sachdev et al. 2008). The dysfunction potentially arises from recursive interplay between distorted hunger/satiety signals (Muller et al. 2008) and distorted body sensory signals. If due to hypofunction the insula is not able to integrate information efficiently and/or is receiving inaccurate information, disturbance in body size awareness may result (Fig. 203.4).

203.6.3 Amygdala-Hippocampal Hyperfunction

The amygdala plays a role in modulating body image. There are several transient factors that negatively affect the perceptual and attitudinal body image components in healthy women, including imagining of different social situations (Haimovitz et al. 1993), recent food intake (Vocks et al. 2007), and induction of negative mood states (Plies and Florin 1992). In anorexic women, recent food intake causes increased distortion of size estimation (Crisp and Kalucy 1974). The amygdala plays a dynamic role in body image by assigning affective significance to every changing external and internal sensory event. A functional magnetic resonance imaging (fMRI) study in which AN subjects viewed images of high-calorie or low-calorie food showed increased activation in the left hemisphere of insula, anterior cingulate gyrus, and amygdala-hippocampal region (Ellison et al. 1998; Uher et al. 2004) which make up the fear network. In anorectic patients, confrontation with

their own distorted body shape was associated with activation of the right amygdala (Seeger et al. 2002).

Resting studies showed increased perfusion (Takano et al. 2001), and structural studies showed persisting atrophy to the amygdala-hippocampal complex (Giordano et al. 2001).

This is suggestive of high anxiety and stress-induced damage (Harrison and Critchley 2007). The development of phobias is likely to develop during the dieting phase and evolve with the disease. Clinically one observes a generalizing of fears with a decreasing range and amount of foods consumed, people with whom food is consumed, and places where food is consumed. The amygdala has a specific role in enhancing memory consolidation. A receptor stimulated by adrenaline, the alpha-2B receptor, acts to consolidate memories. Individuals with one of two variants of this receptor have better emotional memories (De Quervain et al. 2007). A similar mechanism could arguably make AN brains vulnerable to the sensitization of high calorie food (Sachdev 2009).

The widespread inhibition seen in self-processing in AN (Sachdev et al. 2008) may be mediated via the amygdala. Subcortical input to the cortex is weak but feedback is massive (Logothetsis 2008). Specialized sensory information travels from the thalamus via a quick pathway to the amygdala and a slower pathway to the cortex (LeDoux 1996). The amygdala projects to the cortex including the insula (Shelley and Trimble 2004) and visual cortex (Chen et al. 2009). Feedback from the cortex to subcortical structures may modulate the quality of sensory information it receives early in an emotional episode.

203.6.4 Left–Right Hemispheric Imbalance

The role of the right hemisphere in body-related processes seems relatively stronger than the left hemisphere (Springer and Deutsch 1998). It has been suggested that the left hemisphere stores prototypes more effectively and anorexic women store an inappropriately fatter body image. In a divided visual field experiment, anorexic women judged themselves equal to fat distortions of their own body, more quickly when the stimuli was presented to the left hemisphere (Smeets and Kosslyn 2001). Lesions in the fronto-parietal regions that have mimicked AN have had a right hemispheric preponderance.

Anosognosia (unawareness of illness) of the emaciated state often occurs in AN. It is often masked by the opposite assertion of being fat but sometimes the person just claims to be of normal weight. Anosognosia usually occurs in a right hemispheric stroke and when confined to the right parietal lobe the unawareness tends to be confined to body image. A possible explanation for this phenomenon is that with a right–left hemispheric imbalance, the dominant left hemisphere compensates by creating a false mental schema (Ramachandran and Rogers-Ramachandran 1996). One can speculate that in AN, a distorted body template in the left parietal lobe falsely dominates the hypofunctioning right parietal lobe/template.

203.7 Prognostic Implications and Treatment

Body image disturbance causes significant distress, persists even following otherwise successful treatment (Windauer et al. 1993), and is a reliable predictor of relapse (Rosen 1990). The large number of studies concerning the assessment of negative body image in AN stands in contrast to the few attempts to influence the way these patients actually experience their bodies. Although treatment

programs specifically targeting body image concerns have been developed, no randomized controlled trials for adolescent and adult eating disorders exist (Herpertz-Dahlmann and Salbach-Andrae 2009). Cognitive techniques are used to identify and modify negative body-related thoughts. Treatment approaches that address the disturbance in body size awareness directly aim to correct the distortion by providing corrective feedback. Components include body exposure and desensitization using full-length "mirror confrontation" with the aim of developing a more objective or realistic view of their shape. Small pilot studies using mirror confrontation have shown improvement in body dissatisfaction and body avoidance in AN (Key et al. 2002; Vocks et al. 2007). Body image therapy is often a component of AN treatment and requires research into its efficacy.

203.8 Applications to Other Areas of Health and Disease

The treatment of AN requires a unified team including dieticians, nurses, psychologists, psychiatrists, and physicians. The most difficult aspect of treating a person with AN is engagement in the therapeutic process. This is in no small part due to the fear caused by body size distortion. Nutritional, psychological, and nursing care can be informed by this, in particular in understanding why sometimes patients seem to sabotage treatment.

Inclusion of strategies that are psycho-educative and mindfulness-based allows acceptance of some degree of body distortion while the patient, family, and treating team work together toward recovery. Demonstrating a biological basis to AN may help in decreasing stigma within the community and families.

Body size distortion seems to be present across eating disorders including bulimia nervosa (BN), binge eating disorder and obesity. People of a healthy weight with BN may perceive themselves as fat and people who are obese may underestimate their size (Bruch 1973). As with AN, treatment interventions need to increase the patient's awareness of their size distortion, with the aim of normalizing the eating behavior.

203.9 Conclusions

AN is a window into the new neuroscience in which the psychological and neurobiological interweave like vaporous threads. It illustrates how the environment can act on the brain to produce changes which in turn influence the environment the individual creates (Sachdev 2009). In this sense, it can serve to take the blame away from patients and their families, who are all victims of the brain's distortion. It helps explain why AN sufferers are so trapped by the illness. In effect, the young woman is being asked by others to put on weight, while her own brain is telling her the one thing she dreads, that "she is already fat."

While acknowledging psychological and social factors, one must accept that in true AN women distort their body size. Various explanatory models for disturbance in body size awareness have been outlined. The unifying theme is that there is discrepancy between the body size perception and its internal template representation. This causes distress and phobic avoidance of an ever-increasing list of factors associated with weight gain. There is a breakdown in self-awareness that leads the anorexic woman to vehemently deny her low weight, which is congruent with her experience, albeit irrational, of the judgment of those around her.

Summary Points

- Some body schema disturbances can be accounted for purely by neurobiological explanations. The disturbance in body size awareness can be explained plausibly only by including psycho-social factors in an extension of the neurobiological hypothesis.
- There is evidence of body size distortion and body image disturbance in some healthy girls and young women prior to developing AN. As actual body size increases around puberty, and changes occur in body shape, dissatisfaction with body image occurs for a number of psycho-social reasons, and young women often resort to weight-reducing diets.
- The "distorted size awareness" is clinically detectable after rapid and substantial weight loss. There is a spectrum of insight into the emaciated state, ranging from open acknowledgment to total denial.
- Brain imaging shows that women with AN seem to process the bodies of *other* women in the same way that healthy women do, indicating that there is no disturbance in the functional capacity of the perceptual part of the brain.
- Brain activity is quite discrepant when an anorexic woman processes her *own* body, with decreased activation in fronto-parietal network, in particular the insula, the prefrontal cortex, and precuneus.
- Body image and body size disturbance causes significant distress during illness and recovery, persists even after weight restoration, and is a predictor for relapse.
- Though a number of treatments for body image disturbance have been described, no controlled trials have yet been carried out into their effectiveness.

Definitions

Body schema: The conscious tactile-kinesthestic (felt) awareness of one's own body.

Body dissatisfaction: Negative emotions and cognitions toward one's body size or appearance.

Body size distortion: Distortion in size awareness which is modulated by cognitive style, emotional state, and introceptive awareness.

Body image: A theoretical dynamic construct of the body with physical, perceptual, visceral, emotional, and cognitive dimensions. It subsumes the definitions of body schema, body dissatisfaction, and body size distortion. It is a product of biological, psychological, and socio-cultural forces.

Anosognosia (from Greek, "a" without, "nosos" disease and "gnosis" knowledge): A broad term which could be used for denial of any type of neurological deficit. The unawareness in anosognosics persists despite logical arguments and the demonstration of contradictory evidence. There is a spectrum of insight into body size distortion in AN with a proportion of patients unaware of their emaciated state.

Somatoparaphrenia: The person disowns the paralyzed left limb, finds it repugnant, may try to dispose it, and rationalizes its presence in incongruous ways. It is often brought about by extensive right-sided lesions or localized to the R superior parietal lobule or more rarely insular damage. The delusion disappears after some weeks though the paralysis remains.

> **Key Point**
>
> **AN Without Body Size Disturbance**
>
> It is worth noting that there is a subgroup of AN *without* disturbance in body size awareness.
>
> These women, as equally unwell as *true* anorexics, do not report a significant drive for thinness or a morbid fear of becoming fat. They acknowledge their emaciation and seem to restrict food to avoid somatic symptoms and anxiety. Prevalence within AN overall varies but has been reported in up to 20% of the AN population (Ramaciotti et al. 2002). Lasegue (1873) originally described "vague sensations of fullness, of pain occurring postprandium or at the beginning of the meal." Tourette (1895) labeled his group "Anorexia Gastrique" as they seemed to suffer a phobic anxiety about gastric pain. The visceral and emotional symptoms are present in all anorexic patients but in this atypical group, they dominate the clinical picture. The groups may represent opposite ends of the spectrum of body size distortion with a mixture in between. One could hypothesize that there may be differences in the underlying neural disturbance between the two extremes.
>
> Subjective awareness of emotional state is based on the neural representation of the physiological state. This function is carried out by the anterior insula cortex (Craig 2009). The right anterior insula showed the greatest activity in those who were most viscerally aware (Critchley et al. 2000). The sensitivity to interoceptive information is increased by lean body composition (Rouse et al. 1988). Anxiety and anxiety disorders are prevalent in women who develop eating disorders (Raney et al. 2008). The atypical group may initially restrict food as a result of visceral sensations and distressing emotions, and eventually develop a phobic avoidance.
>
> Bruch (1978) acknowledged the existence of earlier descriptions but wrote, "yet I call it a new disease because it is only in the last 15 years to 20 years that AN is occurring at an increasingly rapid rate." The atypical group may have been the predominant presentation over 100 years ago. The cultural bias toward thinness which has resulted in the "normative discontent" (Rodin et al. 1985) that healthy women feel about their bodies may have *negatively selected* for the true anorexic and explains the increased prevalence of AN.

Chapter 204
Motor Learning Approaches for Improving Negative Eating-related Behaviors and Swallowing and Feeding Skills in Children

Justine Joan Sheppard

SLP   Speech-language pathologist

204.1 Introduction

Infants and young children experience a complex of sensations, movements, and interactive behaviors during eating and swallowing. These early experiences support the development of eating and swallowing skills and shape the child's behaviors for participation in eating situations. Both acquisition of eating skills and associated motivations for eating and eating-related behaviors are often affected when events occur during the development of eating skills that disrupt this process. The risk for the disruption of eating motivation and behaviors is intensified if the child has a co-occurring physiological or psychological disorder (Chatoor 2009b; Cooper-Brown et al. 2008; Lefton-Greif and Arvedson 2007; Sullivan 2008). Food refusal and disruptive mealtime behaviors may be exacerbated as the child struggles to avoid eating challenges that require skills that have not yet developed sufficiently to meet the demands (McKirdy et al. 2008; Sheppard 2008).

Although the prevalence of this profile of co-occurring delay in acquisition of developmental skills for eating and motivational and behavioral difficulties associated with eating is not known, the interaction is suggested by the high prevalence of feeding disorder in children with developmental delays, 33–80%, as compared with that in typically developing children, 25–45% (Burklow et al. 1998; Linscheid 2006). Clinical experience in both diagnosis and treatment of children with swallowing and feeding disorder support the contention that consideration of this association between skills and behaviors is central to resolving both problems and achieving the desired outcomes of mature skills and appropriate eating behaviors (Sheppard 1994, 2008). The purpose of this chapter is to consider the strategies derived from research on acquisition of skilled movement behaviors that may be useful for their treatment.

204.2 Developmental Acquisition of Mature Motor Skills for Swallowing and Eating

Typically, children acquire the generally recognized sequence of "milestone" eating skills from birth to 2 years. These include competencies for sucking, transition from nipple to spoon feeding, biting and chewing foods from soft to firm, from single pieces to multiple pieces, complex consistencies, drinking from cup and straw and independent feeding with hands and a progression of utensils culminating in mature function (Delaney and Arvedson 2008; Carruth and Skinner 2002). Underlying these milestone skills are subskills and related neuro-motor competences that support the advancing skills and the child's nutritional need to consume increasing amounts of food within a conventional meal time period. The underlying competencies include: (a) changes in the biomechanics of the oral-pharyngeal phase of swallowing from a suck-swallow to the mature pattern for bolus manipulation and propulsion, (b) ability to swallow larger boluses, (c) ability to swallow more viscous boluses, and (d) ability to tolerate and manage increasing coarseness in food texture and increasing variety of food tastes (McKirdy et al. 2008; Sheppard 1994). Furthermore, these skills and subskills are dependent on parallel development in the collaborative functions, breath control, body postural control, and use of shoulder, arm, and hand (Carruth and Skinner 2002).

Inherent in this developmental process is learning to identify and integrate experiential information associated with eating and swallowing that includes contact sensation for touch, pressure, temperature, and taste; distance sensations for smell, vision, and hearing; proprioceptive information for position and movement of joints and muscles, body position in space, respiration, hunger, thirst, and the condition of the gut (Table 204.1)(Hadders-Algra 2000b; Sheppard 2008).

There is a level of physiological maturity that determines the earliest age at which the child can engage in learning each of these skills (Sheppard 1994; Sheppard and Mysak 1984); however, the age at which children achieve functional competency varies with the individual care-giving practices for introduction of utensils and food types, for seating during eating, for presenting opportunities for advancing eating skills and independence, and for supporting the child in mastering these skills. The typical period for acquisition of these milestones coincides with a period of brain plasticity that facilitates learning of the skills and the co-occurring, motivational, and behavioral dynamics (Johnson 2004; Kolb et al. 2004). For example, specific intervals within this period of brain plasticity have been found to be significant for chewing skills and taste tolerances. Six months of age has been noted to be the critical and sensitive period for beginning acquisition of chewing skills, with aversive responses to texture and difficulty in acquiring chewing skills occurring when chewable foods are introduced after age 10 months (Illingworth and Lister 1964; Johnson 2004). Differential awareness and preference for tastes have been noted to emerge from birth through 2 years of age (Menella and Beauchamp 1998) with experience-dependent effects found in the first six months (Gerrish and Menella 2001).

204.3 Acquisition of Motivation and Pragmatics for Eating

Maturation of eating skills and the emotional underpinnings for the pragmatics of eating develop in tandem. The pragmatics of eating refers to its social components, the context-dependent behaviors for eating, and the relationships between the involved parties. Homeostasis, attachment, separation, and individuation, evolving as physiological and emotional capabilities, are expressed in the

Table 204.1 The developmental progression of eating skills and subskills culminating in mature swallowing and feeding function

Milestone eating skill	Swallowing and feeding subskills	Related postural and manipulative subskills
Sucking	• Suck–swallow–breathe coordination for nipple feeding • Expression–suction balance needed for a specific nipple system • Oral grasp and containment of nipple and fluid • Ability to expel nipple from mouth • Generalization of sucking skills/performance to different nipples, feeding partners, and independence	• Alerting, orienting head and mouth toward food and opening mouth • Semi-reclining postural alignment and stabilization • Holding hands on breast/bottle during sucking • Strength and stamina for task
Transition feeding from nipple to spoon	• Adjustment of oral initiation of the reflexive swallow and pharyngeal phase swallowing dynamics to accommodate changing oral and pharyngeal anatomy • Swallow–breathe coordinations for larger and more viscous boluses • Removing food from spoon, containing and transferring into place for swallowing • Ability to expel food	
Spoon feeding variety of foods that do not require mastication	• Transition of swallow dynamics from suck–swallow to propulsion swallow • Sensory tolerances for variety of food tastes and textural coarseness • Ability to contain and process coarser and more viscous food and transfer into place for swallowing • Tongue propulsion forces for more viscous and larger boluses	• Transition from semi-reclining to upright postural alignment and stabilization • Increasing participation in feeding with upper body movement toward approaching bolus
Biting	• Alignment of mandible and maxilla for severing • Crushing force onset and offset for biting • Ability to contain and expel pieces	• Independence strategies – holding food in hand while controlling oral participation (beginning finger-feeding)
Chewing	• Mouth opening timing, size and shape adjustments for bolus characteristics, and techniques of the feeder • Ability to contain, collect, and transport for mastication and expelling • Ability to coordinate mandible, tongue, and cheek movements for mastication • Ability to control cyclical crushing force onset and offset • Judgment of swallow-ready consistency • Tongue propulsion dynamics for progression of increasing levels of chewing difficulty • Tongue propulsion forces for more viscous and larger boluses	• Independence strategies – self-feeding with fingers

(continued)

Table 204.1 (continued)

Milestone eating skill	Swallowing and feeding subskills	Related postural and manipulative subskills
Drinking from cup and straw	• Lip and cheek coordination for maintaining mouth on cup or straw • Ability to sip • Sequential sip-swallow • Ability to contain and control a low viscosity/low cohesiveness bolus • Ability to initiate time of swallow for the faster moving liquid bolus	• Head–neck postural alignment and control for cup/straw drinking • Independence strategies – holding cup or straw in hand while controlling oral participation
Independence	• Coordinating /controlling skilled, simultaneous hand–mouth functions • Pacing size of bolus • Pacing rate of food intake • Alternating foods and food and liquid • Maintaining acceptable, age-appropriate neatness	• Upper body and upper extremity control • Maintaining utensils and food on tray/table

The motor capabilities in developmental swallowing and feeding skills are expressed in milestones. Embedded in these milestones are the underlying swallowing and feeding subskills, the related postural and manipulative capabilities, and stamina for performance and completion of the meal

Table 204.2 The pragmatics for swallowing and eating activities

Pragmatic categories in eating	Examples
Tolerance for variation in eating activities	• Eating environments • Eating partners • Food tastes and viscosities • Postural alignments and seating
Psychosocial skills	• Separation and emerging independence • Regulation of feeding routines • Compliance to guiding adult • Dyad reciprocity
Attending	• Transition to and from other activities • Maintaining attention • Alternating attention
Self-reliance	• Tolerating trial and error learning • Persisting at task following error

The pragmatics of eating emerges as a developmental sequence resulting from the psychosocial interaction between the child and their social environment

interactive pragmatics of eating. Eating is a setting in which the infant and young child are seen to practice these emerging psychosocial skills. Strategies for dyadic reciprocity; for communicating hunger, satiety, and preferences; and for asserting independence are worked out by infant and caregiver in the arena of their daily eating experiences (Chatoor 2009a; Davies et al. 2006; Satter 1990). These behaviors are expressed in the natural environment as an integral part of swallowing and eating function (Table 204.2).

The child's motivation for eating and the pragmatics for expressing eating preferences result from the accumulated intrinsic (organic) and extrinsic (environmental and interpersonal) experiences that are associated with eating and the resulting conditioned expectations for positive and negative outcomes. Conditioned aversions and affinities associated with eating tend to be relatively resistant to

change over time. General observation of typical populations suggests that preferences (and aversions) for food, eating partners, and eating routines tend to be long lasting.

204.4 Abnormal Diet-related Eating Skills and Behaviors

It is useful to conceptualize pediatric swallowing and feeding disorders as consisting of a complex interaction of developmental, psychosocial, and organic features that cut across etiologies. These features have been considered in classification systems. Manikam and Perman (2000) postulated the categories of medical, nutritional, behavioral, psychological, and environmental as etiologies for pediatric swallowing and feeding disorder. They found these etiologies to occur in clusters, rarely as independent causes. Burklow et al. (1998) segmented the medical etiology into structural, neurological, cardio-respiratory, and metabolic categories with the additional, "behavioral issues." In their study most children presented with more than one category of disorder, with 85% coded as having behavioral problems as part of the cluster. Other comorbidities have been reported. Digestive function problems, including esophageal reflux, and frequent middle ear infections, have high prevalence in children seen for early feeding intervention (Fluehr et al. 2004; Sullivan et al. 2000). Prematurity and associated neonatal intensive care unit (NICU) experience, vision and hearing impairments, and speech-language pathology (SLP) diagnoses, including speech and language disorders and delays and familial issues have been seen to cluster with the need for swallowing and feeding intervention (Fluehr et al. 2004). The high prevalence of behavioral problems across classifications and etiologies suggest that behavioral problems may occur as both a primary problem, associated with psychological and neuropsychiatric etiologies, and a secondary problem, occurring in children with primary anatomical, neurological, medical, and developmental etiologies.

Udall (2007) conceptualized functional categories of pediatric swallowing and feeding problems as developmental, gut motility, behavioral problems, and neurological impairment. The developmental category included skill sets (subskills and milestone skills) needed for advancing from nipple feeding, through the various developmental levels of function leading to mature, independent, nutritionally satisfactory, swallowing, and feeding behaviors. Although the developmental sequences and age expectations for eating skills and subskills in typically developing children and the characteristics of delayed development have been well documented (see Delaney and Arvedson 2008, for a recent review), information is sparse on the prevalence of delayed development of skills in the various etiologies or diagnostic categories of swallowing and feeding disorder.

Delayed development of eating skills and subskills may occur as a primary disorder in children with cognitive impairment and neuro-motor disorders, such as cerebral palsy and apraxia. Additionally, the delay may be secondary to those medical or behavioral disorders that interfere with the child's access to the sensory and motor experiences necessary for advancing skills Whether the failure to develop skills is seen as a primary or secondary disorder, symptom-specific intervention is needed to support acquisition of mature swallowing and eating skills and behaviors and to develop optimum quality of performance (Hadders-Algra 2000b; Manikam and Perman 2000; Sheppard 2008).

204.5 Treatment Approaches

Given the complexity of pediatric swallowing and feeding disorder, a multifactorial approach is indicated that assures that medical problems have been stabilized or resolved, the caregiver is included in the process, informed, and supported appropriately, the child's swallowing capabilities are determined

to be adequate for the demands of the program, the therapeutic tasks are within the child's physiological capabilities with respect to oral, pharyngeal, esophageal, and gastrointestinal function and the child's nutritional status is not compromised (McKirdy et al. 2008; Schauster and Dwyer 1996). In general, research has focused on strategies to improve medical, behavioral, and movement disorder (Manikam and Perman 2000), in some instances combining a variety of interventions (McKirdy et al. 2008; Williams et al. 2007) and in some instances exploring effectiveness of an individual strategy or category of strategies (Gisel 1996; Pizzo et al. 2009; Pinnington and Hegarty 2000).

The question of whether it is more effective to treat the behavioral and movement aspects of swallowing and feeding disorder separately or in a combined program was addressed in a study of school-aged children who exhibited both negative behaviors and impaired skills (Bailey and Angell 2005). In this study, the combined program resulted in greater improvement in both mealtime behaviors and skills than did the same strategy sets implemented separately.

204.6 Treating the Developmental Motor and Behavioral Disorder

Dynamic Systems Theory (DST) has provided the foundation for strategies to treat developmental motor disorders (Thelen 1995). The theory posits development as resulting from the interactions of body biomechanics, brain structures, psychosocial characteristics and specific environmental stimulation, support, and structure. Rather than consider motor development as an unfolding of a predetermined sequence of skill as had earlier theories (Hadders-Algra 2000a), DST posited an interaction between nature and nurture that suggested that trial and error learning and behavior were integral to the process. Hadders-Algra (2000b) further postulated that structured sensory and motor experiences form neuronal networks that support the child's learning for advancing developmental skills and improving their efficiency.

The motor sciences literature provides research-based guidance for optimizing the learning environment. This evidence base can be used to advantage to advance eating skills and prevent or remediate negative mealtime behaviors. The strategies have been found to be effective for transitioning school-aged children from tube to oral feeding. These children exhibited food refusal and negative eating behaviors that, heretofore, had prevented their developing the skills needed for a successful transition and subsequent maturation of eating skills and behaviors (McKirdy et al. 2008). The program consisted of five steps to address the differential training needs at the early, intermediate, and advanced stages of motor skill learning. The first three steps supported the early learning stage during which behaviors were brought under control of a guiding adult in instructional noneating and eating-related tasks. The fourth step supported early and intermediate stage learning during which eating skills were trained in individualized sequences that were configured for the child's physiological and developmental capabilities. The fifth step supported the advanced stage in which the skill levels were advanced to enable eating with new eating partners and in new environments. The five steps were repeated, as needed, as transitions were made from one training objective to the next.

204.7 Motor Learning Strategies

Motor learning strategies are appropriate for selecting appropriate practice tasks, developing and improving the child's eating behaviors, and structuring the child's practice opportunities (Tables 204.3 and 204.4).

Table 204.3 Developmental attention skills and examples of parallel developmental eating activities

Developmental levels of attention	Examples of eating activities
Focused attention to a simple continuous target	Sucking from a nipple
Sustained attention to repetitive targets	Dependent eating of sequence of spoonfuls of a single food; self-feeding sequence of bites
Selective attention	Maintaining eating in a distracting environment
Divided attention	Eating while attending to instructions for guiding the activity
Alternating attention	Alternating eating and drinking; alternating eating and use of signing or speech to communicate

Attention skills emerge as an embedded hierarchy with performance at each subsequent level dependent on the level of mastery of the previous levels. Ability to attend is a skill that is differentiated from motivation to perform which is a behavior

204.7.1 Improving Behaviors for Eating

Considerations in motor learning for improving behaviors are attention to task, tolerance for the task conditions, and acquiring and maintaining motivation to comply with the instructions of the guiding adult (Schmidt and Wrisberg 2004; Danielson 2002; Sheppard 2008). These are precursors for successful training and are established, reestablished, and advanced as the program objectives and related tasks are advanced.

Attention to task has been conceptualized in a developmental, five-level hierarchy that includes sustained attention, selective attention, divided attention, and alternating attention (Sohlberg and Mateer 1989). Development of attending skills occur in parallel with eating behaviors and have been observed to be precursors for participation in eating tasks (McKirdy et al. 2008). See Table 204.3 for examples of categories of attention demands and examples of associated eating tasks. Building skills for attention to task occurs in the early motor learning stage for each skill and sub-skill and is a limiting factor in the rate of the progression of skills leading to mature swallowing and eating function.

Tolerance of the experiential information is established in the early learning stage, as well (Hadders-Algra 2000b; McKirdy et al. 2008; Sheppard 1994, 2008). It is seen as the capability of the child to maintain a calm and alert state as unfamiliar experiences are introduced. Negative behavior, such as decompensation and avoidance, occur when the tolerance level is exceeded by the duration, complexity, or intensity of the experiential information. In order to engage in eating tasks, adequate tolerances are required for sitting in a chair, smells, tastes and textures of food, utensils, social closeness of the guiding adult, the eating environment and, for self-feeding including food and utensils on the high chair tray or table in front of the child, and holding food or utensil in hand while processing food in mouth (Sheppard 1994, 2008).

Motivation to comply with the instructions of the guiding adult is an instructional strategy that supports learning in tasks that are not intrinsically motivating. In some children, eating is a motivation in itself (Satter 1990). Deficient motivation for engaging in eating is seen as a maintaining factor for pediatric swallowing and feeding disorders. Thus, compliance to the guiding adult substitutes for motivation to eat as a means for maintaining instructional control (McKirdy et al. 2008). Positive reinforcement (Kerwin 1999), and escape extinction (Hoch et al. 2001) have been found to be effective strategies for maintaining motivation at early, intermediate, and advanced stages of mastery. Extrinsic feedback regarding number of trials remaining before completion of task (see next) has been found to be useful, as well, in establishing and maintaining motivation to comply with the guiding adult (McKirdy et al. 2008; Schmidt and Wrisberg 2004).

Table 204.4 Approaches and strategies used in motor learning that are applicable to pediatric swallowing and feeding disorder

Motor learning focus	Motor learning approach/strategy	Desired outcome
Attention to task	Exercises to develop sustained focus on task that is adequate for task demands	Reduction of negative behaviors and increase in neutral and positive behaviors in eating and drinking tasks
Tolerance for experiential information	Regulating selection and complexity of sensory information in order to maintain a quiet alert state in response to the sensory experience associated with the set up, performance, and conclusion of the eating/drinking task	
Motivation to comply with the guiding adult	Exercises to develop and improve child's ability to follow the instructive guidance of an adult mediator promptly and with optimum effort	
Task specificity	Exercises using the target task with respect to its sensory conditions, motor components, and expected outcome	Achieving optimum efficiency, accuracy and retention in acquisition, and maintenance of eating and drinking skills and subskills, and acquisition and retention of appropriate neutral or positive mealtime behaviors
Variability in developmental sequence	Flexible selection of program objectives with respect to expected, normal developmental sequences in order to accommodate individual competencies, skills, and preferences	
Implicit learning	Using behavior modification strategies, including cuing and positive reinforcement, in natural task structures and environments	
Transfer of learning	Exercises that support advancing skills for performing in all appropriate natural environments	
Rehearsal	Exercises that violate the functional integrity of the target task with the aim of reducing practice errors and negative behaviors	
Maximizing practice opportunities	Providing for maximum number of daily task repetitions in practice and daily routines	
Blocked and random practice routines	Organizing task sequences for repetition of a single task (blocked sequence) or for random sequencing of two or more tasks	
Extrinsic feedback	Information provided to the child regarding number of task repetitions remaining, adequacy of their task performance, and adequacy of their compliance to the guiding adult	

The evidence base in motor learning provides criteria for selecting practice strategies that will optimize the improvement of behaviors and the learning of skills at early, intermediate, and advanced stages of skill acquisition

204.7.2 Selecting Appropriate Practice Tasks

Task selection is a relevant issue from initiation of treatment to resolution of the swallowing and feeding disorder at each transition toward advancing the child to mature behaviors and skills. Approaches to be considered in selecting tasks are specificity of learning, variability in developmental sequences, implicit learning, and transfer of learning (McKirdy et al. 2008; Sheppard 2008).

Task specificity refers to practicing of the target skill at the beginning, intermediate, and advanced stages of learning. In this strategy, aspects of the sensory information and demands of the task may be simplified or emphasized to facilitate learning. Task specificity has received considerable attention in the ongoing debate on the usefulness of nonfeeding oral motor exercise in treating pediatric swallowing and feeding problems (Bailey and Angell 2005; Clark 2003; Gisel 2008; Manikam and Perman 2000; McKirdy et al. 2008; Williams et al. 2007; Wilson et al. 2008). Evidence from studies of learning for a variety of gross and fine motor tasks indicates that the fastest learning, expressed in number of task repetitions or number of sessions, and the best retention of skill result from practice experiences that most closely approximate the natural environment, the sensory information, and the movement coordinations of the target task (Schmidt and Wrisberg 2004; Sheppard 2005; Thelen 1995). Furthermore, studies of developmental movement characteristics and sequences that compare eating with other oral movement behaviors have demonstrated substantial differences between oral skills in both sensory information and motor demands (Wilson et al. 2008). The lack of equivalency between oral skills has been used to further support specificity of training as a preferred intervention strategy.

Variability in developmental motor sequences has been demonstrated in the normal acquisition of developmental skills. Atypical progressions and patterns of movement have been observed in studies of walking and swallowing tongue postures in young children to result in normal, mature function (Largo et al. 1993; Schwab et al. 1986). Although following developmental sequences for independence in eating, food types and skills may be appropriate in some instances, treatment decisions that were appropriate for the individual child but violated developmental guidelines have resulted in successful behavioral and skill outcomes in making the transition from tube to oral feeding (McKirdy et al. 2008; Williams et al. 2007).

Implicit learning refers to gains in skill resulting from experiences with the target task without directing attention to the training or the change. In this training procedure, naturally occurring tasks are modified to regulate task difficulty. Cuing and reinforcement are used to support the desired changes. Implicit training has been found to result in more effective performance, better retention, and better ability to attend to additional environmental demands as compared with explicit learning conditions (Schmidt and Wrisberg 2004). The benefits of implicit training have been demonstrated in children with special needs as well (Vinter and Detable 2003).

Transfer of learning refers to changes in practice environments and/or training partners, as part of the intervention plan, with the objective of improving skills and behaviors sufficiently for performance in all appropriate natural environments. This may include classroom, community, and home settings with their respective changes in eating partners. The rate of progress is optimized by prompt initiation of the transfer from therapeutic to natural environment at intermediate and advanced learning stages for each skill and subskill (McKirdy et al. 2008).

204.7.3 Practice Strategies

Motor learning approaches to consider when structuring practice sessions are rehearsal strategies, maximizing practice, blocked versus random practice, and providing extrinsic feedback (McKirdy et al. 2008; Sheppard 2008).

Rehearsal refers to practice exercises in which the functional integrity of the target task is disrupted or the task is nonfunctional. Several types of rehearsal strategies have been used in swallowing and feeding programs. Fractionalization of the task refers to practice of parts of a task separately, e.g., biting off and swallowing chewable pieces of food without chewing. Simulations refer to practicing

an alternative to the target task, which may appear to be similar, e.g., using a "chewy tube" (a ridged, flexible, plastic tube) to practice chewing. Simplification refers to disrupting the natural task with the aim of reducing difficulty, e.g., slowing the rate. Segmentation refers to practice of one part of a complex task before adding the next part and practicing the two parts together, e.g., working on acceptance before introducing self-feeding (Chatoor 2009b; Fischer and Silverman 2007; Gisel 1996; Hoch et al. 2001; Linscheid 2006; Pizzo et al. 2009; Williams et al. 2007). The effect of the rehearsal strategies on rate of learning and retention differ depending on the stage of learning and the nature of the task. Some benefit has been found for the use of simulation, fractionalization, and segmentation during the early learning stage. Simplification results in better outcomes than other rehearsal strategies for interactive task sequences as are found in eating and swallowing (Schmidt and Wrisberg 2004).

Maximizing practice opportunities has been found to be the single most important factor related to outcomes for quality of performance and retention of skill (Schmidt and Lee 1999). During the early stage of learning, practice requires more assistance and reinforcement. During the intermediate and later stages of learning, the learner may be more independent. However, in all stages practice should be maximized for improvement and retention of skill (Schmidt and Wrisberg 2004). The benefits of intensive practice for improving swallowing and feeding have been well documented (Bailey and Angell 2005; Cooper-Brown et al. 2008; Gisel 1996; Kerwin 1999; McKirdy et al. 2008; Pizzo et al. 2009; Schmidt and Wrisberg 2004; Sheppard 2005; Williams et al. 2007).

"*Blocked*" *and* "*random*" *practice* refer to the sequencing of trials during practice sessions. In blocked practice there are drill-like repetitions of a single task, e.g., taking bites of cracker until it is finished. In random practice a set of related tasks is performed in random order, e.g., interspersing drinks between bites of cracker. Here again, results differ based on stage of learning. Blocked practice is more effective at the early learning stage as fewer errors may occur. However, random practice results in better retention for intermediate and advanced stages overall (Schmidt and Wrisberg 2004).

Extrinsic feedback refers to information provided to the child before, during, and following practice trials regarding number of trials or amount of time before the practice session is completed, the adequacy of performance, and the adequacy of compliance to the guiding adult. Extrinsic feedback has been found to improve motivation and correction of error. Effects differ depending on the stage of learning, timing of feedback, and the feedback schedule. Overall positive feedback is more effective for supporting learning than is negative feedback. Stronger benefits accrue from feedback during early learning. More frequent feedback yields best results during early learning, while intermittent feedback is more effective during intermediate and advanced stages. Feedback that is provided immediately after a trial is completed increases the likelihood that, under the same stimulus conditions, the action will be repeated (Schmidt and Wrisberg 2004).

204.8 Applications to Other Areas of Health and Disease

Motor learning approaches provide useful evidence-based models for addressing a variety of developmental issues in which behavioral and developmental motor disorders co-occur. Motor learning strategies may be incorporated into therapeutic programs for swallowing-based activities, such as taking oral medications, saliva control, and oral hygiene, in addition to eating and drinking. Furthermore, it may be useful to consider these strategies in habilitation of other developmental motor disorders.

Conceptualization of the differential between acquisition of motor skills and co-occurring behaviors during the critical and sensitive periods and at later ages is helpful for formulating appropriate and effective programs for infants and older children. It is noteworthy that in typically developing children learning of motor skills and their supporting behaviors occur more rapidly

during critical and sensitive periods, that is, learning requires fewer task repetitions and informal training strategies are sufficient to maintain motivation and achieve satisfactory outcomes. In the older child, however, more task repetitions and carefully selected "coaching" strategies are needed to support learning of skills and associated behaviors to achieve the desired outcomes.

Motor learning strategies that are most likely to have broader applications in treatment of pediatric behavioral and nutritional disorders that do not involve neuromotor problems, such as cerebral palsy or apraxia, are implicit learning and the related concept of task specificity. In this regard, optimum learning with respect to rate, retention, and achievement of competency, involves practice of the target task and training within the natural environments.

204.9 Discussion

Intervention for swallowing and feeding disorders in children is a complex process that involves management or resolution of contributing causes, supporting caregivers as they develop their skill sets for participating in the interventions, and habilitation of the child's deficiencies in motivation, behaviors related to eating and the skills, subskills, and underlying competency needed by the child to eat and drink all appropriate foods in all appropriate environments. Key features of this discussion address: (a) consideration of co-occurring abnormalities in behaviors and skills as a unified disorder, (b) the importance of developing tolerable practice routines using the target task, and (3) consideration that a typically developing child acquires these skills and behaviors in three years as an indication of their complexity and the expected duration of the treatment program. See Table 204.5 for key considerations in motor learning approaches for managing eating-related behaviors and co-occurring swallowing and feeding disorders.

Table 204.5 Key considerations in motor learning approaches for managing eating-related behaviors and co-occurring swallowing and feeding disorders

- Motor learning approaches address the continuous process of skill acquisition from emergence through to achievement of mature form and function. In this context, eating is seen as a complex set of motor skills that are related to each other by their common link to nutrition, hydration, and psychosocial participation. Eating-related behaviors are considered to be an integral part of eating function. Optimum efficiency and effectiveness for treatment of problematic skills and behaviors is achieved when intervention addresses this duality as a unified disorder.
- Underlying sensory–motor competencies that support the development of the skill set of mature swallowing and eating skills and behaviors are developed most efficiently within the functional task environment. These underlying competencies are:
    Body postural control,
    Strength, stamina, and precision of movement of oral and pharyngeal structures and upper extremities in eating,
    Praxic competencies for organizing the appropriate motor response to meet the demands of the particular food, utensil, and eating environment,
    Mature attending behaviors, and the abilities to appreciate and integrate the complex environmental and experiential information for generating appropriate responses.
- In typically developing children, this process spans the first two to three years of life. Expectations for habilitation in children presenting with disordered swallowing and feeding should be considered in light of the complexity of the process, the duration of acquisition in the typical population, and the added burden for the child learning these skills and behaviors at ages when brain plasticity is no longer optimum for this learning.

Motor learning approaches view acquisition of complex movement functions, such as swallowing and eating as an interdependent process that includes motivation, behavioral control, attention, and sensory and motor competencies. The goal in a motor learning approach is to optimize outcomes over all these interdependent factors

Summary of Key Points

- Delayed or deficient developmental skills and behavioral problems co-occur as primary and secondary issues in pediatric swallowing and eating disorders.
- Both problems may occur during or after the critical and sensitive periods for acquisition of swallowing and eating skills; however, when they are present after the critical and sensitive period they tend to be more resistant to treatment.
- An integrated treatment program that addresses both behaviors and skills has been found to be most effective.
- Motor learning approaches provide models for integrated programs that address both issues. These approaches are appropriate for infants and children.
- These approaches have been successful in habilitating milder disorders, such as acceptance of restricted variety of foods, as well as more severe disorders, such as refusal to transition from tube to oral feeding.
- The evidence base in the motor sciences supports the notion that better outcomes result from interventions that involve practice of functional tasks as they occur typically in the natural environment.
- Motor learning approaches provide specific strategies for behavioral control, task selection, and practice routines that are applicable to swallowing and feeding disorders.
- The desired outcomes for a feeding and swallowing program are:
- Resolution of behavioral issues related to eating as they occur in natural eating environments. These include disruptive mealtime behaviors, food refusal, and abnormally restrictive food preferences.
- Acquisition of age-appropriate skills for independent eating and drinking of all food types.
- Generalization of these behaviors and skills to all appropriate natural environments.

Definitions and Explanations of Key Terms

Attention to task: It is a component of eating behavior that refers to the maintenance of the level of attention that is required for adequate, task performance.

Blocked practice: Describes use of drill-like, repetitive task sequences in a practice session

Complex consistencies: Are solid foods consisting of an aggregate of pieces with varying composition in each bite. This bolus type presents high level of demand for swallowing and feeding skills.

Conditioned aversions: Are negative associations with swallowing and feeding that predispose to negative eating behaviors

Extrinsic feedback: Refers to information provided to the child regarding adequacy of performance and amount of time or trials remaining in the practice session

Homeostasis, attachment, and individuation: Are three stages of emotional/behavioral development in infancy and early childhood.

Implicit learning: Refers to maintenance or improvement in behaviors and skills that results from interventions in the natural task environment that do not disrupt the integrity of the task or draw attention to the learning.

Intrinsic feedback: Refers to experiential information generated by performance of the eating task and its physiological consequences.

Motivation for compliance: Refers to the willingness or desire to conform to the guidance of a leader or authority figure, usually associated with a perceived incentive

> **Motor learning approaches:** Refers to a situation-based model for training skilled movement behaviors that incorporate concepts and strategies for optimizing learning of skills and supporting behaviors.
>
> **Negative eating behaviors:** Refer to a variety of behavioral scenarios, including food/meal refusal, verbal and physical aggressions and fleeing, associated with meal and snack situations, and of sufficient severity or persistence to interfere with nutrition, hydration, or acquisition of swallowing and feeding skills.
>
> **Random practice:** Describes use of randomly sequenced practice of skill components in complex tasks
>
> **Rehearsal:** It is a training strategy in which the natural task that is the target of training is modified or a similar task is substituted as a means for facilitating learning
>
> **Task specificity:** Refers to the differences in experiential information, movement skills, and behaviors between traits and knowledge as significant considerations for training
>
> **Tolerance of the sensory array:** Refers to the ability to maintain a calm and alert state while experiencing the sensory aggregate during practice.

Chapter 205
The Young and Adolescents: Initiating Change in Children's Eating Behavior

Tom Baranowski, Teresia O'Connor, and Janice Baranowski

Abbreviations

IRM   Item response modeling
BMI   Body mass index

205.1 Introduction

Changing dietary behavior can be important for health concerns (e.g., to manage diabetes, prevent obesity, treat food allergies), or just appearance (e.g., more slender self presentation). Behavior change programs may use interpersonal methods (e.g., a physician, health educator, dietitian, or behavior therapist), electronic self-management (e.g., websites designed for self-monitoring diet and setting goals to change), or even videogames (Baranowski et al. 2003a). Whatever the target behavior or the medium, the behavior change principles and procedures are the same.

Dietary behavior change programs for children have generally had weak effects (Ammerman et al. 2002). When more substantial changes have occurred (Epstein et al. 2001), it appears likely to have been due to the self-selected (e.g., responses to media advertisements) and thereby more highly motivated nature of the sample, who would likely have benefitted from any of a variety of types of programs offered. Furthermore, when changes have occurred, they have usually been detected immediately after the program, but not over longer time intervals (Thompson et al. 2009). Thus, a distinction has arisen between factors in the initiation and in the maintenance of change. Little is known about how to maintain changes once initiated (Fuglestad et al. 2008), especially among children. Thus, this chapter focuses on initiating dietary change, and uses the mediating variable model (Fig. 205.1) as a framework for understanding how interventions should work. The basic model is expanded to guide research on more realistic interventions. In each case, more research is needed to provide a firmer scientific foundation for what has been essentially an intuitive and ad hoc process.

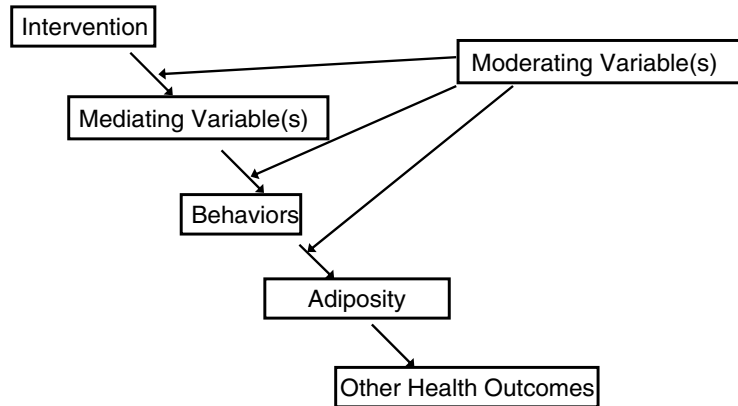
mediating variable model as an
organizing framework


205.2 Simple Mediating Variable Model for Initiating Dietary Behavior Change

The mediating variable model started as a tool to analyze what variables accounted for relationships (Baron and Kenny 1986), and thereby provide the "science" for program evaluation. A model targeting childhood obesity and its sequelae can be found in Fig. 205.1. This is the simplest presentation of this model with only one intervention component and one mediating variable.

The mechanisms of action of the mediating variable model start with the implementation of a program. The implemented intervention impacts mediating variables, i.e., influences on the targeted behaviors. Changes in mediating variables change behavior. Changes in behavior change adiposity. Moreover, changes in adiposity influence downstream phenomena (e.g., metabolic syndrome, food allergies, social attractiveness/acceptance, etc.). Thus, behavior change programs are really mediating variable change programs. Variables can also moderate the relationships in the mediating variable model, i.e., differentially allow or enable the intervention to have its effects. For example, some interventions have worked with girls, but not boys; hence, gender would be a moderating variable (Gortmaker et al. 1999). Most attention has been paid to demographic variables as moderating variables, but mediating variables could also be moderators, e.g., an intervention has an effect only among those with high preference for a food at baseline (e.g., Latif et al. in press).

Assumptions of the mediating variable model include that targeted behaviors are strongly and causally related to the health outcome of interest. If not causally related, changes in the behavior will not effect changes in the physiological processes. If not strongly related, then even extensive change in the behavior may effect only small changes in the physiological processes. Using the same reasoning, the targeted mediating variables must be causally and strongly related to the behavior. Intervention procedures must be selected and implemented that can change the mediating variables enough to change the behaviors enough to have the desired impacts on the physiological processes. Interventions must also be thoroughly implemented. If interventions are not thoroughly implemented with high fidelity to the original design, whatever effects are detected will have come more by chance than by design. The relationships from intervention implementation to physiological change are multiplicative which means the effects of even strong relationships early in the chain of events can be minimized by weak links anywhere along the chain. To be able to study these relationships, measures with high levels of validity and reliability are necessary both because low reliability minimizes the ability to detect true strong relationships (Traub 1994), and low validity indicates we would not really know if our interventions are working as theoretically specified.

The ideal intervention would be based on highly predictive theory with substantial formative research to adapt the theoretical constructs to local circumstances, and thereby maximize the likelihood of its effectiveness. The ideal evaluation would use a randomized clinical trial as the design (often a group randomized design when working with groups of children, e.g., in school (Baranowski and Cerin 2008; Donner and Klar 1996), and measure relevant aspects of the environment as moderating variables (Baranowski and Cerin 2008), relevant psychosocial and environmental mediators, the targeted behaviors, and aspects of program delivery (dose, fidelity, reach; Baranowski and Jago 2005) at least before and after the intervention, and at crucial other times.

205.3   Where to Find Mediating Variables

Knowledge used to be considered the primary, if not only, mediating variable (Contento et al. 1995). Termed a theory of enlightened self-interest (Baranowski et al. 2003b), investigators thought that participants would do the behaviors that were in their self-interest, and interventions primarily needed to effectively convey that knowledge. An early literature review of hundreds of published dietary change studies, however, demonstrated that knowledge by itself was not an effective mediator of dietary behavior change interventions (Contento et al. 1995). Thus, some knowledge is a necessary, but not a sufficient, component of a dietary change intervention.

Since then, mediating variables have usually been selected from theory-based cross-sectional studies (Baranowski et al. 1998). A limitation of this source is the inability to assess causality. For example, although self-efficacy has been shown to be related to behavior in a broad variety of cross-sectional studies, one longitudinal study found that behavior predicted later self-efficacy, but not the reverse (Nigg 2001). Another longitudinal study exploded cross-sectional findings by showing that maternal restrictive food parenting practices followed the onset of obesity, but did not precede it (Rhee et al. 2009), thereby minimizing the concern about restrictive parenting causing obesity. The best source of mediating variables would be studies testing what variables mediated dietary change outcomes. Fortunately, there are accumulating studies of what variables mediate dietary change interventions in children (Cerin et al. 2009). Using variables identified from this source should ensure that the variables meet the assumption of causality and that procedures are available to manipulate them. A review of the literature testing mediation in dietary behavior change revealed that the only variable detected as a mediator in multiple studies (thereby minimizing chance findings) was outcome expectancies, i.e., variation in the belief of good or not so good outcomes from engaging in the targeted behavior (a motivational variable; Cerin et al. 2009). This suggests that interventions must carefully identify a targeted population's beliefs about what will happen from engaging in a dietary behavior and then design messages or activities that persuade people that their likely experience of positive outcomes will increase and of negative outcomes will decrease. There is a growing literature on tailored messages (i.e., messages individualized to the beliefs of each participant) which is very promising (de Vries et al. 2008), but little research has been done with tailoring persuasive messages with children.

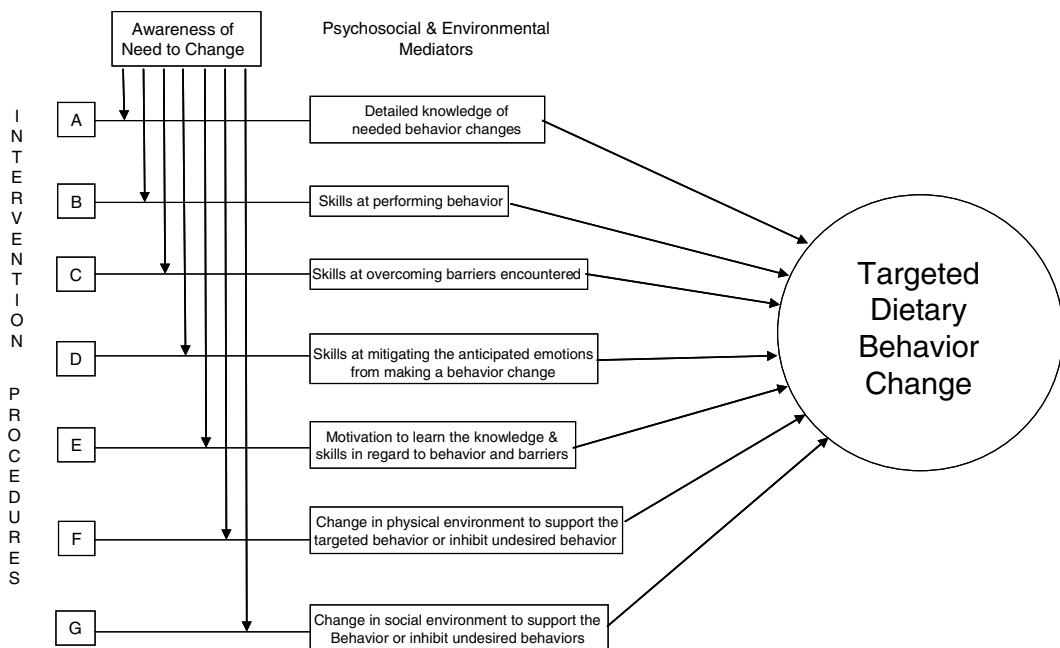
The literature review on mediating variables (Cerin et al. 2009) also revealed that in some cases an intervention exacerbated a mediator that minimized behavior change (i.e., increased a mediator that was negatively correlated with the behavior), called a suppressor effect. For example, at the end of one intervention, participants perceived more barriers, rather than less. This suggests that additional research, done in a more systematic fashion, is needed to design interventions that have desired effects on mediating variables (Baranowski et al. 2009).


Fig. 205.2 Mediating variables for initiating child dietary behavior change

205.4 More Complex Mediating Variable Model

Behavior change is likely a function of more than one mediating variable. Based on the existing research and logic, initiating dietary change likely requires someone to (a) be aware of the need to change; (b) know precisely what changes are needed in their usual routines; (c) develop skills to do them in ways likely to be successful (Brug 2008); (d) anticipate problems or barriers to doing these behaviors and become skilled at overcoming them (Lesley 2007); (e) be sufficiently motivated to initiate these changes at levels necessary to have the desired effects and to resist temptations not to change (Brug 2008); (f) be prepared to mitigate the emotions (e.g., anxiety, frustration, depression, deprivation) likely to occur when changing their behavior (Bagozzi et al. 1998); and (g) organize their environment (both physical and social, at home and other frequented locations) to support the new behaviors, and minimize distractions or temptations not to do the behaviors (Jago et al. 2007). We believe these are the mediating variables needed to initiate changes in a child's dietary behaviors. Thus, an effective intervention would need to have at least seven components (A–G in Fig. 205.2), each targeted at a different mediating variable to successfully initiate a desired behavior change. If one of these variables is already high in a child or their home, then no further changes in that variable may be necessary. How best to induce changes in these variables has received scant attention and therefore requires extensive further research.

205.5 A Two-Mediator Model: Intervening with Parents to Influence Children

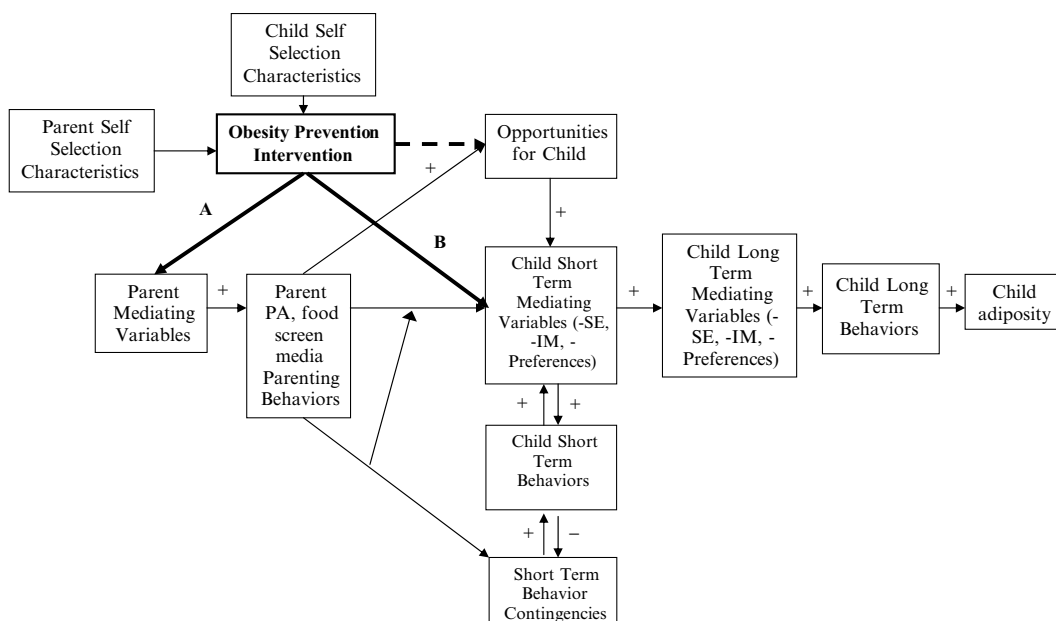
The person responsible for a child's behavior change varies across childhood. In the earlier ages, the parent or guardian is the primary person responsible because the young child can at best reject food, but not select foods to be eaten. Later in childhood, e.g., adolescence, the child often becomes


Fig. 205.3 Multiple mediation model of effects from obesity prevention intervention with parents to child obesigenic behaviors and adiposity

progressively more responsible. This, however, will vary by family, parenting style (Hughes et al. 2005), and the parent's willingness to transfer control. There will be many pathways of change in responsibility from early childhood to late adolescence, and into the adult years. At the point of a major social role change at the end of high school (entrance to the "adult" years), there were remarkable shifts in behavior, likely reflecting shifts at the start of the adult years in who was responsible for behavior change (Baranowski et al. 1997).

Thus, in the earliest years, parents are necessarily the target for a child's nutrition intervention (Ells et al. 2005). However, little attention has been paid to how best involve parents in behavior change interventions. A review of interventions with family components (O'Connor et al. 2009) identified five primary methods by which programs had involved parents: (1) newsletters/homework sent home; (2) fun nights or organized events for families to attend; (3) telephone contact with parents; (4) organized activities for family; and (5) family counseling or parent training. Overall, there was a lack of high quality studies from which to draw systematic conclusions. Despite the poor evidence base, sending printed material home (the method used by the majority of studies reviewed) was not sufficient to effect change. Family counseling/parent training and telephone calls were identified as warranting closer evaluation with well-designed fully powered studies (O'Connor et al. 2010). Intervening with an adult (e.g., the parent) to influence the child introduces more variables and longer chains of effects from intervention to child outcomes. Figure 205.3 presents a more complex and perhaps more realistic, mediating variable model that incorporates mediators of parents' behavioral change to influence children's behavior.

205.6 Why Might It Be Important to Involve Parents?

Parents are an important influence on children's health beliefs and behaviors. While personal child factors have been associated with youth's dietary behaviors (Neumark-Sztainer et al. 2003), parental factors and behaviors have also emerged as important correlates of children's

behaviors. Parental intake (Pearson et al. 2009), parental role modeling (Pearson et al. 2009), availability and accessibility of foods in the home (Pearson et al. 2009) (likely under parental control), parental education and parental rules (Pearson et al. 2009) were important determinants in children's dietary behaviors. Parental influences may also persist beyond adolescence providing support for targeting parental factors to achieve some maintenance of children's lifetime dietary changes.

Parents may influence their children's dietary behaviors both indirectly and directly. Indirectly, they are one of the key determinants of the home environment (e.g., availability and accessibility of foods (Jago et al. 2007)), which in turn influences the child's behavior. Parents also establish an emotional climate in the home through their parenting style (Darling and Steinberg 1993), which has consistently been associated with a wide range of youth behaviors and may facilitate or inhibit parent–child interactions. The most common method to describe general parenting style involves two dimensions of parenting: nurturance and demandingness (Baumrind 2005). Nurturance is the warmth, support, and open communication provided by a parent to a child to promote self-regulation and independence in the child. Demandingness is the expectations, rules, monitoring, and conformation provided by a parent to a child to promote integration into society. By crossing these dimensions, four quadrants or typologies of parenting style emerge: authoritative (high nurturance, high demandingness); authoritarian (low nurturance, high demandingness); permissive (high nurturance, low demandingness); and uninvolved (low nurturance, low responsiveness) (Maccoby et al. 1983). An authoritative parenting style predicted lower risk for overweight in children (Rhee et al. 2006) and increased fruit consumption in adolescents (Kremers et al. 2003). Based on the general parenting style dimensions and typologies, a measure of parental attitudes and behaviors intended to socialize children around feeding was developed (Hughes et al. 2005). Indulgent feeding style was associated with higher child weight status (Hughes et al. 2008).

Directly, parents influence children's dietary behaviors by their food-related parenting practices. Parenting practices are the context-specific behaviors parents use to influence child behavior (Darling and Steinberg 1993). Examples of parenting practices include establishing and reinforcing rules, monitoring, contingency management (if–then statements), praising, and providing choices. Within the feeding context, restrictive parenting practices were consistently associated with greater consumption of less healthy foods and greater weight status (Faith et al. 2004). Conversely, parents who (1) enhanced availability and accessibility of fruit and vegetables, (2) used teachable moments (e.g., use mealtimes to teach about healthy eating), and (3) avoided firm discipline around eating, had children with greater fruit and vegetable consumption than parents who tended to use all parenting practices indiscriminately or had higher use of firm discipline practices (O'Connor et al. 2009). Parenting practices that are context-specific and goal-directed may be easier to change than parenting styles. Therefore, research needs to expand and define effective parenting practices that can be promoted to encourage healthful eating among children.

In order to create effective dietary change interventions that include procedures targeting parents to achieve behavior change in children, there needs to be a better understanding of the variables mediating intervention effects on parents and thereby could be targeted to effect change. Very little research has explored parental mediating variables that potentially affect their food parenting practices. General parental attitudes about obesity were associated with use of restrictive feeding practices with their children, after controlling for covariates including parent and child body mass index (Musher-Eizenman et al. 2007). It is likely that other mediating variables such as parental self-efficacy, intrinsic motivation, subjective norms, and perceived control also affect parental use of effective parenting practices. All these, and potentially others, need to be explored and scales need to be developed and validated for each (Baranowski et al. 2004).

205.7 Measurement

To be able to evaluate intervention programs targeted directly at children, or targeted at parents to influence children, better measures are needed. A simulation study demonstrated that validity coefficients need to be at 0.90 or higher to minimize classification error (De Moor et al. 2003). Since reliability coefficients place limits on validity coefficients, reliability needs to be at this level or higher, as well. Most current measures, however, do not even come close to these levels (Baranowski et al. 2004).

New psychometric methods, called Item Response Modeling (IRM), have become available to enhance our understanding of optimal approaches to measurement and how to improve them (Wilson et al. 2006). IRM fits a latent variable to items which facilitates the comparison of respondents and items along the same latent variable, and thereby permits tests of whether different groups use the same scale in different ways (Baranowski et al. 2006), and whether an intervention affects the meaning of items in a scale (Baranowski et al. 2006). These are among a variety of uses not formerly possible. Application of IRM methods to measures that have been demonstrated to have adequate psychometric characteristics using classical test theory methods revealed severe limitations in the distribution of items along the distribution of participants. This suggests that the existing scale had limited content validity in assessing the full range of beliefs (Watson et al. 2006). Attempting to expand the range of items using theoretically prescribed procedures was not effective (Baranowski et al. 2010). Alternatively, briefer instruments can be developed by eliminating items revealed to be redundant at points along the latent variable, thereby reducing respondent burden (Table 205.1) (Jago et al. 2009).

205.8 Conclusions

We are still in relatively early stages of understanding how to design interventions effective in initiating child dietary behavior change. The mediating variable model is useful in advancing this agenda because it integrates more basic behavioral research with intervention research. Intervention research would benefit from a clearer understanding of the influences of dietary behaviors on health outcomes (Bachman et al. 2006) and the influences on dietary behaviors (Baranowski 2006). Intervention research should progress through a series of formative studies that first indentify the behaviors influencing the health outcomes in a targeted population, next identify the primary causal and stronger influences (mediators) on the targeted behaviors, and finally identify the intervention procedures most likely to effect substantial change in the target mediators (Baranowski et al. 2009). When major

Table 205.1 Key features of item response modeling (IRM)

1. An increasingly used advanced psychometric procedure that fits a latent variable to items in a questionnaire.
2. IRM compares the distribution of the respondents with the distribution of the items, thereby permitting an analysis of the distributional content validity of the items.
3. IRM estimates a latent variable that is not sample-specific: this permits comparison of whether different groups respond to the same item at the same location (called differential item functioning).
4. IRM offers the promise of reducing response burden by eliminating items that are redundant at a particular point on the variable, while maintaining high validity.

This table lists the key features of IRM

interventions have been mounted, thorough mediating variable analyses need to be conducted to elucidate effective mediating variables for use in ensuing trials. Much work remains to be done to elucidate effective ways to change children's dietary behaviors.

205.9 Applications to Other Areas of Health and Disease

Behavior change has been challenging across a broad variety of behaviors and in many demographic groups. Most behavior change programs have emphasized increasing knowledge, which has not been working. The advantage of the mediating variable model is that it integrates the behavior theory literature of influences on behavior with the intervention literature. All these areas of behavior change intervention would benefit from adopting the mediating variable model perspective, both as a conceptual tool to design more effective interventions and as an analytic tool to assess if the intervention worked as designed.

Summary Points

- Dietary behavior change programs have generally not been working.
- New models are needed to understand how programs work, to guide future development.
- The mediating variable model provides a perspective that integrates basic behavioral research with intervention research.
- Mediating variables must be selected from the basic literature on variables shown to be causally and substantially influencing the targeted behaviors.
- The existing literature is weak on identifying variables that causally and substantially influence behaviors.
- One problem is that the designs need to be longitudinal.
- The interventions must include procedures to effectively manipulate the selected mediators.
- The existing literature is weak on identifying these procedures, too.
- Another problem is the low validity and reliability of measures of both the behaviors and the mediators.
- More models are needed to identify pathways of effects that can guide the design of ensuing interventions.

Definitions

Dietary behavior: What a person does when selecting and eating food.
Mediating variable: A variable demonstrated to be on the causal pathway between an intervention and a change in a behavior.
Mediating variable model: The model used to test mediating relationships and to guide the development of interventions.
Moderating variable: A variable for which one category or end of a dimension facilitates behavior change more so that the other category end of a dimension.
Intervention procedures: Activities demonstrated to induce changes in mediating variables.
Theory of enlightened self-interest: Posits that people will change their behavior in response to new knowledge about their behavior, especially the outcomes of their behavior.

Nurturance: Warmth, support, and open communication provided by a parent to a child to promote self-regulation and independence in the child.

Demandingness: Expectations, rules, monitoring, and confrontation provided by a parent to a child to promote integration into society.

Parenting style: Parent attitudes and behaviors that influence the emotional climate that parents create in a home to socialize their children.

Parenting practices: Behaviors used by parents to influence their child in a specific context.

Psychometric methods: Methods to analyze the validity and reliability of measures.

Item response modeling: A psychometric technique that fits a latent variable to items, which permits a variety of innovative tests.

Classical test theory: The traditional psychometric methods.

Outcome expectancy: The set of beliefs about the outcomes (good or bad) from doing a behavior.

Chapter 206
Eating Disorders and Behavioral Aspects of School-Based Prevention Programs

Riccardo Dalle Grave, Lucia Camporese, and Elettra Pasqualoni

Abbreviation

BMI   Body mass index

206.1 Introduction

Eating disorders are one of the most common health problems afflicting female adolescents and young women in Western countries (Lewinsohn et al. 1993). They are characterized by disturbance of eating behaviors and/or weight-control behaviors associated with a specific core psychopathology (i.e., the overvaluation of shape and weight and their control) (Fairburn and Harrison 2003). Either the behavior disturbances or the associated specific core psychopathology are important causes of physical and psychosocial morbidity (Fairburn and Harrison 2003), with an increased risk of death (Agras 2001). Only a subgroup of individuals with eating disorders receive treatment (Newman et al. 1996), and often after many years of illness when their disorder has already become chronic (Herzog et al. 1992). Complete remission has been described in 40% of patients who complete evidence-based treatments (Fairburn et al. 2009), and some need to be admitted to intensive and costly inpatient treatments (Dalle Grave et al. 2008).

The above facts stimulated considerable efforts in developing prevention programs, particularly in schools, because eating disorder typically starts during school age and schools often provide access to adolescents at risk (Dalle Grave 2003). School-based eating disorder programs have been described and evaluated by controlled studies in several Western countries (e.g., Canada, the USA, Norway, Switzerland, the Netherlands, the UK, Italy, Australia, Croatia, and Israel) (Dalle Grave 2003), and a large body of knowledge is available about their effectiveness and limits.

The aims of this chapter are: (1) to review the efficacy of school-based eating disorder prevention programs; (2) to suggest some implications for stakeholders in the health-care sector; and (3) to suggest some strategies to improve the future eating disorder prevention.

206.2 Eating Disorder Prevention Programs: A Few Definitions

Eating disorders prevention programs can be classified into three broad-categories: *universal*, *selective*, and *indicated*. Universal programs are directed at "all" consenting individuals in a given population, such as a given grade level in a school, and aim at reducing risk and promoting protective factors. Selective and indicated interventions target specific subgroups for intervention. Selective interventions target those who are at elevated risk based on group-level characteristics that are not directly related to etiology. Because eating disorders are complex diseases derived by the interaction of genetic and environmental risk factors (Striegel-Moore and Bulik 2007), a selective prevention might focus on asymptomatic children with first-degree affected relatives or with some risk factor supported by multiple independent prospective studies (e.g., elevated perceived pressure to be thin, internalization of the thin-ideal standard of female beauty, obesity, body dissatisfaction, and negative affect) (Shaw et al. 2009). Finally, an indicated intervention involves targeting individuals who either have signs of the disorder (e.g., dieting with an overvaluation of shape and weight and their control) but are in an early stage of a progressive disorder. In practice, this distinction is difficult to maintain. Many universal programs for eating disorder prevention, for example, are focused only on girls and women – and female sex is considered the most powerful potential risk factor for eating disorders. In addition, some selective intervention easily may include individuals with unhealthy weight-loss behaviors – and unhealthy weight-loss behaviors could be both a risk factor and an early sign of an eating disorder.

206.3 The Two Generations of School-Based Eating Disorder Prevention Programs

Two main generations of universal school-based eating disorder prevention programs have been described (Dalle Grave 2003).

The first generation adopted a didactic approach that supplied information with on nutrition, body image, and the nature of eating disorders. The didactic approach produced an improvement in knowledge of eating disorders, but were ineffective in changing dysfunctional attitudes (e.g., the overvaluation of shape and weight and their control) and unhealthy behaviors (e.g., dietary restraint to change or control shape and body weight) (Dalle Grave 2003).

The second-generation programs introduced an interactive and experientially educational approach and other innovative strategies designed to change dysfunctional attitudes and unhealthy behaviors and to target well-established risk factors underlying eating disorder psychopathology. Examples include dissonance-based approach (Shaw and Stice 2008), cognitive restructuring techniques to challenge dysfunctional attitudes about shape, weight, and their control (Dalle Grave et al. 2001; Stewart et al. 2001), messages on video to dissuade against dieting (Paxton et al. 2002), active techniques to foster a change in eating habits, including self-monitoring (Stewart et al. 2001), prevention videotape on dieting and body image (Withers et al. 2002), strategies to improve body image by building general self-esteem (O'Dea and Abraham 2000), and Internet-based multimedia prevention programs based on psychoeducational self-help materials (Winzelberg et al. 1998; Celio et al. 2000).

206.4 Effects of School-Based Eating Disorder Prevention Programs

In the last 10 years, several universal and selective school-based eating disorder prevention programs have been evaluated by randomized control studies and the efficacy of these studies has been analyzed by some systematic reviews (Dalle Grave 2003; Stice and Shaw 2004; Stice et al. 2007; Yager and O'Dea 2008).

The three key findings of a recent meta-analysis are (Stice et al. 2007): (1) 51% of the prevention programs examined produced significant reductions in at least one established risk factor of eating disorder psychopathology; (2) 29% of the prevention programs resulted in significant reductions in eating disorder psychopathology, and (3) some prevention programs reduced eating disorder psychopathology and prevented its increase: an increase that was reported by control groups. These outcomes are encouraging, considering that first-generation prevention interventions were not effective at reducing eating disorder psychopathology and or eating disorder risk factors (Shaw et al. 2009).

Some aspects of school-based prevention programs examined by the reviews appeared to be related to positive program outcomes (Dalle Grave 2003; Stice and Shaw 2004; Stice et al. 2007; Yager and O'Dea 2008).

1. *Selective prevention programs generally tend to obtain more positive results than universal programs.* Most universal programs achieved their knowledge acquisition goals, but only some produced positive effects on dysfunctional attitudes and none a persistent change of unhealthy behaviors. Most of the selective programs, on the contrary, produced positive effects both on dysfunctional attitudes and dysfunctional unhealthy behaviors. Positive effects on high-risk subjects were also observed in some universal programs, but not in all the studies (Becker et al. 2008). Two main reasons could explain the poorer results observed in the universal programs with respect to targeted programs (Dalle Grave 2003): (1) the level of dysfunctional attitudes and unhealthy behaviors in unselected samples may be so low that it is difficult to detect any significant intervention effect; (2) the unselected sample may not be sufficiently motivated to fully engage in the prevention program.

2. *Didactic interventions produced fewer positive effects than interactive interventions.* Most didactic interventions produced changes in knowledge acquisition but very few induced changes in dysfunctional attitudes and unhealthy behaviors. This observation adds further evidence to the conclusions by prevention researchers in other areas that psychoeducational didactic interventions are less effective than interventions that actively engage students and teach new skills (Dalle Grave 2003).

3. *Programs that focused on older participants (older than 15 years) produced stronger prevention effects on dysfunctional attitudes and unhealthy behaviors.* One possible explanation of this observation is that few students are engaging in unhealthy weight-control behaviors or evidencing significant eating disorder psychopathology at a younger age (11–12 years). It is therefore very difficult to achieve statistically significant decreases in dysfunctional attitudes and unhealthy behaviors. The efficacy of prevention programs in young students should be evaluated following them through their high school years to determine the long-term effects of program participation (Dalle Grave 2003). Another possibility is that younger subjects without eating, shape, and weight concerns may not be sufficiently motivated to fully engage in the prevention program. Finally, interventions may be more effective in older adolescents because they are delivered during the peak-risk period when eating disorder psychopathology emerges (Shaw et al. 2009).

4. *Prevention programs delivered by trained professionals are more effective than those delivered by endogenous providers (e.g., teachers, and counselors).* Two main reasons may explain this finding (Shaw et al. 2009). First, endogenous providers have competing demands (e.g., teaching) that obstruct the maintenance of fidelity to the program. Second, endogenous providers often receive less training on the program compared with trained professionals.

5. *Some contents of the intervention seem to produce better outcome.* The number of procedures and techniques used in the programs varied considerably as did overlap between programs with positive and negative outcomes. These make it difficult to conclude whether the specific contents of the prevention programs have positive effects on dysfunctional attitudes and unhealthy behaviors. Dissonance-induction interventions seem to produce larger effects for thin-ideal internalization, body dissatisfaction, dieting, and negative affect, and eating disorder psychopathology than programs without this content (Stice et al. 2007). Positive results have been obtained with programs

focused on: body acceptance, health education activities that build self-esteem, healthy weight-control behaviors, critical analysis of the thin ideal, and the use of computers and the Internet as a delivery medium (Stice et al. 2007; Yager and O'Dea 2008). On the contrary, interventions with a psychoeducational focus and with sociocultural content and a stress and coping focus had limited effects (Stice et al. 2007, Shaw et al. 2009). These data indicate that the prevention of eating disorder psychopathology can be obtained by several and different procedures and strategies and probably also by some nonspecific factors not evaluated by the studies. Table 206.1 reports a summary of the most promising school-based prevention programs evaluated by the research.

206.5 Implications for Stakeholders in the Health-Care Sector

Three main practical implications for stakeholders in the health-care sector can be suggested from results obtained by school-based eating disorder prevention programs.

1. There is no statistical evidence that school-based prevention programs for eating disorders have harmful effects (Pratt and Woolfenden 2002; Dalle Grave 2003). To date, the results obtained by these programs can reassure parents, teachers, and other stakeholders that these interventions have no general harmful effects on student attitudes and behaviors.
2. The encouraging results from selective prevention programs for high-risk individuals might stimulate stakeholders in the health-care sector to promote selective interactive prevention programs for middle to late adolescent subjects with high risks for eating disorders. The programs should preferably be delivered by professional interventionists and should address eating disorder risk factors and promote healthy weight-control behaviors. Since targeted programs have the intrinsic potential to produce stigmatization in participants, future research is needed to develop models and strategies to avoid this undesirable effect. Some recent technology-based efforts (CD-roms, Internet-based homework, guided chat rooms) may help to solve these problems.
3. The poor results obtained by universal eating disorder prevention programs in early adolescents as evaluated in controlled trials suggest that for the moment it is not advisable to spend money for indiscriminate universal eating disorder prevention. However, since some clinical cases derive from low-risk groups, research on universal prevention should continue and the school remains an important place where this type of study is possible. Since universal programs are generally ineffective in improving unhealthy behaviors, in designing a universal prevention program it is mandatory to place more emphasis on behavioral changes by including a stronger link between knowledge and attitudes and behaviors (Steiner-Adair et al. 2002).

Table 206.2 reports some suggestions for stakeholders in the health-care sector to optimize the implementation and evaluation of school-based eating disorder prevention programs (Dalle Grave 2003).

206.6 Strategies to Improve the Future Eating Disorder Prevention

The poor outcome of universal eating disorder prevention programs may largely be attributed to our limited knowledge of eating disorder risk factors and by the insufficient efficacy of the methods used to manipulate the identified potential risk factors (see Table 206.3). However, the encouraging results obtained by the second-generation programs suggest that research has the potential to improve the outcome from eating disorder prevention intervention.

Table 206.1   Promising school-based eating disorder prevention programs

Program	Description
The body project (Shaw and Stice 2008)	The program is based on social psychological principle of cognitive dissonance. The theory postulates that encouraging girls and women to take an active position against the culturally mandated thin ideal, they will experience cognitive dissonance with a shifting of their belief systems toward an antithin-ideal stance. The intervention (3- and 4- session versions) reduced the risk for future onset of both eating disorder symptoms and obesity and mental health-care use at 1-year follow-up (Stice et al., 2006). Through a 3-year follow-up experimental group showed significantly greater decreases in thin-ideal internalization, body dissatisfaction, negative affect, eating disorder symptoms, and psychosocial impairment and lower risk for eating pathology than controls. Most importantly, the intervention reduced in the experimental group the risk for onset of threshold and subthreshold anorexia nervosa, bulimia nervosa, and binge-eating disorder compared with controls (6% vs. 15%) (Stice et al. 2008)
Healthy weight intervention (Stice et al. 2006)	The program was originally designed as a control group in a study testing the dissonance program. It is a brief 4-session intervention that teaches participants how to achieve and maintain a healthy weight by making small, gradual changes in diet and exercise. The intervention reduced the future onset of both eating disorder symptoms and obesity and result in improved psychosocial functioning and reduced mental health-care use at 1-year follow-up (Stice et al. 2006). The intervention also reduced the onset of eating disorders at 3-year follow-up (Stice et al. 2008)
Girl talk (McVey et al. 2004)	Girl Talk is a brief (6-sessions) interactive intervention focused on promoting critical media use, body acceptance, healthy weight-control behaviors, and stress management skills using a peer-support group. The intervention administered by public health nurses in a school, led to increases in weight-related esteem and decreases in dieting at post-test and 3-month follow-up among middle schools girls compared with the control group (McVey et al. 2003a). A subsequent evaluation of the intervention in other schools, however, did not replicate these positive findings (McVey et al. 2003b)
Student bodies (Winzelberg et al. 2000)	Student Bodies is an 8-week computer-administered program based on cognitive–behavioral body-dissatisfaction interventions that provides information on eating disorders, healthy weight-control behaviors, and nutrition. It also includes e-mail support interchange. The program showed produced a significant reduction of body dissatisfaction (Low et al. 2006), and positive outcome have been replicated by others (Taylor et al. 2006)
Weigh to eat (Neumark-Sztainer et al. 1995)	Weight to eat is a psychoeducational intervention that incorporates social–cognitive principles for behavior change. It is aimed to improve knowledge, attitudes, behaviors related to nutrition and weight control, body and self-image, and promoting greater self-efficacy in approaching social pressures regarding excessive eating and dieting. An effectiveness trial that evaluates the 10-session intervention administered by a health educator found that it produced significant improvements in knowledge, healthy weight-control behaviors, dieting, and binge eating at 6-month follow-up, although only the effects for binge eating remained significant at the 2-year follow-up
AIDAP eating disorder prevention program (Dalle Grave and De Luca 1999)	The AIDAP program is based on a broad cognitive–behavioral conceptualization of eating disorders and it was designed to prevent the development of eating disorders by reducing the prevalence of dietary restraint and the level of concern on shape and body weight in participants. It uses an interactive and not didactic educational approach with the inclusion, as in cognitive–behavioral therapy, of cognitive restructuring, homework, role-play, and practical activities and group discussions. The 6-session program, evaluated in Italy by a controlled study, produced in the experimental group an increase in knowledge, and a decrease in some attitudes maintained at 12-month follow-up (Dalle Grave et al. 2001). An evaluation of the program in a sample of young students confirmed its efficacy in reducing eating disorder attitudes and dieting behavior (Pokrajac-Bulian et al. 2006)

Table 206.2 Suggestions for stakeholders in the health-care sector to optimize the implementation and evaluation of school-based eating disorder prevention programs (Dalle Grave 2003).

1. The program must be easily inserted in the context of the school with lessons no longer than 50 min
2. Providers should be extensively trained before beginning the interventions
3. The program should be written in a manual to facilitate intervention fidelity and dissemination
4. Fidelity should be cheeked by a supervisor who evaluates several recorded prevention sessions
5. In order to eliminate possible contamination effects, it is advisable to use a control group in a separate site
6. The administration of the program should be across a wide spectrum of people with the involvement of parents, teachers, and school administrators
7. Booster sessions should be routinely planned to reinforce the maintenance of the positive effect of the intervention
8. Programs should select quantitative and qualitative outcome measures for evaluating potential negative effects
9. Short- (6 months) and long-term (1 or more years) follow-up assessments should be routinely conducted in prevention research

Table 206.3 Some of the potential risk factors for anorexia nervosa and bulimia nervosa (Dalle Grave 2003; Fairburn and Harrison 2003; Striegel-Moore and Bulik 2007)[a]

General factors
- Female
- Adolescence and early adulthood
- Living in a Western society

Individual-specific factors
- Family history
  - Eating disorders
  - Depression
  - Alcoholism (bulimia nervosa)
  - Obesity (bulimia nervosa)
- Premorbid experiences
  - Neonatal complications
  - Adverse parenting (especially low contact, high expectations, parental discord)
  - Sexual abuse
  - Family dieting
  - Critical comments about eating, shape, or weight from family and others
  - Occupational and recreational pressure to be slim
  - Media exposure to images of thin people
- Premorbid characteristics
  - Low self-esteem
  - Anxiety and anxiety disorders
  - Obesity (risk factor for bulimia nervosa)

[a]Risk factors are defined as "antecedent condition associated with an increase in the likelihood or adverse, deleterious, or undesirable outcomes" (Kazdin et al. 1997)

206.6.1 Enhancing Reliance on Risk-Factor Research When Designing New Prevention Programs

Most of the school-based prevention programs have been designed without being guided by modern research on risk factors (e.g., retrospective case–control studies and prospective cohort studies). Even though few eating disorder risk factors are yet known with confidence, it is advisable that future prevention programs are designed targeting empirically established risk factors.

It is also important to develop new instruments for detecting high-risk individuals based on the last findings derived by risk-factor research.

206.6.2 Improving the Design of the Eating Disorder Prevention Trials

Most of the eating disorder programs are affected by a number of methodological limitations. Many studies did not include a control group, and therefore they are unable to distinguish intervention effects from the effects of passing time. Several prevention trials did not use randomization to assign participants to condition and only a few used a placebo control condition. In many cases, sample sizes and follow-up were inadequate and did not reach meaningful conclusions. Many studies do not calculate effect sizes, making it difficult to interpret the real effects of the intervention. Most of the studies used outcome measures based on self-report assessment questionnaires. Such instruments tend to overestimate psychopathology and are not the ideal way of assessing eating disorder features. Furthermore, outcome measures evaluated only changes in certain dysfunctional attitudes and unhealthy behaviors and not the real effect on the prevalence and the incidence of eating disorders. These and other methodological limitations should be overcome by the future research studies.

206.6.3 Importing Strategies from the Treatment of Eating Disorders

The prevention programs could improve with the inclusion of some useful strategies adopted by the self-help with books. The self-help intervention produced positive outcome in the treatment of bulimia nervosa and binge-eating disorder (Loeb et al. 2000; Dalle Grave 1997). Self-help books may be used either by subjects on their own (pure self-help) or with guidance from therapists (guided self-help). The contents of some self-help books (Fairburn 1995; Dalle Grave 1998) are derived from cognitive–behavioral therapy of bulimia nervosa, the most effective therapy evaluated by controlled trials (Wilson and Shafran 2005). Self-help with manuals uses some effective strategies to increase motivation to change, to decrease dietary restraint, and to reduce the overvaluation of shape, weight, and eating control. Positive effects would be likely including these strategies taken from the self-help manual approach in future selective and indicated programs.

206.6.4 Integrating Eating Disorder and Obesity Prevention Programs

There are several reasons for integrating eating disorder and obesity prevention (Neumark-Sztainer 2003; Haines and Neumark-Sztainer 2006; Dalle Grave 2003). First, eating disorders and obesity often co-occur. Case–control studies found that obesity is a potential risk factor for bulimia nervosa (Fairburn et al. 1997) and binge-eating disorders (Fairburn et al. 1998) and binge-eating disorder is very common among persons with obesity (de Zwaan 2001). Second, one intervention is obviously cheaper than two, an important issue to consider in a period of global financial crisis. Third, the elimination of some conflicting information on diet, physical activity, and body image, and their potential iatrogenic effects coming from interventions delivered separately (e.g., some preventive obesity strategies, such as monitoring food intake, might promote excessive concern over eating control, and vice versa strategies aimed at eliminating any form of cognitive restraint may favor overeating and the onset of overweight) (Dalle Grave 2003).

An integrated approach, including both strategies to prevent obesity following a healthy lifestyle and to prevent eating disorder accepting the genetic diversity of human body, is a challenge to be tested in the next generation of prevention trials. However, to develop effective prevention interventions, the identification of risk factors shared between obesity and eating disorder is essential. Some preliminary data indicate that dieting, media use, body image dissatisfaction, and weight-related teasing may be relevant both for the development of eating disorder and obesity (Haines and Neumark-Sztainer 2006).

Support to the integration of the two fields comes from the data of one study indicating that a school-based obesity prevention program aimed to promote healthful nutrition and physical activity produced a significant greater reduction in experimental group of new onset disordered weight-control behaviors (self-induced vomiting or use of laxatives or diet pills to control weight) than in control group (Austin et al. 2007).

206.6.5 Creating an Environment with Lower Risk

Sociocultural factors seem to play a key role in the development of eating disorders. Support for these statements come from four lines of evidence (Striegel-Moore et al. 2007): (1) the preponderance of female cases of eating disorders; (2) the increasing incidence of eating disorders associated with the decreasing ideal body weight size for women; (3) the higher incidence and prevalence of eating disorders in cultures that value female thinness; and (4) the significant relationship between thin-ideal internalization and future disordered eating.

It is very improbable that simple and brief school-based prevention programs will be able to produce a real reduction in the incidence and prevalence of eating disorder without a strong action aimed to change some sociocultural risk factors. The shift from a prevention model based on personal responsibility toward a public health prevention model has been also advocated for obesity (Brownell and Horgen 2004). Public health organizations are responsible for ensuring the safety of the public and environmental changes (Brownell and Horgen 2004), including the body size of the fashion models portrayed in the media, the control of the advertising of the diet industry, the availability of the dresses for all the size, the fight against the stigma associated with obesity of, and the availability of healthy food. An example of the combination of education with public health intervention that produced positive changes in the population is the antismoking campaign combined with high tobacco taxes.

Efforts to change some potential environment eating disorder risk factors have been implemented in Spain, France, and Italy. In Italy, for example, where fashion is no doubt an important part of its culture and society, the "National Manifest of Self-regulation in Italian Fashion against Anorexia" has been published which was recommended, as versus obliged, to be adopted by the fashion designers. The key recommendations include: (1) to disseminate an healthy Mediterranean beauty model; (2) to protect the fashion models' health not allowing those with a diagnosis of clinical eating disorder (evaluated by a M.D. using current diagnostic criteria, including Body Mass Index (BMI)) to participate at fashion shows; (3) to ban the models under the age of 16 from the fashion shows; (4) to stimulate the fashion industry to include in their collection dresses of all the sizes; (5) to adopt the internal regulation of the fashion industries to adopt specific measures to ensure the respect of the manifest principles. In addition, the "Tavolo Moda e Salute" (tr. Fashion and Health Table) has been recently opened by the Milan mayor. The aim of this initiative, which sees the participation of eating disorder scientific societies, fashion designers, and political authorities, is to develop for the next Milano Expo 2015 concrete social–cultural actions to prevent eating disorder.

Although no data are available on the impact of public health initiatives, these initial efforts open a new era in the prevention of eating disorder, which have the potential to address with success the sociocultural risk factors of eating disorders.

206.7 Conclusions

School-based eating disorder prevention is still in its infancy. Recently, however, promising results have been achieved in identifying potential risk factors and small, but significant, progress has been made in developing and evaluating innovative interventions. Results obtained by the school-based controlled trials must reassure parents, teachers, and stakeholders in the health-care sector that school-based eating disorder prevention programs do not have harmful effects on student attitudes and behavior. Selective prevention programs have obtained promising results, and positive effects have been obtained using an interactive format, dissonance approach, and by focusing on participants in middle to late adolescence. Universal prevention expectations have unfortunately been disappointed, especially with children and young adolescents. The combination of school-based prevention program with public health strategies aimed at creating an environment with lower risk seem essential to achieve a real reduction in the incidence of eating disorders.

206.8 Applications to Other Areas of Health and Disease

Randomized experimental trials on eating disorder prevention programs could help to isolate the role of risks factor on eating disorder psychopathology, and could help to improve the identification of risk factors shared between obesity and eating disorder.

Summary Points

- The first-generation programs using didactic approach were ineffective in changing dysfunctional attitudes and unhealthy behaviors.
- The new generation programs, adopting an interactive educational approach and other innovative strategies (e.g., dissonance-based approach, healthy weight-control behaviors, cognitive restructuring techniques, strategies to improve body image by building general self-esteem, and strategies using Internet and other modern technology), obtained significant reductions of some established risk factor for eating disorder, and a significant reduction of eating disorder psychopathology.
- Good results have been obtained by selective prevention programs, using an interactive format, dissonance approach, and by focusing on participants in middle to late adolescence.
- Potential strategies to improve the future eating disorder prevention include:
  - Enhancing reliance on risk-factor research when designing new prevention programs
  - Improving the design of the eating disorder prevention trials
  - Importing strategies from the treatment of eating disorders
  - Integrating eating disorder and obesity prevention programs
  - Creating an environment with lower risk

Definitions and Explanations

Universal prevention: Programs targeting "all consenting individuals in a given population".
Selective prevention: Programs targeting to those who are at elevated risk to develop the disorder.
Indicated prevention: Programs targeting individuals who either have signs of the disorder but are in an early stage of a progressive disorder.

Key Points

- Selective prevention programs generally tend to obtain more positive results than universal programs.
- Didactic interventions produced fewer positive effects than interactive interventions.
- Programs that focused on older participants (older than 15 years) produced stronger prevention effects on dysfunctional attitudes and unhealthy behaviors.
- Prevention programs delivered by trained professionals are more effective than those delivered by endogenous providers (e.g., teachers and counselors).
- Some contents of the intervention produced better results (e.g. dissonance-induction interventions, body acceptance, health education activities that build self-esteem, healthy weight-control behaviors, critical analysis of the thin ideal, the use of computers and the Internet as a delivery medium).

Chapter 207
Treating Obesity in Childhood: Behavioral Considerations

Fiona Davies and Louise A. Baur

Abbreviations

BMI   Body mass index weight/height^2 (kg/m^2)
RCT   Randomized–controlled trial

207.1 Introduction

The high prevalence of child and adolescent obesity in most developed, and many developing, countries highlights the need for effective treatment of affected individuals. This chapter provides a brief overview of the prevalence, causes, and consequences of child and adolescent, and then focuses on the behavioral approaches used in its management.

207.2 Obesity in Childhood and Adolescence: An Overview

207.2.1 Rising Prevalence of Obesity

Childhood obesity is a major public health problem facing most westernized, and many westernizing, communities (Lobstein et al. 2004). Over the past 2 decades, the pediatric obesity epidemic has spread throughout the world, with some countries in economic transition now having prevalence rates higher than those in the US. The worldwide prevalence of overweight (including obesity) in children and young people aged 5–17 years is approximately 10%, with that of obesity alone being 2–3%. However, certain regions and countries have particularly high rates of pediatric obesity. For ample, more than 30% of children and adolescents in the Americas, and approximately 20% of those in Europe, are overweight or obese, with lower prevalence rates being seen in sub-Saharan Africa and Asia, although prevalence rates are rising rapidly in those countries undergoing

nutrition transition. Sociodemographic differences also occur, with overweight being high among the poorer children in developed countries, and the richer children in developing countries.

207.2.2 Complications

Not only is obesity increasingly common, but obese children and adolescents may suffer from a range of both immediate and future comorbidities, as shown in Table 207.1 (Lobstein et al. 2004). Because of the range of potential obesity-associated comorbidities, children and young people affected by obesity should have a formal medical assessment.

207.2.3 Etiology of Obesity: An Overview

What factors lead to the development of obesity? Put simply, obesity is a chronic disorder affecting energy imbalance, i.e. there is a disturbance in the balance between energy expenditure and energy intake. This energy imbalance arises as a consequence of a complex interaction between genetic, social, behavioral, and environmental factors.

Energy balance is influenced by a detailed set of physiological pathways, of which the hypothalamus acts as the central regulator of energy homeostasis and energy intake. Circulating peripherally derived factors, including satiety signals derived from the gastrointestinal system, as well as long-term signals of energy stores (leptin, insulin) and short-term hunger (ghrelin) modulate this system. The resultant energy regulation system protects against weight loss, but does not protect against weight gain (Spiegelman and Flier 2001). With increasing body fatness, the resultant increase in circulating leptin (the principal fat store size signal) has only a limited effect on reducing food intake, presumably due to cellular resistance to leptin signaling.

There is a strong familial association with obesity, with many studies showing that part of this association is through a shared genetic predisposition (Bouchard 2009). While genetic factors make

Table 207.1 Potential complications of obesity in childhood and adolescence

System	Health problems
Cardiovascular	Hypertension, adverse lipid profile (low HDL cholesterol, high triglycerides, high LDL cholesterol)
	Medium- and long-term: Increased risk of hypertension and adverse lipid profile in adulthood, increased risk of coronary artery disease in adulthood, left ventricular hypertrophy
Endocrine	Hyperinsulinemia, insulin resistance, impaired glucose tolerance, impaired fasting glucose, type 2 diabetes mellitus *Medium- and long-term*: Increased risk of type 2 diabetes mellitus and metabolic syndrome in adulthood
Hepatobiliary	Nonalcoholic fatty liver disease, gallstones
Neurological	Benign intracranial hypertension
Reproductive	Polycystic ovary syndrome, menstrual abnormalities
Orthopedic	Back pain, slipped femoral capital epiphyses, tibia vara, ankle sprains, flat feet
Psychosocial	Social isolation and discrimination, decreased self-esteem, body image disorder, bulimia
	Medium- and long-term: Poorer social and economic "success", bulimia
Respiratory	Obstructive sleep apnea, asthma, poor exercise tolerance
Skin	Acanthosis nigricans, striae, intertrigo

This table lists the range of potential obesity-associated complications in childhood and adolescence, by organ system. In some cases, medium- to long-term complications are listed, as well as the more immediate problems

Table 207.2 Summary of strength of evidence on factors that might promote or protect against weight gain and obesity (Adapted from World Health Organization 2003)

Evidence	Decreased risk	No relationship	Increased risk
Convincing	Regular physical activity		Sedentary lifestyles
	High dietary intake of NSP [a] (dietary fiber)		High intake of energy-dense micronutrient-poor foods
Probable	Home and school environments that support healthy food choices for children		Heavy marketing of energy-dense foods and fast-food outlets
	Breastfeeding		High intake of sugars – sweetened soft drinks and fruit juices
			Adverse socioeconomic conditions
Possible	Low glycemic index foods	Protein content of diet	Large portion sizes
			High proportion of food prepared outside the home (developed countries)
			"Rigid restraint/periodic disinhibition" eating patterns
Insufficient	Increasing eating frequency		Alcohol

This table shows the strength of evidence (i.e. insufficient, possible, probable, or convincing) on factors that might promote or protect against weight gain and obesity. The table is adapted from a World Health Organization (2003) publication in which these factors are considered in detail

[a]*NSP* nonstarch polysaccharides

a major contribution to an individual's susceptibility to the development of obesity, unless the "correct" environmental conditions exist, an individual's genetic predisposition for obesity may not be fully expressed. The increased prevalence of obesity in recent decades in genetically stable populations highlights the central role of recent important environmental trends in the development of the obesity epidemic. Table 207.2 summarizes the strength of the evidence for factors associated with promotion of, or protection against, the development of obesity in both adult and pediatric populations, as outlined in a World Health Organization report (World Health Organization 2003). The varied range of factors influencing both energy expenditure and intake emphasizes the obesogenic nature of the broader environment in westernized societies.

207.2.4 Overview of Management

Given the significance of child and adolescent obesity, in terms of both prevalence and complications, and the broader obesogenic environment in which individuals live, how can it be tackled? While primary prevention will be vital in curbing the epidemic, treatment of those children and adolescents who are currently obese is needed to improve both their immediate and long-term health outcomes. The broad principles of treatment should include the following elements (see Table 207.3):

- Assessment and treatment of any medical and psychosocial comorbidities
- Family involvement
- A developmentally appropriate approach (different approaches for adolescents and children)
- Long-term behavior change
- Long-term dietary change
- Increased physical activity
- Decreased sedentary behavior
- Consideration of the use of pharmacotherapy in adolescents

Table 207.3 Basic principles of management of obesity in childhood and adolescence

Assess and treat medical or psychosocial comorbidities

Family involvement

Developmentally appropriate approach

- *Preadolescent children: focus on parents*
- *Adolescents: consider separate sessions for the young person and parent(s)*

Long-term behavioral change

Long-term dietary change

- *Energy reduction*
- *Food choices that are lower in fat and have a lower glycemic index*
- *Reduction in high-sugar foods and drinks*
- *Water as the main beverage*
- *Avoidance of severe dietary restriction*
- *Appropriate portion sizes*
- *Modified eating patterns (regular meals, eat together as a family, avoid eating while watching the television)*

Increase in physical activity

- *Incidental activity*
- *Active transport options (e.g. walking, cycling, using public transport)*
- *Lifestyle activities*
- *Organized activities*
- *Improved access to recreation spaces and play equipment*

Decrease in sedentary behavior

- *Television, computer, play-station, and other small-screen recreation*
- *Alternatives to motorized transport*

Consideration of pharmacological therapy

- *Consider use of sibutramine or orlistat in moderately to severely obese adolescents, as an adjunct to lifestyle modification*
- *Metformin may be indicated in insulin-resistant adolescents*

This table lists the basic principles of management of obesity in childhood and adolescence. More details of long-term behavioral change are given in the rest of the chapter

The 2009 Cochrane Review on treatment of child and adolescent obesity included 64 randomized–controlled trials (RCTs) and provides some guidance as to the effectiveness of clinical interventions (Oude Luttikhuis et al. 2009). The review noted that there are limited quality data, making it difficult to recommend one treatment program over another. However, the review showed that combined behavioral lifestyle interventions, compared to standard care or self-help, can produce a significant and clinically meaningful reduction in overweight in children and adolescents in the short and long term. The review also highlighted that in obese adolescents consideration should be given to the use of either orlistat (a gastrointestinal lipase inhibitor) or sibutramine (a centrally acting appetite suppressant), as an adjunct to lifestyle interventions, although this approach needs to be carefully weighed up against the potential for adverse effects.

The rest of this chapter focuses on the evidence for, and practicalities of, behavioral change in the management of child and adolescent obesity.

207.3 Introduction to Behavioral Interventions

The behavioral research tradition has led to the widespread therapeutic use of behavioral modification techniques in a variety of settings, including education, parenting, and health. Behavioral therapies focus particularly on operant conditioning and the use of reinforcement to change the frequency of

Table 207.4 Matching behavioral techniques to behavioral antecedents and consequences

	Antecedents	Behavior	Consequences
Patient factors	Access to screens	Eating too much	Weight gain/loss
	Negative affect	Eating the wrong foods	Low self-esteem
	Parental feeding style	Too much screen time	Health problems
	Attitudes to food/activity	Low physical activity	Bullying
	Family/peer norms		Social isolation
	Sports facilities		
	Individual differences		
Behavioral techniques	Cognitive restructuring	Problem-solving	Behavioral contracting
	Preplanning	Self-monitoring	Reinforcement
	Goal setting	Parenting training	Shaping
	Stimulus control	Relapse prevention	
	Modeling		

This table lists patient factors, which may precede obesogenic behaviors (antecedents), examples of obesogenic behaviors, and their consequences. The table also describes behavioral techniques, which can be used to manage each of these areas

occurrence of a behavior. Operant conditioning relates to voluntary behavior, which is maintained by consequences. Behavioral therapies aim to change both the stimulus conditions and the consequences of behavior in a positive way. In obesity treatment, for example, this may mean reducing cues to eat (stimulus control), so that eating occurs less frequently and increasing positive reinforcement for exercise so that exercise behaviors happen more often. There is strong evidence that behavior modification, used correctly, is successful in changing the frequency of behavior in real-world settings.

Stemming from the behavioral tradition, cognitive–behavioral therapies incorporate the idea that thoughts and beliefs are also important drivers of behavior and that by introducing more helpful thinking patterns behavioral changes can be achieved more readily. The cognitive–behavioral therapies make three basic assumptions that – cognition affects behavior, cognition can be monitored and changed, and changes in cognition can lead to changes in behavior (Dobson and Dozois 2001). Cognitive–behavioral therapies combine behavioral and cognitive change techniques.

At its best, behavioral modification relies on a thorough behavioral assessment or functional analysis, which looks at the antecedents and consequences of behavior for each individual, with the aim of changing the behavioral contingencies driving the behavior. Similarly, cognitive–behavioral therapy is based on individualized case formulations, which link thoughts and beliefs to behavior and emotions. The match between the main behavioral change techniques and behavioral contingencies is provided in Table 207.4.

In obesity treatment, cognitive and behavior modification strategies are often manualized and taught to the parents of obese children, so that the parents may use them to help change their children's behavior and may also use them for themselves in a whole of family approach. Children, especially older children, are often taught the same strategies. The interventions discussed below can thus be targeted at children alone, at parents alone, at parents and children, or at the family as a whole. Behavioral and cognitive interventions are aimed at changing obesogenic behaviors and altering energy balance in a favorable direction. Without intervention, obesogenic behaviors and their associated weight gain track into adulthood, reinforcing the need for early intervention.

207.3.1 Overview of Behavioral Interventions in Obesity Treatment

The majority of RCTs in childhood and adolescent obesity treatment utilize predominantly behavioral modification techniques, with some trials including cognitive interventions or other approaches

such as parenting training. A review of the RCTs in the latest Cochrane Review (Oude Luttikhuis et al. 2009) shows that the most common techniques are self- or parental monitoring, stimulus control, goal setting or contracting, reinforcement, and contingency management. In particular, Epstein and colleagues have published a variety of studies on the treatment of pediatric obesity over the last 20 years, which have included many of these traditional behavioral modification techniques (e.g. Epstein et al. 1985, 2005). Other frequent techniques include modeling, preplanning, problem-solving, parenting training, and cognitive restructuring. Details of the various cognitive and behavioral treatment techniques are described in the next section.

Details of the exact components of treatment programs tend to be lacking in obesity treatment research; this may be partly due to the lack of a common language for behavioral change interventions, as suggested by Abraham and Michie (2008). It may also be due partly to the requirements of journals for brief articles (Baranowski et al. 2003). This has an impact on the ability of other researchers and practitioners to replicate the treatment programs. This is in contrast to the manualized approaches common in clinical psychology research, which allow for relatively precise replication in a clinical context. However, it is still possible to draw some broad conclusions about the interventions that should be considered in obesity treatment programs.

There is strong evidence that parental involvement in treatment of childhood obesity is important, and that behavioral change techniques need to be taught to parents so that they can change the home environment. For example, if parents change their own behavior so that there are few or no energy-dense foods at home, this is likely to have an impact on the child's weight as it reduces access to these foods. McLean et al. (2003), in a systematic review of 16 studies, found that targeting both children and parents for weight loss, training parents in behavior change, and teaching a greater number of behavior change techniques were all associated with greater weight loss.

207.4 Specific Behavioral Techniques in Obesity Treatment

207.4.1 Self-Monitoring

Self-monitoring is a core component of behavioral approaches, and is widely used in obesity treatment. Although many studies do not provide details of the self-monitoring requirements, those that do typically include recording food intake, physical activity and/or sedentary behavior, and weight (e.g. Epstein et al. 1995; Saelens et al. 2002; Johnston et al. 2008). Self-monitoring as a behavioral technique is often used in a more comprehensive form in other contexts, in which people record their behavior, along with its antecedents and consequences. It is assumed that this allows a greater awareness of both their behavior and how it is influenced by the environment, and therefore allows a greater capacity to change the behavior including changing the antecedents and consequences. It is often the first step in treatment. Some obesity researchers have described more comprehensive approaches to self-monitoring (e.g. Braet et al. 2004; Kalavainen et al. 2007) and a more comprehensive approach is suggested in many studies by the inclusion of stimulus control and contingency management techniques.

Self-monitoring has been associated with greater weight loss in both children and adolescents, including both low-income and minority groups with severe obesity. In addition, parental self-monitoring has been associated with greater self-monitoring among children and adolescents, as well as with greater weight loss (e.g. Kirschenbaum et al. 2005; Germann et al. 2006a). In the studies described above, self-monitoring involved parents and children writing down each day all food consumed (including calculating grams of fat and calories), the number of steps taken per day as

measured by a pedometer, and exercise done. It follows that helping clients to adhere to self-monitoring is a worthwhile component of behavioral interventions for obesity. Overall, the research suggests that a useful level of child and parental self-monitoring would include writing down daily food intake, physical activity and sedentary behavior. In addition, weight should be monitored at intervals (perhaps weekly). Ideally, writing down the triggers for eating or sedentary behavior, as well as their outcome would be useful – particularly where patients are having difficulty adhering to diet or activity recommendations.

207.4.2 Goal Setting, Behavioral Contracting, Reinforcement, and Contingency Management

Following on logically from self-monitoring, which identifies current behavior, are a number of techniques focused around changing current behaviors in the desired direction. Goal setting, behavioral contracting, reinforcement, and contingency management are related techniques, which are used in one form or another in most of obesity treatment studies (e.g. Epstein et al. 1995; Saelens et al. 2002; Johnston et al. 2008). Goal setting is the identification of desired behavior or outcomes and may refer to the setting of specific targets for weight loss, but may also refer to target behaviors such as food intake, active play, or limiting the time spent watching television. Reinforcement is the systematic use of rewards for desired behavior and goal achievement, while behavioral contracting specifies in advance the relationship between behavioral or outcome goals and rewards. Shaping uses reinforcement for gradual approximations to the goal behavior. This suggests that obesity treatment programs should specify behavioral and outcome goals, match suitable rewards for goal achievement, and specify these in a behavioral contract. Goals might include weight loss, dietary goals, decreased sedentary behavior (such as watching TV or using computer games), or time spent in active play. Depending on the age of the child, rewards could include praise, privileges, or nonfood treats such as outings or toys for active play. Younger children benefit from more frequent rewards, while older children may respond to longer term rewards.

207.4.3 Stimulus Control

Stimulus control in obesity treatment involves changing environmental factors, which trigger obesity-related behaviors. There has been considerable basic research on the environmental factors influencing food intake, such as variety, container size, and distraction (e.g. Kahn and Wansink 2004; Wansink and Cheney 2005; Remick et al. 2009). There has also been significant research on parental feeding styles and childhood obesity (e.g. Moens and Braet 2007; Rhee 2008). These studies provide a good starting point for stimulus control in obesity treatment. The aim of stimulus control is to decrease cues to eat unhealthy food by having it less accessible and decreasing reminders to eat, decreasing cues for sedentary behaviors such as watching television, and increasing cues for activity by making it part of the routine and increasing access to options for active play. Epstein et al. (1995) used strategies such as not keeping energy-dense foods at home, having exercise equipment such as bikes readily available, and turning the television to the wall. The nature of the cues for different behaviors may also vary between individuals, and between different families and homes. For example, if people regularly eat in front of the television, the television may itself become a cue (conditioned stimulus) for eating (Epstein et al. 1995). In this situation, decreasing access to the television may also help to decrease food intake. See Table 207.5 for an explanation of stimulus control.

Table 207.5 Key features of stimulus control

1. A stimulus is a cue or trigger for a particular behavior
2. By controlling the stimulus, it is possible to control the behavior
3. Stimulus control is a set of techniques for controlling stimulus conditions in an attempt to control specific behaviors
4. In obesity treatment, stimulus control techniques can be used by parents, and by children, to assist in managing obesogenic behaviors

This table explains the use of stimulus control in managing obesogenic behaviors

207.4.4 Preplanning and Problem-Solving

Preplanning and problem-solving are aimed at preventing future obesity-related behaviors and have been widely used in treatment studies (e.g. Epstein et al. 2000a). Preplanning is used to anticipate and prepare for high-risk situations for unhealthy behaviors such as parties or rainy weather. For example, if it is apparent that on holidays or outings family eating habits change to include more fried or energy-dense food, preplanning is aimed at identifying changes that could be made, such as preparing lunch at home or carrying a water bottle rather than buying soft drink. Problem-solving is aimed at solving identified problems to ensure a better result in the future and to help with maintenance of change; it can be used as part of preplanning.

207.4.5 Parenting Training

Parenting training has also been used in a number of studies, and is likely to be particularly suited to parents of younger children who have greater control over their child's behavior. Typically, parenting training covers a range of behavioral, and sometimes cognitive, modification techniques, which were traditionally used to address excessive disruptive behaviors in children. It also aims to increase positive, prosocial behaviors in both parents and children. Obesity-conducive behaviors in children (e.g. demanding large portions of unhealthy food) or resistance to healthy behaviors (e.g. refusing to go for a walk with a parent) can be conceptualized as disruptive behaviors; it therefore seems logical to include parenting training in childhood obesity treatment programs. Parenting training allows parents to be targeted as the primary means of behavior change in the child both through their own authority and by acting as role models (e.g. Golan et al. 1998, 2006). Ideally, parenting training equips parents to set limits on unhealthy behavior, while maintaining a high level of support and encouragement for their child. Another important area in which parents can influence their children is through their own behavior. This is known as modeling, and requires the parents to "do what they say," by maintaining their own healthy habits (e.g. Epstein et al. 1985).

207.4.6 Cognitive Restructuring

Cognitive restructuring has been used in number of studies to address unhelpful beliefs, which may prevent behavior change or help to maintain unhealthy habits (e.g. Duffy and Spence 1993). Generally, cognitive restructuring could be used to change the antecedents of behavior, but may also be used to change the consequences of behavior by influencing how people respond to success or

failure in behavioral or outcome change. Ideally, this would be preceded by a cognitive–behavioral assessment and self-monitoring to identify the unhelpful beliefs or thoughts, which influence the likelihood of obesity-related behavior. Parental beliefs such as "he deserves a treat" and "it's not fair I have to make my child do this" can be particularly powerful barriers to behavior change, and ultimately weight loss.

207.4.7 Relapse Prevention

Relapse prevention is the structured preparation for maintenance of behavior change, and has been used in some obesity treatment studies (e.g. Kalavainen 2007). Relapse prevention usually involves identification of the warning signs for slipping back into old behaviors, strategies for addressing this if it occurs, a description of what behaviors need to be maintained, and strategies for maintaining new habits. For example, a warning sign might be failing to be active for several days in a row, or an increase in snacking. The relapse prevention plan would then identify what to do to return to activity or decrease snacking. Relapse prevention plans may include any of the techniques already discussed. For example, ongoing self-monitoring may be part of the plan.

207.5 Review of the Evidence Base for Behavioral Techniques in Obesity Treatment

The literature shows that, when used in combination, behavioral modification techniques are successful in changing obesogenic behaviors and aiding weight loss (Oude Luttikhuis et al. 2009). However, we do not know precisely which techniques should be used, when in treatment they should be introduced, and which aspects of behavior change (e.g. diet, activity, sedentary behavior, parenting) are best suited to which techniques. Nor do we know which individuals and families would respond best to different approaches.

207.5.1 Psychological Models of Obesity

The development of validated psychological models of obesity and weight gain, which integrate eating behaviors, sedentary behaviors, and physical activity, would aid progress in the field by helping clinicians to make better treatment decisions. While a number of health behavior change models exist, and have been applied in obesity research, much more remains to be done to understand the moderating and mediating variables which may contribute to behavior change, and thus intervention outcome (Baranowski et al. 2003).

Some of the models that have received attention include Behavioral Learning Theory, Social Cognitive Theory, the Health Belief Model, the Theory of Reasoned Action or Theory of Planned Behavior, the Transtheoretical Model, and ecological models (Baranowski et al. 2003). Behavioral economics is a recent approach that has been used in obesity treatment (e.g. Epstein et al. 2005). However, much of the available research using these models focuses on one behavior (e.g. decreasing sedentary behavior) at a time, and does not integrate environmental and biological factors, which

may also influence behavior change (Baranowski et al. 2003). The role of emotions in obesity have also been somewhat overlooked (Baranowski et al. 2003), although recently the links between negative emotional states and binge eating are starting to receive some attention (e.g. Stice 2002), as are the links with bullying (e.g. Suisman et al. 2008).

207.5.2 Treatment Planning

Much of the research base consists of multicomponent treatment programs, and consequently it is difficult to know which parts of the intervention are the active ingredients (Braet et al. 2004). Some studies published by Epstein and colleagues investigate one additional component at a time, but these are additions to an existing multicomponent treatment program (e.g. Epstein et al. 2000a, b). For example, Epstein et al. (2000b) investigated whether it was better to target a decrease in sedentary behaviors or an increase in active behaviors at two levels of intensity of intervention (low and high). They found similar results for both levels of intensity and for either target behavior – all four conditions were effective in reducing overweight as can be seen in Fig. 207.1.

Fig. 207.1 Change in percent overweight from baseline for obese children receiving low or high exercise or sedentary behavior interventions. Results from a study performed by Epstein et al. (2000b) in 8–12-year-old children who, at baseline, were 20–100% overweight. All participants received a 6-month program (20 sessions; involving both child and parent) and were randomized to one of four experimental groups: (**a**) high sedentary (20 h/week decrease in targeted sedentary behavior; n = 22 at baseline); (**b**) low sedentary (10 h/week decrease in targeted sedentary behavior; n = 23); (**c**) high exercise (32.2 km [20 miles]/week increase in physical activity; n = 23); or (**d**) low exercise (16.1 km [10 miles]/week increase in physical activity; n = 22). Change in percent overweight from baseline is shown for experimental group at 6 (end of program), 12, and 24 months. Changes from baseline were significant at 6, 12, and 24 months (*P* < 0.001) (Reprinted from Epstein et al. 2000b, with permission. Copyright © (2000) American Medical Association. All rights reserved)

As mentioned earlier, there are also a variety of behavioral approaches to obesity treatment, and many aspects of treatment planning remain unclear, including methods, timing, intensity, and tailoring (Lobstein et al. 2004). Finally, despite the dominance of cognitive–behavioral therapy in mental health, the majority of the RCTs in the Cochrane Review (Oude Luttikhuis et al. 2009) utilize predominantly behavioral approaches, with cognitive techniques being used less often. Well-designed studies comparing behavioral to cognitive–behavioral therapy approaches may shed some light on the best approach.

The studies included in the Cochrane Review (Oude Luttikhuis et al. 2009) are focused on the active phase of treatment, rather than prevention or maintenance of weight loss. Just as we need to know how to apply behavioral interventions in treatment, we also need to know how to apply them in prevention and maintenance. It is important to draw a distinction between those factors which cause a problem (addressed by prevention programs), those that maintain a problem and/or predict treatment outcome (addressed by treatment programs), and those factors which predict maintenance of treatment outcomes (addressed by relapse prevention). For example, conscientiousness as a personality trait might improve treatment outcome by enhancing adherence to treatment but be unrelated to the causes of obesity, or negative emotional states might maintain obesity by triggering binge eating but not be a causal factor. Similarly, self-monitoring might assist in the treatment phase but not in prevention, or problem-solving might assist in the maintenance phase but not in the treatment phase. Given the difficulty of maintaining weight loss over time, an understanding of both the predictors of weight loss and the predictors of weight maintenance is critical to obesity treatment. While current programs are focused on weight loss and measure maintenance over time, it may be that different skills or strategies are required for the maintenance stage. In addition, prevention programs may need to target different variables to treatment programs.

207.5.3 Individual Differences in Treatment Response

It is the nature of clinical trials that there are exclusion criteria for participation, as this allows a purer test of treatment effects. Because of this, real-world implementation of programs used in clinical trials may not always obtain equivalent outcomes. An understanding of the effect of individual differences in family situation, culture, personality, or other circumstances such as physical or developmental problems is needed in order to adequately tailor interventions to different groups. The interaction between child and parent factors may also be important; for example, difficult child temperament and a parenting style low in behavioral control was found to be more common in obese children and adolescents compared to an equivalent nonobese sample (Zeller et al. 2008). In addition, the complications of obesity may in and of themselves affect treatment success. For example, social exclusion impairs self-regulatory capacity and the ability to resist eating unhealthy snack foods (e.g. Baumeister et al. 2005), and this may also apply to the effects of weight-related bullying in overweight children or adolescents. That is, an understanding of the effects of individual differences or circumstances on the effectiveness of treatment would aid clinicians in making the best choice of treatment options for their particular client group or for an individual child or family.

Thus, while we know that behavioral interventions are a vital contributor to treatment outcome in obesity, there is still a lot to be learnt. Theoretical developments such as models of obesity-related behavior in childhood are required, as is research on individual differences in treatment response, and basic research on the drivers of obesity-related behaviors. Finally, the development of a common

language and manualized approaches, which can be replicated in clinical settings would provide a worthwhile advance in obesity treatment.

207.6 The Challenges of Delivering Behavioral Therapy in Clinical Practice

As discussed previously, published research on obesity treatment, including the studies included in the Cochrane review, may not be representative of usual clinical practice due to the use of stringent exclusion criteria (Oude Luttikhuis et al. 2009). For example, typical exclusion criteria include psychiatric conditions in parent or child, learning disabilities, and extreme obesity. The cases seen in clinical practice may therefore be far more complex than the typical families seen in clinical trials and require a different approach. In the Weight Management Service at The Children's Hospital at Westmead in Sydney, it is common to see families with multiple psychosocial problems including mental disorders, learning disabilities, chronic illness or disability, poverty, and domestic violence. These families have multiple barriers to behavioral change and often have difficulty adhering to treatment recommendations or carrying out behavioral tasks such as self-monitoring, do not attend treatment reliably, or drop out early. This phenomenon is also common in the research literature, with reported rates of attrition in the Cochrane Review as high as 42% (Oude Luttikhuis et al. 2009).

Attrition appears to be an important factor affecting treatment outcome, with children who attend treatment reliably much more likely to achieve weight loss (e.g. Reinehr et al. 2009; Germann et al. 2006b). This may be due to a number of factors, including the increased treatment intensity which comes with regular attendance. For example, for parents to effectively use behavioral change techniques with their children, they need to attend treatment sessions in order to learn the techniques in the first place. A range of factors may be important in attrition. These fall into two broad categories – patient factors and treatment service factors. Potential patient factors include psychosocial barriers, a lack of effective parenting skills, problems with motivation, parental perceptions of their child's health, the child not wanting to attend, or barriers to adherence to treatment (e.g. Reinehr et al. 2009; Cote et al. 2004). Potential treatment service factors include the time commitment required to attend treatment, insufficient follow-up, perceived quality of care, insufficient tailoring, a lack of attention to child engagement in treatment, and less than optimal therapeutic relationships (e.g. Cote et al. 2004).

Research on the success of psychological therapies in general demonstrates that a range of factors contribute to treatment outcome (e.g. Asay and Lambert 1999). These include client factors (e.g. demographic factors, personality, and individual differences such as hope), therapist factors (e.g. skills or empathy), relationship factors (specifically, an effective working relationship between the health professional and their patient), and technique factors (i.e. the specific therapeutic approach used). The research described above suggests that this framework may also be applicable to obesity treatment programs, and may provide a framework for understanding problems with attrition or adherence to treatment.

In summary, in order for children to benefit from an obesity treatment program they and their parents need to attend reliably, complete the program of treatment, adhere to treatment recommendations, and change their behavior. Parental behavior change is likely to be particularly challenging and yet is central to treatment success. Adherence to the treatment program is likely to be especially challenging for families with multiple psychosocial barriers. Possible approaches include designing the service to cope with these barriers by the inclusion of specialist staff, excluding these types of

families from the treatment program until problems are resolved, or building comprehensive links with other types of social services to meet the needs of these families.

207.6.1 Other Challenges in Treating Child and Adolescent Obesity

The above overview of behavioral management of pediatric obesity provides an evidence base for a range of therapists as they seek to treat children and adolescents affected by obesity. However, there are several challenges in translating such evidence into everyday clinical practice. Following are some considerations.

207.6.2 Gaps in the Current Evidence Base

The 2009 Cochrane Review on treating child and adolescent obesity (Oude Luttikhuis et al. 2009) has highlighted a number of gaps in the research evidence, as summarized below:

- What interventions work best for:

  ○ Different levels of obesity severity, ages, and developmental stages?
  ○ Long-term maintenance of healthy weight following initial treatment of obesity?
  ○ Specific ethnicities, religious groups, or culturally diverse populations?

- What family characteristics promote weight outcome success?
- What is the role of self-esteem and the family's capacity to change behavior in effective treatment?
- What are the most cost- and resource-effective methods of treating pediatric obesity in different health-care settings?
- What is the role of bariatric surgery in the treatment of severely obese adolescents?
- What are the potential harms as well as benefits of different interventions?

207.6.3 Patients with Psychosocial Comorbidities, and Few Experienced Staff

Most of the studies looking at strategies for behavioral management of obesity in children and adolescents have typically been performed in white, middle-class, intact families where the degree of motivation for change is relatively high and where there are few, or no, associated psychosocial comorbidities (Oude Luttikhuis et al. 2009). But the reality of pediatric obesity, in western societies at least, is that it is more common in families from lower socioeconomic groups, with single parents and often a range of associated psychological or social problems (Lobstein et al. 2004). Likewise, many of the obesity behavioral management studies to date have taken place in tertiary-level units with highly skilled staff (Oude Luttikhuis et al. 2009). However, usual weight management services in many countries have a smaller complement of experienced staff and there may be little, or no, clinical psychologist input into the treating team. Thus, the current evidence base of behavioral management of obesity will need to be adapted to use with such clinical situations (see Table 207.6 for some suggestions). How do you provide services when patients have a range of psychiatric or social problems, and where the therapists are unlikely to include a social worker or clinical psychologist?

Table 207.6 Potential barriers to behavioral change in families attending obesity treatment programs

Barrier	Effect	Potential intervention strategy
Family in crisis (e.g. domestic violence)	At risk, and unable to focus on weight management	Crisis intervention
		Case management until the situation has stabilized
		Involvement of additional support services such as child protection
Poverty	Access to healthy food	Focus on low-cost food alternatives
	Access to activities and recreation space	Provision of low-cost physical activity alternatives
Culturally and linguistically diverse clients	Service may not be provided in their first language	Use of interpreters
	Cultural practices may not fit with standard advice on diet and activity	Culturally sensitive weight management advice
Learning disabilities or developmental disorders	Ability to benefit from education about diet and activity	Greater family involvement
		Intensive practical intervention
		Involvement of specialist support services
Mental disorders	Unable to attend treatment or focus on weight management	Involvement of mental health treatment and support services
	Poor motivation	Case management until the situation has stabilized
	At risk	
Physical health problems	May not be able to participate in physical activity due to functional limitations	Provide alternative options

This table lists the barriers to obesity treatment, their effect on treatment response, and some options for intervention

There is an urgent need for obesity management studies performed in such everyday, "real-life" clinical situations.

207.6.4 Providing a Weight Management Service in a Resource-Poor Environment

Despite the high prevalence of pediatric obesity, in many regions and countries there are relatively few resources to provide effective treatment of those who are affected by the problem. Thus, therapists may find themselves practicing in environments where they are relatively unsupported. Following are some practical suggestions for providing services in such a situation:

- Wherever possible, establish links with other weight management health professionals, for professional support, continuing education, and shared care.
- Consider shared care arrangements. For example, can the patient be comanaged by a family doctor, dietitian, and/or clinical psychologist?
- Explore the use of more time-efficient strategies such as group programs and at least some use of email and phone contacts with patients.
- Where possible, consider educating referring health professionals in some basic obesity management principles, so that they are better able to manage patients independently of more specialized intervention.
- Provide guidelines on the assessment and treatment of patients which can be used by a range of health professionals.

- Set realistic goals for treatment, rather than expecting to obtain the results found in well-funded research settings.
- Focus on sound implementation of core behavioral modification techniques. For example, introduce self-monitoring and practice it with the patient in session, check for understanding of why monitoring is important, and follow-up to ensure monitoring is being done.

207.6.5 Considerations in Establishing and Running a Pediatric Weight Management Service

Despite the increasing public recognition of the problem of obesity in many countries, the planning for effective treatment services, especially for children, has lagged behind. Following are some reflections on the elements found useful in establishing and running a pediatric weight management service.

207.6.5.1 Staffing

Effective staffing of a pediatric weight management service, whether a large multidisciplinary service, or a smaller one with fewer therapists, is vital. Because obesity management involves work that crosses traditional discipline boundaries, staff members should be flexible and willing to move outside usual professional "silos" of knowledge. They should have good teamwork skills, cultural competence, and a respectful attitude toward obese people. The latter is very important, as there are many examples of health professionals, including those working in obesity management, having negative and stigmatizing attitudes toward obesity and obese people (e.g. Schwartz et al. 2003). Importantly, staff should be child and youth friendly, and readily able to work with families.

In most cases, a multidisciplinary clinical team is required. Ideally, a larger service should include a senior nurse (often the "conductor of the orchestra"), and a pediatrician or adolescent physician, dietitian, clinical psychologist, social worker, and exercise professional. In practice, many services do not have the full complement of health professionals. In this case, we would recommend that professionals treating children or young people with obesity should liaise, as needed, with other health professionals who can provide complementary skills.

207.6.5.2 Physical Facilities

The clinic facility should be readily accessible by, and comfortable for, big people who may have problems with mobility. There should be access to the disabled and wide corridors and doorways, with chairs that are sturdy and can seat large people. Weight scales should allow sensitive measurement of very large people (e.g. 250+ kg) and, in the case of medical or nursing assessment, there should be large blood pressure cuffs. Mirrors should be minimized.

A range of strategies may help to destigmatize the experience of attending a weight management clinic for individual children and their families. For example, consider the name of the clinic – "Weight Management Clinic" may be less confronting than, say, "Obesity Clinic". Front desk staff should also be trained to make patients feel relaxed and at ease. An additional strategy in our clinical service is the use of a highly interactive video game (e.g. Eye-Toy™; Sony Computer Entertainment Inc.),

which is set up in part of the waiting room and which encourages high levels of safe physical activity within the confines of a clinic. Children can take turns to play games, or can play together.

207.6.5.3 Database and Service Audit

The weight management service should be supported by a database that can also allow audit and research studies to be undertaken. Measurements of height and weight should be entered onto an electronic database, and body mass index (BMI) calculated and plotted on an electronic BMI for age chart.

207.6.5.4 Health Professional Training

Ongoing health professional training of many levels of staff is required, from undergraduate level through to continuing postgraduate professional education, and for many types of clinician. Because obesity management is a relatively new discipline, there may not be appropriate continuing professional education services available, even in large tertiary-level institutions. Staff should therefore be encouraged to seek such training out, or to develop their own training opportunities, perhaps in liaison with their clinical service, the broader hospital or their professional body, as appropriate.

207.6.5.5 Liaison with Other Clinical Services

Coordination with clinical services that manage obesity-associated medical comorbidities is vital, and may include Psychiatry, Adolescent Medicine, Sleep Unit, Hepatology, Endocrinology, Dermatology, General Medicine, Gynecology, and Orthopedics. Shared protocols for assessment and management may need to be developed and key staff in the other services may require additional training regarding obesity. Families and young people with severe obesity may also have significant family dysfunction, psychiatric comorbidities, and/or parenting concerns; hence, the importance of effective links with Psychiatry, Social Work, and even Child Protection Services, and the need for obesity clinical staff to have a good understanding of the psychosocial aspects of pediatric medicine.

207.7 Applications to Other Areas of Health and Medicine

Obesity is associated with a range of other pediatric health issues, which may be the primary reason for presentation to health practitioners. These include complications of obesity, such as type 2 diabetes, obstructive sleep apnea, or fatty liver disease, as well as conditions or therapies for which obesity may be a complication, such as congenital neuromuscular disease or long-term steroid therapy. In most of these cases, clinicians should recognize that effective management of obesity is likely to be required. Importantly, patients or their families may not always recognize the need for weight management intervention, and hence clinicians should approach this issue in a sensitive manner. At the same time, ignoring "the elephant in the room" of obesity, may be potentially detrimental to the health of the child or adolescent. While treatment advice may need to be modified if, for example, patients have limitations to movement (e.g. spina bifida) or severe dietary restrictions

(e.g. significant food allergies), the broad principles of therapy, as outlined above, can be applied to all patients and their families.

Summary Points

1. Child and adolescent obesity is prevalent in many countries, and may be associated with a range of medical and psychosocial complications. Early intervention is critical as childhood obesity tracks into adulthood.
2. Effective management of pediatric obesity involves family involvement, a developmentally appropriate approach, long-term behavior change, long-term dietary change, increased physical activity, decreased sedentary behavior, and consideration of use of pharmacotherapy in adolescents.
3. Evidence suggests that behavioral modification techniques should be used in pediatric obesity treatment. Training in these techniques is recommended for all health professionals involved in obesity treatment, with the involvement of specialist staff wherever possible.
4. The most commonly used behavioral strategies in pediatric obesity trials include self- or parental monitoring, stimulus control, goal setting or contracting, reinforcement, contingency management, modeling, preplanning, problem-solving, parenting training, and cognitive restructuring. These strategies are aimed at changing obesogenic behaviors and altering energy balance.
5. In usual clinical practice, challenges may include appropriate management of families with multiple psychosocial barriers, and providing behavioral management where there is limited availability of a clinical psychologist.
6. A multidisciplinary weight management service should provide a welcoming and destigmatizing environment, easy physical access for large people, and staff with good teamwork skills and a respectful attitude toward obese people.

Key Terms in the Behavioral Treatment of Obesity

Behavioral contracting: Explicitly links goals to reinforcement in an agreement. That is, desired behaviors are specified in detail along with their specific reward. For example, a child may be allowed 15 min playing a computer game as a reward for an hour of active play.

Cognitive restructuring: Is a technique used in cognitive–behavioral therapies and refers to identifying and challenging unhelpful thoughts and generating more helpful alternatives. For example, a belief that emotional distress is best relieved by eating chocolate or another comfort food might be modified by an alternative belief that talking to a friend may be more helpful.

Goal setting: Involves setting clear behavioral targets. For example, a goal may be to eat a specified number of servings of vegetables per day, or to be active for a certain period each day.

Modeling: Is an approach stemming from social learning theory in which clinicians or parents demonstrate the types of behaviors that are required. An example would be parents changing their own eating or activity habits in the desired direction for the child.

Parenting training: Involves teaching parents skills in behavior management. In obesity research, this often refers to limit setting, with the aim of decreasing obesity-related behaviors. For example, by teaching a parent how to cope with a child who is constantly asking for food.

Preplanning: Is advance preparation for handling challenging situations such as parties or outings in order to assist compliance to diet and activity goals. For example, developing a strategy to decrease food intake at a buffet by using a smaller plate.

Problem-solving: Generally refers to a structured process involving several steps – identifying the problem, generating options, evaluating the options, choosing an option, planning, implementation, and monitoring. For example, problem-solving could be used to determine the best option for increasing incidental activity.

Randomized–controlled trial: An experimental design comparing at least one treatment group with a control group, and where participants are randomly assigned to group.

Reinforcement: In obesity treatment, this usually refers to positive reinforcement, which is providing praise, rewards, or attention for desired behaviors in order to increase their frequency. Reinforcement is about the consequences of behavior. For example, parent's praising their child for being physically active or eating their vegetables. It is related to goal setting and behavioral contracting.

Relapse prevention: Is a process of identifying the early warning signs for the re-emergence of problematic behaviors, and developing a plan and coping responses to deal with the signs of relapse.

Self-monitoring: Involves patients (or their parents) observing and recording their behavior and how it relates to their environment in a diary or other record. Ideally, the record should include the behavior as well as its antecedents and consequences. For example, noting that more snacking occurs in front of the television.

Shaping: Is the process of reinforcing gradual changes to behavior on the way to a goal. For example, praising a child for turning off the TV after a shorter viewing period than usual.

Stimulus control: Changing the environment to reduce cues for undesirable behavior, and increase cues for desired behaviors. That is, changing the antecedents of behaviors. For example, decreasing television time reduces exposure to ads for food and may decrease cues to snack.

Chapter 208
The Potential of Internet-Based Programs for Eating Disorder Prevention in Students

Katajun Lindenberg, Markus Moessner, and Stephanie Bauer

Abbreviations

AN	Anorexia nervosa
AN_{TSI}	Anorexia nervosa total severity index (SEED)
BMI	Body mass index
BN	Bulimia nervosa
BN_{TSI}	Bulimia nervosa total severity index (SEED)
ED	Eating disorders
EDNOS	Eating disorders not otherwise specified
ICT	Information and communication technology
SEED	Short Evaluation of Eating Disorders (Bauer et al. 2005)
WCS	Weight Concern Scale (Killen et al. 1994)

208.1 Introduction

College is a time of numerous changes, including moving away from home and fending for oneself. Entering university is often combined with elevated stress levels and high pressure, due to increased responsibility and lifestyle rearrangements. Not surprisingly, the transition from high-school to college is known to be a vulnerable phase to develop mental disorders (Dyson and Renk 2006). Besides anxiety and depression, disturbed eating behavior is observed frequently in college students, especially in females (Delinsky and Wilson 2008).

Unaccustomed freedom in college life can lead to changes in eating patterns formerly set by family routine (Hesse-Biber and Marino 1996). Easy access to high-calorie cafeteria food, limited kitchen facilities, and small budgets for meals contribute to unhealthy college eating habits. A phenomenon called "freshman fifteen" (Holm-Denoma et al. 2008) is used to describe the average weight gain of 15 lbs by students in their first year of college. This may be caused by increased alcohol intake, consumption of fast food, lack of sleep and regular exercises, and late night meals (Delinsky and Wilson 2008).

The peak onset of eating disorders (ED) has been found to correlate with the time when adolescents leave home and start college (Striegel-Moore et al. 2003). Although full ED syndromes like anorexia

K. Lindenberg (✉)
Center for Psychotherapy Research, University Hospital Heidelberg, Bergheimer Straße 54,

e-mail: katajun.lindenberg@med.uni-heidelberg.de; lindenberg@psyres.de

nervosa (AN) and bulimia nervosa (BN) are quite rare and affect only two to four per cent of the population (Striegel-Moore et al. 2003; Hoek 2006), subthreshold ED are more prevalent and represent similar levels of functional impairment to full ED (Stice et al. 2009). In a representative study of more than 4000 college-age students, nearly half of the students (46%) reported that they were trying to lose weight (Lowry et al. 2000).

Disturbed eating can be caused by stress, negative events or adverse moods. As an example, binge eating has been found to be associated with negative affect. Furthermore, increased levels of stress and coping with pressure might also result in weight loss, when students try to maintain control over eating and skip meals (Fairburn et al. 2008). To avoid weight gain, a substantial proportion of female adolescents apply unhealthy weight regulation methods like excessive exercise, abuse of laxatives, diet pills, self-induced vomiting, or fasting (Grilo 2006).

It is estimated that almost half of the female college students display disturbed eating behaviors or try to lose weight. Hence, we consider ED prevention to be particularly indicated in this age cohort.

208.2 Eating Disorder Prevention Programs

Programs for prevention of ED have existed since the late 1980s (Fingeret et al. 2006), targeting mainly high-school and college-age students. Because some risk factors for ED are considered potentially modifiable (Stice 2002), most ED prevention concepts focus on reducing these factors (e.g., improving body image and promoting a healthy, well-balanced diet, and nutrition).

Results from a meta-analysis by Stice and Shaw (2004) showed that selective (in contrast to universal) programs, which were offered solely to high-risk individuals older than 15 years of age, were more effective than programs provided to unselected samples. It is assumed that high-risk individuals might be more motivated to engage actively in the prevention program because they experience higher distress. Interactive programs in contrast to didactic program formats were found to produce stronger effects. Further, programs containing several follow-up sessions resulted in higher intervention effects compared to brief, single-session programs.

Social psychology experiments show that inducing individuals to act in a manner that is contrary to their attitude (cognitive dissonance) reliably produces attitudinal change (Festinger 1957). Stice et al. (2008) used this principle of dissonance induction to reduce thin-ideal internalization as part of an ED prevention program for high-risk high-school and college students. The program was found to reduce risk for future threshold and subthreshold ED onset by 60% over a 3-year follow-up relative to assessment-only controls (Stice et al. 2008).

Over the past years, internet-based programs have shown promise in improving ED prevention approaches. For example, the program "Student Bodies" contains a cognitive–behavioral intervention in combination with moderated forum boards for college-age students. "Student Bodies" was found to reduce body image concerns at 12-months follow-up, and to reduce ED incidence in a subgroup of students with elevated body mass index (BMI) and compensatory behaviors (Taylor et al. 2006).

208.3 Challenges in ED Prevention

ED prevention is challenged in many ways. The main challenges are listed in the following section.

208.3.1 Target Group

Full-syndrome ED are rare in the general population, which underlines the need to develop prevention programs for specific target populations, in which the risk is elevated. However, targeting the right population is a complex issue, because empirical evidence on whether and when high-risk individuals develop ED is scarce.

Over the past decades, thinness has increasingly become a standard of female beauty. Many women and girls strive for the thin ideal advertised in the media, and dieting has become a part of their lifestyle. ED risk factor literature identifies dieting and restricting food as risk factors for developing an ED (Jacobi et al. 2004). The majority of dieters, however, do not develop full-syndrome ED. As mentioned above, the prevalence of ED is low, although almost half of all college-age students report trying to lose weight. Dieting can take many forms, from starvation to moderate calorie restriction to a preoccupation with the distinction of good and bad foods (French and Jeffery 1994). The discrepancy between an oversupply of food and the strive for thinness is ubiquitous in western societies, and maintaining a well-balanced diet can be helpful to avoid weight gain and prevent obesity. Many individuals are not aware of their disturbed behavior or deny having eating problems. However, the transition from healthy to at-risk dieting is smooth and difficult to identify.

Moreover, college-age students are a challenging target group. Compared to school-based programs, where the intervention can be integrated as part of the curriculum, it is difficult to motivate students in college to participate in a prevention program. College life is exciting and many students may not pay a lot of attention to mental and physical health or underestimate the consequences of their unhealthy lifestyle. Consequently, they do not necessarily feel the urge to engage in an ED prevention program.

208.3.2 Psychological Barriers to Seek Help

Seeking help is a big effort for many individuals suffering from ED. Only about half of all individuals affected by AN and BN take up ED treatment (Cachelin et al. 2006; Waller et al. 2009). Success rates for treatment of chronically ill cases are poor, whereas early intervention was found to be predictive for treatment success (Reas et al. 2000). Several reasons keep individuals from asking for help. Many report feelings of shame and fear of stigma or do not consider their level of impairment as being a serious psychological problem. Furthermore, individuals with ED symptoms often report that fear of disclosure from others kept them from undergoing treatment (Cachelin et al. 2006). Many individuals are unfamiliar with mental health services and consider seeing a therapist as a sign of weakness (Meyer 2001).

208.3.3 Timing of Prevention Efforts

The process of falling ill is relatively unknown. People develop ED symptoms at different points in their life. Because prevention comes too late for individuals who already show manifest ED symptoms, some authors argue that prevention should be offered as early as possible (e.g., Celio et al. 2000). However, it is questionable whether prevention programs targeting young age groups can ultimately lead to sustainable effects on preventing ED onset many years later. Thus, the challenge is to find the optimal timing for prevention and a time and cost efficient way to guarantee sustainability of the preventive effects.

Table 208.1 Key features of individualized prevention

1. Prevention in large, heterogeneous populations, in which different individuals might need different intensity of support, requires a specific strategy to balance benefits and burdens of the prevention effort.
2. Stepped care interventions contain modules of varying intensity. The main idea of stepped care is to try the lowest intensity first and to provide more intense (and more costly) interventions only to those individuals, who need more support.
3. Information and communication technologies enable time and cost efficient matching of intervention intensity to personal needs. Online screening procedures can assess risk categories and recommend the most appropriate level of support. Low-intensity modules can be administered completely automated. Administration of participants and longitudinal monitoring, that allows timely reactions to dysfunctional changes and referral to more intensive modules, become more feasible with technology-enhanced programs.

This table summarizes the key features of individualized prevention and highlights the potential of technology-enhanced programs to tailor interventions to individual needs

208.3.4 Overcoming the Challenges: Individualization of Support

Universal prevention programs targeting unselected samples do not appear appropriate for a rare disease, because only very few individuals are expected to fall ill. Therefore, targeted prevention seems more promising, although it is a challenge to identify the high-risk population. It is crucial to address these individuals in a low-intensive, anonymous way, to overcome psychological barriers to help-seeking. Symptom courses of high-risk individuals can then be observed over time in order to intervene promptly, when disturbed eating behavior shifts to ED pathology.

To address different needs of individuals at different times, innovative approaches suggest to individualize prevention programs and to offer modules of varying intensity (Bauer et al. 2009). Each participant can use the type and amount of support that he or she needs by matching support intensity to the individual level of impairment. Following the idea of stepped care, low-intense modules should be offered first, while more intensive (and more costly) modules should be reserved for those individuals only who need more support. The key features of individualized prevention are summarized in Table 208.1.

208.4 The Internet as an Opportunity for Health-Care Delivery

The technological developments in recent years offer many opportunities to improve health care. They enable the implementation of such above mentioned, individualized, stepped care interventions and have advantages for both providers and users.

208.4.1 Provider Perspective

Information and communication technologies (ICT) enable providers to offer online support and to tailor interventions to individual needs. The scope and geographical coverage of the internet allows large populations to be addressed at relatively low effort. In addition, computer-based data collection makes assessment of health-related parameters more time and cost efficient than traditional paper–pencil questionnaires. In particular, the administration of participants and longitudinal assessments (monitoring) becomes more feasible with technology-enhanced programs. The continuous monitoring of symptoms at short intervals (e.g., weekly) allows prompt reactions to dysfunctional changes and, if necessary, individualized adaptation of the intervention.

208.4.2   User Perspective

The number of users looking for help in the internet is increasing. Easy access and anonymity may play an important role. Interventions of low intensity offer the possibility to get information and exchange experience with other users or counselors in an anonymous way, e.g., via forums or chat rooms. Anonymity makes asking for help easier, particularly when feelings of shame and fear of stigma play a role. Affected individuals can get support from peers who find themselves in comparable situations ("peer support"), or from professional counselors. Low-intense and anonymous offers can bridge the gap between health care and everyday life and encourage users to seek professional treatment. In addition, internet offers can be accessed independently from time and place, which facilitates access to health care particularly in rural areas (Bauer and Kordy 2008).

In the area of prevention, broadly disseminated, easy access interventions are of special importance. One example will be introduced in the following.

208.5   Es[s]prit: An Internet-Based Program for ED

The internet-based program Es[s]prit was developed for the prevention and early intervention of ED in college-age students (Bauer et al. 2009). The program integrates different areas of mental health care from prevention up to early detection, early intervention, and regular face-to-face counseling and treatment, by offering different modules of varying intensity.

The main idea is to individually tailor the support, so that each Es[s]prit user can get the support that he or she needs. In contrast to standardized programs, Es[s]prit is flexible in terms of duration of the intervention and amount of support, i.e., it is up to the participants which modules they want to use to which extent and for how long.

The conceptualization of prevention in several stepped modules (stepped care) allows to adjust prevention intensity to individual needs. Low-intensive modules are mainly automated, so that large populations can be addressed at relatively low effort. The higher the module intensity, the more support costs are required. However, the proportion of the population, which might need this intensive way of support, is relatively small.

The development of symptoms during participation in Es[s]prit is expected to be highly heterogeneous. For some individuals, anonymous, low-intensity counseling, supportive monitoring, peer support, and psychoeducation may be sufficient to reduce symptoms. However, others may develop severe ED symptoms over time. These individuals can be identified by an automated alarm system and referred to the consultation chat (see below), where the anonymous contact can be used to motivate users to seek more intensive treatment, i.e., inpatient or outpatient treatment.

The most important tool enabling the individualization is ICT. All Es[s]prit components are internet-based and mainly automated. The symptom monitoring and feedback system, which also identifies deteriorations and indicates referral to more intensive modules, is organized by the data management system Web-Akquasi (Percevic et al. 2006).

208.5.1   Es[s]prit Modules

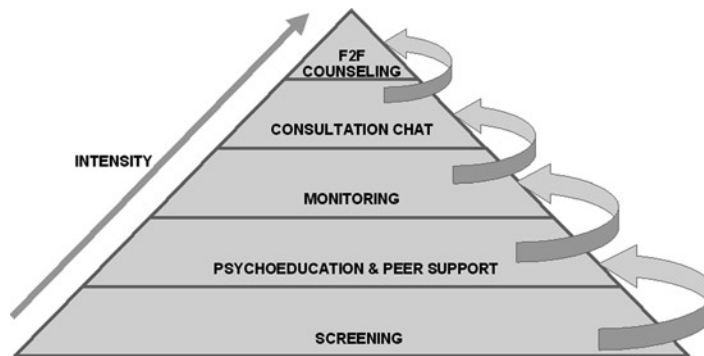
Es[s]prit contains five modules that are explained in the following section, ordered by increasing intensity (see also Fig. 208.1).


Fig. 208.1 Individually tailored stepped care: Five modules of increasing intensity for individualized prevention and early intervention of ED. This figure shows the five Es[s]prit modules in increasing intensity from bottom to top. According to the idea of stepped care, modules of lower intensity (screening, psychoeducation and peer support, supportive monitoring and feedback module) are completely automated. Only the higher intensive modules (consultation chat and face-to-face counseling) need personal resources, but the proportion of the population that needs this intensive way of support is relatively low

208.5.1.1 Screening

The online screening assesses the individual risk of developing an ED. The Weight Concern Scale (WCS) developed by Killen et al. (1994), a commonly used screening instrument (e.g., Taylor et al. 2006), serves as measure to identify high-risk individuals. Depending on the individual screening result, participants receive a feedback message, either inviting them for registration (to have access to some or all Es[s]prit components) or explaining the reason of exclusion.

Healthy individuals have access to the psychoeducative pages of Es[s]prit and are invited to register and participate in the moderated internet forum. While there is no need for healthy individuals to improve their eating attitudes and eating behavior, they can help to provide peer support and offer advice to other users (high-risk individuals). In addition, they are informed that they can repeat the screening in case they need further support in the future.

Individuals showing weight and shape concerns or slight ED symptoms are expected to bear a higher risk of developing an ED. Therefore, individuals scoring above the threshold of a WCS score of 40 and/or showing slight symptoms (i.e., mild bingeing, BMI < 18.5 or mild compensatory behavior) are invited to register for Es[s]prit with access to all components.

Individuals who report manifest ED symptoms (i.e., frequent bingeing or purging, BMI < 17.5) are excluded from registration and directly referred to a cooperating counseling center, because the offer of Es[s]prit as a prevention program would probably not be sufficient for these severely affected individuals. In case that these users do not want to seek face-to-face treatment, they are provided with internet addresses for online support.

At registration, participants must agree with the user conditions and can choose a pseudonym as username to communicate anonymously. Participants receive an email containing a link to activate their account before they can use Es[s]prit, to make sure that they can be contacted, if necessary.

208.5.1.2 Psychoeducation and Peer Support

The Es[s]prit website contains detailed information on ED in general, risk factors, first signs of an ED, and self-help strategies. All individuals can access the information pages illustrated by comprehensive

personal examples. The information material is provided with support of the German Federal Center for Health Education (Bundeszentrale für gesundheitliche Aufklärung (BZgA) 2007).

Furthermore, all registered users can share information and discuss different questions in a moderated internet forum. The forum posts are checked by the Es[s]prit administrator on a daily basis and inappropriate messages such as pro-anorectic or aggressive statements are deleted.

208.5.1.3 Supportive Monitoring and Feedback System

Es[s]prit contains a supportive monitoring and feedback module that assesses relevant factors and behaviors weekly via a brief online assessment and serves for both early detection of deteriorations and continuous support. The monitoring data are stored and organized by the data management software Web-Akquasi, which automatically schedules the weekly assessments and sends reminder emails containing a link that forwards the user to the respective assessment. Data entered by the user are directly evaluated with regard to current symptom status and symptom change compared to the previous assessment. Immediately after answering the questionnaire, participants receive an automated feedback message related to their symptom development, containing reinforcement of improvements, and advice on how to counteract negative developments.

The monitoring assesses four dimensions of risk: (1) body dissatisfaction, (2) overconcern with body weight and shape, (3) balanced nutrition and eating behavior, and (4) binges and compensatory behavior. Each dimension has a predefined functional and nonfunctional range resulting in two status categories (functional and nonfunctional, see Fig. 208.2), and four change categories over 2 weeks: continuously functional (f), continuously nonfunctional (n), improved from nonfunctional to functional (i), and deteriorated from functional to nonfunctional (d) (see Fig. 208.3). Given the four patterns of change on each of these four dimensions plus the two status categories, when no comparison is possible (in week 1), monitoring results can be classified in 16 categories ($2 \times 2 \times 2 \times 2$) for the first week and 256 categories from the second week onward ($4 \times 4 \times 4 \times 4$). The feedback algorithm was described in detail by Moessner et al. (2008). A total of about 3,000 feedback messages (10–15 per category in order to avoid repetitions) are stored in the Web-Akquasi database.

Fig. 208.2 Supportive monitoring and feedback system – Evaluation example: Assessing change from week 1 to week 2 on the example of the dimension "body dissatisfaction." This figure illustrates how the monitoring and feedback system assesses change over 2 weeks on the example of the dimension "body dissatisfaction": scores in the functional range in week 1 and in the nonfunctional range in week 2 are evaluated as deterioration

dimension	status week 1	status week 2	change
body dissatisfaction	nonfunctional	nonfunctional	n
over concern with body weight and shape	functional	nonfunctional	d
balanced nutrition and eating behavior	nonfunctional	functional	i
binges and compensatory behavior	functional	functional	f

n = nonfunctional, d = deteriorated, i = improved, f = functional

> **Feedback:**
> "Going through phases where you do not feel good about your body is absolutely normal. Keeping your body properly nourished by eating regular meals and snacks is the key to feeling positive about your body in the long run. You have done a great job with improving your eating!"

Fig. 208.3 Supportive monitoring and feedback system – Evaluation algorithm: Example feedback message according to symptom change on each of the four monitoring dimensions. This figure illustrates the evaluation algorithm. Given the four change categories (n, d, i, f) on each of the four dimensions, participants' monitoring courses over 2 weeks can be classified in $4 \times 4 \times 4 \times 4 = 256$ categories (see text for details). This example feedback message refers to scores in the nonfunctional range on "body dissatisfaction", deteriorations in "overconcern with body weight and shape", improvements in "balanced nutrition and eating behavior", and scores in the functional range in "binges and compensatory behavior"

In case of deteriorations, the feedback messages contain suggestions for alternative behaviors to interrupt the dysfunctional development. If indicated, the use of other support modules is recommended (i.e., forum, chat, or face-to-face counseling). An alarm system intervenes when predefined alarm criteria (i.e., low BMI, frequent binging or purging) are reported by a participant. An alert mail is automatically sent to the administrator, who in turn contacts the corresponding participant via email to motivate him/her to use the consultation chat. The chat can then be used to motivate the participant to seek face-to-face treatment, if necessary.

208.5.1.4 Consultation Chat

The anonymous consultation chat allows for an early, low-intensity intervention and is guided by a clinician. Chat sessions are provided in two different settings: Users can participate in group chat sessions, which are offered on a monthly basis for a duration of 90 min. Furthermore, participants can register for an individual 1-to-1 chat (30 min), if they want to discuss more private issues that they do not want to share with other users in the group setting. Prior to the individual chat, the online counselor can access all information available on impairment and symptom courses of this specific participant by using the Web-Akquasi software. The early, anonymous contact via chat can then be used to motivate severely impaired participants to seek treatment in one of the cooperating counseling centers and to refer them to the regular health-care system.

208.5.1.5 Face-to-Face Counseling

The cooperation with counseling centers is crucial to ensure that affected individuals get help without delay. Feelings of shame and fear prevent some of the affected individuals from undergoing treatment. Therefore, it is important to motivate severely impaired individuals to seek help. Once they are motivated, it is necessary to refer them to regular treatment early, because long waiting periods can have a negative influence on motivation (Schmidt et al. 2008).

208.5.2 Experiences with Es[s]prit

208.5.2.1 Screening

Es[s]prit has been offered to University of Heidelberg students since February 2007. The program does not exclude non-students; however, flyers and posters advertised it only at the University of Heidelberg. Until September 2009, $N = 1582$ completed the initial self-test on the web page (see Fig. 208.4). According to the screening results, Es[s]prit seems to attract many individuals who are already affected by severe ED symptoms or in treatment. From all users who completed the screening questionnaire, $N = 236$ (15%) were excluded because of current ED treatment and $N = 299$ (19%) because of too severe ED symptoms. In total, 48% of all screened users met the inclusion criteria for participation. One hundred and seventy (25%) out of 671 users, who were invited for participation because of high-risk according to the WCS score, registered for full participation in Es[s]prit. In addition, 13 out of 77 (17%) individuals, who were invited because of mild ED symptoms, registered for the program.

Healthy individuals who show neither weight and shape concerns nor ED symptoms are not invited for full participation. However, they can register for participating in the online forum, to get and provide peer support. Out of those $N = 299$ healthy individuals, $N = 9$ (3%) registered for the forum.

Internet-based modules facilitate the screening procedure in many ways. On the other hand, providers cannot control who registers for the program. $N = 8$ participants, who were excluded in previous screenings, registered for the program by repeating the screening several times and manipulating some scores (i.e., assumedly providing false information). As they signed up for the chat, however, they were told that the support they get by using Es[s]prit was not sufficient for their level of impairment.

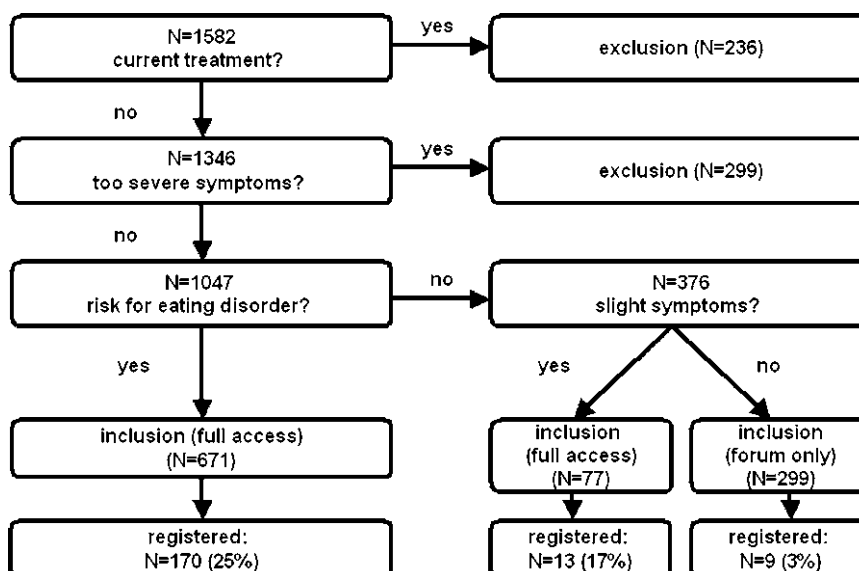

Fig. 208.4 Screening results. This figure illustrates the screening procedure. From a total of 1,582 participants, almost one-third have been excluded because of either current treatment or too severe symptoms ($N = 236$ and $N = 299$, respectively). Participants with neither risk nor slight symptoms were invited to the forum only, whereas at-risk participants or individuals who showed first symptoms were invited with full access to all components (see text for details)

In total, $N = 200$ participants registered for Es[s]prit; $N = 191$ of them had full access to all modules and $N = 9$ only access to the forum.

208.5.2.2 Participants

Participants were mainly females (88%) with a mean age of 27.8 years (SD = 10.3), whereas about 25% of all participants were older than 30 years of age. The mean BMI of Es[s]prit users was 23.6 (SD = 5.7), including a subgroup (25%) of overweight people (BMI > 25).

The sample of Es[s]prit users is characterized by high-risk with a mean WCS score of M = 65.5 (SD = 19.5) and a relatively high level of impairment, measured by total severity scores (TSI) from the Short Evaluation of Eating Disorders (SEED) for AN and BN (Bauer et al. 2005). The Anorexia nervosa total severity index (SEED) (AN_{TSI}) and Bulimia nervosa total severity index (SEED) (BN_{TSI}) scores are higher than in a healthy population (Es[s]prit users: M = 0.9, SD = 0.4 and M = 0.9, SD = 0.6, respectively; healthy controls: AN_{TSI} M = 0.5, SD = 0.3 and BN_{TSI} M = 0.2, SD = 0.3), but lower than those of a clinical sample (AN patients: AN_{TSI}: M = 1.9, SD = 0.5 and BN_{TSI}: M = 1.0, SD = 0.7; BN patients: AN_{TSI}: M = 0.9, SD = 0.5 and BN_{TSI}: M = 2.1, SD = 0.6).

208.5.2.3 Utilization of Modules

One hundred and twenty-seven out of 191 (71.7%) registered participants, who had full access to all Es[s]prit components, activated their account by clicking the link in the activation e-mail. The forum was used by 26 participants who posted 226 messages in total.

The monitoring was used in average 6.7 times per user (SD = 9.6) until deregistration, and 9.3 times (SD = 14.2) by those participants who were still using the program at the time of data analysis. The alarm system has sent alert mails for eight participants so far, who were contacted by the administrator and invited for the consultation chat. All of them replied after being contacted by the administrator. In total, $N = 11$ participants used the consultation chat at least once, and 8 out of those 11 indicated that finally they were prepared to seek face-to-face counseling or treatment. The actual health-care utilization cannot be assessed due to the anonymity of the program.

208.5.2.4 Acceptance and Satisfaction

Three months after registration and at deregistration, participants are asked to evaluate the program. Two thirds of the program evaluations were assessed at deregistration, therefore the results might be negatively biased (because early deregistration might be associated with poorer satisfaction). When we asked for the main reason for participation, 76% named the anonymity of the program (see Fig. 208.5). For 71.5% of the users, Es[s]prit was the first offer they ever used to get help concerning eating-related problems.

Overall, Es[s]prit was evaluated positively: 50% of the users rated the program as being either "very helpful" or "helpful", and 48% as "neutral"; 67% were altogether satisfied with the program, 60% would participate again, and 70% would recommend it to a friend, if they were worried about his/her eating behavior. More than 1/3 of all participants said that without Es[s]prit they would not have known whom to ask with regard to their ED-related questions. When participants were asked to evaluate the specific components, the majority of them rated the various modules as good concepts (see Fig. 208.6). About 30–60% of all participants experienced the different components as helpful.
Fig. 208.5 Reasons for participation in Es[s]prit. The reasons for participation in Es[s]prit are shown in this figure as percentage of participants who named this specific aspect. Multiple responses were allowed

Fig. 208.6 Acceptance of Es[s]prit modules. Three months after registration and at deregistration participants were asked to evaluate the program. This figure shows the percentage of participants who rated the Es[s]prit modules as being good concepts (*black bars*) and personally helpful (*gray bars*). *Note*: participants are free to decide on whether and how intensive they want to use the specific modules

208.5.2.5 Feasibility

The program is running reliably and technically stable. Most of the components are automated, i.e., the screening, registration, weekly monitoring and feedback system, as well as the alarm system.

208.6 Conclusion

Es[s]prit offers a time and cost efficient way to address large populations with relatively low effort: For most participants, the low-intensity (and less costly) components, which are completely automated and do not need any personal resources, seem to be sufficient. Personal resources are needed to react in case of alert mails, to observe the forum activity and to provide chat sessions. This is in line with the idea of stepped care.

The forum is not used as frequently as expected. An explanation for that could be the huge offer of internet portals and self-help groups in social network platforms. The supportive monitoring and feedback system is used frequently by the participants and appears to be a good way to identify those who develop symptoms (early detection). Those participants, who were still in the program at the time of data analysis, have used the monitoring more frequently on average, which may indicate that they benefit more than individuals who decide to deregister early.

Overall, the subgroup of overweight individuals tends to benefit less from Es[s]prit. Some feedback messages related to dieting and restricting food are perceived as inadequate by overweight participants, who apply these behaviors as methods to avoid further weight gain, while according to the feedback system it is perceived as dysfunctional behavior. The conflicting recommendations for overweight and underweight individuals are a challenge in ED prevention and might be solved by approaches that promote healthy eating in general.

The chat proved to be a good way to communicate anonymously and motivate impaired participants to start a more intensive treatment.

By most of the participants, various modules were rated as good concepts in general, and as personally helpful by 30–60% of the users (depending on the specific module). Overall, Es[s]prit was found to be well accepted in a college-age sample, although there is still room for improvement. On the other hand, all modules are anonymous and mainly automated, which makes Es[s]prit feasible to address large populations at reasonable effort.

208.7 Applications to Other Areas of Health and Disease

Internet-based, individualized, stepped care prevention programs tailoring offer to individual needs such as Es[s]prit might be beneficial for many kinds of mental disorders. One advantage of internet-based offers lies in their potential to automate screening, reminder, feedback, and alarm functions. These advantages are essential for the prevention of mental disorders, because tailoring is the only way to help the few affected people without unnecessarily bothering the large group of healthy individuals. Prevention programs could further be implemented as combined programs by screening for risk for various disorders (e.g. depression, anxiety, addiction, and ED) and recommending the use of the most appropriate modules.

Similar to step-up care, i.e., offering modules of increasing intensity for health promotion and prevention, internet-based platforms may also be used as step-down interventions for maintenance treatment, aftercare, and relapse prevention.

Finally, such programs (especially the supportive monitoring and feedback component) appear promising for patients with multiple illness episodes or chronic conditions. Alarm systems may help to detect deteriorations early. This would allow timely referral to e.g., booster sessions or, if needed, more intensive treatment, which is ultimately expected to reduce suffering and increase the symptom-free time.

Summary Points

- Numerous changes and high-stress levels are assumed to make college students more vulnerable to develop mental disorders such as ED.
- Low-intensity, anonymous offers appear promising to address students at-risk of developing an ED.
- Individually tailored, stepped care programs can help to match the appropriate level of support to the diverse needs of individual users.
- Monitoring and alarm systems can identify deteriorations in symptom courses automatically and refer participants to more intensive support levels without delay.
- ICT enables the time and cost efficient implementation of a stepped care approach.

Key Terms

- **Targeted prevention:** In contrast to universal prevention, which targets unselected samples, targeted prevention addresses high-risk groups.
- **Individualized care:** In contrast to standardized programs, individualized care is flexible in duration and amount of support. Each individual is free to decide which of the interventions offered by the provider he/she wants to use depending on personal needs, preferences, and choices.
- **Stepped care:** Stepped care programs allocate intensity and therapeutic resources depending on participants' individual impairment and symptom course.
- **Monitoring:** Monitoring denotes the longitudinal observation of symptoms and behaviors. It is used to provide supportive feedback and identify deteriorations early.
- **Early intervention:** Early intervention refers to the timely provision of professional therapeutic support soon after the manifestation of ED symptoms. Early intervention is assumed to be associated with a more favorable treatment course of mental disorders.

209.1 Introduction

Problems of overweight and obesity have reached epidemic proportions (Ogden et al. 2002). Globally, approximately 1.6 billion adults (age 15+) were classified as overweight and of those at least 400 million were obese (World Health Organization [WHO] 2005). The World Health Organization projects these statistics to increase; by 2015, approximately 2.3 billion adults will be overweight and more than 700 million will be obese all over the world. In the USA, obesity prevalence doubled among adults between 1980 and 2004. More than one-third of adults, or over 72 million people, were obese in 2005–2006. This included 33.3% among adult men and 33.2% among adult women (US Department of Health and Human Services [USDHHS] 2007). Adult obesity rates continued to rise in 37 states; rates rose for a second year in a row in 24 states, and for a third year in a row in 19 states. Mississippi had the highest rate at 31.7%, with Colorado at the lowest rate of 18.4% (Robert Wood Johnson Foundation [RWJF] 2008). Table 209.1 summarizes some key points related to obesity.

Multiple measures have been used to define overweight and obesity. Body Mass Index (BMI) has been one of the most widespread measures: BMI = Weight (kg)/[height (m)]^2 with overweight

Table 209.1 Key points related to obesity

- Globally, approximately 1.6 billion adults were classified as overweight and of those at least 400 million were obese.
- In the USA, it is estimated that approximately 300,000 deaths annually are attributed to obesity-related conditions.
- For a large majority of individuals, overweight and obesity result from excess calorie consumption and/or inadequate physical activity.
- The Surgeon General's *Call to Action to Prevent and Decrease Overweight and Obesity* identified the importance of individuals, families, communities, schools, worksites, organizations, government, and the media to work together to build solutions to prevent and control overweight and obesity in the USA.
- The prevention of weight gain and the maintenance of a healthy weight in people with a healthy weight or modest weight loss in overweight individuals is likely to be easier, less expensive, and potentially more effective than the treatment of obesity after it has fully developed.
- Successful weight management to improve overall health for adults requires a lifelong commitment to healthful lifestyle behaviors emphasizing sustainable and enjoyable eating practices and daily physical activity.

Table 209.2 Obesity measures

Measure	Criteria
Body mass index	Overweight: 25.0–29.9 kg/m^2
	Obesity: >30 kg/m^2
Waist circumference	Men: > 102 cm
	Women: > 88 cm
Waist-to-hip ratio	≥ 1.0
Neck circumference	Men: ≥ 37 cm
	Women: ≥ 34 cm

classified as a BMI of 25–29.9 kg/m^2 and obesity as a BMI over 30 kg/m^2 (USDHHS 2007). Additional obesity measures used in the literature include waist circumference, waist-to-hip ratio, and neck circumference. See Table 209.2 for a summary of these measures.

209.2 Consequences of Obesity

In the United States, it is estimated that approximately 300,000 deaths annually are attributed to obesity-related conditions. Obesity has been related to an increase in the risk of a variety of physical consequences including cardiovascular disease, high blood pressure, high cholesterol, type 2 diabetes, stroke, certain types of cancer, gallbladder disease, osteoarthritis, sleep apnea, and respiratory problems (USDHHS 2007). In fact, type 2 diabetes rates rose in 26 states; and in four states, more than 10% of adults now have type 2 diabetes (RWJF 2008).

Besides physical consequences, psychological factors, which have been related to those dealing with obesity, include depression and low self-esteem (USDHHS 2007). A widespread stereotype and negative attitude toward overweight and obese individuals has led to discrimination, as well as feelings of shame and guilt among these individuals (Cossrow et al. 2001). Only a few studies have been reported on the topic of overweight stigmatization, but common threads of prejudicial treatment and discrimination were apparent (Table 209.3).

Societal costs cannot be dismissed, as the economic burden of adult obesity not only affects the individual, but society as a whole. In the USA, the national health-care expenditures related to overweight and obesity in adults were estimated between $98 billion and $129 billion (Institute of Medicine [IOM] 2004), with about 9% of the national health-care budget spent on the direct costs of obesity and its consequent diseases. Medical costs associated with overweight and obesity involved

Table 209.3 Consequences of obesity

Types of consequences	
Physical	*Increased risk of developing*:
	• Cardiovascular disease
	• High blood pressure
	• High cholesterol
	• Type II diabetes
	• Stroke
	• Certain types of cancer
	• Gallbladder disease
	• Arthritis
	• Sleep disturbances
	• Asthma
Psychological	• Depression
	• Low self-esteem
	• Feelings of shame and guilt
	• Stigmatization
	• Discrimination
Societal	• Medical costs
	• Morbidity costs
	• Mortality costs

both direct and indirect costs (USDHHS 2007; Wolf 1998). According to Finkelstein et al. (2003), direct medical costs included preventive, diagnostic, and treatment services. In contrast, indirect costs were related to morbidity (income lost from decreased productivity, restricted activity, and absenteeism) and mortality costs (the value of future income lost by premature death).

209.3 Determinants of Obesity

Overweight and obesity are caused by numerous and complex factors. Body weight is shaped by a combination of genetic, metabolic, behavioral, environmental, cultural, and socioeconomic influences (USDHHS 2007; WHO 2005). Some of the determinants have been considered nonmodifiable, such as genetics, sex, age, and race. However, most of the population was more likely affected by the influences of surroundings, opportunities, or conditions predisposing individuals to obesity (Moreno et al. 2004).

For a large majority of individuals, overweight and obesity result from excess calorie consumption and/or inadequate physical activity (PA) (Office of the Surgeon General 2001). Very few Americans meet the majority of the Dietary Guidelines for Americans (US Department of Agriculture [USDA] and USDHHS 2005), with only 3% of all individuals meeting four of the five recommendations for the intake of grains, fruits, vegetables, dairy products, and meat. The quality of diets consumed was determined using the Healthy Eating Index-2005 (HEI-2005), a tool designed to measure diet quality in terms of compliance with the key, diet-related recommendations of the 2005 Dietary Guidelines for Americans. The HEI-2005 includes 12 components: total fruit; whole fruit; total vegetables; dark green and orange vegetables and legumes; total grains; whole grains; milk; meat and beans; oils; saturated fat; sodium; and calories from solid fats, alcoholic beverages, and added sugars. Component scores for the US population aged 2 and older were below the maximum possible score for every component, except for total grains and meat and beans; with the total

Table 209.4 Modifiable behaviors related to obesity treatment and prevention

Behaviors	
Physical activity	Participation in at least 60 min of moderate-to-vigorous physical activity (PA) per day
Sedentary behaviors	Limiting screen time (television, video game, and computer use) to less than 2 h/day
Fruit and vegetable consumption	Eating five or more servings of fruit and vegetables daily
Sweetened beverage consumption	Increasing water consumption in relation to the amount of sweetened beverages consumed

score reported as 57.5 out of a possible 100. Scores were particularly low for dark green and orange vegetables and legumes, whole grains, sodium, and calories from solid fats and added sugars. Additionally, nine out of ten Americans were unaware of the number of calories they consumed each day.

With regard to physical activity, less than one-third of adults engage in the recommended amount, and 40% of adults engage in no leisure-time PA (USDHHS 2000). According to the Physical Activity Guidelines released in 2008, all adults should avoid inactivity, with health benefits increasing as PA increases. The guidelines recommend at least the equivalent of 150 min/week of moderate-intensity aerobic PA for substantial health benefits and 300 min/week of moderate-intensity PA for more extensive health benefits (USDHHS 2008).

Sedentary behaviors, including television viewing, have also been associated with an increased risk of overweight and obesity. The BMI of those who watched more than 2 h of television per day was associated with overweight or obesity in both men and women. Also, watching more than 2 h of television per day was related to higher intakes of energy and macronutrients, which corresponded to an increased likelihood to be overweight (Bowman 2006). The 2-day mean television hours were 2.3 h (95% CI, 2.2–2.4 h) for normal weight adults, 2.6 h (95% CI, 2.5–2.7 h) for overweight adults, and 3.0 h (95% CI, 2.85–3.15 h) for obese adults.

Supported by the American Medical Association (Goutham 2008), four well-recognized behaviors have the capability of offsetting the development and treatment of obesity (See Table 209.4). These behaviors include participating in at least 60 min of moderate-to-vigorous PA per day; limiting screen time (television, video game, and computer use) to less than 2 h per day; increasing water consumption in relation to the amount of sweetened beverages consumed; and eating five or more servings of fruit and vegetables daily. Determinants of obesity considered modifiable, prevalent, and relatively easy to change should directly relate to the treatment and prevention of obesity in adults.

209.4 Call to Action

The Surgeon General's *Call to Action to Prevent and Decrease Overweight and Obesity* (2001) identified the importance of individuals, families, communities, schools, worksites, organizations, government, and the media to work together to build solutions to prevent and control overweight and obesity in the United States. Healthy People 2010 also recognized the importance of increasing the proportion of adults who were at a healthy weight and reducing the proportion of adults who were obese (USDHHS 2000). Interventions that modify factors for obesity can be for prevention or treatment. Interventions for prevention and treatment of obesity can be behavioral, pharmacological, surgical, or environmental.

209.5   Review of Obesity Treatment Interventions in Adults

Treatment interventions are implemented with overweight or obese individuals with a goal of weight loss. According to Wilson and McAlpine (2006), the following should be considered: does treatment cause weight loss? does weight loss improve outcomes? can weight loss be maintained? what are the health implications of failing to maintain a loss? and is treatment available? Most programs designed to promote weight-loss for individual adults have had limited long-term success for a majority of the participants (Tsai and Wadden 2005). Existing guidelines call for clinicians to promote sustained weight loss in their obese adult patients. The US Preventive Services Task Force (USPSTF 2003) guidelines suggest that high-intensity counseling coupled with behavioral interventions building skills, motivation, and support will produce sustainable weight loss. A summary of treatment interventions aimed at targeting adult obesity in the United States, with results published since 2000, can be found in Table 209.5.

A total of 19 treatment interventions were found, with approaches including structured meal plans, dietary adherence, supervised exercise classes, use of supplements, self-weighing, social support, internet-based tutorials, behavioral counseling, individualized plans, and feedback. Most of the interventions ($n = 11$) were not based on any explicit behavioral theory. The Transtheoretical Model was most widely used ($n = 4$), followed by social cognitive theory ($n = 2$). In terms of duration, interventions ranged from 9 to 52 weeks, with the longest intervention conducted over a 9-year period. Both group sessions and one-on-one counseling were utilized as a means to deliver the programs. In addition, two programs relied strictly on internet-based communication and two programs incorporated telephone-based coaching and counseling. A majority of the interventions reported on anthropometric measures such as body weight, waist circumference, percentage body fat, and HDL/LDL levels. Significant changes were found in all but two interventions. Caloric intake, PA levels, outcome expectations, physical functioning, vitality, mental health, and quality of life were also measured.

209.6   Review of Obesity Prevention Interventions in Adults

Preventive interventions are implemented with an unselected population that may be normal weight or obese with a goal of prevention of weight gain. The prevention of weight gain and the maintenance of a healthy weight in people with a healthy weight or modest weight loss in overweight individuals is likely to be easier, less expensive, and potentially more effective than the treatment of obesity after it has fully developed. Therefore, assessing and comparing programs for reducing the current prevalence of obesity is very important (Yates and Murphy 2006). Public health obesity prevention efforts have focused mainly on individual education and an emphasis on teaching behavioral skills (Schmitz and Jeffery 2000). Commonly suggested educationally modifiable public health strategies to combat obesity are promoting breastfeeding, limiting television viewing, increasing physical activity, increasing fruit and vegetable intake, controlling portion size, and limiting soft drink consumption (Gerberding and Marks 2004). A summary of prevention interventions aimed at adult obesity in the United States, with results published since 2000, can be found in Table 209.6.

Fewer prevention interventions were found ($n = 5$) compared to the treatment interventions mentioned above. The focus was more on lifestyle changes, with topics such as increasing PA and meeting dietary recommendations. Only one intervention was not based on any explicit behavioral theory, with cognitive–behavioral approach ($n = 2$), social marketing theory ($n = 1$), and social cognitive theory ($n = 1$) used as a framework for the others. In terms of duration, interventions ranged from 3 months to 5 years, with monthly follow-ups and continued individual/group sessions a part of a majority of

Table 209.5 Obesity treatment interventions in adults

Study/ Year	Theory	Intervention	Duration	Major findings
Metz et al. (2000)	No known behavioral theory	• Overweight and obese (BMI ≥ 25 and ≤ 42) individuals (*n* = 302) with hypertension/dyslipidemia or type 2 diabetes mellitus were randomly assigned to prepared meal plan or usual care diet (UCD) for 52 weeks • The prepared meal plan was formulated to provide recommended levels of sodium, fat, fiber and was fortified to meet 100% of recommended dietary allowance for 22 essential vitamins and minerals	52 weeks	• In the prepared meal plan group, the average weight loss from baseline was 6.9 ± 4.0, 7.8 ± 6.3 kg after 26 weeks, and 5.8 ± 6.8 kg after 52 weeks as compared to UCD group losing 2.3 ± 3.6 kg after 12 weeks, 2.4 ± 5.4 kg after 26 weeks, and 1.7 ± 6.5 kg after 52 weeks. The difference between two groups was significant (*p* < 0.001) • In both groups, both interventions improved blood pressure, total and low-density lipoproteins, cholesterol, glycosylated hemoglobin, and quality of life
Jakicic et al. (2002)	No known behavioral theory	• Three groups: (a) long bouts of exercise, (b) short bouts of exercise, (c) short bouts of exercise combined with home exercise equipment • Focused on modifying both eating (reducing fat intake to 20–30% of total calorie intake, which was between 1,200–1,500 kcal/day using structured meal plans) and exercise behaviors (maintain exercise to 200 min/week) • Group meetings were scheduled weekly for months 1–6, biweekly for months 7–12, and monthly for months 13–18	18 months	• The mean decrease in weight from baseline to 18 months was −7.8 ± 7.5 kg (*p* < 0.001) • The mean decrease in BMI from baseline to 18 months was −2.8 ± 2.7 kg/m² (*p* < 0.001) • The mean increase in PA from baseline to 18 months was 1,146 ± 1,300 kcal/week (*p* < 0.001) • The mean reduction in energy intake from baseline to 18 months was −498.1 ± 783.7 kcal/day (*p* < 0.001) • The mean reduction in fat intake from baseline to 18 months was −27.4 ± 38.4 g/day (*p* < 0.001)
Karanja et al. (2002) – Steps to Soulful Living	Social support	• 26 weekly group meetings & a weekly supervised exercise class (*n* = 66, African-American women) • Dietary goal was to reduce fat intake to 25% of total energy & exercise goal was to exercise 3–4 times a week for 30 min or more • Intervention had five key elements: (1) increasing identification between counselors and participants, (2) building social support, (3) providing information in a demonstration format, (4) involving family and community, (5) increasing program ownership	26 weeks	• Over the 26 weeks women lost a mean of 3.7 ± 5.1 kg or a mean loss of 3.3% of their body weight • 56% of the participants lost 2.4 kg (5 lb) or more • Participants who attended at least 75% of the group meetings lost a mean of 6.2 kg at 6 months and those who attended fewer meetings lost a mean of 0.9 kg

Study	Theory	Duration	Intervention	Results
Miller et al. (2002) Diet, Exercise, and Weight Loss Trial (DEW-IT)	No known behavioral theory	9 weeks	• Lifestyle intervention group ($n = 22$) and control group ($n = 23$) • Lifestyle group required DASH (Dietary Approach to Stop Hypertension) diet, reduced sodium, weight-loss goal of 10 or 1.25 lb/week for 8 weeks, and exercise for 30–45 min	• From baseline to follow-up BMI decreased by -1.9 kg/m² in life style group and was significant when compared to control group ($p < 0.0001$) • From baseline to follow-up weight decreased by -5.5 kg in life style group and was significant when compared to control group ($p < 0.0001$)
Tate et al. (2003)	No known behavioral theory	1 year	• One group ($n = 46$) received Internet-based tutorial on weight loss, a new tip and link each week, and directory of weight-loss resources • Second group ($n = 46$) in addition received behavioral e-counseling and interacted with counselors via e-mail about calorie and fat intake, and exercise energy expenditure	• Behavioral e-counseling group had greater reduction in weight (-4.4 vs. -2.0 kg, $p = 0.04$), body mass index (BMI) (-1.6 vs. -0.8 kg/m², $p = 0.03$, and waist circumference (-7.2 vs. -4.4 cm, $p = 0.05$) when compared to Internet group • Both groups reported significant reductions in caloric intake between 0 and 12 months ($p < 0.001$) • For both groups mean increase in exercise energy expenditure did not differ from 0 to 12 months ($p = 0.26$)
Mayer-Davis et al. (2004) – Pounds off with empowerment	Goal setting	12 months	• 3 interventions based on a goal of achieving 10% weight loss over 12 months: Intensive lifestyle intervention, reimbursable lifestyle intervention, and usual care • Intensive lifestyle intervention included group sessions led by nutritionists, written materials, encouragement and suggestions for PA at low-to-moderate intensity for sedentary people, dietary modifications, and self-monitoring tools • Reimbursable lifestyle intervention was condensed and included four 1-h sessions over 12 months and 3 group sessions and 1 individual session • Usual care included 1 individual session by a nutritionist	• Weight change at 6 months was significantly greater among intensive lifestyle participants compared with usual care participants (2.6 vs. 0.4 kg, $p < 0.01$) • At 12 months, greater proportion of intensive lifestyle participants had lost 2 kg or more than usual care participants (49% vs. 25%, $p < 0.05$) • No change in weight was observed between reimbursable lifestyle and usual care participants

(continued)

Table 209.5 (continued)

Study/ Year	Theory	Intervention	Duration	Major findings
Finch et al. (2005)	Outcome expectations theory	• Two groups: one group received positive- or optimistic-outcome expectations and second group received balanced-outcome expectations (both positive and negative) • 8 weekly, 1-h group sessions involving presentation by facilitator and a group discussion • First 4 sessions influenced expectations about losing weight • Second 4 sessions were designed to implement self-designed weight-loss plan	8 weeks, follow-up at 18 months	• No significant differences in weight change by treatment group were observed at 8 weeks, $F_{(3, 212)} = 0.70$, $p < 0.40$; 6 months, $F_{(3, 201)} = 0.01$, $p < 0.93$; or 18 months, $F_{(3, 181)} = 0.18$, $p < 0.67$ • Positive outcome expectations and satisfaction were found to be associated with weight loss
Kennedy et al. (2005)	No known behavioral theory	• Two treatment groups: Group intervention ($n = 20$) and individual intervention ($n = 20$) • Group intervention: nutrition education in six monthly group meetings using group discussion. • Individual intervention: 15 individualized meetings, record keeping, and basic dietary assessment using computer software	6 months	• Mean weight loss in all participants at 6 months was 3.3 kg (s.d. 3.5, $p < 0.05$). In group-based intervention, mean weight loss was 3.1 kg (s.d. 3.5, $p < 0.05$) while in individual intervention it was 3.4 kg (s.d. 3.5, $p < 0.05$) • Mean BMI decrease in all participants was 1.2 kg/m^2 (s.d. 1.3, $p < 0.05$). In group-based intervention, it was −1 (s.d. 1) while in individual intervention it was −1.3 (s.d. 1.3, $p < 0.05$)
Blissmer et al. (2006)	Transtheoretical model	• RCT in which all participants ($n = 144$) completed a 6-month clinical weight-loss program and were randomized into two 6-month extended care groups. The program focused on changing lifestyle rather than weight loss. The extended care group received two additional individualized TTM reports, via mail, at 9 and 12 months.	24 months	At 6 months, there were increases in the physical and mental composite measures as well as physical functioning, general health, vitality, and mental health subscales of the SF-36. Despite some weight regain, the improvements in the mental composite scale as well as the physical functioning, vitality, and mental health subscales were maintained at 24 months. There were no significant main effects or interactions by extended care treatment group or weight-loss group (whether or not they maintained 5% loss at 24 months)

Study	Theory	Description	Duration	Results
Howard et al. (2006) – Women's Health Initiative Dietary Modification Trial	No known behavioral theory	• Groups of 8–15 participants underwent a series of sessions to promote dietary and behavioral changes to reduce dietary fat to 20% and increase consumption to ≥ 5 fruits and vegetables in first 12 months, after that 4 per year • Additionally 3 individual interviews that used targeted messages and provided personalized feedback • The control group received diet-related education materials	9 years	• Women in the intervention group lost weight in the first year (mean of 2.2 kg, $p < 0.001$) and maintained lower weight than control women during an average 7.5 years of follow-up (difference, 1.9 kg, $p < 0.001$ at 1 year and 0.4 kg, $p = 0.01$ at 7.5 years) • Weight loss was greatest in women who reduced their percentage of energy from fat
Nelson et al. (2006) – HOLDSS	Transtheoretical model & social cognitive theory	• Patient-centered personal risk counseling based on stage of change. – Stage of change was assessed at each visit and intervention accordingly tailored. • Measurements at baseline, 6 weeks, 3 months, 6 months	6 months	• At 6 weeks, the mean body weight change from baseline was 2.7 lb as compared to 0.6 lb in control group ($p < 0.01$); at 3 months, the mean body weight change from baseline was 5.2 lb as compared to 1.3 lb in control group ($p < 0.001$); at 6 months, the mean body weight change from baseline was 5.6 lb as compared to 0.9 lb in control group ($p < 0.01$) • Changes in behavior and its antecedents not measured
Schneider et al. (2006)	No known behavioral theory	This study was designed to examine the effects of a 10,000 steps exercise prescription on sedentary, overweight/obese adults ($n = 56$), and to examine the effects of adherence on body composition and cardiovascular risk factors	36 weeks	38 participants (68%) wore pedometers daily for 36 weeks and were available for post-testing. Significant improvements were noted in mean values for walking volume, body weight, BMI, percentage body fat, fat mass, waist circumference, hip circumference, and high-density lipoprotein. The adherers had large improvements in body composition measures, whereas the nonadherers showed little or no change in these variables
Burke et al. (2007)	No known behavioral theory	The joint effects of personal preference of dietary treatment and a calorie-restricted, low-fat lacto-ovo-vegetarian diet compared with a standard calorie-restricted, low-fat omnivorous diet were examined. RCT ($n = 176$)	18 months	No significant interaction between preference and dietary treatment. The only effect observed for diet was a borderline significant decrease in LDL:HDL cholesterol for the LOV-D group ($p = 0.06$). Within the LOV-D groups, those who were 100% adherent had significant reductions in monounsaturated fat ($p = 0.02$) and total fat ($p = 0.05$) intakes at 18 months

(continued)

Table 209.5 (continued)

Study/ Year	Theory	Intervention	Duration	Major findings
Johnson et al. (2008)	Transtheoretical model	Overweight or obese adults were randomized to no-treatment control or home-based, stage-matched multiple-behavior interventions for up to three behaviors related to weight management at 0, 3, 6, and 9 months	24 months	Significant treatment effects were found for healthy eating, exercise, managing emotional distress, and untreated fruit and vegetable intake progressing to Action/Maintenance at 24 months. The groups differed on weight lost at 24 months. Covariation of behavior change was much more pronounced in the treatment group, where individuals progressing to Action/Maintenance for a single behavior were 2.5–5 times more likely to make progress on another behavior. The impact of the multiple-behavior intervention was more than three times that of single-behavior interventions
Carr et al. (2008) –ALED-I	Transtheoretical model & Social cognitive theory	Internet-delivered theory-based PA behavior change program intended to improve cardiometabolic disease risk factors in sedentary overweight adults. RCT with delayed-intent-to-treat control group	16 weeks	Both groups had similar baseline PA levels. ALED-I increased PA by an average of 1,384 steps/day ($p = 0.03$) compared to 816 steps/day ($p = 0.14$) for the control group. Waist circumference and Coronary Risk Ratio decreased in the ALED-I group and did not change in the control group.
Lutes et al. (2008) –ASPIRE	No known behavioral theory	The ASPIRE group ($n = 20$) was provided brief instruction about nutrition and PA and asked each week to choose and make one small, potentially permanent change in food choices and caloric intake and one small change in physical activity; a standard educationally-based treatment group ($n = 20$); a wait list control group ($n = 19$). Active treatment groups received identical resistance and aerobic training programs	4 months	Intention-to-treat analyses showed that participants in the ASPIRE group lost significantly more weight than the standard and control groups (−4.4 vs. −1.1 and +0.1 kg, respectively), and the greater initial weight loss in the ASPIRE group was sustained 3 months after active treatment (4.1 kg)
Tucker et al. (2008)	No known behavioral theory	Eleven 30-min telephone coaching sessions were spaced throughout the study; the initial conversation lasted 60–90 min. Supplement or placebo capsules were taken daily over the 17 weeks. RCT ($n = 60$ men, 60 women)	17 weeks	Subjects taking the supplement lost more 3.1 ± 3.7 kg of weight ($F = 4.1$, $p = 0.045$). Participants receiving coaching lost more: 3.2 ± 3.6 kg of weight ($F = 4.8$, $p = 0.032$). Subjects receiving both the supplement and coaching lost the most weight, implying an additive effect ($F = 2.9$, $p = 0.039$)

Goldfinger et al. (2008) –Project HEAL	Community based participatory research	1 year	Twenty-six overweight and obese African-American adults lost a mean of 4.4 pounds at 10 weeks, 8.4 lb at 22 weeks, and 9.8 lb at 1 year. Participants reported decreased fat consumption and sedentary hours, and improved health-related quality of life
Van Wormer et al. (2009) –Weigh By Day	No known behavioral theory	12 months	Self-weighing was a significant predictor of body weight over time. Participants lost about 1 extra pound for every 11 days they self-weighed during treatment. In addition, participants who self-weighed at least weekly were 11 times more likely to lose at least 5% of their pretreatment weight after 6 months. Improvements attenuated after 12 months

Project HEAL: Healthy Eating, Active Lifestyles, a peer-led weight-loss program, was developed through extensive collaboration with community members and experts in nutrition, exercise, and peer education

A prospective cohort design was utilized to examine 100 participants enrolled in a weight-loss trial that encouraged frequent, objectively measured self-weighing at home. The intervention consisted of a 6-month behavioral weight-loss program that employed telephone counseling, a written manual, and a home tele-monitoring scale

Table 209.6 Obesity prevention interventions in adults

Study/Year	Theory	Intervention	Duration	Major findings
Kuller et al. (2001) – Women's Healthy Lifestyle Project	Cognitive–behavioral approach	• Participants were randomly assigned into control group ($n = 275$) and lifestyle intervention group ($n = 260$) • Aimed at increasing leisure time physical activity, preventing weight gain, and preventing the increase of LDL cholesterol • Restrict dietary fat to 25% • Intensive group program during the first 6 months and follow-up individual/group sessions from 6 through 54 months	5 years	• In the lifestyle intervention group the weight change at 6 months was –10.7 lb ($p < 0.01$), at 18 months –6.7 lb ($p < 0.01$), at 30 months -4.7 lb ($p < 0.01$), at 42 months –2.2 lb ($p < 0.01$), and at 54 months –0.18 lb ($p < 0.01$) • Corresponding significant reductions were also found in waist circumference as compared to control group
Bachar et al. (2006) – Cherokee Choices	Social marketing theory	• Components: Worksite wellness for adults, church-based health promotion, and social marketing using TV documentary series, and TV advertisements • Worksite wellness program ($n = 86$) and church wellness program had healthy cooking demonstrations, classes on exercise techniques, and	3 years	• 88% completed the worksite wellness program and 56% met the goals • 70.9% lost weight (29.1% < 5 lb, 12.8% 5 to < 10 lb, 20.9% 10 to < 20 lb, 8.1% ≥ 20 lb) • In 86 participants, 0.85 kg/m^2 change in BMI between June 2002 and June 2005
Ash et al. (2006)	Cognitive–behavioral approach	A randomized–controlled trial ($n = 176$) of two intervention groups, a group-based cognitive–behavioral therapy lifestyle intervention, Fat Booters Incorporated – (FBI) and individual-ized dietetic treatment (IDT) and control group receiving an information booklet only (BO). The intervention groups involved weekly contact for 8 weeks with monthly follow-up to 6 months and further follow-up at 12 months, conducted in real practice setting	1 year	A statistically significant difference between groups was observed for weight change over time ($p < 0.05$). Change in weight for the FBI group was significantly greater than the BO group at 3 and 12 months ($p < 0.05$). Significant differences in self-efficacy were observed over time ($p < 0.02$), with both intervention groups having greater self-efficacy than the BO group

Study	Theory	Description	Duration	Results
Whitt-Glover et al. (2008)	Social cognitive theory	A faith-based PA intervention on daily walking and moderate- and vigorous-intensity PA ($n = 87$). Sedentary black adults participated in eight group sessions that included discussion of physical activity–related topics, an instructor-led PA session, and weekly incentives to promote physical activity. Walking was assessed weekly in steps per day by using a pedometer	3 months	After 12 weeks, moderate- and vigorous-intensity PA increased by 67 ± 78 and 44 ± 66 min/week, respectively ($p \leq 0.01$), and daily walking increased by $1,373 \pm 728$ steps per day ($p < 0.001$)
Eiben and Lissner (2006)–Health Hunters	No known behavioral theory	Women, 18–28 years old ($n = 40$), with at least one severely obese parent, were randomized to the intervention or control group of the "Health Hunters" program. During 1 year of follow-up, the intervention group received an individualized behavioral program focusing on food choice, physical activity, and other lifestyle factors	1 year	The intervention group displayed significant improvements in body weight, BMI, waist circumference, waist-to-hip ratio and self-reported physical activity. Changes in body composition, although not significant, suggested that the intervention tended to be associated with improved body composition

the interventions (*n* = 3). Programs were implemented in the community, worksites, and via faith-based settings. All five interventions achieved some sort of success, with significant reductions in weight, waist circumference, BMI, an increase in PA and daily walking, as well as self-efficacy.

209.7 Components Among Successful Interventions

The American Dietetic Association (ADA) takes the stance that successful weight management to improve overall health for adults requires a lifelong commitment to healthful lifestyle behaviors emphasizing sustainable and enjoyable eating practices and daily PA (ADA 2009). Components among successful interventions, both treatment and prevention, revolved around a similar mentality.

The use of theory was important in the design and measurement of the interventions. Particularly in the treatment interventions, very few mentioned the use of theory. In terms of measuring an individual's motivation to change, the Transtheoretical Model was widely used. Just as important, however, is adequately measuring and documenting changes in behavioral constructs of the theory chosen (Sharma 2006). As a whole, even the interventions that cited use of theory did not report on all behavioral constructs in relation to the desired behavior change.

Behavior modification strategies incorporated into successful interventions included: self-monitoring such as keeping food and exercise diaries; stress management coping strategies such as meditation and relaxation techniques; stimulus control in which individuals learn how to shop for healthy food and consciously avoid situations in which overeating occurs; problem-solving techniques; contingency management where individuals learn to reward behavior change and; building social support through friends and family to assist in motivation and reinforcement. Those interventions which centered on the individual and their goals resulted in better adherence (Ash et al. 2006), which has been related to greater outcome measures. Individualized stage-matched, multiple behavior interventions had significant effects on progression to action/maintenance for healthy eating, exercise, managing emotional distress, and weight among those most at risk (Johnson et al. 2008).

209.8 Recommendations for Enhancing Obesity Prevention and Treatment Interventions

After reviewing both treatment and prevention interventions related to obesity in adults, the interventions must target both PA and nutrition behaviors. Lifestyle interventions with a focus on incorporating favorable changes in eating and exercise behavior into daily routines appear to be more effective than those without this focus (Seo and Sa 2008). Changes including increased fruit and vegetable consumption, decreased fat intake, decreased consumption of sweetened beverages, adequate consumption of water, and restricting portion sizes are important aspects to dietary improvements (Barton and Whitehead 2008).

Encouraging adults to participate in PA must be integrated into any treatment or prevention intervention. For those trying to prevent significant weight gain, recommendations are for at least 150 min/week of moderate-intensity physical activity. Modest reduction in weight gain have been reported for the above recommendations; however, for those individuals who are overweight or obese, there is a greater weight loss and enhanced prevention of weight gain for levels of moderate-intensity PA of 250–300 min/week (American College of Sports Medicine [ACSM] 2009). Results from short-term interventions (≤6 months) have shown the enhanced magnitude of weight loss when

the intervention focuses on a combination of diet plus PA (Jakicic et al.); reported reductions in body weight of 11.4%, 8.4%, and 0.3% in males participating in 12 weeks of diet plus exercise, diet alone, or exercise alone, respectively.

There is need for all interventions to be based on behavioral theories. Use of behavioral theories helps aid the understanding of which components work and to what extent, helps in timing the interventions, and makes professional communication and comparison easier (Sharma 2006). Theories such as the Transtheoretical Model really helped to individualize the intervention, increasing the likelihood for success (Johnson et al. 2008; Seals 2007).

In terms of setting, more interventions should target community and worksite settings where early stages of obesity can be detected and programmatic efforts initiated in a timely manner. By targeting existing social networks, locating programs in places where individuals already gather, and utilizing community members who already have the trust of their members, interventions are more likely to be deep-rooted in the community – and therefore more successful (Goldfinger et al. 2008). Employee social networks may be leveraged through worksites to facilitate weight loss and maintenance (Benedict and Arterburn 2008). Churches may be an ideal setting for prevention efforts, particularly in African-American communities, because of their central role in spiritual guidance, communication, social support, and networking (Whitt-Glover et al. 2008). Interventions need to be targeted toward multiethnic and minority adults. Strategies recommended include incorporating individual sessions, family involvement, and problem-solving strategies into multicomponent programs that focus on lifestyle changes (Seo and Sa 2008).

In terms of the duration of the intervention, interventions that are at least 6-month long must be planned. Studies incorporating interventions with face-to-face contact with participants occurring more than once a month had greater success than those where contact occurred less than once per month (Benedict and Arterburn 2008). When possible, individualized, one-on-one counseling should be used as an educational approach (Johnson et al. 2008). Counseling delivered electronically and by phone proved to be effective if face-to-face interaction was not possible.

Beyond individual obesity treatment and prevention programs, public policy becomes a powerful means to effect change in order to alter population-level diet and PA behavior. Some of the most significant factors include the high cost of healthy foods, the location of grocery stores, access to safe places to exercise, and the availability of preventive health-care services (RWJF 2008). Such change can also be used to modify social norms, where the healthy choice becomes the accepted standard (McKinnon et al. 2009).

209.9 Applications to Other Areas of Health and Disease

Overweight and obesity have been related to such a myriad of physical consequences, most of which relate to increased morbidity and mortality (USDHHS 2007). We have already seen that being overweight and obese leads itself to a variety of diseases. In terms of both treatment and prevention, it seems that primary care providers are missing opportunities to help their patients (Boardley et al. 2007). There has been an increase in weight-related education with those clinics which have started to routinely record BMI. In addition, patients have reported the desire to receive information and help from their primary care physician, making this the ideal time to incorporate strategies to both treat and prevent adult obesity. Reasons most primary care providers do not talk to their patients about weight management and/or prevention include time constraints, not enough training, lack of financial incentive, and failure to believe that patients can be successful (Boardley et al. 2007). Providing education to physicians and related occupations would be beneficial in the targeting of the obesity issue.

209.10 Conclusion

Despite widespread acknowledgment that obesity is endangering the health of millions of Americans; the country is still failing to respond clearly or comprehensively. The diversity of both obesity treatment and prevention interventions which were found to be effective was promising, as it increased the likelihood of finding a suitable program which could be adapted to specific community needs. Nonetheless, programs must be developed around community needs, and be guided by those that have already been successful. As Doak et al. (2006) stated, "There is no need to reinvent the wheel" (p. 129). Building on successful interventions and relating them to specific community needs will increase the chance of success. Improving an individual's ability to sustain achieved weight loss and prevent weight gain remains a major challenge in the management of overweight and obesity (Lang and Froelicher 2006) and must also be considered in the implementation of future interventions.

The most effective obesity prevention and treatment requires collaboration among health-care providers, nurses, dietitians, psychologists, health educators, community leaders, and policy makers (Lang and Froelicher 2006). There is a need for continued research addressing strategies that focus on the underlying societal causes of obesity through action in sectors such as transport, environment, employment conditions, education, health and food policies, and social and economic policies (Lemmens et al. 2008). According to Dr. Risa Lavizzo-Mourey, President and CEO of the Robert Wood Johnson Foundation, "We must work together, governments, schools and communities, to improve nutrition and increase PA for all ages. We must ensure that strong policies are implemented and enforced in every state, not only to help reverse existing obesity rates, but to prevent obesity among our nation's children—and generations to come" (RWJF 2008).

Summary Points

- The diversity of both obesity treatment and prevention interventions that were found to be effective was promising.
- Programs must be developed around community needs, and guided by those that have already been successful.
- Interventions which centered on the individual and their goals resulted in better adherence.
- Effective obesity prevention and treatment programs focus on both increasing PA and modifying dietary behaviors.
- The most effective approach in obesity prevention and treatment requires collaboration.
- Public policy changes can be used to modify social norms, where the healthy choice becomes the accepted standard.

Key Terms

Overweight: BMI of 25–29.9 kg/m^2.
Obesity: BMI over 30 kg/m^2.
Direct medical costs: Costs related to preventive, diagnostic, and treatment services.
Morbidity costs: Income lost from decreased productivity, restricted activity, and absenteeism.
Mortality costs: The value of future income lost by premature death.
Treatment intervention: Implemented with overweight or obese individuals with a goal of weight loss.
Prevention intervention: Implemented with an unselected population that may be normal weight or obese with a goal of prevention of weight gain.

Chapter 210
The Use of a Cognitive Behavioral Program for Diabetes and Cardiovascular Risk Reduction

Jeroen Lakerveld, Sandra D.M. Bot, and Giel Nijpels

Abbreviations

CBP   Cognitive behavior program
CVD   Cardiovascular diseases
MI   Motivational interviewing
PST   Problem-solving treatment
RCT   Randomized, controlled trial
T2DM   Type 2 diabetes mellitus
TPB   Theory of planned behavior
TTM   Transtheoretical model

210.1 Introduction

Overweight, reduced physical activity, smoking, and an unhealthy diet are lifestyle-dependent risk factors that are associated with cardiovascular diseases (CVD) and type 2 diabetes (T2DM) (Reaven 1995; Yusuf et al. 2004; Willi et al. 2007). Changing these risk factors has the potential to postpone or prevent the development of CVD and T2DM. Although prescribing risk-lowering drugs seems to be easier and more widely accepted by medical practitioners and patients, interventions that lower CVD and T2DM risk by improving lifestyle are likely to be safer and less expensive than drug therapy (Montori et al. 2007). Moreover, changing lifestyle behavior has been shown to be at least as effective as drug treatment in reducing the rate of progression to T2DM in people with impaired glucose tolerance (Knowler et al. 2002; Gillies et al. 2007). In addition to CVD and T2DM, changing an unhealthy lifestyle might also lower the risk of other diseases and ailments, and might have a positive influence on the lifestyle behavior of family members. That is, of course, if the lifestyle program leads to a structural behavioral change. Numerous lifestyle programs have been developed, and many of them use a cognitive behavioral approach to target the lifestyle of participants. Lifestyle interventions based on behavioral or cognitive–behavioral strategies have been reported to be more effective than health education or instruction alone (King et al. 1998;

J. Lakerveld (✉)
Department of General Practice and the EMGO Institute for Health and Care Research, VU University Medical Center, van der Boechorststraat 7, 1081 BT, Amsterdam, The Netherlands
e-mail: j.lakerveld@vumc.nl

Petrella and Lattanzio 2002; Wadden et al. 2004; Shaw et al. 2005). Cognitive–behavioral programs (CBPs) are interventions based on the principles underlying cognitive–behavioral therapy. The term cognitive–behavioral therapy is used in various ways to refer to behavior therapy, cognitive therapy, and therapy based on the pragmatic combination of principles of behavioral and cognitive theories (British Association of Behavioural and Cognitive Psychotherapies 2009). Because the word *therapy* can be interpreted as the attempted remediation of a health problem such as a disease or disorder, the word *program* is preferable in the context of prevention. Thus, CBPs can be seen as programs that share a theoretical basis in behavioristic learning and cognitive psychology, and that use instruments of change (methods, techniques) derived from these theories.

CBPs that are described in the literature vary in many ways. The programs differ with regard to setting, instruments of change, target population, theoretical background, time to follow-up, outcome measures, and effectiveness. Furthermore, they target different lifestyle behaviors, such as dietary behavior, smoking, physical activity, or a combination. By means of reviews that are published on this subject, an overview is given of lifestyle intervention programs with a cognitive behavioral approach to reduce the risk of CVD and T2DM in adults. Additionally, often used instruments of change and influential theoretical models are discussed. This qualitative "review of reviews" is intended to give an overall picture of the current knowledge, rather than an exhaustive summary of the relevant published literature.

210.2 Data Sources

In order to underpin our overview with available scientific evidence, the electronic databases MEDLINE and the Cochrane Database of Systematic Reviews were searched to identify reviews that focus specifically on randomized, controlled trials (RCTs) based on cognitive and behavioral intervention strategies. The search terms included *lifestyle intervention*, *prevention*, *cardiovascular diseases*, *diabetes*, *cognitive*, and *behavior*. Reviews were eligible for inclusion if they were lifestyle orientated and focused on diet, nutrition, increased physical activity, individually or in combination. Reviews with smoking as the main focus were not included. The reviews had to satisfy the inclusion criteria for RCTs listed in Table 210.1.

Table 210.1 Criteria for the inclusion of reviews for this chapter

Category	Criteria for inclusion
Time period	Publication date January 1965 to April 2009
Publication language	English
Study population	Human adults only
	Healthy or high-risk populations
Study design	Review including RCTs or studies with a quasi-experimental design
Intervention setting	Primary care
Intervention components	One or more of the following intervention types: individual counseling, support groups, classes, telephone or e-mail contact
Outcomes reported	Absolute or relative risk of CVD/ mortality or T2DM.
	Lifestyle behavior (physical activity, dietary behavior), weight, body-mass index

210.3 Effectiveness of Cognitive–Behavioral Programs

Reviews that evaluated the effectiveness of CBPs are summarized in Table 210.2 (dietary interventions), Table 210.3 (physical activity interventions) and Table 210.4 (a combination of dietary and physical activity interventions).

Interventions appear to be more successful in changing the lifestyle behavior of high-risk populations than that of general, healthy populations (Ebrahim and Davey 2000; Ammerman et al. 2002; Davies et al. 2004; Gillies et al. 2007; Fleming and Godwin 2008). Extensive programs that have a multiple risk factor approach and include long follow-up booster sessions tend to be effective in changing the risk of CVD and/or T2DM (King et al. 1998; Miller and Dunstan 2004; Gillies et al. 2007; Orozco et al. 2008). Furthermore, effective interventions included those that applied behavioral or cognitive–behavioral strategies (King et al. 1998; Shaw et al. 2005).

Interventions were found to vary widely in the range and type of techniques used, even when targeting the same behavior among similar participants. The theoretical underpinning of the various interventions is also very diverse, and is often not clearly described in reviews. On the other hand, many theoretical models underlying CBPs are more or less comparable, and contain elements that are similar to theoretical models such as the theory of planned behavior (TPB), the theory of self-regulation or the transtheoretical model (TTM).

Despite the popularity of the TTM, in recent years it has been the subject of increased criticism, leading to discouragement of further use of this theory (van Sluijs et al. 2004). The focus and key concepts of frequently used influential theoretical models are presented in Table 210.5.

Many programs that use cognitive behavioral approaches include one or more (elements) of the following instruments of change:

210.3.1 Risk Communication

Involving participants in decision-making concerning the management of their risk may improve their adherence to lifestyle programs. A barrier to the implementation of lifestyle changes is often misperception of the risk (van Steenkiste et al. 2004a, b). As a result, the participants are not encouraged and motivated to change their lifestyle. This concept is also incorporated in Leventhal's self-regulation model (Leventhal 1982). This theory assumes that the cognitions of a patient with regard to a personal health issue determine the attitude of the patient (see also Table 210.5). Risk communication aims to create awareness and to resolve a possible mismatch between the patient's actual risk and perceived risk. Examples of risk communication tools are: risk tables/user-friendly risk charts or providing a risk-adjusted age (Grover et al. 2007).

210.3.2 Motivational Interviewing

Motivational interviewing (MI) is a counseling method with which to elicit behavioral change by helping people to explore and resolve ambivalence in a respectful counseling atmosphere (Miller and Rollnick 2002). It is a well-known method of counseling. The therapeutic relationship is more like a partnership or companionship than a situation with expert/recipient roles. Motivation is an integral part of changing an individual's behavior and stimulating the adaptation to good healthy

Table 210.2 Reviews of cognitive behavioral programs based on dietary interventions for diabetes or cardiovascular risk reduction

Authors	Title	Included interventions	Results/conclusions
Ammerman et al. (2002)	The efficacy of behavioral interventions to modify dietary fat and fruit and vegetable intake: a review of the evidence	Behavioral dietary interventions in promoting dietary change related to chronic disease risk reduction	Interventions appeared to be more successful in positively changing dietary behavior among populations at risk of (or diagnosed with) disease than among general, healthy populations. The majority of the interventions reviewed resulted in meaningful improvements in dietary factor behaviors associated with the prevention of chronic disease, particularly among individuals at elevated disease risk. Small group interaction and goal-setting seem to be the most effective component of dietary interventions
Ashenden et al. (1997)	A systematic review of the effectiveness of promoting lifestyle change in general practice	Trials examining the effectiveness of dietary advice by several primary care health workers	The effectiveness of the trials included in this review was very mixed. No clear result can be given due to the heterogeneity of the trials. The individual results of the trials reported only small changes in behavior; no substantial changes. General practitioners should direct their efforts toward high-risk groups in which the potential for substantial change may be greater
Gillies et al. (2007)	Pharmacological and lifestyle interventions to prevent or delay type 2 diabetes in people with impaired glucose tolerance: systematic review and meta-analysis	RCTs that evaluated interventions to delay or prevent T2DM by means of dietary programs	Lifestyle interventions focusing on diet reduce the rate of progression to T2DM in people with impaired glucose tolerance. Lifestyle interventions seem to be at least as effective as drug treatment.
Nield L. et al. (Nield et al. 2008)	Dietary advice for the prevention of type 2 diabetes mellitus in adults	RCTs of 12 months or longer with dietary advice for the prevention of T2DM as intervention	Dietary advice appears to be effective in reducing the risk of T2DM compared to a control group over six years. However, there are no high-quality data on the efficacy of dietary intervention for the prevention of T2DM.
Pignone MP et al. (Pignone et al. 2003)	Counseling to promote a healthy diet in adults: a summary of the evidence for the U.S. Preventive Services Task Force	RCTs that examined the effectiveness of counseling in changing dietary behavior	Dietary counseling of patients by primary care providers produces modest changes in self-reported consumption of saturated fat, fruits and vegetables, and possibly dietary fiber. Interventions that are more intensive were more likely to produce important changes than brief interventions, but they may be more difficult to apply to typical primary care patients. Interventions using interactive health communications, including computer-generated telephone or mail messages, can also produce moderate dietary changes. Their effect on health outcomes is unclear.

Table 210.3 Reviews of cognitive behavioral programs based on physical activity interventions for diabetes or cardiovascular risk reduction

Authors	Title	Included interventions	Results/conclusions
Ashenden et al. (1997)	A systematic review of the effectiveness of promoting lifestyle change in general practice	Trials which assessed brief to intensive exercise advice	The effectiveness of the trials included in this review was very mixed. No clear result can be given due to the heterogeneity of trials. The individual results of the trials reported only small changes in behavior; no substantial changes
Eakin et al. (2000)	Review of primary care-based physical activity intervention studies: effectiveness and implications for practice and future research	Primary care-based physical activity interventions	Primary care-based physical activity counseling is moderately effective in the short term, although there is considerable variability across studies. Studies in which the interventions were tailored to participant characteristics and which offered written materials to patients produced stronger results
Eaton and Menard (1998)	A systematic review of physical activity promotion in primary care office settings	Physical activity promotion in primary care setting	There is limited evidence from well-designed trials that office-based physical activity promotion in primary care settings is efficacious in promoting changes in physical activity that could conceivably have lasting clinical benefits
Gillies et al. (2007)	Pharmacological and lifestyle interventions to prevent or delay type 2 diabetes in people with impaired glucose tolerance: systematic review and meta-analysis	RCTs that evaluated interventions to delay or prevent T2DM by means of dietary programs	Lifestyle interventions focusing on physical activity reduce the rate of progression to T2DM in people with impaired glucose tolerance even more than studies with interventions focusing on diet. Lifestyle interventions seem to be at least as effective as drug treatment
King et al. (1998)	Physical activity interventions targeting older adults. A critical review and recommendations	Physical activity interventions; community based	Effective interventions included those that employed behavioral or cognitive–behavioral strategies as opposed to health education or instruction alone. In addition, programs that also used either a supervised home-based format or a combination of group- and home-based formats typically reported comparable or better physical activity adherence relative to programs that used a class or group format only. Ongoing telephone supervision of the physical activity program was shown to be an effective alternative to face-to-face instruction, resulting in adherence rates over extended periods of time (i.e. up to 2 years)

Table 210.3 (continued)

Authors	Title	Included interventions	Results/conclusions
Orozco et al. (2008)	Exercise or exercise and diet for preventing type 2 diabetes mellitus (T2DM)	Exercise interventions of at least 6 months duration	No firm conclusion can be drawn about the effectiveness of exercise alone in preventing T2DM
Petrella and Lattanzio (2002)	Does counseling help patients get active?	Studies focusing on physicians promoting physical activity	Most studies found positive relationships between counseling and change in level of physical activity. No long-term effect of the interventions was established

habits. The five main guiding principles of MI are: express empathy, develop discrepancies, avoid argumentation, roll with resistance, and support self-efficacy (see also Table 210.6).

210.3.3 Problem-Solving Treatment

Problem-Solving Treatment (PST) is a brief, structured psychological intervention that can be defined as the self-directed cognitive–behavioral process by which a person attempts to identify or discover effective or adaptive solutions for specific problems encountered in everyday life (Mynors-Wallis 2005). PST aims to increase a person's ability to solve problems in a structured way and to increase the person's self-management. This is done in seven stages (see Table 210.7). The treatment involves an active collaboration between participant and therapist, with the participant taking an increasingly active role in planning the treatment and implementing activities between the treatment sessions. The therapist helps participants to gain a sense of mastery over their difficulties.

210.3.4 Booster Calls/Booster E-mails

Preventing or delaying a relapse to the "old" and unwanted lifestyle behavior is an important step in producing long-lasting behavioral change, and booster sessions can be an essential instrument. Telephone or e-mail booster sessions act as a reminder for the participants to reinforce what they have learned, e.g. during face-to face sessions, and to give them support and feedback. In this way, maintenance sessions might facilitate the consolidation of skills learned during earlier sessions, and thereby prolong their use even after the booster sessions have ended.

210.4 Authors' Conclusions

Research on the effectiveness of cognitive behavioral programs for CVD and T2DM risk reduction has increased, but the results of trials are not consistent. Systematically reviewing these trials is complicated, because there is much heterogeneity in the study design, the theoretical underpinning,

Table 210.4 Reviews of cognitive behavioral programs based on a combination of dietary and physical activity interventions for diabetes or cardiovascular risk reduction

Authors	Title	Included interventions	Results/conclusion
Ebrahim and Davey et al. (2000)	Multiple risk factor interventions for primary prevention of coronary heart disease	Studies using counseling education to modify more than one cardiovascular risk factor. At least 6 months follow-up	The pooled effects suggest multiple risk factor interventions have no effect on mortality. Changes in risk factors were relatively modest and in some cases may have been overestimated for methodological or statistical reasons
Gillies et al. (2007)	Pharmacological and lifestyle interventions to prevent or delay type 2 diabetes in people with impaired glucose tolerance: systematic review and meta-analysis	RCTs that evaluated interventions to delay or prevent T2DM with a focus on diet and exercise	Lifestyle interventions focusing on a combination of physical activity and diet reduce the rate of progression to T2DM in people with impaired glucose tolerance. Lifestyle interventions seem to be at least as effective as drug treatment
Goldstein et al. (2004)	Multiple behavioral risk factor interventions in primary care: summary of research evidence	Interventions addressing multiple behavioral risks	There is evidence for the efficacy of medium- to high-intensity dietary counseling by specially trained clinicians in high-risk patients. There is fair to good evidence for moderate, sustained weight loss in obese patients receiving high-intensity counseling, but insufficient evidence regarding weight-loss interventions in nonobese adults. Evidence for the efficacy of physical activity interventions is limited. There remain to be large gaps in our knowledge about the efficacy of interventions to address multiple behavioral risk factors in primary care.
Miller YD & Dunstan DW (Miller and Dunstan 2004)	The effectiveness of physical activity interventions for the treatment of overweight and obesity and type 2 diabetes	Studies focusing on increasing the level of physical activity or reducing sedentary behavior	Strategies that combine diet and physical activity are more effective than physical activity alone. Combined lifestyle strategies are most successful for maintained weight loss, although most programs are unsuccessful in producing long-term changes. There is little evidence of compliance to prescribed behavior changes. Limited evidence suggests that continued professional contact and self-help groups can help to sustain weight loss. Evidence suggests that interventions can lead to small but clinically meaningful improvements in glycemic control, even in the absence of weight loss.

(continued)

Table 210.4 (continued)

Authors	Title	Included interventions	Results/conclusion
Orozco et al. (2008)	Exercise or exercise and diet for preventing T2DM	RCTs with at least 6 months follow-up and with T2DM incidence as outcome measure	Interventions aimed at increasing exercise combined with diet are able to decrease the incidence of T2DM in high-risk groups
Shaw et al. (2005)	Psychological interventions for overweight or obesity	RCTs of psychological intervention versus a comparison intervention with weight change as outcome measure	People who are overweight or obese benefit from psychological interventions, particularly behavioral and cognitive–behavioral strategies, to enhance weight reduction. They are predominantly useful when combined with dietary and exercise strategies. The bulk of evidence supports the use of behavioral and cognitive–behavioral strategies in order to change the lifestyle behavior of participants

Table 210.5 The focus and key concepts of frequently used behavioral change theories

Theory/ model	Focus	Key concepts
Theory of planned behavior (Ajzen 1985)	Attitude toward behavioral change, the perceived pressure of important others, and perceived behavioral control. These are linked to the intention, which is directly linked to behavioral change. Perceived behavioral control also has a direct link with change	Attitude Subjective norms Perceived behavioral control Intention
Theory of self-regulation (Leventhal 1982)	An approach is for the participant to realize a personal health issue and understand the factors involved in that issue. The participant must decide upon an action plan for resolving the health issue. The patient will need to deliberately monitor the results in order to appraise the effects, checking for any necessary changes in the action plan	(Health) threat Representations of the threat Response
Transtheoretical model (Prochaska and DiClemente 2005)	Readiness to change or attempt to change a health behavior varies among individuals and within an individual over time. Relapse is a common occurrence and part of the normal process of change	Precontemplation Contemplation Preparation Action Maintenance
Protection motivation therapy (Rogers 1983)	According to this theory, there are two sources of information: (1) environmental (e.g. verbal persuasion, observational learning) and (2) intrapersonal (e.g. prior experience).This information elicits either an "'adaptive' coping response (i.e. the intention to improve one's health) or a 'maladaptive' coping response (e.g. avoidance, denial).	Threat appraisal Coping appraisal Protection motivation response
Social cognitive theory (*Bandura* 1986)	Behavior is explained by dynamic interaction among personal factors, environmental influences, and behavior.Each factor affects each of the others and determines behavioral change.	EnvironmentSituation Behavioral capability Expectations Expectancies Self-control Observational learning Reinforcements Self-efficacy Emotional coping responses Reciprocal determinism

the target population, and the content and delivery of the interventions. In order to be able to draw conclusions about the effect of CBPs on absolute CVD or T2DM risk, there is a need for studies with a longer time to follow-up. Overall, some concluding observations can be made: the effectiveness of CBPs is greater in participants who are at high risk than in participants with a lower risk. Furthermore, extensive programs with a multiple risk factor approach and long-term follow-up booster sessions appear to work best.

Examples of such studies are the Diabetes Prevention Program (Knowler et al. 2002), the Diabetes Prevention Study (Lindstrom et al. 2003), and the Da Qing Study (Pan et al. 1997). However, criticism that is often heard is that the interventions that work best are very labor-intensive. For instance, in one study 16 face-to-face sessions provided by case managers were needed to achieve the target weight reduction and exercise levels (Knowler et al. 2002).

Theory is the only foothold we have in the development of behavioral dietary and physical activity interventions, and the application of theory should improve the likelihood of effectiveness of the

Table 210.6 Key features of motivational interviewing (Miller 1983)

1. Express empathy
   (a) Acceptance and understanding facilitates change
   (b) Skillful reflective listening is fundamental
   (c) Ambivalence is normal
2. Develop discrepancies
   (a) Awareness of consequences is important
   (b) Engage in a discussion between present behavior and valued goals
   (c) Participant-driven rationale for change
3. Avoid argumentation
   (a) Arguments are counterproductive
   (b) Judging (why?) breeds defensiveness
   (c) Resistance is a signal to change therapeutic strategies
   (d) Labeling is unnecessary
4. Roll with resistance
   (a) New perceptions are invited but not imposed
   (b) The participant is a valuable resource for solutions
   (c) Collaboration is valued
   (d) Mutually negotiated solutions
5. Support self-efficacy
   (a) Hope is motivating
   (b) Participant is responsible for choosing and initiating
   (c) There is hope in the range of alternatives

Table 210.7 Key stages of problem-solving treatment (Mynors-Wallis 2005)

Problem-Solving Treatment consists of seven stages:
1. Explanation and rationale
2. Problem definition
3. Establishing SMART goals
4. Generating solutions
5. Selecting preferred solution
6. Implementing solution
7. Evaluation of progress

interventions (Brug et al. 2005). Theories stimulate researchers to consider which elements should be included in their intervention, and why. Such programs therefore need to be theory-driven. Behavioral change theories are conceptual models that can be used to chart the biological, cognitive, behavioral, psychosocial, and/or environmental determinants of changes in an individual's behavior. Theories also provide a good basis for evaluation of the intervention, not only in terms of "does it work", but also: "how does it work?" This is an important issue, because in this way it is possible to determine which elements are effective in the intervention, or, on the other hand of equal importance, why an intervention was ineffective (Michie and Abraham 2004).

Although many traditional theoretical models have been used as a framework for various interventions, they have only been able to explain the variance in actual behavioral change to a limited extent. More understanding of the determinants that precede behavioral change may result in the development of more integral models, which include, for instance habit strength. It is suggested that frequently performed behavior is often a matter of habit, which does not involve repeated decision making (Aarts et al. 1998). This has consequences for our view of models in which intentional determinants are used to predict behavior, e.g. as in the TPB. It is even suggested that traditional health education approaches may have limited value for strongly habitual health-related behaviors (de Bruijn et al. 2009).

Although they form a population that experiences the most problems due to an unhealthy lifestyle, people of lower socioeconomic class are less likely to participate in lifestyle interventional trials (Lakerveld et al. 2008a). Changing health behavior can only be effective if the program is tailored with the orientation and knowledge of the target population. For example, the more externally oriented locus of control of people of lower socioeconomic class implies that they less frequently believe that changing their behavior will have an effect on their health, which makes it more difficult for them to change their behavior. This might partly explain why they benefit less from lifestyle interventions than people in higher socioeconomic classes do. In addition, people of lower socioeconomic class often live in a deprived neighborhood, which in itself is a risk factor for unhealthy behavior, because of greater exposure to unfavorable physical and social factors. Measures can be taken to increase the number of participants in an intervention, such as making it convenient for them to join a program and reducing the barriers for participation. Locating the program in close proximity to the homes of the participants, or offering incentives, might be helpful in this respect. The challenge is to reach this subgroup, in order to eliminate health disparities among different segments of the population.

Generating a long-lasting change in lifestyle behavior in order to reduce the modifiable risk factors for CVD and T2DM is difficult and complicated, but not impossible. Although promising results of trials have been published, solid, theory-driven trials with a long follow-up period are still needed in order to make it possible to determine the effectiveness for cognitive behavioral programs on absolute CVD or T2DM risk reduction.

Currently, a start has been made by undertaking a comprehensive RCT to study the effectiveness of a CBP aimed at lifestyle changes in people who are at risk (Lakerveld et al. 2008b). The program addresses several components of the TPB and the theory of self-regulation, and makes use of the effective components and instruments of change that are described earlier. The specific focus is on motivation and self-management to achieve change in structural lifestyle behavior. The counseling methods that are used in the intervention are MI and PST. MI is used with the aim to reinforce the participant's attitude and behavioral intention (according to the TPB), and elicit, clarify, and resolve ambivalence associated with behavioral change (see also Tables 210.6 and 210.7). PST is then used to support the participant in finding ways to overcome this discrepancy, to strengthen the participant's perceived behavioral control, and to provide the tools to overcome barriers that hinder a structural change in lifestyle behavior. Nurse practitioners in the participating general practices provide these counseling sessions. The participants receive a maximum of six individual 30-min counseling sessions, followed by 3-monthly booster sessions by phone for a period of 1½ years. The primary outcome measures are the diabetes risk score and the cardiovascular risk score. The risk of developing diabetes will be assessed by means of a risk function, calculated according to data from the ARIC Study (Schmidt et al. 2005). Absolute cardiovascular risk will be assessed with a risk score, calculated according to the SCORE project (Conroy et al. 2003). Secondary outcome measurements include differences in lifestyle behavior (dietary behavior, physical activity behavior, and smoking behavior) and the cost-effectiveness and cost-utility of the CBP.

A process evaluation will be carried out to study the effective and ineffective elements of the intervention. This will provide information on aspects of the study that may increase or reduce the effectiveness of the program, and could be valuable for the further development of interventions that are (more) effective and feasible.

In our opinion, there are certain requirements that must be met by the participants in order to achieve successful behavioral change: first of all, they need to realize that they are at higher risk; second, they need to be willing to change; and third, they need to be able to change. To meet these requirements, specific "instruments of change" might be of use; e.g. risk communication, MI and/or PST, respectively.

210.5 Applications to Other Areas of Health and Diseases

Some instruments that are used in CPBs for CVD and T2DM risk reduction are derived from other health fields in which they are effectively applied. For instance, MI is used extensively for psychological diseases and the treatment of addiction to smoking and alcohol (Rubak et al. 2005).

PST (with the T standing for *therapy* instead of *treatment*, in this case) has been applied for a wide range of psychological disorders in many areas. For example, it has been found to be suitable for deliberate self-harm patients (in reducing rates of depression, hopelessness, and suicidal ideation after a suicide-attempt), for strengthening problem-solving abilities and assertiveness in mildly mentally retarded people, in palliative care, and in diabetes care.

Summary Points

- Lifestyle interventions based on behavioral or cognitive behavioral strategies are more effective than health education or instruction alone.
- Programs need to be theory-driven.
- The effectiveness of programs is greater in participants who are at high risk of developing CVD or T2DM than in participants with a lower risk.
- An approach combining diet and physical activity appears to be the most effective.
- Intensive and long-term involvement with the participants will more likely result in a structural behavioral change.
- Promising instruments of change are: risk communication, motivational interviewing, and problem-solving treatment.

Key Terms

Cognitive behavioral program: Aims to help participants or patients change the way of thinking, feeling, and behaving. It is used as a treatment for various mental health and physical problems, but also to change unwanted lifestyle behaviors such as smoking, physical inactivity, or an unhealthy diet.

Cardiovascular disease: Refers to the class of diseases that involve the heart or arterial blood vessels. Examples of cardiovascular diseases are cerebrovascular accident (stroke) and myocardial infarction (heart attack).

Type 2 diabetes mellitus: The most common form of diabetes. This chronic (lifelong) disease is marked by high levels of glucose in the blood. Family history and genetics play a large role. Low activity level, poor diet, and excess body weight (especially around the waist) increase the risk for type 2 diabetes.

Risk communication: An interactive process of exchanging information and opinions on health risks between participants or patients and caregivers.

Motivational Interviewing: Is a directive, client-centered counseling style for eliciting behavior change by helping clients to explore and resolve ambivalence.

Problem-solving treatment: A fairly short and simple treatment. It can be provided by a doctor or a trained nurse or counselor. Participants or patients are taught how to cope with problems and helps them to take small steps toward coping.

Key Features of Cognitive Behavioral Programs

- The term cognitive behavioral program is used in various ways to refer to programs based on behavior therapy, cognitive therapy, or a combination of these two.
- Cognitive behavioral therapy is traditionally used to treat depression, but nowadays its foundation is also employed in other areas, for instance in lifestyle behavioral change interventions.
- Habits (such as unwanted lifestyle behaviors) are acquired and can be unlearned using cognitive behavioral programs.
- Cognitive behavioral programs are based on the idea that thoughts, emotions, and behavior interact closely.
- Influencing the participant's concepts is a key element to influence emotions and behavior.
- The emphasis is on the behavior at present and in the future, rather than behavior in the past.
- cognitive behavioral program can be done individually or with a group of people.

211.1 Introduction

The worldwide prevalence of diabetes is currently 150 million and is expected to increase to 300 million by the year 2025. The global obesity epidemic is contributing to a rapid increase in diabetes prevalence. People with diabetes are more likely to experience limitations in mobility, social role function, and activities of daily living. Given the growing disability burden of diabetes, a better understanding of ways to help people with diabetes sustain active, productive, and fulfilling lives is needed. The identification of modifiable factors associated with disability in diabetes may lead to methods for reducing the disability burden of this common chronic disease.

According to the most recent recommendations of worldwide nutrition studies, changes in dietary composition could play a significant role in improving insulin sensitivity and reducing the risk of diabetes and its complications. The brain senses and then responds to nutrient-related signals arising from changes in intracellular energy content or the availability or metabolism of substrates such as free fatty acids. Dietary changes may reduce the risk of diabetes.

211.2 Obesity in Diabetes

211.2.1 Overview

The incidence of obesity and type 2 diabetes is increasing throughout the world. A World Health Organization (WHO) consultation on obesity recently summarized prevalence data and found that the incidence was increasing not only in the Western world but also in all other regions. The association between obesity and the risk of developing type 2 diabetes has been repeatedly observed in both cross-sectional and prospective studies. In particular, central abdominal obesity is predictive of the development of type 2 diabetes (Lundgren et al. 1989; Ohlson et al.1985). Although there is a general agreement that obesity and type 2 diabetes can, to a certain extent, be explained by genetic factors, the rapid increase over the last few years indicates that the environment, rather than genetic make-up, is responsible for the increase (Campbell et al. 2001).

Body mass index (BMI) and body weight gain are strongly associated with diabetes risk (Colditz et al. 1995). A weight gain of 11–20 kg in 14 years of follow-up increased the age-adjusted relative diabetes risk 5.4-fold in female nurses who had normal weight (BMI, 22–25 kg/m^2) at age 18 years relative to nurses with normal weight at age 18 years who had no weight gain or a weight loss of more than 5 kg. In addition to overall obesity, body fat distribution, especially increased intra-abdominal fat, is a predictor of type 2 diabetes (Chan et al. 1994; Han et al. 1998). The BMI of middle-aged women was strongly correlated with the 3-year incidence rates of type 2 diabetes (Mishra et al. 2007), whereas annual weight changes during this period did not significantly predict the onset of type 2 diabetes (Mishra et al. 2007).

211.2.2 Glycemic Control and Weight Management in Diabetes

The results of large studies such as the Diabetes Control and Complications Trial (DCCT) (9) have demonstrated that glycemic control is an essential factor for improving clinical outcomes for people with diabetes. Intensive therapy strategies designed to lower blood glucose concentrations reduce microvascular complications such as retinopathy and nephropathy. Weight gain was significantly greater in the cohort of patients receiving intensive treatment with insulin or sulfonylureas relative to the cohort receiving dietary intervention and conventional treatment (Gottesman 2004). These results suggest that the health-care provider must strive to maintain a balance between achieving glycemic control and controlling weight when designing a treatment regimen (Fig. 211.1) for an individual patient. In obese people with type 2 diabetes, weight loss clearly improves hyperglycemia and lowers the risk of comorbidities such as hypertension and dyslipidemia (Wing et al. 1987). Dietary therapy can reduce fasting blood glucose levels in overweight type 2 diabetic patients, although the degree of improvement is influenced more by the restriction in caloric intake than by body weight (Wing et al. 1987). Moreover, caloric restriction has an important regulatory effect on metabolism that is independent of weight loss; reducing caloric intake often improves glycemic control more rapidly than weight loss (UKPDS 1990).

211.2.3 Dietary Composition

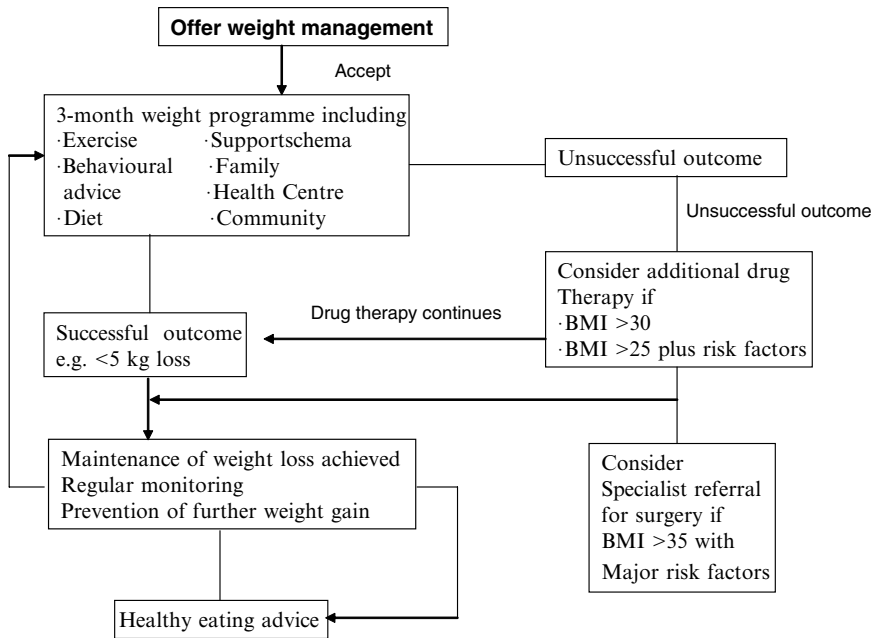
Appetite may be influenced by a variety of physiological, psychological, emotional, and cultural factors. It has long been established that a transient decline in blood glucose is recognized by the


Fig. 211.1 Standard procedure for treating obesity in Type 2 diabetes. The standard procedure takes the Type 2 diabetes patients into account as well and constitutes a simple straightforward approach to successful long-term treatment of the obese Type 2 diabetes patients. To integrate the factors of diet, exercise, drug therapy, and environment, this procedure is a key to successful long-term treatment for obesity

central nervous system and influences hunger and meal-seeking behavior (Campfield et al. 2003). Blood glucose dynamics and diet are linked in a complex relationship, and strategies to regulate blood glucose levels must be designed depending on the diet.

Controversy still exists regarding whether lowering of dietary fat intake enhances weight loss by itself, rather than through energy restriction. Majority of the evidence shows that energy restriction is the overriding factor linked to weight loss in type 2 diabetes after the consumption of usual low-fat, high-carbohydrate diets (NIH 1998). While weight loss relates to energy deficit alone, the composition of the weight-reducing diet can, however, affect glycemia and lipid levels. Replacement of saturated fat with either monounsaturated fat or carbohydrates was shown to equally affect weight loss in obese diabetic subjects and positively affect lipid levels, supporting other evidence that energy content is the major determinant of weight loss (Gumbiner 1999); the replacement of saturated fats was achieved by advising the subjects to replace certain foods. The study questions the dogma that still governs dietary instruction in diabetes, and emphasizes the need to make dietary changes as simple as possible for diabetic patients already burdened with the procedures associated with managing diabetes (NIH 1998). As yet, no scientific evidence exists to show that greater or more sustained weight loss occurs in diabetes by such manipulations as the intake of foods with low glycemic index or raising the protein proportion in the diet, although there is some concern with regard to the possible adverse effects associated with the consumption of high-protein foods by diabetic subjects. Similarly, very-low-calorie diets result in more rapid weight loss initially, but the weight loss is not sustained in the long term (Heilbronn et al. 1999). Such low-calorie diets could predispose to greater binge-eating activity and are recommended in medical emergencies, and should be accompanied with careful monitoring of glucose levels and early reduction in medication (Garner et al. 1998).

To conclude, multiple components of a healthy diet, e.g., high fiber and low saturated fats, reduce diabetes risk and contribute to sustained weight loss; they should therefore be included in long-term

lifestyle interventions. Dietary composition plays a key role in diabetes prevention, primarily by sustaining long-term weight loss and secondarily by initiating weight loss and reducing the risk of diabetes.

211.2.4 Nutritional Education and Coping Skills Training in Diabetes

Prediabetic individuals or those with diabetes should receive individualized nutritional education, preferably provided by a registered dietitian familiar with diabetes nutritional education. Behavioral factors (including missing meals, alcohol intake, lack of exercise, and poor recognition of the need to self-treat) also contribute to hypoglycemia risk. These risk factors can be modified with patient education (Boyle et al. 2007).

Autonomy in daily treatment will enable patients to introduce behavioral adaptations in their daily life, thereby allowing them to control the disease throughout their life-span. Nutritional education would allow for a permanent, voluntary, and conscious change in habits and eating behaviors. Eating behavior appears to be a reflection of the individual's personality, with its strengths and weaknesses; rational beliefs; and family and personal history. Major barriers to weight loss that are often overlooked are psychological and behavioral factors. Many people eat in response to negative emotions. To save time, questionnaires can be sent out to the patient as a means of self-evaluation before their weight management appointment; the successful completion of the questionnaires can serve as an indicator of the patient's level of motivation and compliance. Psychological evaluation should include determining possible underlying depression. If the patient is found to be suffering from depression, this factor should be considered as part of the patient's weight management (Plodkowski et al. 2003).

The six key behaviors (strategies) that successful weight-loss maintainers use include (i) a low-calorie, low-fat diet; (ii) eating breakfast; (iii) consistent patterns of eating; (iv) high levels of physical activity; (v) regular self-monitoring of weight; and (vi) preventing weight regains from turning into big relapses (Wing et al. 2001). Diabetes requires a substantial degree of patient involvement for effective self-management. Although diabetes education has been the standard of care, it is clear that provision of knowledge alone does not change behavior. Coping skills training (Fig. 211.2) is a cognitive–behavioral intervention that focuses on improving competence and mastery by retraining

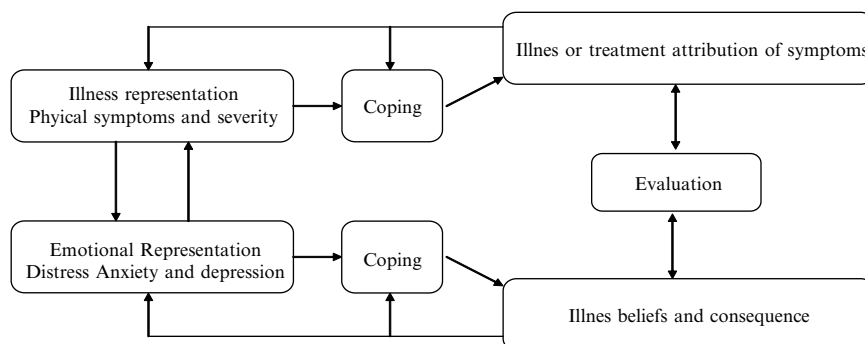

Fig. 211.2 A dynamic model of coping skills training in health and Illness. This model includes the treatment perceptions and the common-sense model of self-regulation behaviors. It reflects a dynamic interaction between the three stages (representation, coping, and appraisal) and parallel processing: cognitive and emotional processes may operate independently, although they generally interact

inappropriate or nonconstructive coping styles and patterns of behavior into more constructive behavior.

Cognitive–behavioral modification is comprised of three steps: (i) recognition of thoughts and feelings; (ii) problem solving; and (iii) guided self-dialogue. The first step is encouraging the individual to reflect on how they think and then respond to situations. The individual's thoughts are then assessed to determine whether the thoughts are based on fact or assumption. Once the thoughts are assessed, the next step is to solve the patient's social problem(s). The third step is teaching the individual to use his or her thoughts to guide the decision made in the previous step. A pen and paper should be used when teaching this skill. Group members can list their negative thoughts and then the member and the group can formulate alternate positive thoughts to counter the negative thoughts (Grey et al. 2004). However, further studies on the relationship between behavioral interventions using problem solving and glycemic and psychosocial outcomes in adults should be carried out. Coping skills training may still be an important methodology for health-care providers to use in assisting patients to control blood glucose levels and lose weight, in combination with nutritional education and exercise to decrease BMI, hypertension, or hyperlipidemia (Grey et al. 2004).

211.3 Gastrointestinal Complications in Diabetes

211.3.1 Overview

GI motility disturbances, including esophageal motor dysfunction, gastroparesis, intestinal enteropathy (which can cause diarrhea and constipation), are often found in a substantial number of patients with diabetes mellitus (Fig. 211.3). Cross-sectional epidemiological studies suggest that the prevalence of GI symptoms is increased in both type 1 and 2 diabetic subjects (Bytzer et al. 2001a). Some studies have noted that the incidence of GI motility disturbances is higher in female diabetic patients than in males (Bytzer et al. 2001b). Gastropathy may result in delayed emptying of solids and ingestible particles, rapid emptying of liquids, bezoar formation, malnutrition, and weight loss.

The causes of GI motility disturbances remain unclear. Autoimmune damage; metabolic insults that alter critical cellular pathways and essential trophic factor signaling, resulting in smooth muscle atrophy and neural apoptosis; and transdifferentiation (Horvath et al. 2006; Rayner et al. 2006) have been suggested as causes in the literature. Other potential etiologies of intestinal dysfunction in patients with diabetes include ischemia and hypoxia due to microvascular disease of the GI tract; mitochondrial dysfunction (Leinninger et al. 2006); the formation of irreversible, advanced glycation end products; and peroxynitrite-mediated endothelial and enteric neuron damage (Hoeldtke et al. 2002). In vitro studies also suggest that hyperglycemia can induce apoptosis of enteric neurons and impair phosphatidylinositol 3-kinase (PI3K) pathway activity. However, apoptosis can be prevented by glial cell-derived neurotrophic factors (Rayner et al. 2006; Leinninger et al. 2006).

Several issues should be considered while treating a patient with GI dysmotility, such as the patient's nutritional status, pain management, prokinetic therapy, symptom suppression, and the consideration of endoscopic or surgical management. Attention to nutritional status is of paramount importance in the management of these patients. Specific deficiencies should be identified and appropriate replacements instituted (Sellin et al. 2008).
Fig. 211.3 Possible complications involved in gastrointestinal motility disorder. Diabetes can potentially affect any part of the gastrointestinal tract. The common gastrointestinal complications of diabetes include dysphagia, gastroesophageal reflux disease, gastroparesis, diarrhea, and constipation

211.3.2 Esophageal Complications and Treatment

Up to 50% of diabetic patients have esophageal abnormalities, including GI motility disturbances and/or acid reflux (Kinekawa et al. 2001). In a previous study, esophageal symptoms were found to be slightly more prevalent in patients with diabetes than in control subjects; however, they were proportionately less common than measured changes in motility (Talley 2003).

Esophageal complications of diabetes can be successfully treated. Gastroesophageal reflux disease (GERD) can be managed effectively with medicines that are conventionally used to reduce acid reflux. Antireflux surgery, however, is recommended only for patients with disease that is refractory to medical treatment. Patients with oral and esophageal candidiasis are treated effectively by improving glycemic control and administering oral antifungal agents, such as fluconazole. Symptomatic dysphagia, however, is more difficult to manage, particularly in the presence of advanced diabetic motor neuropathy. In these cases, early diagnosis of dysphagia is important, and glycemic control should be resorted to for treating this reversible condition (Sellin et al. 2008).

211.3.3 Diabetic Gastroparesis and Treatments

211.3.3.1 Symptoms and Diagnosis

Diabetic gastroparesis usually occurs during the onset of chronic diabetes; it is a frequent and sometimes troubling complication of the disease. Epigastric fullness, bloating, nausea, and vomiting may be indications of gastroparesis. These symptoms, although nonspecific, are caused by delayed gastric emptying (Lysy et al. 2006). Recurrent symptoms have a deleterious impact on nutrition and

limit the ability of oral hypoglycemic agents to control blood sugar. Recurrent episodes of hyperglycemia have been linked to delay gastric emptying (Lysy et al. 2006). The assumed pathogenesis of this link is that chronic hyperglycemia leads to neuropathic changes and dysfunctional innervations of the stomach and, therefore, to delayed gastric emptying and alteration of antroduodenal motility (Horowitz et al. 2005), which induces a sense of fullness.

Hyperglycemia can limit the efficacy of some prokinetic agents (Rayner et al. 2005). These findings were found to be statistically significant, but it is not clear whether they are clinically meaningful. Nevertheless, glycemic control remains the bedrock of therapy for diabetic gastroparesis. Hormonal changes might also be an important factor in diabetic gastroparesis.

A diagnosis of diabetic gastroparesis is usually made on the basis of the patient's medical history. Physical examination does not usually aid in diagnosis. Delayed emptying of a labeled solid material in the absence of any anatomic abnormalities is considered diagnostic for gastroparesis. Concomitant GI can be ruled out through endoscopy. The most useful diagnostic technique for gastroparesis is nuclear scintigraphy. Other techniques that have been used for diagnosing gastric emptying in previous studies include breath tests, the use of radiopaque markers, electrogastrograms, capsule endoscopy, and measurement of antroduodenal motility (Sellin et al. 2008).

211.3.3.2   Dietary Modification

Products of fat digestion are known to slow gastric emptying, while nondigestible solids may predispose to gastric bezoar formation. Therefore, small-volume, frequent meals, that are low in insoluble fiber and fat are generally recommended, despite a lack of evidence to support this approach (Rayner et al. 2005; Abell et al. 2006) Thorough chewing, remaining upright for 1–2 h postprandially, and supplementation with multivitamins have also been advocated. Increasing the proportion of energy provided as liquids rather than solids may be beneficial because delayed liquid emptying is rare. An elemental diet is limited by unpalatability (Kuo et al. 2007) but may be a short-term option, despite the lack of evidence to support its superiority over polymeric feeding. Total parenteral nutrition is expensive and impractical, and is associated with potentially serious complications, including sepsis.

Indications for nutritional supplementation include weight loss of ≥10% during a period of 3–6 months, inability to maintain recommended body weight, and severe symptoms requiring hospitalization or nonpharmacological intervention (e.g., nasogastric tube to relieve nausea and vomiting) (35,36 Rayner et al. 2005; Abell et al. 2006).

211.3.3.3   Therapeutic Options

Therapy depends on the severity of symptoms, the ability of patients to maintain adequate nutrition, and their responsiveness to therapy. The primary aim of therapy is to optimize glycemic control. Hyperglycemia induces the development of autonomic neuropathy; blood sugar control can be used as a possible approach to reverse abnormal motility. Beyond the critical factor of glycemic control, the treatment of diabetic gastroparesis is similar, in general, to that of regular gastroparesis. Therapies may involve diet modification, pharmacotherapy, and more invasive approaches to treat "gastric failure." A low-fat, low-residue diet accompanied by frequent small meals can minimize postprandial fullness. Avoidance of nutrients that delay gastric emptying (fat, fiber) may also improve gastroparesis (Abell et al. 2006).

Several therapeutic agents (Tables 211.1 and 211.2) are available to treat patients with diabetic gastropathy. These include prokinetic and antiemetic agents, as well as analgesics for pain management.

Table 211.1 Treatment options for gastroparesis disorder

Treatment	Mechanism	Adverse effects	Evidence comments
Metoclopramide (Reglan), 10 mg four times daily	Serotonin(5-HT3)receptor antagonist, central dopanine(102)receptor antagonist	Dystonic reactions, tardive dyskinesia extrapyramidal symptoms hyperprolactinemia	Symptoms improved in 25–62% of patients
	Normalize gastric slow-wave dysrhythmias by inhibiting gastric smooth muscle relaxation produced by dopamine		Physicians should discuss the risk of tardive dyskinesia with their patients and document this discussion in the medical records
Erythromycin 250 mg three times daily	Motilin receptor agonist Prokinetic effects via action on gastroduodenal motilin receptors	Nausca, vomiting abdominal pain: antibiotic resistants	Most studies are open-label design
Bethanechal (Urechaline) 25 mg four times daily	Nonspecific chalinergic muscarinic receptor agonist	Salivation : blurred vision : abdominal cramps and bladder spasm	Not a ture prokinetic agent
Batinlitmen laxin type A (Botox)	Inhibits acetylchaline release from synaptic vosicles in pylorus		Most studies are open-lable design
Surgery	Gastric decompression, partial gastrectomy with Roux-en-Y gastriojejunostomy		No well-designed studies for diabetic gastroparesis studies are nonrandomoized, unblendded, or care series
Gastric electric stimulation	Electric stimulation with high-energy, long-duration pulses	Possible infection, gastric erosion	No well-designed studies; more data are needed

This table lists the key facts of treatment options for gastroparesis. Treatments are listed in order from most to least likely to be used (Sellin et al. 2008). Therapeutic considerations depend on the severity of symptoms, the ability of the patient to maintain adequate nutrition and their responsiveness to therapy. Generally, more severe symptoms still require pharmacologic intervention

Table 211.2 Common used prokinetic drugs

Drug	Mechanism of action	Administration route	Dose(mg)	Adverse reactions
Erythromycin	Motilin agonist	IV, oral	50–250 (3-4 times per day)	Nausea, vomiting, abdominal pain, arrhythmia
Cisapride	5-HT4-receptor agonist: 5-HT3-receptor antagonist	Oral	10-20 (2-4 times per day)	Arrhythmia, abdominal pain, diarrhoea, headache
Metoclopramide	D2-receptor antagonist: 5-HT3-receptor antagonist; 5-HT4-receptor agonist	IV, SC, IM, oral	10	Dystomia, tardive dyskinesia, sedation, hyperprolactinaemia
Domperidone	D2-receptor antagonist	Oral	10–20 (2-4 times per day)	Hyperprolactinaemia, dry mouth, headache

This table lists the key facts of the most commonly used prokinetic agents include metoclopramide, domperidone, erythromycin and cisapride. The mainstay of pharmacological therapy of the gastroparesis is the use of prokinetic agents. The aim of therapy is to improve symptoms by accelerating gastric emptying, despite a poor correlation between the two (Kuo et al. 2007)

5-HT serotonin, *D* dopamine, *IM* intramuscular, *IV* intravenous, *SC* subcutaneous

The prokinetic effect is theoretically elicited through a coordinated set of pressure waves moving through the antrum, pylorus, and duodenum. However, there is little evidence of their efficacy in GI motor disorders; further, they are associated with a high prevalence of side effects outside of the GI tract. Both metoclopramide and domperidone are antagonists of dopamine receptors that may inhibit gastric emptying, although the dopamine receptor-mediated pathway in the brain stem may regulate nausea. Metoclopramide and domperidone exert their therapeutic effect by blocking these actions. Metoclopramide can also act as an agonist of 5-hydroxytryptamine receptor subtype 4 (5HT-4) to stimulate the cholinergic neural pathway in the stomach (Kuo et al. 2007). Metoclopramide is the most widely used drug for the treatment of diabetic gastroparesis because it brings about short-term improvements in both symptoms and gastric emptying rates. Patients are often treated with meto-clopramide for long-term management of diabetic gastroparesis, but its real efficacy has not been proven (Camilleri et al. 2007).

Erythromycin acts as a molecular mimic of motilin to stimulate motor activity, primarily in the upper GI tract. Erythromycin binds to the motilin receptor and initiates similar biologic effects. Erythromycin administered in low doses (50–100 mg) will effectively correct gastroparesis even in patients with refractory symptoms. Erythromycin administered intravenously and as an oral liquid suspension are more potent prokinetic agents than the tablet form (Abell et al. 2003). Cisapride and tegasorod are 5HT-4 agonists that induce the release of acetylcholine from myenteric cholinergic neurons along the GI tract. They are available in both tablet and suspension form (Lata et al. 2003).

There are also some innovative approaches to treat diabetic gastroparesis. An intrapyloric injection of botulinum toxin may decrease pylorospasms associated with gastroparesis and can improve symptoms (Jones 2002). Moreover, no serious adverse effects have been noted. Gastric electrical stimulation as a therapeutic modality for diabetic gastroparesis is an attractive concept that involves surgical intervention; however, the device sometimes has to be removed because of complications (Bromer et al. 2005). In individuals who are undernourished, enteral feeding can be an option. Nevertheless, surgery for treating gastroparesis should be resorted to as a last option; however, post-operative complications limit the efficacy of surgical intervention in the treatment of diabetic gastro-paresis (Abell et al. 2003).

In sum, complications can most often be resolved with simple approaches such as dietary modi-fication. As the severity of symptoms increases, a more aggressive approach must be considered if patients fail to respond to more conventional approaches. However, possible therapeutic options are limited and are not necessarily evidence based.

211.3.4 Intestinal Complications and Treatments

211.3.4.1 Diarrhea

Diarrhea is a more clinically relevant and troubling problem in patients with diabetes. There are at least two possible causes of diabetic diarrhea. The first is impaired adrenergic regulation of fluid and electrolyte transport secondary to decreased α2-adrenergic input. The second is slow intestinal transit and subsequent bacterial overgrowth. Nonetheless, multiple other etiologic factors must be considered in the clinical evaluation of diabetic diarrhea. Possible etiologies include rapid intestinal transit, bacterial overgrowth, medications (e.g., metformin, acarbose, or miglito), the use of artificial sweeteners, celiac disease, pancreatic insufficiency, or nondiabetic diarrhea.

It is commonly assumed that the rate of small bowel transit is reduced, leading to bacterial over-growth in patients with diabetes. However, rapid gastric emptying can also accompany decreased intestinal transit times. Individuals with diarrhea and associated autonomic neuropathy, primarily

diabetic, can have an extremely rapid orocecal transit time (<20 min) and a positive glucose or lactulose hydrogen breath test (Watkins et al. 2003). Differentiation of rapid-transit from slow-transit diarrhea is important. Antibiotic treatment is appropriate for slow-transit diarrhea with bacterial overgrowth, whereas rapid-transit diarrhea might be more effectively treated with more conventional antimotility drugs such as loperamide.

Therapeutic strategies should be specifically tailored to target the underlying pathophysiology, which include diet modification for patients with celiac disease or rotating antibiotics for those with bacterial overgrowth in the small bowel. If the specific cause of diarrhea cannot be identified, empiric therapy with basic antidiarrheal agents (e.g., loperamide) is a reasonable starting point. A trial of clonidine is an option for patients in whom it is well tolerated. Although there have been reports on the effectiveness of octreotide in patients with diabetic diarrhea (Camilleri et al. 2007), its use is often not required.

211.3.4.2 Celiac Disease

Between 3% and 8% of individuals with diabetes have celiac disease. Celiac disease is a genetic autoimmune disease in which an immune response is triggered by the consumption of foods containing gluten – wheat, rye, and barley. The disease is characterized by a range of symptoms that can include gas, bloating, diarrhea, weight loss, and other gastrointestinal problems. Most people who have celiac disease do not know they have it, and some are asymptomatic. The symptoms are diverse and nonspecific (Hill et al. 2005). The introduction of the tissue transglutaminase test (TTG) (Greenberg 2008) has simplified the diagnosis of celiac disease.

Celiac disease is treated entirely through dietary management, which consists of removal of gluten from the diet; such a gluten-free diet is a lifelong dietary requirement (Table 211.3). Further, temporary nutritional supplementation may be provided to patients suffering from clinical disorders related to celiac-induced nutritional deficiencies. Once a patient has been established on a gluten-free diet, most guidelines recommend annual TTGs to monitor continued intentional or unintentional gluten exposure. In addition, follow-up through dietary review is also considered helpful.

211.3.4.3 Constipation

Constipation and the use of laxatives are relatively common in patients with diabetes (Maleki et al. 2000). The prevalence of constipation is higher in women than in men and is more prevalent among patients with diabetes who are taking medications that promote constipation (e.g., Ca^{2+} channel

Table 211.3 Gluten-free foods

Foods of these types that are fresh (nonprocessed) and unseasoned are gluten free
Meat; fish; milk; juice, coffee; tea; cheese; fruit; vegetables; potatoes; rice; butter; cream; olive oil…
Processed foods that are usually gluten free
Popcorn, corn chips, potato chips; chili; yogurt; Asian soups with rice noodles; ice cream; many candies…
Foods that normally contain gluten can be purchased gluten free
Pasta; pizza; bread; crackers; cookies; cake mixes; soup mixes; soy sauce…

Treatment of celiac disease is entirely through dietary management, which consists of removal of all gluten from the diet. The gluten-free diet is a lifelong dietary requirement. This table lists the key facts if the sorts of gluten-free foods. Patients should be instructed to always check tables packaged foods to ensure that ingredients are gluten free

blockers) (Maleki et al. 2000). In this patient population, constipation most likely results from slow transit caused by smooth muscle myopathy, autonomic neuropathy, or neuroendocrine imbalances.

The radiopaque marker method, a noninvasive technique for measuring colonic stool transit frequency, provides information on segmental colonic transit time. Prolonged colon transit in diabetic patients, particularly in diabetics with constipation compared to those without constipation, may be due to a slow transit in the left and rectosigmoid colon. However, delayed transit is not a specific finding in diabetics, since idiopathic constipation is characterized by either exaggerated reservoir functions of the ascending and transverse colon or an impairment of the propulsive function in the descending colon (Darwazeh 1991).

There are no specific treatments for diabetes-associated constipation, although improved glycemic control may be beneficial (Maleki et al. 2000). In most cases, however, diabetic patients are treated the same way as those with idiopathic chronic constipation. In the absence of defecatory dysfunction, bulking agents, osmotic laxatives (e.g., polyethylene glycol 3,350 powder), and stimulant laxatives can be used. The new Cl-channel agonist, lubiprostone, might also be beneficial, as it has been shown to be effective in patients with chronic constipation (Ambizas et al. 2007).

211.4   Conclusions

- According to the most recent recommendations of worldwide nutrition studies, changes in dietary composition could play a significant role in improving insulin sensitivity and reducing the risk of diabetes and its complications.
- Multiple components of a healthy diet (e.g., high fiber and a low saturated fat intake) reduce diabetes risk and contribute to sustained weight loss.
- Coping skills training may be an important methodology for health-care providers to use in assisting diabetic patients to control blood glucose levels and lose weight, in combination with nutritional education and exercise to decrease BMI, hypertension, or hyperlipidemia.
- Strategies for weight loss include decreasing total energy intake, maintaining a balanced deficit diet, increasing physical activity, and adjusting energy balance to prevent weight regain.
- Gastrointestinal symptoms are common in patients with diabetes, but are also prevalent in the general population. Any part of the gastrointestinal tract can be affected, and presenting symptoms depend on the affected parts.
- Treatment should be directed at tighter glycemic control and reduction of symptoms, which can improve the clinical condition of many diabetic patients. However, in some patients, effective clinical management is problematic because no therapies are available to prevent or treat the underlying disease mechanisms (Camilleri et al. 2007).

Key Terms

Obesity: A condition that is characterized by excessive accumulation and storage of fat in the body and that in an adult is typically indicated by a body mass index of 30 or greater.
Gastroesophageal reflux disease: A highly variable chronic condition that is characterized by periodic episodes of gastroesophageal reflux usually accompanied by heartburn and that may result in histopathologic changes in the esophagus – abbreviation GERD.

SCT	Social Cognitive Theory
SLT	Social Learning Theory
SPPA	Self-Perception Profile for Adolescents
TPB	Theory of Planned Behavior
TRA	Theory of Reasoned Action

212.1 Introduction

Public health professionals increasingly recognize that the media have a significant influence on the behavior of young people with regard to nutrition, dieting, eating disorders, body image, overweight, and obesity. In their review of research on the media's influence on health, the Committee on Public Education of the American Academy of Pediatrics (2001) stated that research has shown primary negative health effects on body concept, self-image, nutrition, dieting, and obesity.

L. Bergsma (✉)

P.O. Box 245209, Tucson, Arizona 85724
e-mail: lbergsma@u.arizona.edu

Some researchers estimate that youth spend 33–50% of their waking hours with some form of mass media (Strasburger and Wilson 2002). Children and teens are spending an increasing amount of time using "new media" like computers, the Internet, and video games, without cutting back on the time they spend with "old" media like TV, print, and music. A recent study found that the total daily media exposure of young people increased from 7:29 to 8:33 h between 2000 and 2005, counting time as double when multitasking with two different forms of media (Kaiser Family Foundation 2005). The large amount of time youth spend with media makes it critical to address related health concerns.

Public health professionals have used many strategies to address the effects of media on health. Regulating media content, limiting children's media use, and social marketing are approaches that have been used traditionally, but media literacy education has emerged in the last 20 years as a promising alternative to the censorship of regulating "unhealthy" programming or limiting media use (Heins and Cho 2003). Media literacy has been defined as "the ability to access, analyze, evaluate, and create media in a variety of forms" (Thoman and Jolls 2005). Rather than trying to protect youth from potentially harmful messages, media literacy education to promote health involves them in a critical examination of media messages that influence their perceptions and practices. It is designed to give youth the critical thinking skills necessary to ameliorate the influence of these messages and make healthy choices (Bergsma and Carney 2008).

212.2 Theoretical Foundations

The theoretical foundations for health-promoting media literacy education derive from a combination of the Theory of Reasoned Action (TRA), in which a causal chain of beliefs, attitudes, and behavioral intentions drives *behavior* at the individual level, while Social Learning Theory (SLT) explains that people are learning at the interpersonal level not only from their own experiences, but by observing the actions of others and the benefits of those actions (Glanz and Rimer 2005).

At the interpersonal level, theories of health behavior assume that individuals exist within and are influenced by a social environment. The opinions, thoughts, behavior, advice, and support of the people surrounding an individual influence his or her knowledge, beliefs, attitudes, and behavior. The social environment of youth includes many influences, primary among which are family, friends, school, and the media. It is social learning that is examined in media effects research; for example, see "The Role of Media in Childhood Obesity" (Kaiser Family Foundation 2004) that reviews more than 40 studies on the role of media in the dramatically increasing rates of childhood obesity in the United States.

Social Cognitive Theory (SCT), which evolved from SLT, has been used successfully as the underlying theory for behavior change in areas ranging from dietary change (Baranowski et al. 1993) to pain control (Lorig et al. 1999). Integrating concepts and processes from cognitive, behaviorist, and emotional models of behavior change, it includes the constructs of reciprocal determinism, behavioral capability, expectations, self-efficacy, observational learning, and reinforcement.

212.2.1 Constructs of Health-Promoting Media Literacy Education

Social Cognitive Theory and the Theory of Planned Behavior (TPB), which evolved from the TRA, contain the same additional behavioral construct – that of self-efficacy or perceived locus of control – which falls within the category of individual empowerment. This empowerment construct is also clearly a component of media literacy education. Pioneer media literacy educator Elizabeth Thoman advocates a philosophy of empowerment through media literacy education, based on the work of Paulo Freire (1970, 1973). At the heart of this philosophy is an inquiry process developed into a

construct called the empowerment education spiral and consisting of four components – awareness, analysis, reflection, and action – all designed to enable people to fully comprehend and act upon the content, form, purpose, and effects of media messages (Thoman and Jolls 2005). From a public health perspective, Bergsma (2004) shows that the pedagogical links between health promotion and media literacy can be traced to Freire's empowerment education model.

In addition to *empowerment*, three other constructs must be included within a health-promoting media literacy education intervention to change beliefs, attitudes, intentions, and behaviors. In health promotion, it is generally accepted that knowledge is necessary but insufficient to change health behavior. Therefore, while media literacy education has a knowledge construct that provides information about such things as how and why different forms of media operate as they do, including the manipulating design of advertising, this knowledge alone will seldom result in behavior change, although health-promoting media literacy education research clearly shows that *knowledge about the media and the health issue* can change beliefs and attitudes (Bergsma and Carney 2008). Finally, media literacy education must help people develop the *habits of inquiry* and the *critical analysis and expression skills* that they need to be critical thinkers (National Association for Media Literacy Education 2007) about the health issue, and therefore better informed for making decisions about behavior change.

Health-promoting media literacy education to achieve behavior change addresses people at both the individual level and the intrapersonal level of social interaction with, and learning from, media messages of all kinds, including those from narrative contexts such as film and persuasive contexts such as advertising and promotion. Figure 212.1 posits an integrated individual and interpersonal model for achieving behavior change in which the four constructs of health-promoting media literacy education act as buffering influences between the media environment in which we live (outside the model) and the individual and interpersonal behavioral change constructs of the Theory of Planned

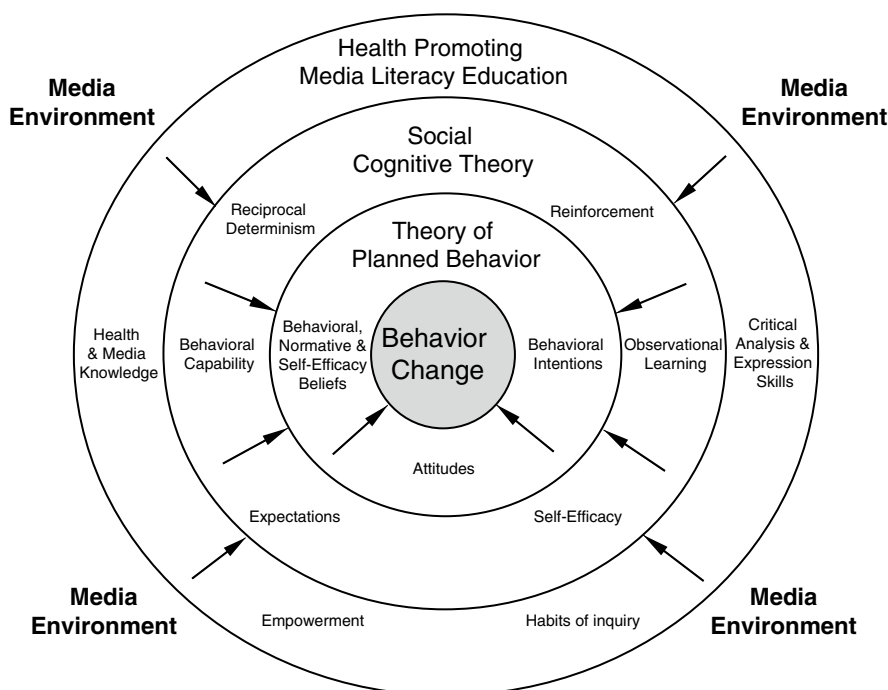

Fig. 212.1 Integrated individual and interpersonal health-promoting media-literacy education model. This figure presents an integrated model of behavior change that involves providing the health information and media literacy life skills necessary for living in a media-saturated environment that can undermine health lifestyle choices

Behavior and Social Cognitive Theory. It is important to note that within these theoretical contexts, people can be influenced both positively and negatively by media messages, resulting in behavior change that is healthy or unhealthy. Health-promoting media literacy education helps establish the media and health knowledge, critical analysis and expression skills, habits of inquiry, and individual empowerment that potentially will lead individuals to make healthy decisions for themselves. It is within this context that we next explore the research literature on the use of health-promoting media literacy education to address dietary-related public health concerns.

212.3 Review of the Literature

212.3.1 Study Selection

A total of 23 studies were reviewed for possible inclusion in this literature review, and five studies were ultimately selected. Studies were reviewed using the criteria established for a prior systematic review of the effectiveness of health-promoting media literacy education (Bergsma and Carney 2008) as follows:

- Studies were published in English from 1990 to December 2008.
- Studies were peer reviewed or dissertations and publicly available via a searchable index.
- Studies described the sample, study design, intervention, and evaluation measures.
- Studies included an experimental media literacy intervention that focused on improving nutrition or reducing eating disorders in youth.
- The media literacy intervention was longer than 25 min.
- Studies focused primarily on teaching critical media literacy skills, and the media literacy intervention was not a smaller part of a larger curriculum.

Six studies were excluded because they did not meet these primary selection criteria. From the remaining 17 studies, five studies were selected to explore here (Table 212.1) because they provided a representative sample of all of the studies examined, they demonstrated effectiveness or served as a foundational study for subsequent research, they were conducted over a 10-year period from 1998 to 2008, they focused on eating disorder prevention, they dealt with study populations of diverse ages, they utilized somewhat similar study designs but diverse intervention lengths ranging from 45 min to 9 h, and they took place in different settings including classroom, community, and laboratory (Table 212.2). They also taught a majority of the five media-literacy concepts (Table 212.3) and they utilized many of the same measurement tools (Table 212.4).

Table 212.1 Five studies selected for review

1. The effect of media analysis on attitudes and behaviors regarding body image among college students (Rabak-Wagener et al. 1998)
2. Primary prevention of disordered eating among preadolescent girls: Feasibility and short-term effect of a community-based intervention (Neumark-Sztainer et al. 2000)
3. Comparison of media-literacy programs to strengthen college women's resistance to media images (Irving and Berel 2001)
4. Media literacy as a prevention intervention for college women at low- or high-risk for eating disorders (Coughlin and Kalodner 2006)
5. The effectiveness of media literacy and eating disorder prevention in schools: A controlled evaluation with 9th grade girls (Dysart 2008)

This table presents the titles of the five studies reviewed in this chapter along with the citation for each study

Table 212.2 Key points for comparison of studies

Study author(s)	Rabak-Wagener et al. (1998)	Neumark-Sztainer et al. (2000)	Irving and Berel (2001)	Coughlin and Kalodner (2006)	Dysart (2008)
Focus	To investigate how a media literacy education intervention that focused on critiquing popular fashion advertisements and creating more inclusive fashion advertisements would affect beliefs and behaviors about individual body image	To promote body acceptance and prevent dieting behaviors among preadolescent girls via enhancement of media literacy and advocacy skills.	To compare the effectiveness of two distinct media literacy interventions at reducing body dissatisfaction and increasing skepticism about media messages that depict a thin ideal of beauty	To reduce eating disorder risk factors, particularly internalization of the thin body ideal and body dissatisfaction, and to determine the degree to which level of risk for an eating disorder (low or high) interacts with the effects of media literacy	To reduce primary eating disorder risk factors, including sociocultural attitudes toward appearance, self-perception, relevant eating disorder behaviors, body dissatisfaction, drive for thinness, bulimia behaviors, thin body ideal internalization, self-esteem, and anxiety about physical appearance.
Theoretical basis	Media advocacy reframing theory	None discussed	Cognitive model of emotional response and the message interpretation process model (Austin and Johnson (1997))	Sociocultural model of eating disorders and cognitive–behavioral theory	Social cognitive theory, cognitive dissonance theory, cognitive–behavioral theory, social comparison theory, Identity theories of psychosocial development, and feminist theories
Sample population (n)	105 female & male undergraduate students from healthful living classes at a medium-sized metropolitan university in the Midwest U.S., aged 18–23. Intervention = 44 women & 16 men Control = 31 women & 15 men	226 female fifth and sixth grade students from 24 Midwestern Girl Scout troops, average age 11. Intervention = 115 Control = 111	110 female college students from an introductory psychology classes at Washington State University, average age 19. Internally oriented intervention = 31 Externally oriented intervention = 27 Video-only intervention = 28 Control = 24	92 female undergraduate students in introductory women's studies courses at a rural university, average age 20. Intervention = 45 (26 low-risk & 19 high-risk) Control = 47 (31 low-risk & 16 high-risk)	62 female high-school students from a private school in North Carolina, aged 14–15. Intervention = 31 Control = 31
Research design	Pretest post-test design	Pretest, post-test, and 3-month retest design	Pretest post-test design with three experimental groups and a control group	Pretest delayed post-test (8 weeks) design	Pretest, post-test, and multiple retest (6 weeks and 6 months) design
Setting	In class	Community based	Lab/classroom small groups of 2–6	In class	In class, 3 small groups/condition
Length	6.5 h	9 h	45 min	3 h	5.3 h
Teacher	Researcher and instructor	Girl scout troop leader	Researcher	Researcher	Researcher

This table lists key points from the five studies reviewed in this chapter, including study author(s), study focus, theoretical basis for study, sample population of study, research design used in study, setting and length of study, and study intervention teacher

Table 212.3 Media literacy core concepts included in study interventions

Study author(s)	Media literacy concepts included[a]
Rabak-Wagener et al. (1998)	1,2,4,5
Neumark-Sztainer et al. (2000)	1,2,3,4
Irving and Berel (2001)	1,3,4
Coughlin and Kalodner (2006)	1,2,3,4
Dysart (2008)	1,2,3,4,5

This table shows which of the five core concepts of media literacy listed below were included in each of the studies reviewed

[a]Numbers refer to *Media Literacy Core Concepts* (Thoman and Jolls 2005) taught as follows:

1. *All media messages are constructed.* Intervention taught about how the media differs from reality, evaluating what is shown compared to real life experiences.

2. *Media messages are created using a creative language with its own rules.* Intervention taught about recognizing advertising/production techniques or creating/producing media messages.

3. *Different people experience the same message differently.* Intervention explored how media affects different people, what people can do to avoid negative effects of media, or that people can take action to change the media.

4. *Media have embedded values and points of view.* Intervention taught how to identify stereotypes, myths, biases, values, lifestyles, and/or points of view represented in or omitted from media messages.

5. *Most media messages are constructed to gain profit and/or power.* Intervention taught about the purpose of advertising or marketing strategies, skepticism toward advertising, or creating counteradvertising. (Bergsma and Carney 2008)

The five studies discussed in this literature review examine the impact of health-promoting media literacy education on nutrition and diet behavior among youth and adolescents. The studies focus specifically on media literacy interventions that seek to reduce a composite of eating disorder risk factors and assess changes in media-related knowledge, attitudes, and behaviors. The goal in developing media literacy interventions that teach young girls to think critically about media messages that promote thinness is to prevent body dissatisfaction and subsequent eating disorders (Berel et al. 1998; Levine and Smolak 2006).

Following is a close examination of each of the five health-promoting media literacy education intervention studies (Table 212.1), in order of the date of the study from oldest (1998) to most recent (2008), for the purpose of identifying what is known and what still needs to determined about the impact of health-promoting media literacy education on nutrition and diet behavior.

212.4 Study Details

212.4.1 First Study Title: The Effect of Media Analysis on Attitudes and Behaviors Regarding Body Image Among College Students (Rabak-Wagener et al. 1998)

The overall goal of this study was to determine how college students' beliefs and behaviors about their body image were affected by participating in media analysis, specifically analyzing and reframing fashion advertisements. The study is unique among the studies reviewed here in that the study population (n = 105) included both men and women between the ages of 18 and 23. The study utilized a pretest, post-test only design, with one intervention (44 women and 16 men) and one control group (31 women and 15 men).

Table 212.4 Measures utilized

Study author(s)	Rabak-Wagener, et al. (1998)	Neumark-Sztainer et al. (2000)	Irving and Berel (2001)	Coughlin and Kalodner (2006)	Dysart (2008)
Measures[a]	11-item survey to measure beliefs and behaviors regarding fashion advertising images	Dieting behaviors Perceived Weight status Knowledge about body changes during puberty Print media Habits Self-efficacy to affect weight-related social norms Perceived satisfaction Perceived affect Body satisfaction Scale – 6-item version (Slade et al. 1990) Sociocultural Attitudes Towards Appearance Questionnaire (SATAQ) (Heinberg et al. 1995)	Eating Disorder Inventory (EDI-2) (Garner 1991) Physical Appearance State and Trait Anxiety Scale (PASTAS) (Reed et al. 1991) Sociocultural Attitudes Towards Appearance Questionnaire SATAQ (Heinberg et al. 1995) Media Attitudes Questionnaire MAQ (Irving et al. 1998) Positive and Negative Affect Scale (PANAS) (Watson et al. 1988)	Questionnaire for Eating disorder diagnosis (Q-EDD) (Mintz et al. 1997) Eating Disorder Inventory EDI-2 (Garner 1991) Sociocultural Attitudes Toward Appearance Questionnaire SATAQ (Heinberg et al. 1995) Personal Appearance Comparison Scale PACS (Thompson et al. 1991)	Self-Perception Profile for Adolescents (SPPA) (Harter 1998) Eating Disorder Inventory (EDI-3) (Garner 2004) Sociocultural Attitudes Towards Appearance Questionnaire (SATAQ-3) (Thompson et al. 2004) Rosenberg Self-Esteem Scale (RSES) (Rosenberg 1965) Physical Appearance State and Trait Anxiety Scale (PASTAS) (Reed et al. 1991) Media Attitudes Questionnaire (MAQ) (Irving et al. 1998)

This table provides a comparison of the measures utilized in the studies reviewed, in order to determine which studies used the same measures and which used different measures. Note that several of the studies adapted the measures and did not use all items from every measurement tool

[a]Measures with no citation were developed specifically for the study

212.4.1.1 Intervention Design

The intervention took place in a college classroom over a total of 6.5 h and was delivered by the researcher and an undergraduate course instructor. The intervention group first watched the video *Slim Hopes* (Kilbourne 1995) and then discussed fashion industry norms and critically analyzed fashion advertisements. The intervention made an effort to include analysis of male and female fashion advertisements, though the video content was focused primarily on females. Finally, the intervention included a creative component in which the students reframed fashion advertisements.

212.4.1.2 Measures

The researchers developed an 11-item survey instrument to measure beliefs and behaviors pertaining to fashion advertising images. Using a 7-point Likert-type scale, study participants responded to behavior statements such as "I make decisions about dieting or exercise based more upon how I look than on my health status," and belief statements such as "Adult models in advertisements have an ideal body size and shape."

212.4.1.3 Results

At pretest, both the intervention and control group strongly agreed with the following behavior statement more than any other: "I make decisions about dieting or exercise based more upon how I look than on my health status." While the intervention group demonstrated significant changes in beliefs about body image when compared to the control group, there were no significant changes in behavior. When analyzing the data by gender, however, the study revealed that women in the intervention group did, in fact, show significant changes in both body image beliefs and behaviors, indicating that the study was more successful among women than men, and that behaviors are more difficult to change than beliefs.

212.4.2 Second Study Title: Primary Prevention of Disordered Eating among Preadolescent Girls: Feasibility and Short-Term Effect of a Community-Based Intervention (Neumark-Sztainer et al. 2000)

For this study the researchers designed and evaluated a community-based intervention, entitled *Free to Be Me*, to promote body acceptance and prevent unhealthy dieting behaviors among preadolescent girls via the enhancement of media literacy and advocacy skills (Neumark-Sztainer et al. 2000). The study included an intervention (n=115) and control group (n=111) of 226 fifth and sixth grade Girl Scout troop members, average age 11 years, and used a pretest, post-test, 3-month retest design.

212.4.2.1 Intervention Design

The intervention focused on the interaction between socioenvironmental, personal, and behavioral factors, following the Social Cognitive Theory concept of reciprocal determinism. The girls learned steps to combat the negative impact of media on their body image and self-esteem by comparing

body types of real women to those seen in magazines, analyzing magazines and television commercials for positive and negative media messages and imagery, and creating and performing commercials or skits with positive messages about body image and self-esteem. They were also encouraged to increase their sense of self-efficacy to combat weight-related social norms presented in the media. The intervention took place over six 90-min sessions and was conducted by Girl Scout troop leaders. The published study includes a detailed content outline of the intervention sessions.

212.4.2.2 Measures

Measures included dieting behaviors; body-related knowledge and attitudes; media-related knowledge, attitudes, and behaviors; and program satisfaction and perceived effect. Participants were asked about specific dieting behaviors over the past month such as if they were currently trying to lose weight, had started a diet, or tried to lose weight to look like girls on television. The study also measured unhealthy eating behaviors including taking laxatives, skipping meals, purging, using diet pills, and perceived binge eating.

To measure body-related knowledge and attitudes, participants reported their perceived weight status ("underweight," "somewhat underweight," "just the right weight," "somewhat overweight," or "overweight"). A 6-item version of the Body Satisfaction Scale (Slade et al. 1990) was used to produce a summary body satisfaction score concerning attitudes toward participants' height, weight, body shape, thighs, stomach, and face. True/false questions were used to assess knowledge of how one's body changes during puberty, while the Sociocultural Attitudes Towards Appearance Questionnaire (SATAQ) (Heinberg et al. 1995) measured acceptance of various body types.

Another item adapted from the SATAQ was used to measure internalization of the media's ideal body image, as well as participants' knowledge of the media's effect on their body image, food choices, and dieting behaviors. To study the print media choices of the participants, they were asked about their reading behaviors and intentions (read, plan to read, never read) regarding several magazines aimed at adolescent females, including *Girl's Life, American Girl, New Moon*, and *Seventeen. American Girl* and *New Moon* were considered more positive media choices than the other magazines, based on their lack of advertising and focus on promoting self-esteem as opposed to fashion. Self-efficacy to affect weight-related norms in the media and within one's peer group was assessed with a seven-item scale developed for this study that included statements such as: "I can do something about the types of advertisements shown on TV and in the magazines," and "If someone teased one of my friends about her body size, I would stand up for her and try to be supportive"(Neumark-Sztainer et al. 2000).

Other aspects the researchers took into account were program satisfaction overall, satisfaction with specific activities, and the participants' perceived effect on their attitudes and behaviors. Perceived effect was assessed with questions such as, "Do you think the program helped you to feel better about yourself?"

212.4.2.3 Results

At baseline, 30% of the participants indicated that they were trying to lose weight and perceived themselves to be overweight, but fewer girls reported they had tried to lose weight to look like girls on television or had used unhealthy dieting behaviors. Overall there were no statistically significant changes in dieting behavior, although the trend was in a positive direction. While at post-test 20% indicated they were trying to lose weight (less than at baseline), at follow-up that number increased to 25%, the same as reported by the control group. The intervention had a modest post-test impact on body-related knowledge and attitudes, but this also was not sustained at 3-month follow-up.

The intervention had significant impact on media-related behaviors. At post-test and follow-up, when compared to the control group, intervention participants reported a significant increase in self-efficacy to combat weight-related social norms and showed a significant decrease in internalization of the thin body ideal portrayed in the media. Intervention participants were also significantly less likely than those in the control group to have read *Seventeen* magazine at post-test and 3-month follow-up, opting instead for the more girl-friendly publication *New Moon.* A majority of the participants and Girl Scout troop leaders indicated overall satisfaction with the program.

212.4.3 Third Study Title: Comparison of Media-Literacy Programs to Strengthen College Women's Resistance to Media Images (Irving and Berel 2001)

This study examined whether two distinct and brief (45 min) media-literacy interventions could reduce negative body image in a sample of college women (n=110) and promote media skepticism about the realism, similarity, and desirability of media messages that depict a thin ideal of beauty. The study compared both an internally oriented intervention to address negative body image and internalization of the thin ideal (n=31) and an externally oriented intervention to address media skepticism (n=27). In addition to the two intervention groups, the pretest, post-test research design also included a video-only intervention (n=28) and control group (n=24). The average age of the study group was 19.

212.4.3.1 Intervention Design

Participants in the externally oriented intervention were encouraged to think critically about the media and challenge unhealthy messages at three levels: personal, interpersonal, and societal. First, they watched a 15-min abridged version of the *Slim Hopes* video (Kilbourne 1995) and then they participated in group discussion and learned to evaluate media by asking the "3 Rs" questions: (1) Is it real? (2) Is it right? and (3) How do I reinforce these messages in my own life? (Austin and Johnson 1997).

Participants in the internally oriented intervention also viewed the abridged version of *Slim Hopes* and participated in group discussion, but unlike the externally oriented intervention, this group went on to discuss how media exposure compounds negative body image and to learn about body image constructs, including perceptions, beliefs, attitudes, and behaviors. Participants also learned how to self-monitor their negative body image thoughts and take steps to ensure that media exposure does not increase them.

The video-only group watched the abridged *Slim Hopes* video and participated in a short discussion, for a total of 15 min. All intervention participants completed a pretest before the intervention and a post-session questionnaire immediately after the intervention, while women in the no-intervention control group completed the questionnaire only. At the end of all four conditions, the investigator distributed postcards from About-Face, a San Francisco-based media activism organization (www.about-face.org).

212.4.3.2 Measures

The study measured body dissatisfaction, media skepticism, intention to engage in media activism, and changes in affect as a result of the interventions. Body dissatisfaction was assessed with the Eating Disorders Inventory-Body Dissatisfaction (EDI-BD) scale (Garner 1991), and awareness and

thin ideal internalization were measured using the Sociocultural Attitudes Towards Appearances Questionnaire (SATAQ) (Heinberg et al. 1995). Anxiety about weight and physical appearance was assessed with the Physical Appearance State and Trait Anxiety Scale-Weight measure (PASTAS-W) (Reed et al. 1991).

Prior to study participation, participants completed the Media Attitudes Questionnaire (MAQ) (Irving et al. 1998), to assess media skepticism, and provided information on Body Mass Index (BMI). The 22-item MAQ includes six subscales that assess perceived realism of media images, perceived similarity to models portrayed in media, desirability of looking like models portrayed in media, identification with models portrayed in media, positive expectancies associated with being thin, and intentions to engage in dieting behavior. No pretest was performed regarding body image and internalization variables, and specific dieting behaviors were not measured in the study.

Intention to engage in media activism was assessed by providing participants, immediately after the post-test, with postcards to send to the media activism organization in order to receive free information, and tracking how many postcards were sent. Finally, changes in affect as a result of the various interventions were measured using the Positive and Negative Affect Schedule (PANAS) (Watson et al. 1988).

212.4.3.3 Results

The study concluded that all three interventions, externally oriented, internally oriented, and video-only, were successful in increasing skepticism about media images that depict a thin ideal of beauty and were "particularly effective at reducing participants' perceptions that media images depicting a thin standard of beauty are *realistic* and *similar* to participants themselves" (Irving and Berel 2001).

There were no differences between the intervention groups and control group on body image variables, socioculturally determined attitudes toward appearance, and affect. Although the internally oriented intervention was specifically aimed at reducing negative body image and internalization of the thin ideal, neither of these results was obtained. Specific results on the subscales of the MAQ were not reported in the published study, including results concerning intentions to engage in dieting behavior.

Finally, more participants (36%) in the video-only intervention sent a postcard requesting information from the media activism organization than those in the internally oriented intervention (19%), the externally oriented intervention (15%), and the control group (5%), indicating that the interventions had a differential impact on intentions to engage in media activism.

212.4.4 Fourth Study Title: Media Literacy as a Prevention Intervention for College Women at Low- or High-Risk for Eating Disorders (Coughlin and Kalodner 2006)

This study stands apart from others in that participants were screened for eating disorder risk at baseline so that results could be analyzed for low- and high-risk individuals. Ninety-two females participated, with 47 in the control group (mean age 19.6) divided into 31 low-risk and 16 high-risk, and 45 in the experimental group (mean age 20.2) divided into 26 low-risk and 19 high-risk. The study employed a pretest 1 week before the intervention and a delayed post-test 8 weeks after the intervention.

212.4.4.1 Intervention Design

The two-session, interactive, discussion-oriented intervention totaled 3 h in length. Entitled Acknowledging and Rejecting the Media's Influence on Eating and Body Image Disturbance (ARMED), it used cognitive behavioral activities to combat body dissatisfaction based on the knowledge that these strategies have improved body image in college women (Butters and Cash 1987; Grant and Cash 1995). The intervention group watched the complete *Slim Hopes* video (Kilbourne 1995), discussed the negative effects of the thin body ideal presented by the media, and learned cognitive behavioral strategies to combat these media messages.

212.4.4.2 Measures

The study measured cognitions, behaviors, and symptoms of eating disorders; awareness and internalization of thin body ideal; and the degree to which participants make social comparisons to their own appearance. Cognitions and eating disorder behaviors were measured using the self-reporting Questionnaire for Eating Disorder Diagnosis (Q-EDD) (Mintz et al. 1997). Participants at low-risk were asymptomatic of eating disorders, while those in the high-risk category included women who fell into the categories of "symptomatic" or "eating disordered."

Eating disorder symptoms were measured with the self-reporting Eating Disorders Inventory-2 (EDI-2) (Garner 1991), using the following four of the 11 subscales: body dissatisfaction, drive for thinness, perfectionism, and ineffectiveness. Awareness and internalization of societal standards were measured using two subscales of the SATAQ (Heinberg et al. 1995), while the Physical Appearance Comparisons Scale (PACS) was used to assess degree of social comparison (Thompson et al. 1999).

212.4.4.3 Results

Compared to high-risk participants in the control group, high-risk participants in the intervention group demonstrated significant reductions in body dissatisfaction, drive for thinness, internalization of societal standards of beauty, and feelings of ineffectiveness. High-risk participants did not show a significant reduction in perfectionism, physical appearance comparisons, or awareness of the thin body ideal. Both intervention and control group low-risk participants evidenced no change in any measured eating disorder risk factor.

Overall, the findings were promising in light of the fact that previous studies of media literacy interventions to address the primary eating disorder risk factors of body dissatisfaction and thin ideal internalization, such as Irving and Berel's 2001 study, did not yield encouraging results. The researchers attributed their success to their analysis of the results based on participant risk factor.

212.4.5 Fifth Study Title: The Effectiveness of Media Literacy and Eating Disorder Prevention in Schools: A Controlled Evaluation with Ninth Grade Girls (Dysart 2008)

This PhD dissertation evaluated an 8-week media literacy intervention aimed at reducing primary eating disorder risk factors in adolescent girls. The study population consisted of 62 high-school females at an all-girls private school, ages 14–15. The study employed a between groups, modified

pretest, post-test experimental design in which the control group participated in a substance abuse intervention for comparison.

212.4.5.1 Intervention Design

The eight intervention sessions were adapted from a variety of sources, including GO GIRLS!™ (Eating Disorders Awareness & Prevention 1998). This program had shown promise in reducing the thin ideal internalization in earlier studies, but the results were not significant, and the intervention showed no change in dieting behaviors (Levine and Smolak 2006). This study hypothesized that the intervention would reduce body dissatisfaction, bulimic behavior, internalization of societal standards of beauty, and weight anxiety.

The 40-min intervention sessions took place once a week over 8 weeks and focused on various topics, including but not limited to the following: how to analyze advertising messages for false motives, how advertisements affect body image, media stereotypes, advertising tactics, contradictory media messages aimed at different targets, and communicating knowledge to a younger female. Participants also watched a different Kilbourne video, *Killing Us Softly III: Advertising Images of Women* (Kilbourne 1999) and participated in a cognitive dissonance exercise by writing letters to younger students about reducing the impact of the thin body ideal.

212.4.5.2 Measures

This dissertation measured behaviors and risk factors of eating disorders, including self-perception, relevant eating disorder behaviors, body dissatisfaction, drive for thinness, bulimia behaviors, sociocultural attitudes toward appearance, thin body ideal internalization, self-esteem, and anxiety about physical appearance. Other media-related measures included assessing media as a source of information and media attitudes. Data were collected pre- and post-intervention at 2 days, 6 weeks, and 6 months following the final intervention session.

Self-perception was only measured pre-intervention with the Self-Perception Profile for Adolescents (SPPA) (Harter 1998), mainly to reinforce the assumption of group similarity achieved through random assignment. Post-intervention measures included the following:

- Eating disorder behaviors were assessed with an updated version of the Eating Disorder Inventory (EDI-3) (Garner 2004), which also includes The Eating Disorder Risk Composite of the following three subscales: drive for thinness, bulimia, and body dissatisfaction.
- The Sociocultural Attitudes Towards Appearance Questionnaire (SATAQ-3) (Thompson et al. 2004), an update revision of the SATAQ used in some of the studies above, was used to measure internalization of media and societal appearance ideals and viewing the media as an important source of information.
- Self-esteem was assessed using the Rosenberg Self-Esteem Scale (RSES) (Rosenberg 1965).
- Anxiety about physical appearance was assessed using the Physical Appearance State and Trait Anxiety Scale (PASTAS) (Reed et al. 1991).
- The Media Attitudes Questionnaire (MAQ) (Irving et al. 1998) was used to assess media realism and similarity.

212.4.5.3 Results

At all post-intervention data collection points, the intervention group reported significant reductions in internalization of the thin body ideal, in the influence of media as a source of information

on appearance, and in seeing oneself and others as similar to media ideals. Drive for thinness differences were significant initially, but did not maintain in subsequent follow-up. Body dissatisfaction differences approached significance at post-test and 6 months, but bulimia, weight-related anxiety, realism, and self-esteem results were not significant throughout the study. At follow-up, the intervention group reported the lowest degree of risk factors for eating disorders.

212.5 Analysis of the Studies

The five studies reviewed here utilized health-promoting media literacy interventions with varying degrees of success in their attempt to achieve changes in unhealthy dieting knowledge, attitudes, and behaviors, and eating disorder risk factors. These and other studies have employed health-promoting media literacy education interventions with a relatively broad range of children, adolescents, and young adults, (Bergsma and Carney 2008) utilizing many different theoretical bases, which implies that this relatively young field of research has not yet identified an ideal critical age group nor a best practice approach.

In addition, the complexity and prevalence of eating disorders moderates any one theory's ability to account for the heterogeneity of the disorders (Dysart 2008). While Social Cognitive Theory may be helpful to address sociocultural risk factors, individual behavioral change must also be addressed through the use of such theories as the Theory of Planned Behavior (Fig. 212.1). Social Cognitive Theory examines the media context surrounding young people, but the Theory of Planned Behavior individualizes that context. The model in Fig. 212.1, therefore, takes into account that media literacy education is, and must be, contextual.

Although most girls are repeatedly exposed to unrealistic societal body image ideals in the media, all girls do not struggle with eating issues. One of the interesting questions for public health is what are the protective factors that prevent some girls from buying into the media stereotypes of skinny women? We hypothesize that one of them is well-developed media literacy skills. In addition, recent research also suggests that an approach combining genetics and environment may provide promise for promoting healthy eating behaviors (Striegel-Moore and Bulik 2007).

212.5.1 Addressing Behavior Change

Research suggests that health-promoting media literacy education interventions may be more effective in preventing unhealthy behaviors than correcting them once they are established (Neumark-Sztainer et al. 2000). As a result, many health-promoting media literacy education interventions are designed to prevent a behavior as opposed to change a behavior. While most studies of health-promoting media literacy education interventions include some measure of attitudes and beliefs, measures of behavior are not as prevalent, and those studies that do address behavior change report mixed and sometimes incomplete results.

The *Free to Be Me* community-based intervention to prevent disordered eating among adolescent girls addressed dieting behavior change in Girl Scout troop members (Neumark-Sztainer et al. 2000), though no statistically significant behavior changes were present at the 3-month follow-up. In the study entitled "Effect of Media Analysis on Attitudes and Behaviors Regarding Body Image Among College Students," the researchers report a significant, positive behavior change among the women in the study with regard to the statement, "I make decisions about dieting or exercising based more upon

how I look than on my health status." Yet they do not provide an actual P value to support their claim of significance (Rabak-Wagener et al. 1998). They do provide measures of significance for women and men on the entire aggregate of five behavioral questions, which demonstrate that women showed significant, positive changes, as compared to the control group, while the men did not. The PhD dissertation study found no change in bulimic behaviors, though these were low at baseline and may have experienced a floor effect (Dysart 2008). In addition, these three studies did not use the same scales to measure behavior change, making it impossible to compare them in any meaningful way.

These examples support past research in health promotion and education, which demonstrates that it is more difficult to change behaviors than beliefs. In a recent systematic analysis of health-promoting media literacy education research studies, it was evident that the majority of outcomes involved knowledge and attitudes and revealed less about actually preventing or changing risky health behavior (Bergsma and Carney 2008). This means that more longitudinal studies are needed to measure more concrete behavioral outcomes such as changes in body mass index or changes in daily dietary regimen to include more fresh fruits and vegetables and less processed foods, for example.

No study reported any results of change in behavioral intention, even though the Theory of Planned Behavior clearly identifies it as an important precursor to behavior change. While the study comparing media-literacy programs to strengthen college women's resistance to media images (Irving and Berel 2001) and the dissertation study (Dysart 2008) used the Media Attitudes Questionnaire (MAQ), which includes two questions that relate to intention to engage in dieting behavior, the former study did not report any findings for these questions and the latter used a modified version of the MAQ that did not include them. Of the 22 items from the MAQ, the two statements related to behavioral intention are: (1) *I plan to go on a diet to lose weight in the next 6 months* and (2) *I want to lose some weight in the next 6 months* (Irving et al. 1998).

212.5.2 Reducing Eating Disorder Risk Factors

Although the studies on a whole may not have succeeded in achieving changes in behavior or behavioral intentions, there were some promising trends in the reduction of eating disorder risk factors, including internalization of the thin body ideal. The SATAQ scale, used in three of the studies, is a commonly used measure for evaluating thin ideal internalization and is, therefore, useful as a consistent benchmark in comparing the effectiveness of health-promoting media literacy education interventions on reducing the thin ideal internalization (Dysart 2008; Irving and Berel 2001; Coughlin and Kalodner 2006).

Reductions in body dissatisfaction were somewhat less prevalent. The dissertation intervention evidenced no significant outcomes in regard to body dissatisfaction, which the researcher suggested might be due to the "deeply imbedded media effects that may require dissonance provoking experiences to change" (Dysart 2008). The *Free to Be Me* community-based intervention with Girl Scouts reported modest changes in body knowledge and attitudes at post-test, but these did not remain at 3-month follow-up. This led the researchers to suggest that because young people are exposed to numerous and constant media messages about the sociocultural thin body ideal, it may not be realistic to expect substantial and long-term changes in body image attitudes from a brief intervention (Neumark-Sztainer et al. 2000). Yet this intervention was nine hours in length, the longest of all the interventions reviewed here.

The authors of the study that examined the 3-h *ARMED* media literacy intervention for college students at low and high risk for eating disorders suggested that the absence of any impact on body image variables may be explained by the difficulty in modifying attitudes toward media and self that

have, over time, become ingrained as a result of the comparison process. They concluded that changes in behavior "may require a longer, more comprehensive intervention program" than was provided in their study (Coughlin and Kalodner 2006). Overall, the longer interventions (Table 212.1) seemed to achieve more significant outcomes than the shorter interventions. A 2006 study of the impact of intervention length on intervention effects indicated that longer interventions may be more successful at reducing body dissatisfaction and thin body ideal internalization (Watson and Vaughn 2006). Clearly, length of intervention is still a major variable that needs study.

All of the studies taught a majority of the critical media literacy concepts, with the shortest intervention teaching only three of the five concepts (Table 212.2). This may also have made that intervention less effective since a recent systematic review of health-promoting media literacy education studies suggests that "effective interventions seem somewhat more likely than ineffective interventions to have taught all the core concepts" (Bergsma and Carney 2008).

212.5.3 Changing Media Attitudes and Behaviors

Media attitudes and behaviors were specifically addressed in four of the five interventions with a strong degree of success. At post-test and 3-month follow-up, the *Free to Be Me* intervention significantly increased the participants' self-efficacy to challenge social norms and significantly decreased internalization of the thin body ideal portrayed in the media. It also impacted the print media choices of the participants, as postintervention they opted for more girl-friendly magazines than those that focused on fashion (Neumark-Sztainer et al. 2000). In the media analysis intervention, college students participated in a critique of fashion advertisements and were then evaluated on changes in beliefs related to fashion images. At post-test, the intervention group showed significantly reduced beliefs with regard to such statements as: "Adult models in advertisements have an ideal body size and shape" (Rabak-Wagener et al. 1998). The interventions in the "Comparison of Media-Literacy Programs to Strengthen College Women's Resistance to Media Images" study significantly increased media skepticism (Irving and Berel 2001), and the dissertation intervention reduced the influence of media as a source of information about appearance (Dysart 2008). Unfortunately, in these studies and others like them, there has not been enough definitive research to show that changes in media attitudes and behaviors result in changes in health behaviors.

In some cases, the researchers utilized the same media literacy program materials. Jean Kilbourne's videos appeared in four out of the five studies; *Slim Hopes* was used in three interventions, while *Killing Us Softly III* was used in a fourth (Kilbourne 1995, 1999). In the study that specifically compared an externally oriented and an internally oriented intervention against a video-only intervention, with *Slim Hopes* remaining the common factor in each intervention, the researchers suggested that the video may have been the common factor in increasing media skepticism across the three interventions. Other studies did not specifically make any link to the inclusion of the Kilbourne videos and the intervention outcomes, positive or negative.

212.5.4 Study Populations

While men and boys are often overlooked in studies of eating disorders, statistics indicate that one third of young men experience body dissatisfaction (Corson and Andersen 2002). The "Effect of Media Analysis on Attitudes and Behaviors Regarding Body Image Among College Students"

(Rabak-Wagener et al. 1998) intervention was the only study that involved both men and women, and it demonstrated a stronger impact on the beliefs and behaviors of the female participants than those of the men. While the researchers made an effort to include fashion advertisements depicting both men and women in the intervention discussion and critique activities, the *Slim Hopes* video was aimed primarily at women and may not have appealed to the men (Rabak-Wagener et al. 1998). Although no other study made an effort to include men, the dissertation study suggested that the lack of young boys in the study population was a limitation to the results (Dysart 2008).

212.5.5 Pedagogical Approach

All of the five studies included in this chapter conclude that media literacy education has significant potential to promote healthy knowledge, attitudes, and behaviors with regard to body dissatisfaction and eating disorders, and it merits further study. Many questions remain, however, regarding which variables contribute more or less to the effectiveness of health-promoting media literacy education. One variable that is seldom examined is pedagogical approach. While the studies provide considerable information on *what* the intervention taught, they provide little, if any, information on *how* the intervention taught it. In other words, we know the content that was taught, but not the pedagogical approach that was used. For example, the *Free to be Me* community-based study provides a good content outline of the intervention sessions, but no information about pedagogical approach. Although the study reports that the Girl Scout troop leaders who took primary responsibility for teaching the program received a detailed leader handbook and three hours of training, and they were monitored for fidelity to the "protocol" by a registered dietician who provided the troop leader training, the "protocol" is only vaguely defined as the "implementation of all sessions as intended." Yet successful health-promoting media literacy education results not so much from *what* is taught as *how* it is taught (Bergsma and Carney 2008), as outlined in the *Core Principles of Media Literacy Education* (National Association for Media Literacy Education 2007). Media literacy education must be grounded in inquiry-based, process-oriented pedagogy. Unfortunately, whether the pedagogical approach used in the sample studies included in this chapter was one of inquiry or indoctrination is unclear, as it is in most such published studies. In order to greatly enhance the field of research on health-promoting media literacy education, future studies must provide more reliable information on the pedagogical approach used by the intervention and examine it as variable that may affect outcomes.

212.6 Applications

Media literacy education interventions have been used to promote health in numerous areas, including violence prevention, tobacco use prevention, alcohol abuse, nutrition and dieting behavior, body image, eating disorders (Bergsma and Carney 2008), sexual behavior (Pinkleton et al. 2008), drug abuse prevention (Doba and Doukoullos 2001), and prevention of marijuana use (DeKorne et al. 2002). Given this body of practice and research on the use and effectiveness of media literacy education to promote health, it is reasonable to assume that this approach to health promotion could be applied to numerous health issues among youth. Interestingly, however, there is little research on its use to promote physical activity. Yet certainly the media give many mixed messages about physical activity that require analysis on the part of both youth and adults in order for them to think critically

Fig. 212.2 Key questions to ask when analyzing media messages. This figure suggests key questions to ask when analyzing media messages, including questions to analyze audience, authorship, messages, meanings, representations, and reality (The table is part of the National Association for Media Literacy Education's *Core Principles of Media Literacy Education in the United States* – www.namle.net/core-principles. Used with permission)

about the numerous constructions of reality about physical fitness activities that the media portray, the values and points of view about physical fitness activities that are conveyed, and how different people might understand the messages differently. Another application would be to engender more critical thinking and behavior regarding safe driving practices among teenagers, despite the mixed messages they receive from the media. Health-promoting media literacy education could be used to empower youngsters to explore the key questions to ask when analyzing media messages (Fig. 212.2) developed by the National Association for Media Literacy Education. Although all the questions are important for critical analysis, a key question for health-related subjects is "What is left out of this message that might be important to know?" because media messages about health issues like tobacco, alcohol, sex, and violence often glamorize them and frequently portray them without consequences. For example, sex in the media is generally portrayed without the three Cs: no commitment, no condoms, and no consequences.

212.7 Summary

Based on everything we have studied and analyzed in this chapter, what do we know and what do we still need to know about the effectiveness of health-promoting media literacy education as it relates to issues of body dissatisfaction, nutrition, dieting behavior, and eating disorders?

The media present an ideal body type that is considerably thinner than the average female. Research demonstrates that exposure to this type of thinness-promoting media contributes to body dissatisfaction, dieting, and unhealthy behaviors. Body dissatisfaction is so pervasive in women that it is becoming a normative trend, and it is increasing for young men as well, highlighting the crucial need for interventions that address this risk factor. Addressing body dissatisfaction through health-promoting media literacy education interventions is imperative because body dissatisfaction is a key risk factor in the onset of disordered eating behaviors.

Numerous studies of the effects of a health-promoting media literacy education intervention on preventing body dissatisfaction, unhealthy dieting, and eating disorders have been conducted over the past 30 years with mixed results. They appear to be more successful in changing knowledge and attitudes than behaviors, a pattern that is consistent with much of the research in health promotion and education. Therefore, health-promoting media literacy interventions may be more effective at preventing the onset of the health problem than in changing behavior once it has become ingrained.

While the research on health-promoting media literacy education is promising, a great deal more study must be done to develop best practices in this field of endeavor.

- We must continue to develop and test theoretical foundations for health-promoting media literacy education, such as the Message Interpretation Process (Austin et al. 2000) and the Integrated Individual and Interpersonal Model of Health-Promoting Media Literacy Education proposed in this chapter (Fig. 212.1).
- Successful studies must be replicated.
- New studies should utilize at least some of the same measurement tools as past ones so that meaningful comparisons can be made.
- More tangible efforts should be made to measure actual behavior change resulting from the interventions or, at the least, changes in behavioral intention(s).
- Finally, because the pedagogical approach utilized in health-promoting media literacy education must be inquiry-based and grounded in critical thinking, not the more traditional health education approach of teacher bestowing knowledge upon pupil, research must pay significantly more attention to *how* the interventions are taught while continuing to examine *what* is taught.

Definitions and Explanations of Key Terms

∗**Media:** all electronic or digital means and print or artistic visuals used to transmit messages.

∗**Literacy:** the ability to encode and decode symbols and to synthesize and analyze messages.

∗**Media literacy:** the ability to encode and decode the symbols transmitted via media and the ability to synthesize, analyze, and produce mediated messages.

∗**Media education:** the study of media, including "hands on" experiences and media production.

∗**Media literacy education:** the educational field dedicated to teaching the skills associated with media literacy.

Health-promoting media literacy education: the education field dedicated to teaching the skills associated with media literacy that can also promote health.

Social Cognitive Theory: a three-way, dynamic, reciprocal theory in which personal factors, environmental influences, and behavior continually interact. A basic premise is that people learn not only through their own experiences, but also by observing the actions of others and the results of those actions.

Theory of Planned Behavior: human action is guided by three considerations: (1) beliefs about the likely consequences of the behavior, (2) beliefs about the normative expectations of others, and (3) beliefs about the presence of factors that may facilitate, or impede, the performance of the behavior.

Body dissatisfaction: discontent with the overall shape and size of one's body.

Thin ideal internalization: the acceptance or endorsement of societal messages about weight, thinness, and attractiveness, in contrast to general awareness of these messages.

Chapter 213
Treatment of the Night Eating Syndrome

Albert J. Stunkard and Kelly C. Allison

Abbreviations

BED	Binge Eating Disorder
BMI	Body Mass Index
CBT	Cognitive Behavior Therapy
HDRS	Hamilton Depression Rating Scale
MDD	Major Depressive Disorder
NES	Night Eating Questionnaire
NES	Night Eating Syndrome
NESHI	Night Eating Symptom History and Inventory
NESS	Night Eating Symptom Scale
NREM	Non-Rapid Eye Movement Sleep
PMR	Progressive Muscle Relaxation
QLES-Q	Quality of Life, Enjoyment, and Satisfaction Questionnaire
SPECT	Single Photon Emission Computed Tomography
SRED	Sleep-Related Eating Disorder
SSRIs	Selective Serotonin Reuptake Inhibitors

213.1 Introduction

The Night Eating Syndrome (NES) is described and defined in the chapter by Lundgren in this book. It was described over 50 years ago as a disorder characterized by evening hyperphagia (eating 25% of the daily food intake after supper) and insomnia, all made worse by stress (Stunkard et al. 1955). Nocturnal ingestions (i.e., waking up from sleep to eat) were first reported by Birketvedt et al. (1999).

NES represents a delay in the circadian pattern of meal times. A consensus was recently reached on a set of diagnostic criteria (see Lundgren's chapter). The two core criteria of NES are evening

A.J. Stunkard (✉)

e-mail: stunkard@mail.med.upenn.edu

hyperphagia and nocturnal ingestions (Allison et al. in press (a)). Awareness and recall of eating episodes distinguishes NES from Sleep-Related Eating Disorder (SRED) (Howell et al. 2009).

Obese persons with NES appear to be less successful at weight loss attempts than those without NES (Stunkard et al. 1955). Gluck et al. (2008) also reported that persons with NES lost less weight (4.4 kg) than those without NES (7.3 kg, $p = 0.003$).

An overlap between NES and Binge Eating Disorder (BED) occurs in 7–25% (Stunkard et al. 1996; Allison et al. 2005,2006, 2007). An important difference between the two disorders is that nocturnal ingestions in NES are not objectively large, approximately 300 calories per episode (Birketvedt et al. 1999). Persons with BED and NES share similar types of psychopathology in relation to their disordered eating, but BED patients have higher levels of psychopathology than do night eaters or control subjects (Allison et al. 2005).

213.2 Serotonin and NES

The most effective four studies for the treatment of NES used Selective Serotonin Reuptake Inhibitors (SSRIs) (Stunkard et al. 2009). The background for these studies was furnished by Single Photon Emission Computed Tomography (SPECT), using ^{123}I-ADAM, a radiopharmaceutical agent selective for the serotonin transporter (Newberg et al. 2005; Lundgren et al. 2009). The diagnosis of NES in this SPECT study was carefully established by a seven-day food and sleep record as well as a clinical interview using the NES History and Inventory (NESHI; unpublished clinical interview). The night eating of these patients was severe (an evening caloric intake of $42.2 \pm 12.3\%$ of total daily caloric intake) and 9.4 ± 3.9 nocturnal awakenings with ingestions per week (Table 213.1).

Lundgren shows that the serotonin binding capacity was greater in night eaters than among control subjects in the midbrain ($p < 0.001$) and temporal lobes ($p < 0.01$) (Lundgren et al. 2009) and at far greater rates than that of patients with Major Depressive Disorder (MDD) (Newberg et al. 2005; Lundgren et al. 2009).

The elevated levels of SERT return a large proportion of serotonin from the synapse to the cell body, leaving a deficit of serotonin at the synapse. This deficit delays the night eaters' circadian rhythms of food intake and several neuroendocrine functions. This serotonin deficit suggests that increased serotonergic activity may alleviate NES. This is precisely what the SSRIs do (Fig. 213.1).

NES has responded to SSRIs in all four studies in which they were used. The first study consisted of case reports of four night eaters who showed strong responses to the SSRIs, paroxetine and fluvoxamine (Miyaoka et al. 2003). Three more studies of night eaters, identified by the Night Eating Questionnaire (NEQ) (Allison et al. 2008) and NESHI were conducted by our group. The first of these three studies was a 12-week open-label trial of sertraline with 17 night eaters, which showed highly significant decreases in the core NES behaviors (O'Reardon et al. 2004). Five subjects who achieved complete remission lost 4.8 ± 2.6 kg while the 12 other subjects gained 0.6 ± 5.4 kg.

Table 213.1 Key features of the treatment of the NES

SPECT studies show that night eaters manifest increased reuptake of serotonin from the synapse.	This reuptake (into the cell body) depletes synaptic serotonin which is believed to be the mechanism of NES.
SSRIs block the reuptake of serotonin and restore serotonin levels at the synapse.	Four studies of SSRIs have been effective in NES.
NES is associated with disorders of eating, sleeping, and mood and dysfunctional cognitions.	Allison et al. developed CBT specifically for NES by combining cognitive treatments for each of these disorders.

Fig. 213.1 Greater SERT bnding in midbrain of night eaters. This figure shows the markedly elevated SERT uptake of 6 subjects with the Night Eating Syndrome (NES) and the lower uptakes of the patients with MDD and matched control subjects (Reproduced from Lundgren et al. 2009, by permission)
Fig. 213.2 Comparison of the NESS scores between two open label studies of sertraline. This figure shows changes in the NESS of two independent studies. One was a long-distance study and the other an open-label trial. Last Observation Carried Forward (LOCF) was used in both studies. The similarity between two different patient groups and different circumstances in treatment is striking (Reproduced from Stunkard et al. 2006, by permission)

The second of the three studies, also an open-label trial of sertraline, enrolled 50 night eaters who lived at a distance from our clinic (Stunkard et al. 2006). They received treatment from their own physicians in consultation with our research team. Patients achieved a 66% reduction in calories consumed after the evening meal, 70% reduction in nocturnal ingestions and, among overweight and obese subjects, a 2.2 kg weight loss. A comparison of the results of the two open-label studies is shown in Figs. 213.2, 213.3, and 213.4. There was a striking similarity in the outcome of these two trials of sertraline, performed with different patients and under very different circumstances.

Our third study was a double-blind, placebo-controlled trial of sertraline with 34 night eaters over a period of 8 weeks (O'Reardon et al. 2006). Dosing was flexible, starting at 50 mg/day and increased,
Fig. 213.3 Comparison of number of awakenings per week in two open label studies of sertraline. The significant decreases in number of awakenings per week were similar in both studies
Fig. 213.4 Comparison of number of nocturnal ingestions per week between two open label studies of sertraline. The significant decreases in number of nocturnal ingestions per week were also similar in both studies

as needed, to 200 mg/day, with a final mean of 126.5 mg/day. Assessed with the Clinical Global Impression of Improvement Scale (Guy 1976), the "responder status" to sertraline (71%) was far greater than the 18% for placebo patients ($p < 0.002$). In addition, caloric intake after the evening meal fell by 68% compared to a 29% decrease in the placebo group ($p < 0.009$). The number of nocturnal ingestions of patients who received sertraline fell by 81% (from 8.3/week to 1.6/week). By contrast, nocturnal ingestions by placebo patients fell by only 14% (from 6.4/week to 5.5/week).

Overweight night eaters lost 2.9 ± 3.8 kg during the 8 weeks of sertraline, compared to 0.3 ± 2.7 kg among placebo subjects ($p = 0.06$ for the full model, and $p = 0.007$ for the main effect at week 8). This is the third time we have reported sertraline producing weight loss in obese persons, while no other studies have reported an independent effect of sertraline on weight loss. It suggests that the weight loss may be the result of restoration of serotonin at the synapse. Decreases in the primary outcome measures were, notably, not correlated with changes in depressed mood. Improvements in NES were evidently not a sole function of an antidepressant effect.

Figures 213.5, 213.6, and 213.7 show changes in three measures of the night eating syndrome in sertraline and placebo subjects in a randomized controlled trial.

Fig. 213.5 Change in caloric intake after supper across 8 weeks of treatment. Proportion of calories consumed after dinner fell from 47.3% to 14.8% in the sertraline group compared to a fall from 45% to 32% in the placebo group (Reproduced from O'Reardon et al. 2006, by permission)
Fig. 213.6 Change in the number of awakenings per week across eight weeks of treatment. Number of awakenings per week fell from 8.8 per week to 2.3 per week in the sertraline group, as compared to 6.4 to 5.5 per week in the placebo group (Reproduced from O'Reardon et al. 2006, by permission)
213.3 Topiramate

There have been case reports of the use of topiramate in treating NES, although they are more commonly reported among patients with SRED (Howell et al. 2009). O'Reardon et al. (2004) found that among a group of six sertraline nonresponders, topiramate produced significant reductions on the Night Eating Symptom Scale (NESS), percentage of calories consumed after dinner, and weight (-4.6 kg over 12 weeks, $p < 0.05$), accompanied by nonsignificant decreases in nocturnal awakenings and ingestions (personal communication with John O'Reardon, M.D., September, 2005).

Fig. 213.7 Weight loss across 8 weeks of treatment. Weight fell by 2.9 kg among the overweight subjects in the sertraline group as compared to a 0.3 kg drop among placebo participants (Reproduced from O'Reardon et al. 2006, by permission)
213.4 d-fenfluramine

The evidence of serotonergic dysfunction in NES, and its restoration of normal function with SSRIs indicate the importance of serotonin in the NES. This suggestion was strongly supported by a study of the treatment of seven night eaters with the serotonergic agent, d-fenfluramine (Spaggiari et al. 1994). The diagnosis of NES in these patients was established by careful clinical studies and polysomnographic recordings. All subjects were fully awake when they ate and remembered its occurrence, ruling out SRED (Schenck and Mahowald 1994). Their NES symptomatology was severe, with a mean of 3.4 eating-related awakenings per night and a duration of 7.4 years. Eating episodes occurred promptly upon waking from nonrapid eye movement sleep (NREM), within 30 s of waking in half of the episodes. The average duration of eating was 3.5 min, followed by a return of sleep. The mean number of calories ingested during the night was said to be 1,200 kcal.

Patients were treated with d-fenfluramine (15–30 mg/night) which produced a "dramatic improvement" in their NES. Night eating episodes fell by at least 50% and were associated with a greater than 70% decrease in total caloric intake. No patients showed any "substantial modification" in their daytime eating habits. One patient dropped out early because of "asthenia and drowsiness."

213.5 Phototherapy

The effect of SSRIs in restoring disordered circadian rhythms to normal raises the question of whether other measures might have the same effect. Foremost among measures to alter circadian rhythms is phototherapy. A reasonable basis for phototherapy of NES is its ability to shift circadian rhythms; a delay in these rhythms of night eaters is a key element of this disorder. It is, significantly, associated with attenuation of the usual nighttime elevation of melatonin and leptin (Birketvedt et al. 1999). The lowered level of leptin at night may well play a role in its failure to suppress night time eating. This rationale led the group of Friedman et al. (2002, 2004) to explore the treatment of NES with phototherapy.

They treated two night eaters with bright light therapy. One was a 51-year-old obese woman with a BMI of 51 and a Hamilton Depression Rating Scale (HDRS) score of 18. She had been treated for depression for 2 years with paroxetine at a dose of 40 mg/day when she reported a worsening in her symptoms (Friedman et al. 2002). The other night eater was a 46-year-old nonobese man with a BMI of 23, and an HDRS score of 16 who complained of fatigue and insomnia (Friedman et al. 2004).

Each patient was treated with bright light (10,000 lux) therapy for 14 consecutive morning sessions of 30 min each; the female patient continued on her dose of paroxetine. After 14 weeks neither patient any longer met criteria for NES, and their scores on the HDRS fell, for the female patient, from 18 to 7, and, for the male patient, from 16 to 4.

One month after the end of phototherapy, all of the female patient's night eating symptoms recurred. Strikingly this relapse did not extend to depression and her HDRS score remained low (6). The patient was again treated with the same bright light protocol for 12 sessions and her NES symptoms were once again "completely suppressed." No further information about her course has been reported.

A tantalizing report from Sweden describes the treatment of four female night eaters with phototherapy (Bylesjo et al. 2006). Treatment was of one hour duration administered some time between 7 and 9 A.M., at a dose of only 1,500 lux. It occurred daily for 10 days and then twice weekly for 4½ more weeks. Three of the patients lost weight from the beginning (from 1.5 to 2.4 kg) and the fourth one gained at first and then lost below her starting weight. Unfortunately, the NES status of the patients was not mentioned after discontinuation.

213.6 Psychotherapy

Efforts to assess psychotherapy for NES have been limited. Only one controlled trial has been reported. This is unfortunate since the effects of medication may not extend over the long term once it is discontinued.

The controlled trial was of 1 week's duration, involving 10 night eaters who practiced 20 min of Progressive Muscle Relaxation (PMR) each morning. Their outcomes were compared to those of a control group of 10 night eaters who sat quietly for 20 min (Pawlow et al. 2003). Immediately after the PMR session, there was a reduction in anxiety, stress, and levels of salivary cortisol. The presumption underlying this treatment was that anxiety is a determinant of NES. This presumption was supported by significant decreases in anxiety that were associated with decreases in evening appetite and increases in morning appetite.

Practicing these techniques for a week led to continuing reduction in stress and anxiety and comparable changes in eating behavior: lower hunger in the evening and greater hunger in the morning. There was a trend for decreased caloric intake in the evening and greater caloric intake in the morning.

213.7 Cognitive Behavioral Therapy

Cognitive Behavioral Therapy (CBT), developed by Beck et al. (1976), is a promising treatment for NES. CBT was pioneered for eating disorders by Fairburn for Bulimia Nervosa (Fairburn 1981) and BED (Fairburn et al. 1993).

Allison et al. (in press (b)) developed a CBT program specifically for NES. NES combines features of eating, sleeping, mood, and stress disorders, and Allison combined previous treatments for each of them. Laying the groundwork for therapeutic intervention, Allison et al. (2004) examined the

specific cognitions associated with eating by persons with NES. Patients were asked to record their thoughts before and after night eating episodes. Among the most common themes were: (1) food cravings (for specific foods), (2) anxiety and agitation ("I could work myself into a panic just thinking about having to go to bed without my snacks"), (3) distress about disruption of sleep, and (4) feeling compelled to eat (particularly to sleep) ("I won't be able to sleep if I don't get some food in my stomach.") These and other dysfunctional thoughts were identified with the use of the Nighttime Eating Assessment (Allison and Stunkard 2007) and were helpful in treatment.

Weight loss was also included as a goal of treatment for overweight and obese patients. To facilitate weight loss and to advance food intake to earlier in the day for all patients, food and sleep logs were kept by all patients. Caloric goals were recommended for overweight and obese participants at 1,200–1,500 kcals for women and 1,500–1,800 kcals for men. A registered dietician analyzed food records to facilitate adherence with these recommendations.

Three questionnaires were administered prior to each therapy session, as they had been in the medication trials: (1) the Night Eating Symptom Scale (NESS) (O'Reardon et al. 2004); (2) the Beck Depression Inventory (Beck 1996); and (3) the Quality of Life, Enjoyment, and Satisfaction Questionnaire (QLES-Q) (Endicott et al. 1993).

213.8 Pilot Treatment

Twenty-five subjects were recruited with the aid of the NESS (O'Reardon et al. 2004) for a pilot study of CBT (Allison et al, in press (b)). Fourteen subjects completed the trial; the remaining eleven dropped out, with most of these discontinuing before the third session. Significant reductions on four major outcome variables were noted using Mixed Model Regression Analysis to maximize data from all participants (Verbeke and Molenberghs 1997): (1) percent of calories consumed after dinner until awakening the following morning 29% (from 35.0% to 24.9%: $p < 0.0001$); (2) Number of awakenings, (from 13.5/week to 8.5/week; $p < 0.018$); (3) number of nocturnal ingestions fell by 70% (from 8.7/week to 2.6/week ($p < 0.0001$); and (4) the NESS fell from 28.7 to 16.3; $p < 0.0001$). In addition, weight fell by 3.1 ± 0.4 kg ($p < 0.0001$) (Allison et al, in press (b)).

The 14 completers, as expected, showed greater improvement in the two core criteria than the results for the entire sample of 25 patients: (1) caloric intake after dinner fell from 36% to 22% ($p < 0.05$) and (2) nocturnal ingestions from 5.6/week to 0.5/week ($p < 0.001$).

The attrition rate in this study was high, reflecting the frequent experience in CBT: persons may not have anticipated the effort involved in keeping records (of food intake, sleep, mood, etc.) and of making sustained behavioral changes. Also, there was a high lifetime comorbidity rate with other psychiatric disorders, including 48% for anxiety disorders, 36% for mood disorders, and 24% for BED. These comorbidities may have reduced patients' ability to improve to change their NES with this active therapy (Allison et al, in press (b)).

213.9 Current Statistics on the Treatment of NES

The NES is a disorder of moderate prevalence, readily diagnosed, and effectively treated. One might well expect that it should be widely and effectively treated. Such is not the case. A survey of 159 night eaters (Goncalves et al. 2009) found that only 27% believed that their physicians had ever heard of the NES and 41% of patients said that their physicians had not listened to their concerns.

213.10 Conclusions

NES is believed to be a disorder of moderate severity in the general population, but higher among obese persons. However, definitive prevalence study data is required. NES appears to result in a deficit of serotonin at the synapse which is remedied by SSRIs and possibly by psychotherapeutic measures. The disorder is not well-recognized by the medical profession and most patients go untreated. Current therapies deserve much wider distribution.

213.11 Applications to Other Areas of Health and Disease

The major problem with the NES is its limited recognition by the medical profession and others. The limited recognition of NES leads to inadequate treatment of treatable disorders and inappropriate treatment of others.

Prominent among specific problems posed by this limited recognition is insomnia, which is frequently encountered in the NES. This insomnia responds readily to standard treatments for NES, particularly the SSRIs. Attempts to treat the insomnia of NES with the usual hypnotics often produce a confusional state in which night eating may also occur. NES can be confused with BED, for which treatments may differ. While NES occurs periodically (nightly), BED does not occur periodically. Furthermore, the food intake of the binges of BED is far greater than the food consumed at night in NES.

Since insomnia, NES, and BED afflict a large number of persons, the distinctions in the diagnoses and consequent treatments are needed; a major information campaign is warranted. The limited recognition of NES is easily diagnosed and effectively treated. The disorder warrants a major information campaign.

Summary Points

- There are three types of treatment for the NES: pharmacotherapy, phototherapy, and psychotherapy.
- SSRIs are the most studied and probably most effective treatment for NES.
- Phototherapy with bright light in the morning has proven effective in controlling NES in a small number of patients.
- controlled trial of PMR produced a reduction in anxiety and evening appetite and an increase in morning appetite.
- pilot study of CBT of 25 night eaters produced a decrease in evening hyperphagia, number of awakenings, and nocturnal ingestions, and a weight decrease of 3.1 kg. The study had a high attrition rate.

Key Terms

Cognitive Behavior Therapy (CBT): psychotherapeutic approach that aims to solve problems concerning dysfunctional emotions, behaviors, and cognitions through a goal-oriented, systematic procedure

Selective Serotonin Reuptake Inhibitors (SSRIs): medications that, as the name indicates, selectively inhibit reuptake of serotonin from the synapse in the brain

Serotonin Transporter (SERT): a protein that moves serotonin from the synapse to the cell body

Single Photon Emission Computed Tomography (SPECT): method of measuring serotonin transporters in the brain by radiography of dye-assisted cells

Phototherapy: method of treatment for circadian disorders using exposure to daylight or to specific wavelengths of light

Progressive Muscle Relaxation (PMR): technique for reducing anxiety by alternately tensing and relaxing the muscles

214.1 Introduction

Eating disorders, including anorexia nervosa (AN), bulimia nervosa (BN), binge eating disorder (BED), and eating disorders not otherwise specified (EDNOS), are complex and relatively uncommon disorders. The reported lifetime prevalence of AN and BN among women ranges from 0.3% to 3.7% and 1.0% to 4.2%, respectively. BED prevalence rates are 1–2.5%, while prevalence rates for EDNOS range from 1.3% to 30.1%. The *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR; APA 2000) groups these disorders as they have common features in the context of separate or distinctive symptom clusters. However, a more parsimonious view has been generated that suggests looking at eating disorders as a whole based on common characteristics seen amongst all the eating disorders. This perspective, or Transdiagnostic model (Waller et al. 2007; Fairburn 2008), stresses common features associated with eating disorders (e.g., overvalued concerns about

e-mail: wayne-bowers@uiowa.edu

eating, weight, and shape) and proposes that those features better define the disorder and have more value when it comes to planning treatment. This model also suggests eating disorders share core psychopathology which helps maintain the disordered behavior. This includes concepts like clinical perfectionism, low self-esteem, an inability to cope appropriately with certain emotional states and interpersonal difficulties. The transdiagnostic model offers more utility when assessing these individuals from a psychological perspective.

Psychological assessment contributes vital quantitative and qualitative information concerning eating disorder symptomatology and general emotional and cognitive functioning. It can be extremely useful when assessing the level or intensity of the disorder and is of tremendous benefit when developing treatment strategies. Psychological testing for this population can be broadly divided into four areas: tests addressing eating disorder symptomatology, personality factors, general psychiatric symptomatology, and intellectual/neuropsychological functioning. For the purpose of this chapter, we will be focusing on eating disorder symptoms, personality factors, and general psychiatric features.

214.2 Tools for Assessing Disordered Eating

Assessment of eating disorder psychopathology can be accomplished by valid and reliable tests targeting this area Table 214.1. Brief, self-report measures such as the Eating Attitudes Test (EAT; Garner and Garfinkel 1979) and Eating Disorders Inventory (EDI; Garner 1991) identify specific aspects of the disorder including desire for thinness, binge/purge behavior, and restraint in eating. The EAT and the first three subscales of the EDI (drive for thinness, bulimic symptoms, and distortion of body image) are additionally useful for documenting change during treatment. A recent valuable assessment tool is the Eating Disorders Examination (EDE; Fairburn and Cooper 1993). This comprehensive, semi-structured interview is designed to assess broad clinical features of an eating disorder, especially attitudes and behaviors related to the illness over the preceding four weeks. Because the EAT, EDI, and EDE are valid, reliable, and easily administrated instruments, repeat administration of these tests can document severity of illness at admission as well as record improvements during treatment. They can also indicate areas of focus in treatment.

214.2.1 Eating Attitudes Test (EAT)

The EAT was designed as an objective self-report measure of the symptoms of an eating disorder in adults and older adolescents (Garner and Garfinkel 1979). The EAT-26 (Garner et al. 1982) is a 26-item scale, shortened from the original 40-item version. Items are rated on a 6-point Likert scale ranging from "never" to "always." The most symptomatic scores receive a score of 3, the next one a 2, and so on. At least three symptomatic responses receive a score of 0. The EAT-26 is often used as a screening tool for eating pathology, with a cut-point score of 20 or higher reflecting concern regarding eating attitudes. Although a score of 20 or higher does not necessarily indicate an individual has an eating disorder, it does indicate concerns regarding body weight, body shape, and eating. In addition to a total score, the EAT-26 yields three subscales: Dieting, Bulimia/Food, and Oral Control.

The EAT-26 has been found to differentiate AN, BN, and BED from controls and can differentiate AN and BN from BED. The test–retest reliability of this measure was high ($r = 0.89$) over a 4–5 week period (Banasiak et al. 2001). Cronbach's alpha for a sample of AN participants was 0.90, demonstrating high internal consistency (Hurley et al. 1990). While the EAT-26 cannot diagnose

Summary of the content, format, administration time, and copyright information for each of the recommended measures of eating and related psychopathology

specific eating disorders it has been used extensively in research on eating disorders. The short nature of the measure and ease of administration lend its use to clinical populations and as a tool for repeated assessment of patients to track progress in treatment. The EAT-26 also has been shown to be a sensitive measure when assessing remission for individuals who have recovered from AN (Garner et al. 1982).

214.2.2 Eating Disorders Inventory (EDI)

The EDI (Garner 1991) is an easily administered self-report measure of psychological traits or constructs, shown to be clinically relevant in individuals with an eating disorder. The third version of the EDI (EDI-3; Garner 2004) provides normative information for females with eating disorders who range in age from 13 to 53 years. Normative protocols were collected in various outpatient and inpatient settings and these data are provided for the following DSM-IV-TR diagnostic groups: (a) AN-Restricting type; (b) AN-Binge-Eating/Purging type; (c) BN; and (d) EDNOS. It is a standardized measure yielding objective scores and profiles that are useful in case conceptualization and treatment planning for individuals who are diagnosed or may be diagnosed with an eating disorder. It can be completed in a relatively brief period and may be administered either individually or in a group setting.

The EDI-3 consists of 91 items organized into 12 primary scales, consisting of three eating-disorder-specific scales (Drive for Thinness, Bulimia, and Body Dissatisfaction) and nine general psychological scales (Low Self-Esteem, Personal Alienation, Interpersonal Insecurity, Interpersonal Alienation, Interoceptive Awareness, Emotional Dysregulation, Perfectionism, Asceticism, and Maturity Fears). The psychological scales are highly relevant to, but not specific to, individuals with an eating disorder. The EDI-3 also provides information regarding concepts that are consistent with psychological theories identified as relevant to development and maintenance of eating disorders.

The EDI-3 is a commonly used assessment instrument in the treatment outcome literature. Internal consistency reliability estimates are above 0.80 and test–retest coefficients range from 0.93 to 0.98. The Drive for Thinness, Bulimia, Body Dissatisfaction, and Interoceptive Awareness subscales of the EDI have demonstrated discriminant validity in distinguishing patients with eating disorders from psychiatric comparison groups (Garner 2004). While not appropriate for diagnosis, the EDI-3

is extremely useful as both a screening measure and a measure for tracking progress throughout treatment. It also is a valuable research tool for assessing areas of psychopathology, identifying meaningful patient subgroups, and assessing treatment outcome. Additionally, it can be helpful in defining areas for psychological intervention and the conceptualization and development of treatment plans.

214.2.3 Eating Disorders Examination (EDE)

The EDE (Fairburn and Cooper 1993) is a semi-structured clinical interview, considered to be the "gold standard" in eating disorder assessment. The EDE assesses frequency of disordered eating behaviors (binge eating, self-induced vomiting, laxative misuse, diuretic misuse, fasting, and excessive exercise) and specific eating disorder features on four subscales: Restraint, Eating Concern, Shape Concern, and Weight Concern. In addition to these subscales, the total EDE score can be used as an index of global eating disorder severity. Disordered eating attitudes and behaviors are assessed for the previous 28-day period using a seven-point scale (ranging from 0 to 6), with higher scores reflecting greater frequency (e.g., "On how many days over the past 28 days have you been consciously trying to restrict what you eat?") or severity (e.g., "Over the past 28 days, how important has your weight been in influencing how you feel, judge, think, or evaluate yourself as a person?").

The EDE has been used extensively in descriptive and treatment outcome research and is sensitive to change over time (Sysko et al. 2005). The EDE subscales have demonstrated good discriminant validity distinguishing between women with eating disorders and noneating disordered controls (Cooper et al. 1989; Fairburn and Cooper 1993), and reasonable concurrent validity with self-reports of vomiting, dietary restraint, and overeating (Rosen et al. 1990). Internal consistency of the EDE subscales has been reported to be 0.75–0.78 for Restraint, 0.68–0.78 for Eating Concern, 0.68–0.70 for Weight Concern, and 0.70–0.82 for Shape Concern (Cooper et al. 1989; Beumont et al. 1993). Further, studies using the EDE have documented high (kappa = 0.83–0.99) interrater reliability (Wilson and Smith 1989; Rosen et al. 1990) and test–retest reliability correlations of 0.70 or higher (Fairburn and Beglin 1994).

As a structured instrument, the EDE requires greater training of interviewers and more time to administer compared to the self-report assessments described above. However, the main advantage of the EDE is that it can be used to make diagnoses of DSM-IV eating disorders. Diagnostic items are assessed for the previous 3-month period to correspond to duration requirements in the DSM-IV. Thus, the EDE is ideal if the purpose of assessment is to generate reliable diagnoses.

The Eating Disorders Examination Questionnaire (EDE-Q; Fairburn and Beglin 1994) is a 33-item self-report version of the EDE interview. Like the EDE, the EDE-Q assesses the main behavioral and attitudinal features of eating disorders over a 28-day period, generating a total score and four subscale scores: Eating Concern, Shape Concern, Weight Concern, and Restraint. This scale also monitors methods of weight control including laxative and diuretic misuse, vomiting, and excessive exercising. Thus, the EDE-Q provides the same information as the EDE in a more easily administered self-report method. However, the EDE-Q should be used to screen for potential eating disorder cases and cannot be used to establish diagnoses.

The EDE-Q has been directly compared with the EDE in two published reports (Hurley et al. 1990; Rizvi et al. 2000), and has consistently performed well. In addition, Beglin and Fairburn (1994) found that the EDE-Q was better at case identification than the EAT-26, another commonly used eating disorder screening questionnaire. More recently, Luce and Crowther (1999) examined the internal consistency and test–retest reliability of the EDE-Q. In their analysis, Cronbach's alphas were used at two different time-periods to assess internal consistency. Alphas ranged from 0.78 and

0.81 for the eating concern subscale to 0.92 and 0.93 for the shape concern. Pearson correlations between time 1and time 2 for the subscales ranged from 0.81 to 0.94 and were all highly significant. These results further support the psychometric adequacy of this measure.

214.3 Tools for Assessing Personality

Awareness of state and trait aspects of personality can aid the psychotherapeutic process. Using assessment tools such as the NEO-PI-R (Costa and McCrae 1985) to assess these dimensional features and the Minnesota Multiphasic Personality Inventory-2 (MMPI-2; Butcher et al. 1989) to assess categorical features is a great asset for treatment and tracking progress. Assessment of personality functioning and the presence of Axis I comorbid disorders such as depression and anxiety disorders (Margolis et al. 1994) with paper and pencil inventories such as the MMPI-2 and/or NEO-PI help to identify patients with these vulnerabilities. Instruments that evaluate state personality features (MMPI-2) can alert health care providers to Axis II diagnoses and personality trait vulnerabilities. At the same time an awareness of personality traits (NEO-PI-R) can also aid the psychotherapeutic process while assessing important dimensional rather than categorical features.

214.3.1 Minnesota Multiphasic Personality Inventory (MMPI)

The MMPI is the most widely used and researched of all personality inventories (Butcher et al. 1989). There are more than 10,000 published articles, books, and chapters about this test. Reliability information on the MMPI-2 basic scales is good with correlation coefficients ranging from 0.67 to 0.92 for males and 0.58 to 0.91 for females. The second edition of the MMPI (MMPI-2; Butcher et al. 1989) is a broad-based paper and pencil questionnaire to assess major patterns of personality and broadly defined areas of psychopathology. It consists of 567 true or false questions that individuals answer based on how they are feeling on that day. The test is divided into two profiles. The validity scales consist of the lie (L), infrequency (F), and correction (K) scales. The L Scale includes common human faults that most people are willing to admit; thus, a person is likely to be exaggerating their virtues or claiming high moral standards if they do not admit to these faults. The F Scale includes pairs of items that ask similar questions to determine any inconsistencies where the clients have contradicted themselves in their responses. Finally, K Scale items are designed to reveal the clients' attempts at clinical defensiveness. Overall, the validity scales are useful in determining if the patient is presenting in an honest and forthright manner.

The clinical scales consist of 10 scales with 8 focusing on broad areas of psychopathology and 2 related to gender role beliefs and social comfort. Scale 1 (Hypochondriasis) is a psychologically based disorder manifested through physical symptoms and reflects a person's preoccupation with physical problems. Scale 2 (Depression) is designed to assess depressed mood or clinical depression. Scale 3 (Hysteria) deals with the client's specific physical complaints and denial of concern about the physical problems, and might detect an inability to deal effectively with life stresses. Scale 4 (Psychopathic Deviate) is intended to assess comfort with rules and regulations, hostility and/or anger, and a tendency to blame others for their problems. Scale 5 (Masculine–Feminine Interests) measures stereotypic masculine and feminine interests and addresses issues related to gender roles. Scale 6 (Paranoia) indicates defensiveness, suspiciousness, and wariness of other people's intentions or motives. Scale 7 (Psychasthenia) reflects feelings of anxiety, concern, obsessive ruminations, and

general maladjustment. Scale 8 (Schizophrenia) taps into feelings of alienation, differentness, confusion, bizarre sensations, isolation, and blatantly psychotic behavior. Scale 9 (Mania) suggests excessive energy, psychomotor acceleration, imperturbability, and scattered behavior. Finally, scale 10 (Social Introversion–Extraversion) measures social shyness, the preference for solitary pursuits, and lack of social assertiveness.

The results of the MMPI-2 are intended to develop inferences about the individual's unique behaviors and way of thinking. Test interpretation can help determine the severity of impairment, outlook on life, approaches to problem solving, typical mood states, likely diagnoses, and potential problems in treatment. The clinician is able to compare a respondent's choices to those of a large normative comparison group as well as to the results derived from earlier MMPI and MMPI-2 studies. The clinician forms inferences about the clients by analyzing their response patterns on the validity and clinical scales using published guidebooks to the MMPI-2. These texts are based on results obtained from over 10,000 MMPI/MMPI-2 research studies (Graham 1987).

Although the MMPI-2 may yield extensive information about the client, it is not a replacement for a clinical interview. The clinical interview helps the test administrator to develop conclusions that best apply to the client from the many hypotheses generated from test results. Furthermore, important aspects of the client's behaviors that were not reflected in the test results may emerge in an interview. For similar reasons, test results should not be interpreted until the clinician has obtained a biopsychosocial history from the client.

214.3.2 NEO-PI-R

The NEO-PI-R (Costa and McCrae 1992) is a 240-item questionnaire developed by factor analytic studies using adult volunteers aged 20–90 years. This test is designed to measure five major dimensions or domains of personality and some of the more important traits or facets that define each domain. Together, the 5 domain scales and 30 facet scores of the NEO-PI-R allow a comprehensive assessment of adult personality. There are five global domains: Neuroticism, Extraversion, Openness, Agreeableness, and Conscientiousness. The five global factors are measures of normal adult personality, and the ranges of very low, low, high, and very high reflect variation from the average or norm. Therefore, this scale represents traits that are present in all individuals to some degree; there is no "cutoff point" which separates those who have a trait from those who do not. Similarly, the ranges are conceptualized in terms of individual differences; high and low scores indicate neither health nor psychopathology, but the degree to which one presents each trait (McCrae and Costa 1990; Costa and McCrea 1992). Each of the five global domains is composed of six facets, which represent groups of intercorrelated traits. Grouping the five domains provides a comprehensive representation of an individual's emotional, interpersonal, experiential, attitudinal, and motivational styles (Costa and McCrea 1992). The NEO-PI-R has useful applications in counseling, clinical psychology, psychiatry, behavioral medicine and health psychology, vocational counseling and industrial/organizational psychology, and educational and personality research.

Neuroticism (N) indicates the range of emotional stability, even-temperedness, and adjustment versus the susceptibility to psychological distress and negative affect. High scores indicate that the presence of distress increases the likelihood that the individual will experience other negative states, including a vulnerability to irrational ideas, decreased impulse control, and a tendency to handle stressful situations poorly, whereas low scores indicate less possibility of maladjustment. Neuroticism taps into a general tendency to experience negative affect (fear, sadness, embarrassment, anger, guilt, or disgust) along with poor impulse control, and lower generalized coping ability. However, it is not

a measure of psychiatric pathology. A very high score on N can occur without significant diagnostic symptoms. Low scores on N reflect emotionally relaxed, calm, even-tempered individuals who can face upsetting situations without getting upset or rattled.

Extraversion (E) suggests the degree to which one is assertive, active, enjoys excitement and stimulation, and has a tendency to be upbeat, energetic, and optimistic. They tend to be cheerful, upbeat, are social, like people, and prefer large groups or gatherings. Individuals low on this dimension are reserved, serious, independent, even-paced, and prefer to be alone. Low scores on E may be seen as less friendly and may be sluggish in demeanor. These individuals may appear shy, but actually simply prefer to be alone or in small groups of well-known individuals. They are not exuberantly happy, but do not usually suffer from unhappiness or pessimism.

Openness (O) refers to one's openness to experience. Open individuals are curious about their intra- and interpersonal worlds and are willing to consider novel and unconventional ideas, experiences, and values. Their lives are experientially rich, and their thinking patterns would be considered intelligent, creative, and divergent. They experience both positive and negative emotions more keenly than do closed individuals. Those with low scores are likely to be conventional in their behavior and outlook, prefer familiar surroundings, and are closed or guarded in their emotional expression. Closed individuals are predictable and conservative in their approach to life and their outlook, and their emotional responses would be somewhat muted.

Agreeableness (A) is concerned with a person's preference between compassion and antagonism. Individuals high in A can be seen as soft-hearted, good-natured, trusting, and altruistic. These individuals tend to be helpful, responsive to others, and empathetic. Individuals low on this factor would be seen as cynical, abrasive, uncooperative, and irritable. They would also be described as vengeful, manipulative, and unfeeling.

Conscientiousness (C) is concerned with control of impulses and temptations and the ability to organize and follow through on tasks. Will to achieve is another way of understanding C. A high C is associated with academic and occupational success and achievement or may lead to compulsive behaviors or workaholic tendencies. These individuals are seen as scrupulous, punctual, and reliable. A high score reflects determined, strong-willed, and resolute behavior, while a low score on C implies less organization, a lower degree of drive and planning and less concern for adhering to standards. Spontaneous behavior lacking thought for the consequences is common for a low score. Low C's are not necessarily lacking in values or morals; however, they may be less exacting in applying them.

Each domain score is comprised of six characteristics, sometimes referred to as facets. If the evaluated person obtains a high score on a certain scale, there is a high probability that the person can be described as suggested above. The higher the score is, the more characteristic these descriptions are for the evaluated person. The same thing happens for low scores: the lower the score is the more characteristic are the typical descriptions for low scores. All dimensions of facets are bi-directional. In other words, a low score on any facet or domain means stronger tendencies toward the opposite character traits and behavioral tendencies.

214.4 Tools for Assessing Comorbid Psychopathology

Often, treatment of comorbid conditions presents as serious a challenge as the primary eating disorder. Affective disorders are the most common Axis I comorbid condition, present in 50–80% of eating disorders. Tests that evaluate depression include the Beck Depression Inventory (BDI; Beck 1961) and the Hamilton Depression Scale (HAMD; Hamilton 1960).

214.4.1 Beck Depression Inventory (BDI)

The BDI-Second Edition (BDI-II; Beck et al. 1996) is a 21-item self-report instrument intended to assess the existence and severity of symptoms of depression as listed in the DSM-IV-TR (APA 2000). Individual questions of the BDI assess mood, pessimism, sense of failure, self-dissatisfaction, guilt, indecisiveness, punishment, self-dislike, self-accusation, suicidal ideas, crying, irritability, social withdrawal, body image, work difficulties, insomnia, fatigue, appetite, weight loss, bodily preoccupation, and loss of libido. Items 1–13 assess symptoms that are psychological in nature, while items 14–21 assess more physical symptoms. Items have been changed to indicate increases or decreases in sleep and appetite, and items labeled body image, work difficulty, weight loss, and somatic preoccupation were replaced with items labeled agitation, concentration difficulty, and loss of energy. Many statements were reworded resulting in a substantial revision of the original BDI.

The BDI takes approximately 10 min to complete, although clients require a fifth–sixth grade reading level to adequately understand the questions (Groth-Marnat 1990). The BDI demonstrates high internal consistency, with alpha coefficients of 0.86 and 0.81 for psychiatric and non-psychiatric populations, respectively (Beck et al. 1988). Test–retest reliability for the BDI found that regardless of whether tests were reissued at 2 or 6 week intervals, scores on the inventory tended to reflect changes in the clinical depth of depression. Groth-Marnat (1990) reports that the revised BDI discriminates psychiatric from non-psychiatric patients and results in higher scores for patients with major depressive disorder compared to patients with dysthymic disorders. Cut score guidelines for the BDI-II are given with the recommendation that thresholds be adjusted based on the characteristics of the sample and the purpose for use of the BDI-II. Total scores between 5 and 9 are considered normal ups and downs; scores between 10 and 18 indicate mild to moderate depression; scores between 19 and 29 indicate moderate to severe depression; while scores between 30 and 63 suggest severe depression. Individuals who score below 4 may be engaging in possible denial of depression or faking good. Scores over 40 are significantly above even severely depressed persons and may suggest a possible exaggeration of depressive symptoms. The BDI is designed for use by trained professionals. While it should be administered by a knowledgeable mental health professional who is trained in its use and interpretation, it is often self-administered.

214.4.2 Hamilton Depression Scale (HAMD)

The HAMD (Williams 1989) is used to assess the severity of depressive symptoms present in both children and adults. The test measures the severity of depressive symptoms in individuals, often those who have already been diagnosed as having a depressive disorder. The 17-item version of the HAMD is more commonly used than the 21-item version. Examples of items for which interviewers must give ratings include overall depression, guilt, suicide, insomnia, problems related to work, psychomotor retardation, agitation, anxiety, gastrointestinal and other physical symptoms, loss of sex drive, hypochondriasis, loss of insight, and loss of weight. It is often used as an outcome measure of depression in evaluations of antidepressant psychotropic medications and is a standard measure of depression used in research of the effectiveness of depression therapies and treatments.

In the 17-item version, nine of the items are scored on a five-point scale, ranging from zero to four. A score of zero represents an absence of the depressive symptom being measured, a score of one indicates doubt concerning the presence of the symptom, a score of two indicates mild symptoms, a score of three indicates moderate symptoms, and a score of four represents the presence of severe symptoms. The remaining eight items are scored on a three-point scale, from zero to two, with zero representing absence of symptom, one indicating doubt that the symptom is present, and two representing

clear presence of symptoms. For the 17-item version, scores can range from 0 to 54. One formulation suggests that scores between 0 and 6 indicate a normal person with regard to depression, scores between 7 and 17 indicate mild depression, scores between 18 and 24 indicate moderate depression, and scores over 24 indicate severe depression.

The HAMD has demonstrated good interrater reliability (average correlation between two raters was.88; Bagby et al. 2004) and high internal consistency in longitudinal studies of patients with eating disorders (alpha ranged from 0.83 to 0.89; Williams 1989). A recent review examining the psychometric properties of this measure across multiple studies concluded that the measure had adequate internal reliability, convergent validity, and discriminant validity (Bagby et al. 2004). It can be administered prior to the start of medication and then again during follow-up visits, so that medication dosage can be changed in part based on the patient's test score. The HAMD is often used as the standard against which other measures of depression are validated.

Because the HAMD is an interviewer-administered and rated measure, there is some subjectivity when it comes to interpretation and scoring. Interviewer bias can impact the results so there is a need to have raters well trained in the use of this measure. As with the BDI, the HAMD is designed for use by trained professionals. While it should be administered by a knowledgeable mental health professional who is trained in its use and interpretation, it is often self-administered.

214.5 Applications to Other Areas of Health and Disease

Psychological assessment of individuals with an eating disorder creates information that can be utilized in treatment and for understanding these serious problems. However, there are other weight related problems for which psychological assessment may be useful. One area is weight management. Psychological assessment may identify an eating disorder that was not readily apparent. Also, assessment can suggest comorbid problems (e.g., depression or anxiety) that could interfere with an individual's attempt at weight loss. A second area is in the use of Bariatric Surgery. Most Bariatric Surgery programs involve psychological/psychiatric assessment prior to the initiation of surgery. Again, psychological assessment may reveal an unapparent eating disorder or co-morbid anxiety or depression that could influence the outcome of the surgery. More importantly, assessment also may reveal an individual's ability to maintain the suggested dietary habits after Bariatric Surgery.

Summary Points

- Eating disorders are complex and multifaceted problems.
- Psychological assessment can determine diagnosis or problem areas.
- Psychological assessment can contribute to effective treatment.
- Psychological assessment can potentially identify comorbid problems.
- Psychological assessment compliments history presented by the individual.

Definitions of Key Terms

Agreeableness: a person's preference between compassion and antagonism.
Asceticism: tendency to seek virtue through pursuit of spiritual needs.
Conscientiousness: concerned with control of impulses and temptations and the ability to organize and follow through on tasks.

Extraversion: the degree to which one is assertive, active, enjoys excitement and stimulation.

Interoceptive awareness: the understanding of internal awareness and bodily sensations.

Neuroticism: the range of emotional stability, even-temperedness, and adjustment.

Openness: one's openness to experience.

Perfectionism: a desire to be perfect and the belief that personal achievements need to be superior.

Restraint: restraint over eating.

Transdiagnostic model: an assumption that AN and BN are one disorder with a single cause.

215.1 Pediatric Feeding Disorders

Feeding behavior in young children lies on a continuum from typical eating behavior, which allows caloric intake adequate for weight gain, linear growth, and satisfactory nutritional intake, to maladaptive eating behavior, which interferes with satisfactory nutritional intake such that weight gain, health, and development are compromised. Pediatric feeding disorders are indicated if a child's maladaptive eating behavior results in insufficient weight gain or significant nutritional deficits or if a child demonstrates severely disruptive behavior at mealtime. It has been reported that clinically significant feeding disorders occur in young children at a 25–45% incidence rate, and in up to 80% of children with developmental disabilities (Linscheid et al. 2003).

Pediatric feeding disorders can be conceptualized in a number of ways; however, the biopsychosocial model is an efficient one to account for both etiological factors and intervention strategies (Kedesdy and Budd 1998; Crist and Napier-Phillips 2001; Fischer and Silverman 2007). Biological

Table 215.1 Key features of pediatric feeding disorders

1. Pediatric feeding disorders are indicated if a child demonstrates eating behavior that results in insufficient weight gain or significant nutritional deficits or if a child displays disruptive mealtime behavior that is distressing to caregivers.
2. Feeding disorders are observed in 25–45% of the general pediatric population.
3. Feeding disorders can manifest as food refusal, selective eating, and disruptive mealtime behavior.
4. Although they can originate with physiological conditions, feeding disorders are often maintained by environmental factors.
5. Support for a behavioral approach to assessment and intervention is well documented.

This table lists the key facts about pediatric feeding disorders

factors contributing to feeding problems include, among others, anatomical difficulties (e.g., delayed development of oral–motor skills, structural abnormalities in the oral cavity, dysphagia) and compromised medical status (e.g., respiratory disorders, gastrointestinal difficulties, neurological conditions). Psychological factors influencing feeding development include the developmental status of the child, the child's temperament, parental management of mealtime behaviors, and the quality of parent–child interactions. Finally, social factors such as family and socioeconomic variables can contribute to or maintain feeding difficulties. The biopsychosocial model concedes that these variables rarely exert their influence in isolation and allows for the interactive nature of these factors.

Consistent with this model, multidisciplinary intervention is often warranted in the treatment of pediatric feeding disorders. For example, medication management or surgical intervention can be implemented to manage gastrointestinal problems, or oral–motor practice can be introduced to advance mechanical skills. However, once these factors have been identified and ameliorated, challenging mealtime behaviors often persist (Table. 215.1). Although feeding problems may originate with a medical or developmental condition, maladaptive mealtime behaviors that were once a result of organic factors often fall under the control of environmental contingencies (Babbitt et al. 1994). This maintenance of maladaptive mealtime behaviors by environmental factors necessitates a behavioral approach to their assessment and treatment, and the effectiveness of the evaluation and treatment of pediatric feeding problems from a behavioral perspective has been well documented (Kedesdy and Budd 1998; Kerwin 1999; Linscheid 2006).

Behavioral intervention programs focus on manipulating antecedent situations and environmental contingencies with goals of modifying maladaptive mealtime behavior, which in most cases subsequently improves nutritional intake and promotes weight gain and linear growth. Behavioral intervention is indicated once medical and mechanical difficulties have been addressed, in order to minimize the adverse effects of physical discomfort or skill deficit. Other considerations for intervention include the feasibility of treatment, medical necessity, and caregiver receptiveness to intervention, and these factors are influenced by the nature and severity of the feeding problem (Kedesdy and Budd 1998). The information necessary for determining the appropriate course of intervention is gathered during interdisciplinary evaluation, which includes behavioral assessment.

Once intervention has been determined to be necessary and viable, treatment goals are established. Goals of behavioral intervention may include modifying nutrition-related behavior such as increasing the volume and variety of foods consumed or increasing caloric intake. Targets of treatment can be related to skill development as well and include advancing the texture of foods eaten and improving a child's willingness to feed himself or herself. Finally, the focus of intervention can be a child's challenging behavior at mealtime or parent–child interactions (e.g., decreasing disruptive mealtime behavior, decreasing caregiver stress at mealtimes, improving the quality of parent–child interactions at mealtimes) (Linscheid et al. 2003; Fischer and Silverman 2007). Just as necessary and

sufficient conditions for treatment are determined via behavioral assessment, treatment goals are formulated based on information gathered during behavioral evaluation.

215.2 Behavioral Assessment of Feeding Disorders

Behavioral assessment methods are utilized in both research and clinical practice in the evaluation of a variety of behavioral disorders. Behavioral assessment can be used for diagnostic and prognostic purposes; more specifically, it can be used to identify the nature or cause of particular problems or to predict future behavior. In addition, behavioral assessment can provide normative data for comparison purposes. Information necessary for the design of effective treatment programs can also be garnered via behavioral assessment. Finally, baseline and outcome data necessary for evaluating treatment efficacy can be obtained through behavioral assessment.

Fundamental tenets of the behavioral assessment of feeding disorders, based on those described by Mash and Terdal (1997), in regard to general behavioral difficulties, are listed in Table. 215.2. A variety of tools and methods have been designed to understand behaviors that are associated with poor nutritional intake (Crist et al. 1994). These evaluation methods allow the user to gather information regarding presenting concerns, contributing factors, and maintaining stimuli. More specifically, behavioral assessment is utilized to evaluate the relationship between mealtime behavior and environmental contingencies (Kedesdy and Budd 1998). Also, treatment goals are established on the basis of information gathered during behavioral assessment. The most common methods for evaluating mealtime behavior include caregiver interviews, observational coding systems, and standardized caregiver self-report measures.

215.2.1 Clinical Interview

The clinical interview is used universally in evaluating behavioral difficulties in young children and is among the most widely used assessment tools in clinical practice (Mash and Terdal 1997). In the behavioral assessment of pediatric feeding problems the clinical interview is utilized to garner information regarding the nature of a child's feeding difficulty, information about the child, information

Table. 215.2 Tenets of behavioral assessment

1. Behavioral assessment is based on the conceptualization of feeding problems as a class of behaviors that interfere with nutritional intake or cause significant caregiver distress and are maintained by environmental contingencies.
2. Key components of behavioral assessment include understanding child behavior, caregiver behavior, and caregiver–child interactions at mealtimes.
3. Behavioral assessment is used to examine behaviors that are directly of interest and considered for modification, rather than behaviors that are indicative of underlying causes of feeding problems.
4. Behavioral assessment may be enhanced by considering multi-method evaluation.
5. Behavioral assessment tools are most useful if they can be utilized as part of an ongoing assessment process rather than at a single time period.
6. Behavioral assessment has an empirical basis (i.e., using psychometrically sound instruments and procedures that are examined empirically).

This Table describes the fundamental tenets of behavioral evaluation as applied to the assessment of pediatric feeding disorders

about the primary feeder, and information regarding caregiver and child interactions, as well as other potential contributing and maintaining factors. It serves as a screening tool to guide further assessment and intervention. Such interviews are typically not standardized, but general models have been created by specialists in the field (Kedesdy and Budd 1998). Most often, the primary caregiver is the source of information gathered during a clinical interview.

215.2.2 Behavioral Observation

Direct observational methods involve the recording of behavior, following established coding systems, and include methods for evaluating the reliability of the information gathered (Mash and Terdal 1997). The advantages of direct observation are numerous, including direct access to behavior, objective evaluation of mealtime behavior, and methods for establishing the reliability of data collected. However, bias may still exist, including the reactivity of the individual being observed and the bias of the observer. Also, direct observational methods are often complex, costly, and time consuming.

Direct mealtime observations of feeding behavior are utilized to objectively evaluate the mealtime routine as well as specific caregiver and child behaviors, all of which may be targets for intervention. Such observations can be conducted and evaluated with or without structured coding systems. For example, specific mealtime behaviors can be identified and their frequency recorded during pre-established intervals (Fig. 215.1). Alternatively, mealtime behaviors can be coded utilizing a variety of standardized observational coding systems, including the Dyadic Interaction Nomenclature for Eating (DINE; Stark et al. 2000), the Mealtime Observation Schedule (MOS; Sanders et al. 1993), the Global Rating Scale for Feeding Situations (GRSFS; Stark et al. 1994), and the Mealtime Interaction Coding System (MICS; Hayden et al. 1998). These standardized measures require review of videotaped mealtimes in order to code the frequency of occurrence of a variety of caregiver and child mealtime behaviors. Two of these measures are described in detail below, and further information can be accessed by contacting the authors of each system.

In addition, functional analysis or functional assessment can be conducted to evaluate observed mealtime behavior. Functional assessment entails the identification of functional relationships between mealtime behavior, and environmental determinants and contingencies (Chung and Kang 2006). Functional analysis has been utilized in a number of studies evaluating mealtime behavior problems in young children and has led to the identification of the most common functions of challenging mealtime behaviors (Munk and Repp 1994; Girolami and Scotti 2001; Piazza et al. 2003). Such assessment has facilitated the development of effective behavioral intervention for the treatment of pediatric feeding disorders.

215.2.3 Caregiver Self-Report Measures

Standardized caregiver self-report measures are utilized to evaluate a caregiver's perception of mealtime behavior problems. Self-report measures are typically questionnaires that require caregivers to provide information regarding parenting practices, child behavior, or emotions related to mealtimes (Mash and Terdal 1997; Crist and Napier-Phillips 2001). Most commonly, caregiver report inventories identify specific mealtime behavioral difficulties encountered by caregivers and assess the frequency and severity of these behaviors.

Examples of caregiver report inventories include the Behavioral Pediatric Feeding Assessment Scale (BPFAS; Crist and Napier-Phillips 2001), the Children's Eating Behavior Inventory (CEBI;
Fig. 215.1 Coding of mealtime behavior. This figure depicts the coding of mealtime behavior without the use of a standardized coding system. Mealtime behaviors of interest (e.g., percentage of offered bites consumed, percentage of intervals in which disruptive behavior is observed, and grams of food consumed) are identified and defined. The occurrence of these behaviors is then recorded according to pre-established intervals. Data is summarized and examined over the course of intervention

Archer et al. 1991), the Screening Tool of Feeding Problems (STEP; Matson and Kuhn 2001), the Infant Feeding Scale (IFS; Chatoor et al. 1997), the Brief Autism Mealtime Behavior Inventory (BAMBI; Lukens and Linscheid 2008), and the Oregon Research Institute Child Eating Behavior Inventory (ORI-CEBI; Lewinsohn et al. 2005), among others. Five of these measures are described below, and each is readily available by contacting the authors.

Caregiver report inventories are often preferable to functional assessment or behavioral observation due to their ease of use and efficient assessment of mealtime behaviors. Caregiver report inventories have been found to be comparable to direct behavioral observation. For example, data collected by Piazza-Waggoner and colleagues (2008) support the utility and validity of the BPFAS as compared to direct observation of mealtime behavior. However, when considering their use in research or clinical practice, it is imperative to consider the most common biases associated with self-report including social desirability, acquiescence, demand characteristics, faking, or lying. As well, it is important to consider the psychometric properties of such measures including reliability, validity, and normative data (Mash and Terdal 1997).

215.3 Behavioral Assessment Tools

215.3.1 Observational Coding Systems

215.3.1.1 Mealtime Observation Schedule (MOS)

The MOS (Sanders et al. 1993) is a direct observation measure of children's eating behavior and parental management of mealtime behavior. The MOS was derived from the Family Observation Schedule (FOS), which was predominantly used in the evaluation of parent–child interactions, for children presenting with oppositional behavior.

The psychometric properties of the MOS were examined in a 1993 study conducted by Sanders and colleagues. The authors revised the FOS by including items related to mealtime behavior problems demonstrated by young children in a series of pilot studies. A preliminary version of the measure with 30 items was examined for reliability. Item retention, deletion, and addition resulted in 17 categories of childhood mealtime behavior and 15 categories of parent behavior (Table 215.3). The MOS requires that users review videotaped meals and code the presence of parent and child behaviors during 10-s intervals over the course of a 20-min meal.

In the 1993 validation study, interrater reliability was determined to be adequate, with kappa coefficients ranging from .71 to .99 for the various parent behaviors assessed and from .50 to .99 for the child behaviors evaluated. In the evaluation of the validity of the measure, the authors examined correlations between in-home parent-reported assessment of mealtime behavior difficulties and observational measures of mealtime behavior as assessed by the MOS. The authors found that mealtime difficulty as reported by parents was significantly correlated with mealtime difficulties as assessed by the MOS.

Table 215.3 Behavior categories of the mealtime observation schedule

Child Behaviors	Parent Behaviors
Disruptive	*Aversive*
Noncompliance	Aversive contact
Complaint	Aversive prompt
Demands	Aversive specific instruction
Physical Negative	Aversive vague instruction
Oppositional	Aversive eating comment
Noninteractional	Aversive social attention
Refuses food	
Holds food	
Spits/vomits	
Leaves table	*Nonaversive*
Plays with food	Praise
	Contact
Appropriate	Prompt
Requests food	Specific instruction
Prepares food	Vague instruction
Bites	Eating comment
Chews	Social attention
Appropriate verbal	Presents food
Engaged in activity	Removes food

This table lists the parent and child mealtime behaviors that are recorded when utilizing the MOS. The occurrence of each behavior during 10-s intervals is recorded

The researchers utilized the MOS to examine the relationship between parental management strategies and the mealtime behavior of toddlers and preschool-age children. They compared these variables between children referred to a clinic for the treatment of feeding difficulties and children without identified feeding problems. The results of the study indicated that children with feeding difficulty demonstrated more disruptive mealtime behaviors as measured by the MOS than children without feeding difficulty, lending support to the validity of the MOS in the evaluation of childhood mealtime behavior problems. In addition, parents of children with feeding difficulty demonstrated higher levels of negative and coercive mealtime behavior management strategies than did parents of children without feeding difficulty.

Sanders and colleagues then used the MOS to examine the mealtime behavior of children with cystic fibrosis as compared to children referred for treatment of feeding difficulties and children with no identified feeding problems (Sanders et al. 1997). They found that children referred to a clinic for treatment of feeding problems demonstrated higher levels of disruptive behavior than children not referred, and children with cystic fibrosis did not differ from children referred for treatment of feeding difficulties, lending partial support to the hypothesis that children with cystic fibrosis demonstrate clinically significant levels of disruptive mealtime behavior. As well, mothers of children with cystic fibrosis demonstrated higher levels of aversive mealtime behavior and lower levels of positive attention than did mothers of children in the comparison groups.

The MOS shows promise as an objective rating scale for documenting observed mealtime behavior problems in young children as well as the mealtime behaviors of caregivers. The MOS has been demonstrated to be a reliable instrument and preliminary data suggests that the MOS can discriminate between children with significant feeding problems and those without. Replication of these findings and further validation are warranted to support its use in research and clinical work with children presenting with feeding problems.

215.3.1.2   Dyadic Interaction Nomenclature for Eating (DINE)

Similar to the MOS, the DINE (Stark et al. 2000) is a behavioral coding system used in the assessment of caregiver and child mealtime behaviors and interactions through direct observation. The DINE was created to examine the occurrence of mealtime behavior problems in children with cystic fibrosis as compared to children without cystic fibrosis in an objective manner (Stark et al. 2000). It was created on the basis of the literature describing children with feeding problems as well as general parenting. The DINE requires the user to carefully review mealtimes that are video recorded. Most behaviors on the DINE are coded as to their occurrence or nonoccurrence during 10-s intervals; however, the overall frequency of a few behaviors is recorded as well.

The DINE is comprised of three categories: parent behavior, child behavior, and child eating behavior (Table 215.4). The parent behavior category requires the coder to indicate the presence of direct commands, interrupted commands, coaxing, parent verbalizations, reinforcement provision, physical prompting, and feeding during mealtimes. The child behavior category designates the presence of noncompliance with direct commands, food refusal, complaints, requests for food, child verbalizations, and occurrences of the child leaving the table. Finally, the child's eating behaviors that are recorded include the number of bites of food eaten and sips of fluid taken. In the initial study, using the DINE, the authors found that although children with cystic fibrosis and their parents did not differ from children without cystic fibrosis in the rate of mealtime behavior difficulty, children with cystic fibrosis and their parents engaged in problematic mealtime behaviors more frequently. As well, parenting strategies utilized did not result in children with cystic fibrosis meeting specified dietary requirements.

Table 215.4 Coding categories in the dyadic interaction nomenclature for eating (Adapted by permission from Stark et al. 2000)

Parent behaviors	Child behaviors	Child eating
Direct commands	Away from table	Bites
Indirect commands	Child talk	Sips
Coax	Food refusal	
Feed	Requesting food	
Physical prompt	Noncompliance	
Reinforcement		
Parent talk		

This table includes the categories of parent and child behavior recorded when utilizing the DINE. Occurrence of parent and child behaviors during 10-s intervals is recorded, while overall frequency of child eating behaviors is recorded

The DINE has been used more recently to examine the mealtime behavior of infants, toddlers, and school-aged children with cystic fibrosis. For example, Powers and colleagues (2005) used the DINE to study the rate of mealtime behavior difficulties in infants and toddlers with cystic fibrosis as compared to children without cystic fibrosis. The authors found that although children with cystic fibrosis did not differ from a comparison group in the rate or frequency of mealtime behavior difficulties, parents of children with cystic fibrosis engaged in higher rates and a higher frequency of providing commands during mealtimes. The results suggested, as did those of Stark and colleagues in the original study, that mealtime behavior problems prevented children with cystic fibrosis from meeting nutritional needs. Similar results were found in a study examining mealtime behaviors of school-aged children with cystic fibrosis (Stark et al. 2005).

The DINE has also been utilized in research with children with type 1 diabetes mellitus (T1DM). Similarly, the authors found that children with T1DM did not differ from children without T1DM in the presence of mealtime behavior difficulties, contrary to what is often reported by parents during clinical interviews (Patton et al. 2004). The authors subsequently utilized the DINE to examine the relationship between mealtime behavior difficulties and glycemic control in children with T1DM (Patton et al. 2006a). They found that although children with T1DM and their parents engaged in mealtime behaviors and interactions that did not differ from children without T1DM, higher levels of mealtime behavior difficulties were significantly related to poorer glycemic control and dietary adherence.

The DINE is a mealtime coding system that has been effectively utilized to evaluate the mealtime behavior and parent–child interactions that occur around mealtimes (details on the coding system are available from the authors). It has been demonstrated to be a valid research tool, compared to psychometrically sound caregiver report measures of mealtime behavior difficulties and correlated with health outcomes in pediatric populations. The clinical utility of the DINE has not been reported, likely because of the complex nature of the scoring system, which requires review of video-recorded mealtimes and reliability ratings.

215.3.2 Standardized Caregiver Report Inventories

215.3.2.1 Behavioral Pediatric Feeding Assessment Scale (BPFAS)

The BPFAS is a caregiver-report instrument utilized to examine patterns of parent and child behavior around mealtimes (Crist and Napier-Phillips 2001). The authors originally created the measure to evaluate mealtime behavior problems commonly observed in young children with cystic fibrosis as

Table 215.5 Categories and sample items from the Behavioral Pediatrics Feeding Assessment Scale (Adapted by permission from Crist et al. (1994). For more information, please contact the author: William.Crist@iwk.nshealth.ca)

	Never	sometimes	always		Problem for you	
Child behavior						
My child eats fruits	1 2 3	4	5		Yes	No
My child comes readily to mealtime	1 2 3	4	5		Yes	No
My child tantrums at mealtime	1 2 3	4	5		Yes	No
My child has a poor appetite	1 2 3	4	5		Yes	No
Parent's feeling/strategies						
I get anxious when feeding my child	1 2 3	4	5		Yes	No
I use threats to get my child to eat	1 2 3	4	5		Yes	No
I feel confident my child gets enough to eat	1 2 3	4	5		Yes	No

This table includes sample items from the BPFAS. Items from both the child and parent sections of the measures are listed

compared to children with no health concerns (Crist et al. 1994). The measure was created using items from the few available rating scales of childhood-feeding difficulties in combination with original items designed specifically for the scale.

The result was a 35-item standardized caregiver report inventory, designed to obtain information on the mealtime behavior of children between the ages of 9 months and 8 years of age (Table 215.5). Twenty-five items are descriptions of childhood mealtime behaviors while the remaining ten items describe caregiver strategies for managing mealtime behavior problems. The measure requires a caregiver to indicate how often his or her child engages in a particular eating behavior or how often the caregiver uses a particular management strategy, using a five-point Likert scale ranging from "Never" to "Always." Items are phrased both positively and negatively, and some items are transformed such that higher scores represent more problematic mealtime behavior. Responses to the Likert-scale items are summed to create a total frequency score.

In addition, a total problem score provides information on the respondent's perception of a child's behavior as problematic. Caregivers are asked to indicate if they consider a particular child behavior or parental strategy to be a problem, indicating "Yes" or "No." The items considered to be problematic by caregivers are summed to create a total problem score.

The BPFAS demonstrates satisfactory psychometric properties, as indicated in two validation studies conducted by Crist and colleagues. In a 1994 study examining the mealtime behavior of children with cystic fibrosis as compared to children with no health problems, the authors reported reliability data for the BPFAS collected from a previous pilot study. They noted that evaluation of internal consistency using Cronbach's alpha indicated values of.88 for the full scale,.84 for the child section, and.74 for the parent section. Also, test–retest reliability over a 2-year interval revealed significant correlations, ranging from.82 to.85 for each of the subscales and the total score.

A second validation study was conducted by Crist and colleagues in 2001. Similar data on internal consistency was revealed (.76 for the full scale in a sample including both children referred for feeding problems and a normative sample). With regard to validity, the BPFAS was shown to discriminate between children referred to clinics for feeding problems and a normative sample. In their 2001 validation study, Crist and colleagues conducted a factor analysis on the 25 child-related items of the BPFAS. A five-factor structure was identified in each of three independent samples. The interpretable factors identified included picky eaters, toddler refusal – general, toddler refusal – textured foods, older children refusal – general, and stallers.

The picky eaters factor comprised items related to a child's willingness to try new foods. The toddler refusal – general factor included items describing disruptive mealtime behavior such as whining, tantrum behavior, and expelling food, whereas the toddler refusal – textured foods factor reflected

refusal behavior specific to chewable foods. The older children – general factor was composed of items unique to older children including delaying meals by talking, getting up from the table, and requesting alternative foods after a mealtime. The authors noted that the stallers factor was less well-defined than other factors; however, it included items such as letting food sit in the mouth, preference for drinking over eating, and not coming readily to the table.

The BPFAS has subsequently been used to evaluate the mealtime behavior of children with chronic illnesses in which feeding problems are prevalent. For example, the BPFAS has been frequently used with the population of children with cystic fibrosis. Crist and colleagues originally designed and validated the measure as part of a line of research examining the mealtime behavior problems of children with cystic fibrosis as compared to healthy children. In these aforementioned studies, the authors used the BPFAS and determined that parents of children with cystic fibrosis perceived their children's behavior as more problematic than a comparison group and that behavioral problems and caloric intake were negatively correlated (Crist et al. 1994). Given this research using the BPFAS with children with cystic fibrosis, the 2001 Consensus Committee on nutrition in children with cystic fibrosis recommended that the BPFAS be utilized in clinical assessment and intervention for children with cystic fibrosis (Borowitz et al. 2002).

Powers and colleagues have utilized the BPFAS in a series of studies assessing the mealtime behavior of infants and toddlers with cystic fibrosis. In a 2002 study, the researchers found that parents of infants and toddlers with cystic fibrosis indicated a higher occurrence of mealtime problems and a greater frequency of child-related behavior problems at mealtimes than did parents of children without significant health difficulties (Powers et al. 2002). Problems endorsed at the highest rate by the families of children with cystic fibrosis included willingness to try new foods, willingness to eat vegetables, poor appetite, and preference for fluids over solid food. In a similar study, the researchers found higher levels of mealtime behavior difficulties in infants and toddlers with cystic fibrosis as compared to children with no identified health difficulties on all four subscales of the BPFAS (Mitchell et al. 2004). In a 2003 intervention study, Powers evaluated the outcome of a behavioral intervention to increase caloric intake in toddlers with cystic fibrosis. The authors utilized the BPFAS at baseline to ensure that there were no significant differences between the comparison and treatment groups in parent-reported feeding difficulties prior to intervention (Powers et al. 2003).

More recently, the BPFAS has been used to assess the mealtime behavior of children with T1DM. Patton and colleagues (2006b) examined the utility of the BPFAS for assessment of mealtime behaviors in children with T1DM and utilized the BPFAS to delineate the patterns of mealtime behaviors common to children with T1DM. In examining the factor structure of the first 25 items of the BPFAS (Child Frequency items), the researchers found that the factors extracted mirrored the five factors identified by Crist and Napier-Phillips (2001). However, they noted two additional factors that are potentially unique to children with T1DM, including a dietary burden factor and a disruptive behavior factor. The dietary burden factor included items such as poor appetite, enjoys eating, and comes readily to the table. The disruptive behavior factor included items related to tantrum and crying behavior. As well, the authors noted that children with T1DM, similar to children with identified feeding disorders, demonstrated food refusal, picky eating, stalling, and difficulty advancing the texture of foods eaten.

The BPFAS has also been utilized to assess eating and mealtime behavior problems in children with autism. Martins et al. (2008) compared the eating behavior of children with autism to typically developing children and siblings using subsections of the BPFAS. The authors found that although statistically significant differences between the eating behavior of children with autism and typically developing children were noted, these differences were diminutive and not likely to be clinically relevant. Thus, the findings of this study provide a catalyst for ongoing research examining the clinical utility of measures such as the BPFAS.

The BPFAS has been used to evaluate the outcome of behavioral intervention for the treatment of pediatric feeding problems. For example, Byars and colleagues utilized the BPFAS to confirm the presence of a significant behavioral feeding problem prior to admission to a multicomponent behavioral intervention program, targeting decreased dependence on gastrostomy tube feedings (Byars et al. 2003). The authors found that at baseline, the group referred for behavioral intervention did not differ from the reference group described in the original Crist and Napier-Phillips(2001) study. This study suggests clinical implications for the BPFAS as a screening tool to determine the presence of significant mealtime behavioral problems warranting intervention.

In sum, the BPFAS is a tool useful in research and clinical practice. As a research tool, the BPFAS has been used to identify feeding problems associated with specific pediatric conditions, for example, cystic fibrosis and T1DM, as well as in children referred for treatment of pediatric feeding problems. Additionally, the BPFAS has allowed researchers to delineate patterns of challenging mealtime behavior observed in these populations, better guiding intervention for these children. Also, the BPFAS can be administered and scored quickly and thus has practical uses in a clinical setting. It can allow health professionals to monitor the presence of feeding difficulties in specific populations of children at-risk for nutritional deficiency, facilitating more prompt intervention. The use of the BPFAS as a proxy for observed mealtime behavior is supported by the research of Piazza-Waggoner and colleagues who found that parental responses on the BPFAS are a reliable report of actual child mealtime behavior (Piazza-Waggoner et al. 2008).

215.3.2.2 Children's Eating Behavior Inventory (CEBI)

The CEBI (Archer et al. 1991) was designed to evaluate the presence of eating and mealtime behavior problems in children with a variety of medical and developmental disorders. The authors created the CEBI due to the dearth of measures available to assess mealtime behavior problems in young children. The authors intended to create an objective measure that could screen not only for the frequency and severity of mealtime problems, as with the BPFAS, but also evaluate the level of caregiver stress related to mealtime behavior.

The CEBI was created from items generated by specialists who worked with children with eating and mealtime behavior problems, as well as literature regarding the assessment and treatment of feeding problems. The inventory was originally a 71-item questionnaire, since reduced to 40 items. Twenty-eight items relate to food preference, motor skills, and mealtime behavior in young children, while 12 items evaluate caregiver emotion and interactions related to mealtime behavior.

As with the BPFAS, a caregiver indicates how often a child engages in a particular eating behavior or how often the caregiver experiences a particular emotion at mealtimes, using a five-point Likert scale with anchors of never, seldom, sometimes, often, and always. Items are phrased both positively and negatively, and some items are transformed such that higher scores represent more problematic mealtime behavior. Responses to the Likert scale items are summed to create a total eating problem score.

Similar to the BPFAS, a total problem score provides information on the respondent's perception of their child's behavior as problematic. Caregivers are asked to indicate if they consider a particular child behavior or parental strategy to be a problem, indicating "Yes" or "No." Items to which a caregiver responded "Yes" are summed to create a total problem score.

In the original validation of the measure, children referred to a clinic for pediatric feeding problems or identified as "at risk" for feeding problems were compared to children not referred to clinics and otherwise considered to be healthy. Cronbach's alpha was used to assess the internal consistency of the measure. In the combined sample, alpha was assessed for four subgroups (two parents with

two or more children, two parents with one child, one parent with two or more children, and one parent with one child). Alphas ranged from .71 to .76 for all participants with the exception of families with one parent and multiple children (.58). Test–retest reliability was assessed over a 4–6-week period, revealing reliability coefficients of .87 for the total problem score and .84 for the percentage of items perceived by caregivers as problematic. With regard to construct validity, both the total eating problem score of the CEBI and the proportion of items perceived as a problem were found to discriminate between children referred to a clinic for treatment of, or at risk for, feeding difficulties and children not referred.

The CEBI has been utilized to evaluate the presence of mealtime behavior problems in children with autism. In a series of studies assessing the nature and prevalence of feeding problems in children with autism, Schreck and Williams utilized the CEBI. The authors found that children with autism presented with significant levels of mealtime behavior problems, including food refusal, specific food preferences, preference for specific utensils, and preference for foods of pureed texture over foods of advanced texture (Schreck et al. 2004). In a follow-up study, further evaluating the nature of mealtime behavior problems in children with autism, the authors replicated their findings that children with autism presented with limited oral intake, a limited variety of foods eaten, and preference for specific utensils or foods (Schreck and Williams 2006).

The CEBI has also been used to evaluate outcomes from an intensive treatment program for children presenting with pediatric feeding disorders (Greer et al. 2008). The authors found that for children admitted to a comprehensive and interdisciplinary intervention program, the severity of mealtime behavior as measured by the CEBI predicted higher levels of caregiver stress upon admission. As well, the authors reported a decrease in CEBI total problem score as well as perception of problems score from admission to discharge, suggesting the effectiveness of the intervention in decreasing mealtime behavior problems. Further study including a comparison group is warranted.

The CEBI has demonstrated utility as a tool for use in research and clinical practice. The validation studies for the CEBI are somewhat more limited than the BPFAS, and some researchers have used a 19-item version of the CEBI (CEBI-R; Archer and Streiner 1994). Further research is warranted to examine the psychometric properties of the brief version of this measure. The authors suggest the possibility of determining a specific score that can indicate the presence or absence of a significant feeding difficulty, which may support the clinical utility of the measure upon further validation.

215.3.2.3 Screening Tool of Feeding Problems (STEP)

The STEP (Matson and Kuhn 2001) was constructed to assist in the early identification and subsequent treatment of feeding problems observed specifically in individuals with mental retardation. Twenty-three items were initially generated from the literature on feeding difficulties in individuals with mental retardation (Table 215.6). Items were created to assess mealtime behavior problems related to aspiration risk, food selectivity, feeding skills, disruptive mealtime behavior, and nutrition-related feeding problems.

In the initial validation of the measure, the inventory was completed by caregivers in a residential facility. As with the BPFAS and CEBI, raters are asked to rate the frequency of the behavior observed as well as the severity of the behavior. The STEP, however, utilizes a three-point Likert scale. With regard to the frequency of behavioral difficulties, a rating of 0 indicates that the behavior never occurs, a rating of 1 indicates occurrence between one and ten times over the past month, and a rating of 2 indicates occurrence of more than ten times over the past month. If the response is 1 or 2, a follow-up question requires the responder to rate the severity of the behavior on a scale of 0 to 3.

Psychometric analysis of the measure was conducted in two studies. A factor analysis in the initial validation study revealed an eight-factor structure, with seven interpretable factors. Reliability

Table 215.6 Sample items from the Screening Tool of Feeding Problems (Adapted by permission from Matson and Kuhn (2001). For more information, please contact the author: johnmatson@aol.com)

Ability to chew	Spits out food
Selective by type	Rumination
Steal food at meals	Selective by feeder
Special equipment	Selective by texture

This table depicts sample items from the STEP. Items are rated on a three-point Likert scale

data was strong for the full measure and variable for each of the subscales (Matson and Kuhn 2001). More specifically, internal consistency for the full measure was modest, with Cronbach's alpha equal to.68. Alpha for the individual scales was variable, ranging from.19 to.70. Test–retest reliability over three weeks was.72 for the full scale and ranged from.26 to.79 for each of the subscales. Interrater reliability was.71 for the full scale and ranged from.55 to.81 for individual scales. A second validation study conducted in 2002 lent preliminary support to the validity of the STEP as a tool to facilitate diagnosis of two specific feeding disorders, rumination and pica (Kuhn and Matson 2002).

The STEP has not been as widely utilized as other measures of mealtime behavior problems. The authors indicate that although some of the psychometric data is modest (e.g., internal consistency and interrater reliability of individual scales), the data for the full scale is strong. Further validation and possible changes to the structure of the scale may elucidate the psychometric stability of the measure. Ongoing study is necessary to determine the clinical utility of this measure as well.

215.3.2.4 Brief Autism Mealtime Behavior Inventory (BAMBI)

The BAMBI (Lukens and Linscheid 2008) was initially designed as a 20-item scale to evaluate the nature of mealtime behavior problems in children with autism. The initial pool of items was generated from the literature describing and evaluating interventions for pediatric feeding problems in children with autism, and the measure was subjected to preliminary psychometric analyses in a pilot study with 50 participants (Lukens 2002). As with the BPFAS, both positively and negatively worded items were included, and items were phrased such that the caregiver is asked to indicate how often his or her child engages in a particular eating behavior. The inventory employs a Likert scale, with responses ranging from 1 to 5, for reporting the frequency of behaviors. A total frequency score is derived from the sum of the items (including the reversed scores), with higher scores representing more problematic mealtime behavior. Preliminary psychometric analyses conducted in that pilot study revealed a reliability coefficient of.61 for the full scale. The scale as initially developed was comprised of a Limited Variety factor, a Food Refusal factor, as well as a number of items that did not load on either factor.

In a validation study for the measure, an additional item was added to create a potential third factor (Lukens and Linscheid 2008). Prior to conducting further reliability and validity analyses, the 21-item BAMBI was examined at the item level, and retention and deletion of items occurred in accordance with examination of item variances, item distributions, and item–scale and inter-item correlations. The resultant 18-item measure (Table 215.7) was subjected to factor analysis, and a three-factor model was selected as the most plausible. Examination of the factor structure suggested that eight items were related to eating a limited variety of foods, five items were suggestive of food refusal and disruptive mealtime behavior, and five items loaded on a third factor and included behaviors that occurred at mealtime which are related to characteristics associated with autism.

Table 215.7 Sample items from the Brief Autism Mealtime Behavior Inventory (Adapted with permission from Lukens and Linscheid (2008). For more information, please contact the author: lukens@email.chop.edu)

	Never	Seldom	Occasionally	Often	Almost
	Every meal				
My child cries or screams during mealtimes	1	2	3	4	5
My child is aggressive during mealtimes	1	2	3	4	5
My child is willing to try new foods	1	2	3	4	5
My child prefers the same foods at each meal	1	2	3	4	5
My child accepts or prefers a variety of foods	1	2	3	4	5
My child prefers only sweet foods	1	2	3	4	5

This table contains sample items from the BAMBI

Evaluation of the internal consistency of the 18-item BAMBI revealed an alpha coefficient of.88 for the full scale. An alpha coefficient of.87 was found for the Limited Variety factor,.76 for the Food Refusal factor, and.63 for the Features of Autism factor. Temporal stability of the measure was supported by a test–retest reliability coefficient over a 7-month period of.87. High interrater reliability was observed as well.

Criterion-related validity of the BAMBI was confirmed by examining correlations between the BAMBI total frequency score and scores on the BPFAS, and positive and significant correlations were found. As expected, these correlations were high but not perfect, given that the BAMBI was not only expected to assess mealtime behavior problems but also to tap into slightly different subdomains of feeding problems than did previously existing measures. Correlations between individual factor scores and external criterion measures supported the construct validity of the individual factors of the BAMBI. For example, the Limited Variety factor was negatively associated with servings of meats, fruits, and vegetables, as assessed by a food frequency questionnaire. The Features of Autism factor was strongly and positively correlated with subscales of the Gilliam Autism Rating Scale, suggesting that this factor does in fact tap into DSM IV characteristics and associated features of autism.

Significant correlations among the factors of the BAMBI evidenced the convergent validity of the measure. In further support of construct validity, the BAMBI total frequency score and total score for each factor successfully discriminated between a group of children with autism and a group of typically developing children, with children in the autism group obtaining higher scores than children in the typically developing group.

Given these results, the BAMBI shows promise as a measure of mealtime behavior problems in children with autism. However, further validation of this measure is necessary before it can be used as a clinical tool. To further confirm the validity of the BAMBI, alternative methods for evaluating mealtime behavior, such as direct observation, should be examined in relation to BAMBI scores. Additionally, discriminative validity should be considered. In the validation study, the BAMBI was found to be important in discriminating between children with autism and typically developing children. The next logical step is to evaluate the ability of the BAMBI to differentiate between children with feeding problems (i.e., clinic-referred) and children without feeding problems (i.e., non-clinic-referred). Finally, cross validation and replication on a larger, independent sample is necessary to confirm the factor structure of the BAMBI.

215.4 Concluding Comments

This review provides information on some of the most commonly utilized assessment tools in the behavioral assessment of pediatric feeding problems. These tools can be employed in both research and clinical practice, and the advantages and disadvantages of each have been presented. Researchers

and clinicians are advised to carefully select appropriate measures, and the purpose of the assessment should guide the choice of measurement methods and tools. For example, it is recommended that practitioners and researchers utilize a tool such as the BAMBI when working with children with autism or the STEP when assessing the mealtime behavior of individuals with mental retardation.

Researchers are encouraged to continue examining the psychometric properties of these measures, as further examination of the nature and prevalence of feeding problems is warranted. Many of the studies described above offer conflicting findings, depending on the type of measures used. For example, when using a behavioral coding system, researchers did not find significant differences in the mealtime behavior of children with cystic fibrosis as compared to children without cystic fibrosis. However, research using caregiver-report measures suggests that children with cystic fibrosis demonstrate a higher frequency of mealtime behavior problems as compared to children without cystic fibrosis. In contrast, there is preliminary evidence that data obtained via observational coding systems correlate with those collected by caregiver-report inventories (Sanders et al. 1993; Piazza-Waggoner et al. 2008). As such, ongoing study examining the validity of these measures as well as the correlation among measures of mealtime behavior difficulties in young children will be beneficial in enhancing these measures for use in research and practice.

Summary Points

- Pediatric feeding disorders are indicated if a child's maladaptive eating behavior results in insufficient weight gain or significant nutritional deficits or if a child demonstrates severely disruptive behavior at mealtime.
- The maintenance of maladaptive mealtime behaviors by environmental factors necessitates a behavioral approach to their assessment and treatment, and the effectiveness of the evaluation and treatment of pediatric feeding problems from a behavioral perspective has been well documented.
- The most common methods for evaluating mealtime behavior include caregiver interviews, observational coding systems, and standardized caregiver self-report measures.
- There are a number of behavioral observational coding systems and caregiver-report inventories that have demonstrated adequate psychometric properties for use in research.
- Further research is necessary to determine the clinical utility of these measures.

Key Terms and Definitions

Pediatric feeding disorders: a class of disorders in which a child's mealtime behavior interferes with the maintenance of adequate weight gain, linear growth, and/or nutritional stability.
Behavioral assessment: a systematic method for evaluating, understanding, and reporting behavior using reliable and valid instruments that involves hypothesis testing, problem-solving, and drawing of conclusions regarding the relationship between behavior and environmental contingencies.
Observational coding system: a method of behavioral assessment in which behavior is observed and recorded according to a pre-established standard and is assumed to be similar to what would typically occur in a child's daily life.
Caregiver self-report inventory: a method of behavioral assessment in which a primary caregiver is asked to respond to questions about a child's behavior.
Reliability: consistency in measurement.
Validity: the degree to which an inventory measures what it is intended to measure.

Chapter 216
Use of the International Personality Disorder Examination (IPDE) and the Millon Clinical Multiaxial Inventory (MCMI) to Assess Personality Disorders in Eating Disorders

Izaskun Marañon and Iratxe Gonzalez

Abbreviations

AN	Anorexia Nervosa
BMI	Body Mass Index
BN	Bulimia Nervosa
BR	Base Rate
BSI	Borderline Syndrome Index
CCG	Clinical Control Group
DSM	Diagnostic and Statistical Manual of Mental Disorders
ED	Eating Disorder
ICD	International Classification of Disorders
IPDE	International Personality Disorder Examination
MCMI-II	Millon Clinical Multiaxial Inventory-II
NCG	Normative Control Group
NPV	Negative Predictive Value
PD	Personality Disorder
PDE	Personality Disorders Examination
PDQ-R	Personality Diagnostic Questionnaire- Revised
PPV	Positive Predictive Value
SCID-II	Structured Clinical Interview for DSM-IV Axis II Personality Disorders
SEN	Sensitivity
SPE	Specificity

216.1 Introduction

The relation between personality characteristics and eating disorders (ED) has been the main area of attention in many pieces of research. The personality of individuals diagnosed with anorexia nervosa (AN) has been described as obsessive–compulsive, introverted, socially insecure, and dependent,

I. Marañon (✉)

e-mail: izasmara@hotmail.com

whereas the personality of patients with bulimia nervosa (BN) has been associated with great impulsivity or low self-esteem. However, this chapter is not dedicated to analyzing the personality traits of patients diagnosed with EDs. The objective is to show the principal instruments that can evaluate personality disorders (PD) in addition to analyzing comorbidity of Axis II diagnostics and eating disorders.

The comorbidity of ED and PD has been studied since the incorporation of the criteria for PDs on Axis II in the Diagnostic and Statistical Manual of Mental Disorders (DSM) (Matsunaga et al. 1998). The development of structured diagnostic interviews, such as the International Personality Disorder Examination (IPDE; Loranger 1995) or Structured Clinical Interview for DSM-IV Axis II Personality Disorders (SCID-II; Spitzer et al. 1987), as well as self-report questionnaires, such as the Millon Clinical Multiaxial Inventory-II (MCMI-II; Millon 1987), has been important for the study of this comorbidity.

The esthetics of beauty–thinness–youth (society is more critical than ever of obesity and aging) has become associated with attractiveness and success in popular society. Bearing this in mind, it is not surprising that alterations in eating habits have nowadays become a significant problem, especially among young people and teenage girls. The prevalence of these clinical disorders ranges from 0.2% to 0.8% of the general population. However, in young girls these rates are higher: between 1% and 2% in the case of AN, and between 2% and 3% in the case of BN. In addition, these disorders are ten times more frequent in women than in men (cited in Echeburúa and Marañon 2001).

Eating disorders are characterized by serious alterations in eating habits in patients. Specifically, the main feature of AN is the refusal to maintain body weight in the lower normal levels (BMI > 17.5, according to the criteria of the World Health Organization) and can exist in the form of drastic diets and excessive physical exercise (restrictive anorexia) as well as binging and purging (compulsive/purging anorexia). BN is characterized by constant binging and use of inappropriate compensatory methods to prevent weight gain such as vomiting or misuse of laxatives and diuretics (purging bulimia) or, in other cases, fasting and excessive exercise (bulimia without purging). Finally, there are other unspecified EDs such as compulsive overconsumption or certain types of morbid obesity.

Furthermore, PDs reflect inflexible behavior patterns that are not adaptive. These patients also show problems in learning effective strategies for coping with daily difficulties. PDs also generate interpersonal conflicts and lead to severe constraints (social and work) in daily life, as well as an increase in subjective discomfort. PDs, as opposed to mental disorders, are stable and reflect a temporary deterioration of the overall person.

According to the DSM-IV-R (American Psychiatric Association 2000), there are ten personality disorders, grouped into three major types (see Tables 216.1, 216.2, and 216.3).

The lack of definition of these disorders, the lack of homogeneity in the populations studied, and the absence thus far of adequate evaluation tools explain the absence of reliable epidemiological data (cited in Echeburúa and Marañon 2001). The frequency, however, is high. People suffering from such disorders can be 6–12% of the general population and 20–40% of patients seen in outpatient psychiatric practices with a slight predominance of women. Specific disorders with a higher prevalence are those of borderline, dependence, avoidance (women are predominant in the first three), and schizotypal type (the latter more common in men) (Table 216.4).

The frequent comorbidity between PDs and Axis I disorders may be due to alteration of personality acting as a predisposing factor of mental disorders. It could also be due to the fact that alteration of personality is a residual sequel of the mental disorder or, lastly, due to the fact that eating and personality disorders can appear independently no matter if one or the other previously exists (Medina and Moreno 1998). In any case, personality disorders are often associated with behavior problems that are very important in everyday medical practice (Dowson and Grounds 1995).

Table 216.1 DSM-IV-TR: Cluster A. Odd or eccentric disorders

Diagnostic	Main features	Common factors
Paranoid disorder	Irrational suspicions and mistrust of others. Hypersensitivity. Constricted emotions	Independent
Schizoid disorder	Lack of interest in social relationships. Emotionally cold. Failure to recognize other people's emotions and feelings	Introvert
Schizotypal disorder	Oddities of thinking, perceiving, communicating and behavior without meeting the criteria for schizophrenia	Badly socialized Emotionally unstable

This table shows the three cluster A personality disorders as defined by the DSM-IV-TR, their main features and characteristics common to all

Table 216.2 DSM-IV-TR: Cluster B. Dramatic, emotional, or erratic disorders

Diagnostic	Main features	Common factors
Antisocial disorder	Continuous and chronic antisocial behavior. Aggressiveness Documented history of a conduct disorder before the age of 15	Dependent
Borderline disorder	Instability in relationships, self-image, identity, and behavior	Extrovert
Histrionic disorder	Pervasive attention-seeking behavior including exaggerated emotions and theatricality. Egocentrism and manipulation	Badly socialized
Narcissistic disorder	Grandiosity. Fantasy of unlimited success. Need for admiration. Lack of empathy	Emotionally unstable

This table shows the three cluster B personality disorders as defined by the DSM-IV-TR, their main features and characteristics common to all

Table 216.3 DSM-IV-TR: Cluster C. Anxious or fearful disorders

Diagnostic	Main features	Common factors
Avoidant disorder	Extreme sensitivity to negative evaluation. Fear of being ridiculed or humiliated. Social inhibition. Low self-esteem	Dependent
Dependent disorder	Turn their decisions and responsibilities over to others. Passivity and dependency of others. Lack of self-confidence	Introvert Badly socialized
Obsessive–compulsive disorder	Perfectionism. Rigidity. Hesitancy. Excessively devoted to work. Find it difficult to express emotions	Emotionally unstable

This table shows the three cluster C personality disorders as defined by the DSM-IV-TR, their main features and characteristics common to all

Table 216.4 Prevalence rates depending on the type of personality disorder

Type	Personality disorders	General population (%)	Clinical samples (%)
A	Paranoid PD	0.5–2.5	4.2–30
Odd and eccentric	Schizoid PD	0.5–4.5	1.4–16.7
	Schizotypal PD	3–5	0.6–20
B	Antisocial PD	1–3	3–41
Immature	Borderline PD	2–3	9.3–40
	Histrionic PD	2–3	1–15
	Narcissistic PD	<1	2–20
C	Avoidant PD	0.5–1	10
Fearful	Dependent PD	15	1.4–33
	Obsessive-compulsive PD	1	3–10

This table shows the prevalence of different personality disorders in the general population and in clinical samples

216.2 Evaluation Tools

This section is devoted to analyzing PD assessment instruments. In this case, however, due to the great number of instruments, we will only analyze those instruments that assess all PDs described in the current psychopathological classifications, whether these are interviews or self-report questionnaires.

216.2.1 Interviews

For the assessment of PDs, interview problems are the same as in all other clinical interviews, but in this case, they appear to be of greater importance. The clinician may obtain a first impression of the patient and then steer the interview toward a point that may not be essential. The clinician can also forget that social and environmental circumstances are the cause of the behavior of the suspected patients, and that this is the sole contributor to the behavior of their personality traits. The possible distortion of the information provided by the patients must also be taken into account.

Notwithstanding the above, the assessment of PD interviews is necessary because they allow direct observation of the patient. This observation is considered necessary for the diagnosis of PDs, but not for other mental disorders which correspond to Axis I DSM-IV-TR (Zimmerman et al 2005).

The two most commonly used interviews to assess personality disorders are discussed below.

216.2.1.1 International Personality Disorder Examination (IPDE)

The International Personality Disorder Examination (IPDE) (Loranger 1995) is a semi-structured clinical interview developed from the Personality Disorders Examination (PDE; Loranger 1988). The aim of the IPDE is to systematically evaluate the presence or absence of the PD criteria described in the current classifications. This is the reason why it has been carried out in two forms, one for the ICD-10 personality disorder criteria and the other for the DSM-IV personality disorder criteria.

The IPDE is developed in a way that aims to provide an optimum balance between a natural and spontaneous clinical interview and standardization and objectivity requirements. The questions are asked in a natural and comfortable sequence by the clinician according to six thematic headings: work, self, interpersonal relationships, feelings, reality testing, and impulse control.

A self-administered IPDE screening questionnaire is available. In this screening test, the items have a true–false answer format. The IPDE screening questionnaire in the DSM-IV form has 77 items. The IPDE screening questionnaire in the ICD-10 form has 59 items. The screening questionnaire assists the interviewer in quick identification of patients with a specific PD. This questionnaire has no diagnostic value and is used to identify those who should have the interview. It can also be used to identify specific disorders and, if necessary, the corresponding part of the interview can be carried out.

The different sections of the interview begin with open questions that offer the subject the possibility to speak about the topic as much as he or she wants, and allow the clinician to establish a base on which to judge the clinical meaning of the answers to the specific questions that follow the open ones. The IPDE interview DSM-IV form has 92 questions and 7 criteria that the interviewer must fulfill once the interview is finished. The ICD-10 form has 64 questions and 3 criteria to be completed by the interviewer.

The IPDE requires a behavior or trait to be present at least 5 years before it is considered a manifestation of the personality. This conservative and somewhat arbitrary convention is intended to

reflect the relatively enduring nature of personality traits and to avoid confusing them with transient or situational phenomena and episodic abnormalities of mental state behavior. The IPDE also requires that at least one criteria of a disorder be fulfilled before age 25, before that particular disorder can be diagnosed.

216.2.1.2 Structured Clinical Interview for DSM-IV Axis II Personality Disorders (SCID-II)

Like the IPDE, the Structured Clinical Interview for DSM-IV Axis II Personality Disorders (SCID-II) (Spitzer et al 1987; First et al 1997) is a semi-structured clinical interview. SCID-II covers all the criteria for the 11 Axis II diagnoses of DSM-IV (including the non-specified personality disorder), the criteria for depressive personality disorder and passive–aggressive personality disorder (both included in appendix B of DSM-IV)

The interview starts with some open questions that assess personality characteristics. It then proceeds to evaluate each of the ten PDs and the two specific Appendix categories in the following order: avoidant, dependent, obsessive–compulsive, passive–aggressive, depressive, paranoid, schizotypal, schizoid, histrionic, narcissistic, borderline, and antisocial PD.

We can give a diagnosis of a non-specified PD in cases where the characteristics of the PD do not meet the full criteria for any specific PD.

The SCID-II uses a four-point scale to rate the intensity of the characteristics examined. It is recommended that the assessor ask as many additional questions for clarification as required. If necessary, the interviewer can use other sources of information in addition to the subject being interviewed.

As a selection or screening tool, the SCID-II has a self-administered questionnaire of 119 items with a response format of yes–no, which corresponds to the questions in the interview. This questionnaire is then used to conduct the interview. Only those questions answered affirmatively in the questionnaire are actually used in the interview stage.

Data on the reliability and validity of the SCID-II is heterogeneous. The kappa index for test–retest reliability, for example, varies from 0.24 to 0.87 depending on the sample and the disorder studied (cited in First et al. 1997).

216.2.2 Self-Report Questionnaires

In the case of self-report questionnaires that evaluate PDs, in addition to the biases that affect the questionnaires in general, it should be noted that this type of tool exaggerates the patient's answers. This is due to the interference of situational factors when answering, as well as the acquiescence bias and a tendency to exaggerate symptoms when it is oneself who describes them.

216.2.2.1 Millon Clinical Multiaxial Inventory (MCMI)

The MCMI-II (Millon 1987) is a self-administered questionnaire consisting of 175 items with a true–false response format. It was built around Millon's personality theory. Each of its scales was established as an operational measure of a syndrome derived from a theory of personality and psychopathology. This theory is based on diagnostic categories, and suggests ten basic styles of personality functioning based on a 5×2 matrix. The two dimensions of the matrix represent the patient's primary source of getting positive or negative reinforcement (retracted individuals, discordant

personalities, dependent, independent and ambivalent) and the basic pattern of instrumental conduct or coping that the patient uses to increase rewards and decrease pain (active and passive pattern).

As far as personality is concerned, the MCMI-III contains 11 moderate personality disorder scales: Schizoid, Avoidant, Depressive, Dependent, Histrionic, Narcissistic, Antisocial, Sadistic (Aggressive), Compulsive, Negativistic (Passive–aggressive), and Masochistic (Self-defeting). It also has three severe personality pathology scales: Schizotypal, Borderline, and Paranoid.

The MCMI-III includes ten symptom scales. Unlike PDs (Axis II), the clinical syndromes of Axis I are best explained as extensions or distortions of the personality patterns that are often relatively brief and transitory. Although each syndrome may occur with all patterns of personality, some syndromes occur more frequently with certain PDs. Because syndromes of Axis I and Axis II patterns can be combined, a model that clearly explains these interrelationships is needed. This is the reason why the MCMI-III includes ten scales, seven of which are moderate syndrome scales: Anxiety, Somatoform, Manic, Dysthymia, Alcohol Dependence, Drug Dependence, Post-Traumatic Stress Disorder; and three severe syndrome scales: Thought Disorder, Major Depression, and Delusional Disorder.

In addition to being created from a theory, the MCMI-III reflects the diagnostic criteria of DSM-IV. In fact, its scales are coordinated with the DSM and its categories.

The first version of MCMI dates from 1977, but since its creation there have been numerous changes to correct the tendency to distort responses, and incorporate new concepts and theoretical aspects of the new versions of the DSM. The MCMI-II was published in 1987 and the MCMI-III in 1994 (Millon 1977, 1987; Millon and Davis 1996).

In the original version of the MCMI-III, internal consistency indices were higher than 0.80 for all scales.

216.3 Review of Comorbidity Between Eating Disorders and Personality Disorders

Subsequently, we separately analyze comorbidity between eating disorders in general, anorexia nervosa, bulimia nervosa, eating disorders not otherwise specified, and personality disorders.

216.3.1 Eating Disorders and Personality Disorders

Gartner et al. (1989) presented the first article of reference related to this topic. The sample consisted of 35 inpatients diagnosed with restricting AN (6), BN (8), or AN and BN (21). The main results were that 57% of the patients met the criteria for at least one PD. Borderline, self-defeating, and avoidant were the most frequently assigned PDs, and no differences were found in the distribution of diagnoses between patients with different ED diagnoses.

Wonderlich et al. (1990) carried out more precise research with 46 eating disorder patients. In total, 72% of the sample met the criteria for at least one PD. More precisely, obsessive personality was more common in AN restrictive type, and borderline and histrionic personality in bulimia.

Kennedy et al. (1990) carried out a study with 44 ED patients (19 with AN, 16 with BN, and 9 with a combination of both disorders). MCMI and BSI were administered both before and after treatment to measure PDs. Before treatment, 93% of the patients met criteria for at least one PD and after treatment, that percentage decreased to seventy-nine percent. When the PD was measured with the

MCMI, the three most frequent PDs at admission were borderline (79.5%), dependent (75%), and passive aggressive (70.5%). Dependent and passive aggressive disorders remained most prevalent at discharge (43.2% and 40.9%, respectively) while the frequency of subjects who met borderline criteria was 31.8% at the time of discharge. With regard to the BSI, 75% subjects met borderline criteria on admission, compared to 41% at discharge.

Norman et al. (1993), with a sample of 87 ED patients (17 anorexics, 58 bulimics, and 12 who met criteria for both bulimia and anorexia), found that 84% were diagnosed as having a PD. The different ED groups did not differ significantly in terms of the overall prevalence rate of PDs. The MCMI (BR > 84) was used to determine the prevalence and profile of PDs.

In research conducted by Grilo et al. (1996), with 136 hospitalized patients diagnosed with various EDs, 84% had one or more PDs. Among these, the most frequent were borderline (71%), avoidance (19.4%), and dependent (12.9%) PDs.

According to a study by Matsunaga et al. (1998) with 108 patients with different EDs, 51% of the sample suffered from PDs, especially from groups B (antisocial and borderline, in the case of bulimia) and C (without clear predominance of one or the other, in the case of anorexia and bulimia).

In the study by Matsunaga et al. (2000), focusing on patients who had recovered from an ED and who had not displayed any symptoms during the previous year, 26% of a sample of 54 patients met criteria for the diagnosis of at least one PD. This percentage is lower than the percentage found in other studies with patients having AN and BN who were still in treatment. Personality disorders were highly variable, but disorders in Group C (obsessive, dependent, and avoidant) were more common than Group B (borderline).

In a study with a Spanish sample in which the structured interview SCID-II was used, Diaz-Marsá et al. (2000) found that 61.8% of patients with an ED met criteria for a PD, while only 5% of the control sample met the criteria.

Inceoglu et al. (2000) evaluated a sample of patients diagnosed with EDs who were attending a day center using the questionnaire PDQ-R and found a comorbidity rate of 49.2%. Curiously, and unlike other studies, the most prevalent disorder in their sample was the paranoid PD (35.4%), followed by borderline personality disorder (33.9%), then dependent (26.2), histrionic (23.1%), and avoidant (23.1%).

Godt (2002) conducted a study with 176 women attending outpatient treatment and submitting an ED. He used the SCID-II to assess PDs and found that one-third of the sample (33%) had at least one PD. The most common disorders were those in group C (26.1%), followed by those in group B (9.7%) and A (3.4%). The most common PDs were avoidant (18.8%), dependent (8.5%), borderline (5.7%), and histrionic PDs (5.1%).

Karwautz et al. (2002), in their study of 45 patients with an ED, used the version of IPDE adapted to ICD-10. The most common PDs were anancastic (22.7% versus 4.7%), anxious (20.5% versus 2.3%), and dependent (13.6% versus 0%).

In studies that compare a sample of patients with ED with a psychiatric control group, it appears that the former are more often diagnosed with at least one PD (Grilo et al. 1996; Striegel-Moore et al. 1999). The same is true in studies that compare the comorbidity with PDs in samples of EDs with control samples of the general population (Herpertz-Dahlmann et al. 2001). Karwautz et al. (2002), in their study of 45 patients with an ED and a control sample of 45 of the patients' sisters who did not present an ED, found that 54% of the patients showed at least one PD, while in only 7% of the patients' sisters was it present.

Other investigations have focused on comorbidity according to gender. Thus, according to the work of Striegel-Moore et al. (1999) with a sample of 161 war veterans (98 men and 63 women) suffering from EDs, 49% of the women and 18% of the men had some form of PD, so this comorbidity was significantly more frequent in women than in men. However, as the average age of the sample

(men: 53.5 years, women 35.3 years) was higher than that normally found in the clinic, this data cannot be used to make generalizations.

In general, when patients are hospitalized, comorbidity rates are higher – ranging from 69% to 74% of the total – than when they are undergoing outpatient treatment (Wonderlich et al. 1990; Braun et al. 1994; Kennedy et al. 1995).

Recent studies (Martín et al. 2009; Vrabel et al. 2010; Zanarini et al. 2009) are longitudinal studies that examine comorbidity rates of PDs in patients with ED before and after treatment. In general, there is a decline in these rates.

216.3.2　Anorexia Nervosa and Personality Disorders

Although some authors suggest that PDs are relatively uncommon in AN (Pope and Hudson 1989; Herzog et al. 1992), it is common to find a relatively high comorbidity rate between both PDs and ANs.

Norman et al. (1993) found that 77.8% of patients with AN met the criteria for at least one PD diagnosis. The most common PDs in this sample were avoidant (47.1%), dependent (41.2%), schizoid (35.3%), and borderline (35.3%).

Wiederman and Pryor (1997), in their study of 165 women with an ED (27 with restrictive AN, 33 with purging AN, and 105 with purging BN), in which the PDs were assessed by MCMI-II, found that the more common PDs in patients with restrictive AN were dependent (77.8%), compulsive (66.7%), self-defeating (63%), and avoidant (59.3%). In patients with purging AN, however, the most common PDs were avoidant (51.5%), self-defeating (51.5%), dependent (48.5%), passive aggressive (45.5%), and compulsive (42.4%). Patients with restrictive anorexia had more PDs than patients with purging AN (77.8% versus 48.5%). Furthermore, patients with AN (66.7% of restrictive and 42.4% of purging) more often had a compulsive PD than patients with bulimia (22.9%).

In the study by Diaz-Marsá et al. (2000), 50% of patients with restrictive AN and 71.4% of patients with purging AN met criteria for at least one PD measured by the SCID-II. Furthermore, 15% of patients with restrictive AN and 21.3% of patients with purging AN had more than one PD. In this study, the most common PDs in patients with restrictive AN were avoidant (25%), obsessive–compulsive (20%), borderline (10%), paranoid (10%), and dependent (5%); and the most common PDs in patients with purging AN were borderline (35.7%), histrionic (28.6%), obsessive–compulsive (21.4%), passive–aggressive (14.3%), dependent (7.1%), avoidant (7.1%), and narcissistic (7.1%).

Inceoglu et al. (2000) found a comorbidity rate of PDs in AN of 45.2%.

Martin et al. (2001), in a sample of 31 individuals (11 with restrictive AN, 9 with purging BN, and 11 controls), found that 54% of patients with AN exceeded the cut-off point of 85 on the MCMI-II on at least one personality scale, whereas 73% of these patients exceeded the cut-off point of 75. With regard to patients with BN, those with AN showed statistically significantly higher scores on the schizoid ($\overline{X}$ = 93.27 versus $\overline{X}$ = 72.11, $p < 0.05$) and phobic scales ($\overline{X}$ = 77.27 versus $\overline{X}$ = 54.33, $p < 0.05$). With respect to the control group, there were statistical differences in nearly all the average ratings, though these did not exceed the pathological cut-off.

In the study by Godt (2002), 20.8% of patients with AN had at least one PD. The most common was avoidant PD (10.4%), followed by dependent PD (4.2%) and borderline PD (4.2%).

As seen in previous studies, PDs are not uniform in AN. However, in general, we can say that the higher comorbidity of restrictive AN occurs with PDs of group C, especially with obsessive and avoidant PD (between 25% and 35% of cases) (Gartner et al. 1989; Gillberg et al. 1995; Thornton and Russell 1997). By contrast, 40% of people with purging AN have comorbidity with borderline

PD (Piran et al. 1988; Fahy and Eisler 1993; Garner and Sackeyfio 1993). In fact, in these cases, there are related problems of impulse control such as self-mutilation, suicide attempts, robberies, etc.

In anorexic patients who were treated successfully a lower morbidity rate is diagnosed. Thus, according to the above quoted study of Matsunaga et al. (2000), only 20% of patients having recovered from AN met criteria for diagnosis of at least one PD.

216.3.3 Bulimia Nervosa and Personality Disorders

According to Bulik et al. (1995) and Levin and Hyler (1986), 63% of bulimic patients have a PD, in particular the borderline disorder, as well as any other from group C (avoidant, obsessive, or dependent) or from group A (paranoid, schizoid, or schizotypal). A revision study (Dolan et al. 1994) pointed to the existence of a comorbidity rate from 24% to 44% between bulimia and borderline personality.

However, comorbidity rates between BN and PDs differ depending on the study; that is, they depend on the diagnostic criteria, the samples, and the diagnostic tools used.

Levin and Hyler (1986), in their study of 24 women with BN who had an appropriate weight and with no other Axis I disorder, assessed PDs by the PDQ and by a personal interview. They found that 62.5% met criteria for at least one PD. The most common PDs in their sample were histrionic PD (37.5%) and borderline PD (25%).

Pendleton et al. (1991) compared, using the MCMI, 37 women with BN with 32 women with other psychiatric disorders and with 30 women from the general population who did not present any psychiatric disorder. The patients with BN presented more avoidant and dependent PDs than patients in the clinical control group. They also presented more schizoid, avoidant, dependent, narcissistic, compulsive, passive aggressive, schizotypal, and borderline personality disorders than women from the normative control group.

Norman et al. (1993) found that 84.5% of patients with BN met the criteria for at least one PD diagnosis. The most common PD in this sample were passive–aggressive (44.8%), dependent (41.4%), histrionic (34.5%), and borderline (25%). Subjects with bulimia had a significantly lower rate of schizoid, avoidant, and schizotypal PDs than the subjects with anorexia or than the subjects with both anorexia and bulimia. Similarly, the bulimics had a significantly lower frequency of Cluster A diagnosis than the other two groups.

Wiederman and Pryor (1997) found that the most common PDs in patients with BN were self-defeating (68.6%), dependent (59%), avoidant (55.2%), and passive–aggressive (42.4%). Furthermore, they noted that patients with BN presented more histrionic PDs (47.6%) than patients with AN (14.8% of the restrictive and 27.3% of the purging). Also, patients with BN presented more antisocial PDs (20% versus 3.7%) and passive–aggressive (52.4% versus 25.9%) than patients with restrictive AN.

In the study by Diaz-Marsá et al. (2000), 66.7% of patients with BN met criteria for a PD and 37.8% of patients had more than one of these criteria. The most common PDs in BN were borderline (33.3%), dependent (23.8%), avoidant (19%), passive–aggressive (14.3%), obsessive–compulsive (14.3%), schizoid (9.5%), and paranoid (4.8%) PD.

Inceoglu et al. (2000) found a comorbidity rate of PDs in BN of 44.1%.

Martin et al. (2001) found that 22% of patients with BN exceeded the cut-off point of 85 on the MCMI-II on at least one personality scale, while 77.8% of these patients exceeded the cut-off of 75. With respect to patients with AN, those with BN showed statistically significant higher scores on the histrionic scale (77.33 versus 45.90). With respect to the control group there were statistical differences in practically all the average ratings, though these did not exceed the pathological cut-off.

Del Rio et al. (2002) evaluated 33 patients with purging BN using the MCMI-II. Of these, 81% had at least one personality disorder according to the questionnaire (RB > 75), and the most common PDs in this sample were avoidant (39.39%), histrionic (39.39%), and self-defeating PDs (39.39%), followed by passive–aggressive (36.36%) and schizoid (30.30%) PDs.

In the study by Godt (2002), 31% of patients with BN had at least one PD. The most common was avoidant PD (18.5%), followed by dependent (13, 6%), histrionic (7.4%), and borderline (6.2%) PDs.

Comorbidity of BN also varies according to sex. Thus, in men with BN there is a higher rate of homosexuality and perfectionism and susceptibility features appear more often (Herzog et al. 1984; Schneider and Agras 1987). In women with BN, in contrast, weight concerns and an obsession with thinness dominated (Joiner et al. 2000).

Finally, as in people with AN, patients with BN who were treated successfully were diagnosed with a lower comorbidity. Thus, according to the study quoted above by Matsunaga et al. (2000), 21% of patients who recovered from bulimia met the criteria for a diagnosis of at least one PD.

216.3.4 Eating Disorders Not Otherwise Specified and Personality Disorders

Morbid obesity has been studied from this perspective. According to Black et al. (1992), 72% of individuals are also affected by PDs (50% more than one). As regards the actual type of deterioration, in general there is some relationship between the behavioral characteristics of borderline personality (impulsivity, self-defeating behaviors, etc.) and morbid obesity, at least in women (Sansone et al. 1996).

However, in other studies on obesity the data is more variable. Thus, disorders submitted by the sample from the study of Black et al. (1992) are diverse (histrionic, borderline, passive–aggressive), without a clear predominance of one over the other. By contrast, the study by Grana et al. (1989) concerning morbid obesity showed that the most prevalent PDs were others, specifically avoidant, antisocial, and obsessive personality. In the study by Guisado et al. (2001), the most prevalent PDs were paranoid, anancastic, schizoid, and anxious.

In conclusion, the prevalence rate of PDs in obese individuals is very high, but very variable too, depending on the methodology and the type of sample used in the studies. However, we cannot establish a clear association between a specific type of disorder and morbid obesity. Conversely, when there is an association between morbid obesity and compulsive overeating, the results are clearer. According to Yanovski et al. (1993), 16% of the obese sample presents PDs, but this rate rises to 35% in the obese who binge. In the latter case, the PDs most frequently involved are borderline (14%) and avoidant (9%).

Finally, it should be noted that in the study by Godt (2002), 36.2% of patients with a non-specified eating disorder had at least one PD. The most common was avoidant PD (27.7%), followed by borderline PD (6.4%).

216.3.5 Personality Disorders and Eating Disorders

When studies focus on PDs and, as a result, on the comorbidity with Axis I disorders, EDs correlate with group B personality disorders (Modestin et al. 1997).

More specifically, borderline PD has a higher rate of comorbidity with BN (it can range from 2% to 47%) than with the rest of the Axis I disorder (Wonderlich 1995). This broad range is related to

the methodological problems of studies (e.g., inexact diagnoses and lack of control groups) and, above all, to some overlap of diagnostic criteria that are common in the borderline disorder (e.g., criterion 4: binging, which is the result of impulsivity) and BN. This overlap in criteria poses a risk of overdiagnosis of borderline PD in subjects with bulimia. In fact, there is usually a decline in the rate of borderline PDs after short-term treatment focused on bulimia symptoms.

The comorbidity of borderline PD may be mediated by the sex of the patients. Specifically, impulsivity (typical of this disorder) is expressed in males as alcohol or drug abuse (men: 63.3–81.9%; women: 38.1–59.1%) and in women in the form of binge eating or unspecified problems (men: 10.8–13.6%; women: 29.5–30.4%) (Zanarini et al. 1998; Zlotnick et al. 2002).

With regard to the comorbidity between BN and borderline disorder, a point of interest is the possible existence of sexual abuse in childhood. In several previous studies it has been indicated that a history of sexual abuse is three times more common in patients with BN than in normal people (Garfinkel et al. 1995) and patients with restrictive AN (Coovert et al. 1989). More recently, however, it has been indicated that bulimics with a previous history of sexual abuse have a more severe clinical picture and a higher rate of comorbidity with the borderline disorder (Claridge et al. 1998).

It should be noted that, in the study conducted by Marino and Zanarini (2001), 33% of patients with borderline PD met criteria for an ED not otherwise specified. Of these patients, 20% had restrictive patterns without weight loss, 37% purges without binging, 37% a pattern of binging without purging, and the remaining 33% had weight loss without menstruation.

216.3.6 Research

The data of comorbidity between EDs and PDs outlined in various studies do not correspond. The discrepancies obtained correspond to various reasons: the type of samples (outpatients or hospitalized patients), the sex and age of the patients, the degree of evolution of the disorder (in an acute period, in a situation of chronic phase or in remission), the diagnostic tools used to assess personality disorders (self-report questionnaires or interviews) and the differences between the diagnostic criteria. An important methodological limitation is the absence of clinical control groups (patients with mental disorders other than anorexia or bulimia) and normal subjects (subjects from the normal population). This means that one should exercise a degree of caution as regards the conclusions reached.

We therefore consider it important now to bring to attention the study from the doctoral thesis of the first author of this chapter (Marañon et al. 2007a, b). This study forms part of a large investigation whose purpose is to measure the comorbidity between PDs and EDs, assessed by the MCMI-II and the IPDE. The main contribution of this study to provide better knowledge of comorbidity between PDs and ED is related to the specific method used. What this means is that, apart from the ED group, there were clinical and normative control groups. The aim of this procedure was to discover whether the frequency and profile of PDs among EDs were different from the normal population and from non-ED patients seeking treatment for another Axis I mental disorder.

According to the results in previous studies of PDs in patients with EDs, this study found that the prevalence rates of comorbidity were high both in IPDE (54.8%) and MCMI-II (77.4%) (see Table 216.5). As expected in previous studies, the highest rates of PD in patients with ED were obtained with the MCMI-II. The correspondence between the IPDE and the MCMI-II in diagnosing personality disorders in patients with eating disorders is very low. The MCMI-II tends to overdiagnose specific PDs and, as a result, it is not a good assessment measure for obtaining PD diagnosis. This finding is consistent with that of Kennedy et al. (1995) using the SCID-II and the MCMI-II to

Table 216.5 Key features of International Personality Disorder Examination

1. IPDE is a semi-structured interview
2. IPDE has two versions that the interviewer can choose: one for the ICD-10 personality disorder criteria and the other for the DSM-IV personality disorder criteria
3. It consists of a self-screening questionnaire whose answers are either true or false
4. The screening questionnaire has no diagnostic value but can be used to select which part of the interview will be carried out
5. The whole interview can be used or it can also be used to identify specific disorders that have given positive in the self-administered questionnaire
6. The patient is asked to answer the questions taking into account how he or she usually is or acts. He or she is also asked to tell us if he or she has experienced a permanent change in his or her way of acting
7. The questions are organized under the following headings: work, self, interpersonal relationships, feelings, reality testing, and impulse control
8. The various sections of the interview begin with open questions that allow the patient to answer with as much information as desired and the interviewer to situate the context for understanding the subsequent responses to specific questions
9. The clinician assesses the responses with a score of 0 if the evaluated behavior is absent, with a score of 1 if the behavior is increased and with a score of 2 if the behavior meets diagnostic criteria or reaches pathological levels
10. IPDE can be administered to subjects aged over 18
11. To implement reliable results the interviewer needs to be trained
12. Qualified interviewers administer IPDE in about 45–60 min. Those who are not trained require more than 90 min

In this table the major features of IPDE are listed, as well as the steps and requirements for administration and correction

assess PDs in patients with EDs. On the other hand, as Wetzler and Dubro (1990) observed in their study, the MCMI-II detects the subjects who may have a possible PD. Therefore, we can conclude that the MCMI-II does not replace a diagnostic interview. The MCMI-II can be used as a screening tool, but not as a personality disorder diagnostic instrument. The high negative predictive value indicates that the MCMI-II performs well in indicating when the disorder was not present during IPDE. In contrast, if the MCMI-II obtained a PD diagnosis, it would probably be a false positive.

It would be possible to say that PD measurement with the MCMI-II is a statistic artifact. It can be understood clearly if we consider that 58% of subjects with at least one PD according to the MCMI-II, have more than four PDs altogether. Another piece of evidence for the above affirmation is that 32% of the AN patients have a schizoid PD assessed with the MCMI-II and not one of the same patients has the same diagnosis measured with the IPDE. In any case these results might also reflect problems in the PD diagnostic criteria, or they could be due to genuine high PD base rates (and comorbidity rates) in ED patients. For the interpretation of these differing results between the IPDE and the MCMI-II, the validity of the PD construct has been taken into account. We cannot forget that the ambiguity of the PD definition could be one of the reasons for the lack of correspondence between instruments.

Taking the above into account, and therefore considering the data from personality disorders obtained by IPDE, the most relevant conclusion of this study was that more than half of subjects with ED (55%) met DSM-IV-TR diagnostic criteria for at least one PD, compared to 22% of the non-ED patients and 9% of the normative control group (See Table 216.6). The main contribution of this study, consequently, is to have proven that this high rate of comorbidity with PDs is specific in EDs and much higher than in other Axis I mental disorders. This finding is consistent with those of previous reports using structured interviews to assess PDs in EDs (Gartner et al. 1989; Matsunaga et al. 1998). It is also consistent with those using only one of the control groups we used (Díaz-Marsá et al. 2000; Grilo et al. 1996; Herpertz-Dahlmann et al. 2001). This fact is a challenge for clinical practices because the presence of a PD in a patient with AN or BN complicates treatment, and the prognosis of the ED becomes poorer.

Table 216.6 Key features of Millon Clinical Multiaxial Inventory

1. MCMI is a self-administered questionnaire
2. The subject must answer 175 questions in a true–false answer format
3. Before beginning to answer the questionnaire the clinician should make sure that the subject has understood the instructions
4. Once the questionnaire is answered, correction can be done manually (with template correction) via Internet or using a local software
5. It should be taken into account whether the subject is a person of the general population, if he or she is an adult undergoing psychiatric treatment in a hospital, or if he/she is an adult undergoing psychiatric outpatient treatment
6. While correcting, the sex of the subject must be specified
7. MCMI can be administered to subjects aged over 18 with a reading level equivalent to 8 years of schooling
8. The subjects typically need about 25–30 min to answer all questions
9. Those whose scales give a score greater than 84 BR are considered pathological

In this table the main characteristics of MCMI are listed, as well as the steps and requirements for administration and correction

216.4 Application to Other Areas of Health and Disease

Beyond the different data found in the published studies, EDs are disorders which are rarely found in a psychopathologically pure state: they are often found with Axis II clinical disorders. The presence of a PD with an ED complicates the clinical picture. Specifically, it makes the early detection of the problem more difficult, as well as making the treatment difficult. It also hinders therapeutic prognosis (cited in Echeburúa and Marañón 2001); in fact, patients with AN and BN who are affected by a PD have a greater incidence of binging, vomiting, symptoms of anxiety and depression, and excessive alcohol consumption, as well as greater difficulties in social integration and an increased frequency of suicide attempts (Gartner et al. 1989; Wonderlich et al. 1990; Braun et al. 1994; Steiger and Stotland 1996; Kozyk et al. 1998; Matsunaga et al. 1998). This fact should be taken into account when planning treatment. To do so, the design of intervention programs that consider personality aspects would be useful, just as the development of specific therapeutic programs for EDs comorbid with PDs is a challenge for clinical research (Palmer et al. 2003).

On the other hand, it seems that the MCMI is not a good diagnostic tool to diagnose PDs in EDs. Therefore, to obtain a reliable diagnosis to determine whether a patient has a PD or not, we recommend evaluation using a clinical interview. In addition, using an interview will allow us to obtain valuable information in order to design specific treatment for a patient, as it will allow us to discover the patient's strong points and his or her weaknesses. However, MCMI may function best as a screening tool and more conservative clinical norms/cut-offs could help correct overdiagnosis problems.

216.5 Conclusion

In this chapter, according to the diagnostic philosophy contained within DSM-IV-TR, PDs have been considered in a categorical way, that is, as discrete entities of abnormal behavior patterns. However, although DSM-IV-TR approaches clinical diagnoses from a categorical perspective, there is increasing empirical research approaching the clinical assessment of PDs from a dimensional perspective (Segal and Coolidge 1998), since one of the most perplexing difficulties in this clinical field is the definition and measurement of personality dysfunction (Sansone et al. 2005). This point needs to be researched further.

In general, the comorbidity of EDs and PDs is very high: it can range from 20% to 80%. When considering PDs by type (A, B, and C), we found that the most prevalent PDs in AN are those from

Table 216.7 Agreement between IPDE and MCMI-II personality disorders

DIAGNOSTIC	IPDE positive (%)	MCMI positive (%)	Agreement (%)	KAPPA	SEN (%)	SPE (%)	PPV (%)	NPV (%)

Cluster B	20.2	33.3	67.85	0.198	52.94	71.64	32.14	85.71
Antisocial	0	13.1	86.90	–	–	86.90	0	100
Borderline	19	8.3	79.76	0.164	18.75	94.11	42.85	83.11
Histrionic	2.4	25	77.38	0.136*	100	76.82	9.52	100
Narcissistic	1.2	11.9	86.90	−0.022	0	87.79	0	98.64
Cluster C	31	28.6	66.66	0.203	42.30	77.58	45.83	75
Avoidant	16.7	14.3	85.71	0.455**	50	92.85	58.33	90.27
Dependent	2.4	11.9	88.09	0.132	50	89.02	10	98.64
Obsessive–compulsive	22.6	11.9	70.23	−0.021	10.52	87.69	20	77.02
Any disorder	54.8	77.4	79.76	0.322	91.30	39.47	64.61	78.94

The frequency of the 12 personality disorders and three clusters, the agreement percentage between the IPDE and the MCMI-II, values for Kappa, sensitivity (SEN), specificity (SPE), positive predictive value (PPV), and negative predictive value (NPV) are presented in this table. Correspondence between the two measures was only marginal. In most of the personality scales the kappa value was around 0, so correspondence between the two measures was only at chance level. Sensitivity refers to the likelihood that the MCMI-II will be positive when there is a diagnostic present according to the IPDE. Specificity refers to the likelihood that the MCMI-II will be negative when the IPDE is negative for a particular diagnosis. Positive predictive value is the probability that the IPDE will be positive when the MCMI-II is positive. Negative predictive value is the probability that the IPDE will be negative when this disorder is absent according to the MCMI-II

* $p < .05$

** $p < .01$

Table 216.8 Frequency of personality disorders in all sample

Personality disorders	ED n = 84		CCG n = 23		NCG n = 23

Non-specified	10	11.9	0	0	0	0	5.933*
TOTAL[a]	46	54.8	5	21.7	2	8.7	20.058**

This table shows the number of patients who present a type of PD as well as a percentage. When all the subjects with an ED were considered together, obsessive–compulsive PD (22.6%) was most commonly found, followed by borderline PD (19%), avoidant PD (16.7%), and not-otherwise-specified PD (11.9%). No diagnoses of schizoid, schizotypal or antisocial PD were made in this sample. The most frequently diagnosed PDs in the clinical control group were borderline (8.7%) and avoidant (8.7%). Finally, in the normative control group there were only two subjects (8.7%) with an obsessive–compulsive PD. When the three groups were compared, the patients with EDs were more frequently diagnosed with a borderline PD ($X^2_2 = 6.11$, $p < .05$) and with a not otherwise specified PD ($X^2_2 = 5.93$, $p < .05$) than the subjects belonging to the two control groups. The overall prevalence rate for at least one PD was 54.8% for the ED sample. In contrast, 21.7% of the clinical control sample and 8.7% of the normative control group showed at least one personality disorder. The differences found between the three groups were statistically significant ($X^2_2 = 20.06$, $p < .001$). PDs were more frequently diagnosed in patients with EDs than in the women of the two control groups
ED eating disorder, CCG = clinical control group, *NCG* normative control group
[a]The total number of people affected by PD is inferior to the total sum of disorders because there are patients who present more than one PD

**$p < .001$

type C. These results are consistent with other studies (Norman et al. 1993; Matsunaga et al. 1998, 2000; Díaz-Marsá et al. 2000; Godt 2002; Marañon et al. 2007a). In the case of BN, in most studies (Norman et al. 1993; Matsunaga et al. 2000; Godt 2002) the most prevalent PDs are those from type B (especially borderline personality disorder). However, in our study (Marañon et al. 2007a), PDs from types B and C are equally common.

In the future, the symptoms related to the presence of PDs in ED patients should be analyzed. This knowledge is necessary to create and to implement differentiated intervention programs that examine the differences between eating disorder patients with or without PDs.

Finally, it seems that it is better to use an interview to diagnose PDs. The MCMI-II overdiagnoses specific PDs and as a result it is not a valid tool for clinical diagnostics.

Summary Points

- Eating disorders (anorexia nervosa and bulimia nervosa) have become a significant public health problem.
- Eating disorders are characterized by serious alterations in eating habits. There is a refusal to gain weight above the lower normal levels.
- Personality disorders reflect inflexible behavior patterns, stable over time, which are not adaptive.

- Eating disorders are rarely found in a pure state: they are often found with personality disorders. In this case, we say that there is comorbidity between the two of them.
- The comorbidity between eating disorders and personality disorders can range from 20% to 80% depend on the study.
- There are different assessment instruments to diagnose personality disorders. Some are interviews (e.g., IPDE) and some self-administered questionnaires (e.g., MCMI).
- The prevalence rate of personality disorders in eating disorder patients differs depending on the diagnostic instrument used to diagnose personality disorders.
- The MCMI is easy and quick to administer but overdiagnoses personality disorders, making false-positive diagnostics.
- The IPDE interview requires a trained interviewer and the administration time is greater, but the diagnostics are more reliable.
- Knowing whether a patient with an eating disorder has a personality disorder or not is important, because comorbidity influences behavior (increases in binging, purging and dietary restrictions) and complicates the treatment.

Key Terms and Definitions

IPDE: The *International Personality Disorder Examination* (IPDE; Loranger 1995) is a semi-structured clinical interview outgrowth of Personality Disorders Examination (PDE; Loranger 1988). IPDEs aim is to evaluate systematically the presence or absence of the personality disorder criteria described in the current classifications. This is why it has been carried out in two modules: one for ICD-10 personality disorder criteria and the other for the DSM-IV personality disorder criteria.

MCMI: The MCMI-II is a 175-item, true–false, self-report questionnaire. It contains eight basic personality scales: Schizoid (1), Avoidant (2), Dependent (3), Histrionic (4), Narcissistic (5), Antisocial (6A), Aggressive–Sadistic (6B), Compulsive (7A), Passive–aggressive (7B) and Self-Defeating (8). In addition to the basic personality patterns, there are three pathological personality scales: Schizotypal (S), Borderline (B) and Paranoid (P). According to the conservative criteria of Weltzler (1990), a base rate score above 84 is considered to be significant.

Eating Disorders: Eating disorders are characterized by serious alterations in eating habits in the patients. Specifically, the main feature of anorexia nervosa is the refusal to maintain body weight in the lower normal levels and can exist in the form of drastic diets and excessive physical exercise as well as binging and purging. Bulimia nervosa is characterized by constant binging and use of inappropriate compensatory methods to prevent weight gain such as vomiting or misuse of laxatives and diuretics or, in other cases, fasting and excessive exercise. Finally, there are other unspecified eating disorders such as compulsive overconsumption or certain types of morbid obesity.

Personality Disorders: Personality disorders reflect inflexible behavior patterns which are not adaptive. Patients with these disorders show problems in learning effective strategies for coping with daily difficulties. Personality disorders generate interpersonal conflicts and lead to severe constraints (social and work) in daily life, as well as an increase in subjective discomfort. Personality disorders, as opposed to mental disorders, are stable and reflect a temporary deterioration of the overall person.

According to the DSM-IV-R (American Psychiatric Association 2000), there are ten personality disorders.

Comorbidity: Presence of more than one disorder at the same time in the same person. Co-occurrence and simultaneous presence of more than one disorder in the same person.

Chapter 217
The Assessment of Bulimic Symptomatology: Factorial Structure and Measurement Invariance of the Bulimic Investigatory Test, Edinburgh Across Gender and Age

Eduardo Fonseca-Pedrero, Susana Sierra-Baigrie, Mercedes Paíno,
and Serafín Lemos-Giráldez, José Muñiz

Abbreviations

APA	American Psychiatric Association
BITE	Bulimic Investigatory Test, Edinburgh
BULIT	Bulimia Test
CAT	Computerized Adaptive Testing
CFA	Confirmatory Factor Analysis
DSM	Diagnostic and Statistical Manual of Mental Disorders
EAT-40	Eating Attitudes Test-40
EDDS	Eating Diagnostic Disorder Scale
EDE-Q	Eating Disorder Examination
EDI-2	Eating Disorder Inventory-2
IRT	Item Response Theory
MI	Measurement Invariance
Q-EDD	Questionnaire for Eating Disorder Diagnoses

217.1 Introduction

Since Russell first described in 1979 what we now know as bulimia nervosa and its subsequent inclusion in the DSM-III (American Psychiatric Association [APA] 1980) as a distinct eating disorder category, characterized by recurrent binge-eating episodes accompanied by inappropriate compensatory methods, many changes have taken place regarding its diagnostic criteria, psychological and pharmacological treatment, and the construction of new assessment instruments. The key facts of the DSM can be seen in Table 217.1.

According to the DSM-IV-TR (APA 2000), the main diagnostic features of bulimia nervosa are the presence of binge eating and maladaptive compensatory methods along with an excessive influence of body shape and weight on self-evaluation. For an individual to receive a bulimia diagnosis, these binge-eating episodes and compensatory methods must occur at least twice a week for a minimum

Table 217.1 Key features of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM)

- It is a categorical system for the classification of mental disorders according to certain established criteria.
- The first edition of the DSM was published in 1952; the latest edition is the DSM-IV-TR (2000) and currently experts are working on the DSM-V.
- It allows proper communication among researchers and clinicians regarding the diagnosis, study, and treatment of different mental disorders.
- It is a useful tool for educational, research, and clinical purposes and it is used by clinicians and researchers throughout the world.
- The terms and codes used in the DSM for classification of disorders are compatible with those provided by the International Statistical Classification of Diseases and Related health Problems (ICD-10) developed by the World Health Organization.

This table summarizes the main features of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM)

of 3 months. The compensatory method employed by 80–90% of bulimics presenting themselves for treatment is self-induced vomiting (APA 2000). After vomiting, the person feels relieved as there is a reduction in physical discomfort and fear of gaining weight. Other compensatory methods employed by bulimic patients include: excessive exercise, use of diet pills, water pills, laxatives, diuretics or enemas, dieting, and ruminatory behavior (APA 2000), all of which have the potential to seriously harm the person's well-being. Bulimia nervosa is associated with significant distress, role impairment, and medical and psychological consequences whichthat severely affect the individual's quality of life. Several comorbid conditions have been shown to be present in bulimia nervosa patients such as depression, anxiety, personality disorders, obsessive–compulsive symptoms, substance abuse, and impulse control problems among others (Albert et al. 2001; APA 2000; Duncan et al. 2006; Echeburúa and Marañón 2001; Stice et al. 2004). Therefore, as bulimia nervosa represents an important public-health concern, finding ways of early detection of at-risk individuals is vital for the prevention of the disorder and its devastating consequences.

Epidemiological data place lifetime prevalence of bulimia nervosa in the range 1–3% (APA 2000), although given the secretive nature of bingeing and purging, and that many individuals with bulimia do not seek help, many cases may go undetected (Hoek et al. 2003). There is a clear gender difference in the prevalence rates of bulimia, with 90% of the cases being female (APA 2000). In addition, research shows that the percentage of individuals with subclinical forms of the disorder, that is, individuals suffering from bulimic symptoms associated with great distress but that may not meet the diagnostic criteria for bulimia nervosa, is fairly high (Chamay-Weber et al. 2005).

It should be mentioned that bulimic symptomatology is not restricted to individuals with eating disorders, but rather studies have shown that bulimic symptoms are also present in the general population (Pinheiro et al. 2008; Rodríguez et al. 2001; Sierra-Baigrie et al. 2009). For example, recent research studies have found that binge eating is present in nonclinical adolescent populations (Rodríguez et al. 2001; Sierra-Baigrie et al. 2009) as well as the use of inappropriate compensatory methods such as self-induced vomiting, laxative misuse, or excessive exercising (Pinheiro et al. 2008).

There is no doubt that adolescence is a period of particular interest for the study of bulimic symptomatology given the numerous psychological, physical, social, and cognitive changes that take place and that can be a source of stress in some individuals (Stice et al. 1998b). On the other hand, epidemiological data show that bulimia nervosa usually begins during late adolescence and/or early adulthood (APA 2000); hence, it is especially interesting to explore the variables associated to the development of maladaptive eating-related behaviors in nonclinical young adolescents.

Thus, bulimic symptomatology is present in a wide range of individuals and may be distributed along a continuum of severity, which goes from the absence of bulimic symptoms to full-blown bulimia nervosa in its extreme (Stice et al. 1998a). In this sense, according to the vulnerability-stress

Table 217.2 Key features of the vulnerability-stress model

- This model, also known as the diathesis-stress model, considers that for an individual to develop a psychological disorder, the conjunction of two factors, vulnerability and stress, must take place to a greater or lesser degree.
- The concept of vulnerability makes reference to certain biological traits mainly of a genetic origin, although not necessarily, which confer a certain predisposition toward a psychological disorder.
- Diathesis is considered a continuous variable that can be expressed with different degrees of intensity and that is in constant interaction with environmental factors.
- The probability of an individual developing a disorder depends on where he or she stands in the vulnerability continuum. Individuals situated at the extreme end present a greater vulnerability toward the development of a psychological disorder; individuals in the middle of the continuum may present subclinical or attenuated symptoms of the disorder.
- The relationship between vulnerability and stress is inversely proportional, that is, individuals with a high vulnerability toward a psychological disorder would require a lesser degree of stress to transit into a severe form of the disorder and those with a reduced level of vulnerability would require a greater degree of stress to develop the disorder.

This table shows the key features of the vulnerability-stress model. This model is possibly one of the most accepted models for the explanation and comprehension of the etiology of many psychological disorders. Its extensive use in clinical and research fields is due to the fact that it offers an easy explanation for the complex interactions occurring among genetic and environmental factors.

Fig. 217.1 Vulnerability–stress model for psychological disorders. In this figure, a representation of the vulnerability-stress model is shown. As can be observed, if an individual stands at the extreme end of the resilience-vulnerability continuum, a lesser degree of stress is required to surpass the threshold and transit toward a more severe form of a given psychological disorder

models, the probability of transiting toward a psychological disorder, in this case bulimia nervosa, would be determined by the interaction between the individual's predisposition and environmental factors (see Table 217.2 for key features of the vulnerability-stress model).

As can be seen in Fig. 217.1, the relationship between both concepts is inversely proportional. An individual who is closer to the normality end of the continuum would require the conjunction of greater stressful events to surpass the threshold; however, a person who is closer to the maladaptive end would require a lesser amount of stress to surpass the threshold and develop a disorder.

Therefore, the study of the presence of bulimic symptomatology in nonclinical populations, such as adolescents who have not yet developed a full-blown eating disorder, is important to further our understanding of this phenomenon and improve our assessment methods in order to detect individuals at high risk for bulimia nervosa and prevent them from developing this disorder.

217.2 Measurement Instruments for the Assessment of Bulimic Symptomatology

The field of psychological assessment of eating disorders, and in particular of bulimic symptomatology, has advanced considerably in the last few years. Table 217.3 shows some of the most widely used instruments for the assessment of eating disorders. In this regard, in the scientific literature, we can find numerous self-reports developed for the assessment of behaviors, symptomatology, and beliefs related to bulimia nervosa. There is no doubt that the assessment of bulimic symptomatology only makes sense if the measurement instruments employed are capable of measuring the construct with all psychometric guarantees. There is no use utilizing self-reports if their psychometric properties have not been exhaustively analyzed since the conclusions and decisions based on the participants' scores on these may be completely wrong or unfounded (Zumbo 2007).

More specifically, for the assessment of bulimic symptomatology we find the Bulimia Test (BULIT) (Smith and Thelen 1984), and the Bulimic Investigatory Test, Edinburgh (BITE) (Henderson and Freeman 1987), although it is true that other self-reports such as the Eating Disorder Inventory-2 (EDI-2) (Garner 1991) assess both bulimic and anorexic symptoms. The EDI-2 (Garner 1991) is a self-report, composed of 64 items in a six-point Likert-type format, which focuses on the description and precise measurement of several behavioral and psychological traits that are common in two eating disorders, bulimia and anorexia nervosa, as well as the severity of the clinically relevant symptomatology. The Eating Disorder Inventory-2 EDI-2 may be utilized as a screening device, outcome measure, or part of typological research but cannot be used for diagnostic purposes. This instrument presents adequate psychometric properties in reference to its internal consistency; test–retest reliability; and content, concurrent, and construct validity (Garner 1991; McCarthy et al. 2002; Miller et al. 2009; Tasca et al. 2003).

For its part, the Bulimia Test (BULIT) (Smith and Thelen 1984), or its revised version the BULIT-R (Thelen et al. 1996), is a self-report which was developed with the aim of solving some of the shortcomings detected in the field of bulimia nervosa assessment. The BULIT is composed of 32 items in a five-point Likert response format (plus four items to obtain information regarding laxative

Table 217.3 Main self-reports used in the assessment of eating disorders

Measurement instruments	Abbreviation	Number of items	Response format	Reference
Eating Attitudes Test	EAT-40	40	Likert 6	Garner and Garfinkel (1979)
Eating Disorder Inventory-2	EDI-2	64	Likert 7	Garner (1991)
Eating Disorder Examination-Questionnaire	EDE-Q	33	Likert 7	Fairburn and Beglin (1994)
Questionnaire for Eating Disorder Diagnoses	Q-EDD	50	Likert 7	Mintz (1997)
Eating Diagnostic Disorder Scale	EDDS	22	Likert and Yes/No	Stice et al. (2000)
Bulimia Test	BULIT	36	Likert 5	Smith and Thelen (1984)
The Bulimic Investigatory Test, Edinburgh	BITE	33	Yes/No and Likert	Henderson and Freeman (1987)

In this table we can see some of the most commonly utilized self-reports for the assessment of eating disorders
